Some definitions are, at least in part, political in nature. For example, in the Stafford Act, USA "*Major disaster means any natural catastrophe. . ., or, regardless of cause, any fire, flood, or explosion, in any part of the United States, which in the* ***determination of the President*** *causes damage of sufficient severity and magnitude to warrant major disaster assistance under this Act to supplement the efforts and available resources of States, local governments, and disaster relief organizations in alleviating the damage, loss, hardship, or suffering caused thereby.*" (According to the Federal Emergency Management Agency (FEMA), during the period 1953–2012 there were 2060 major disaster declarations in the USA, an average of 34 per year. The state with the greatest number is Texas, with 86 declarations.)

Most discussions about disaster are underlain by the assumption that a disaster is an external, existential event, filtered through the worldview of the observer. One differing perspective is that a disaster is entirely interpretive; Erikson (1994) takes this point of view when he notes that "*instead of classifying a condition as trauma because it was induced by a disaster, we would classify an event as disaster if it had the property of bringing about traumatic reactions*."

Disasters are complex and often chaotic events (Koehler, 1995). Unlike definitions in geometry they are not amenable to precise, neat, unambiguous descriptions. Quarantelli (1998) argued that disasters are understood or defined intuitively. The notion is that the word has meaning and can be used successfully without reference to a precise definition; though one may not be able to articulate unambiguously what a disaster is, there would be little doubt of its meaning when experiencing it.

Jigyasu (2005) discusses an "eastern" perspective toward disaster, emphasizing a concept of disaster not as an external event that happens to people, but as being caused by an internal chaos that does not allow people to see the true nature of reality, which can only come from achieving enlightenment. In this view, the external world is an illusion that confuses people and takes them away from the right path to God. This is unlike the discussion above, which has a typical western flavor. Along a very different line, Alexander (2008) presents a conceptual model of "disaster as spectacle" (also referred to as the "Hollywood" model), where disaster mythology defines perception and creates a self-fulfilling prophecy.

The UN International Strategy for Disaster Reduction (ISDR) provides one commonly accepted definition that will be used in the remainder of this entry: "*A serious disruption of the functioning of a community or a society causing widespread human, material, economic, or environmental losses, which exceed the ability of the affected community or society to cope using its own resources*."

The differing views of disaster discussed above have resulted in a variety of models, including ones that consider the environment as cause, others that emphasize social processes, or still others that incorporate various political or ecological systems. The following sections review some of the issues that are important to disaster models.

Disaster models

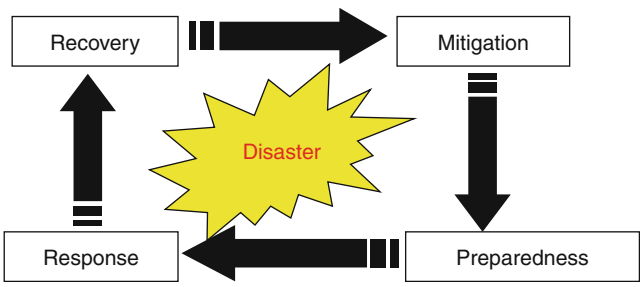
Model limitations

A model, whether it is conceptual, physical, mathematical, statistical, or visual, is essentially a way of perceiving or thinking about something. As such, it is a representation of a system, entity, phenomenon, or process. It is not the "real" world but rather a construct to aid us in understanding it. Users of disaster models should be cognizant of their limitations (Whitehead, 1997; Hewitt, 2010). Too limited an approach to disaster management can lead to, for example, the "paper plan syndrome," which is the illusion of preparation based only upon planning documents. Along these lines, Clarke (1999) presents an interesting discussion of extreme examples of this, calling them fantasy documents, which he defines as "plans as forms of rhetoric, tools designed to convince audiences that they ought to believe what an organization says."

The discussion that follows describes established relationships, thresholds, routings, sectors, or disciplines of study and flows of information/energy/goods. In this sense, they are all similar, being typical representations of western rationalist thought that tends to view the world as machines of greater or lesser complexity that can be tinkered with and adjusted in order to create desired outcomes. Certainly, models are ubiquitous and can be very useful in classrooms and institutions. But, though patterned after successful approaches used in the physical sciences, given the human nature of this subject area, they should be considered more as mechanical metaphors than reality. When applied to the real world, they invite perilous interventions where society assumes that we have more control over the occurrence or outcome of a disaster than we actually do (Scott, 1998). In this way, disaster models expose us to Type III errors, which relates not to the rejection of a hypothesis when true (Type I) or its acceptance when false (Type II), but rather to a hypothesis construction that is poorly related to the real issue at stake.

The disaster models generally used in academia and institutions, which are discussed in this entry, can be critiqued in that they provide a limited view of disasters that tend to be ahistorical (Hewitt, 2010), and present these events as amoral, impersonal happenings. Mostly absent (though abundantly present in media stories) are the visceral reactions of people to tragedy, notions of good and evil, or the narratives that people and peoples tell to understand and define their place in the world and their relationships to others.

Examples of models



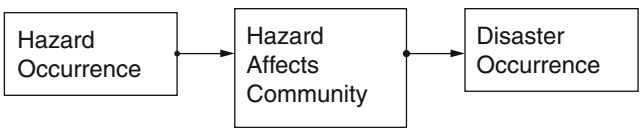
Comprehensive disaster/emergency management

Comprehensive emergency management (CEM) is based upon the four (sometimes five) pillars of mitigation (prevention), preparedness, response, and recovery. Numerous textbooks on the fundamentals of disaster management base their structure on this model, and many government organizations have adopted it (e.g., Coppola, 2006; FEMA, n.d.; ADP, 2007). This model (Figure 1) is normally presented in a cyclic format.

Mitigation refers to long-term actions that reduce the risk of natural disasters such as constructing dams or prohibiting construction in high-risk areas. *Preparedness* involves planning for disasters and putting in place resources needed to cope with them when they happen. Examples include stockpiling water and essential goods and preparing emergency plans to follow in the event of a disaster. *Response* refers to actions taken after a disaster has occurred. The activities of police, firefighters, and medical personnel, during and immediately after a disaster, fall into this category. *Recovery* encompasses longer-term activities to rebuild and restore the community to its pre-disaster state. This period can also provide opportunities to engage in activities that reduce vulnerability and mitigate future disasters, such as strengthening building codes or modifying risky land-use policies.

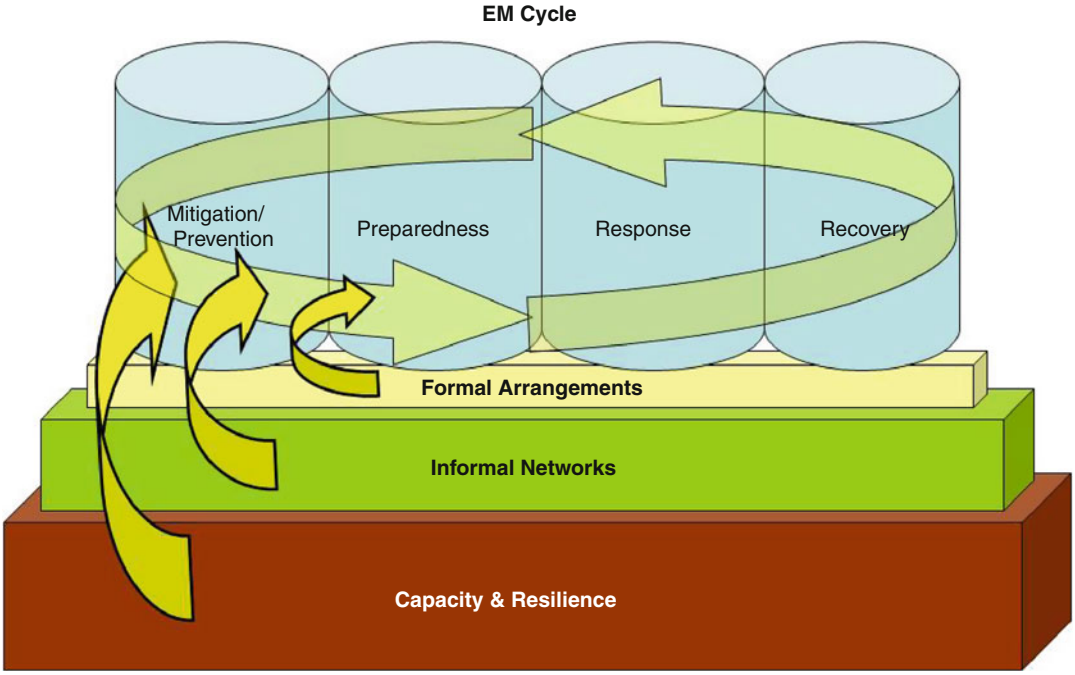
The development of this model represented the acceptance of a much needed and broader philosophy of emergency management from the traditional one, which had emphasized the preparedness and response pillars because of the historical dominance of civil defense and first responders. CEM incorporates an all-hazards approach and emphasizes proactive actions to risk reduction. It is the model that is probably most commonly used by emergency management organizations. Though it is accepted as best practice within many organizations, its shortcomings include that of creating silos of the different pillars, despite their interdependent functions. This is often reflected institutionally, where different departments or institutions are responsible for each of the pillars.

As well, the CEM model does not explicitly differentiate or address issues of capacity/resilience/vulnerability, informal networks, or formal arrangements. Figure 3 is a modification of the CEM cycle that portrays the platforms upon which the pillars rest. It still suffers, however, by representing the pillars as separate when, in fact, they have fuzzy boundaries.



Reflections on Modeling Disaster, Figure 1 The comprehensive disaster/emergency management cycle.

Pressure and release model



This important model was developed largely in response to the hazards' paradigm, which views extreme hazardous events as the cause of disasters (Figure 2). Its greatest contribution was to emphasize the role of society in creating vulnerable communities. It views disasters from a macro-scale perspective of the interaction between social and physical systems.

Within the disaster community, the most common interpretation of "risk" is as a potentially harmful event that is a function of both vulnerability (V) and hazard (H) (i.e., $R = V \times H$) (Sometimes the equation is written as Risk = Hazard × Consequence). This pseudo equation is discussed at length in Wisner et al. (2004) and is the basis of their Pressure and Release (PAR) Model of disaster. This model portrays disaster as an event that is damaging to society due to the complex interaction between hazard and vulnerability. Vulnerability is portrayed as a multifaceted complex process beginning with root causes, which then creates dynamic pressures that result in unsafe conditions. Hazard is portrayed in a simpler manner, as a trigger that exposes vulnerability. These notions are widely referenced in disaster literature (Rodrigeuz et al., 2006) and have been adopted institutionally, for example by the UN International Strategy on Disaster Reduction (UN, 2006).

Etkin (2009) presents an expanded version of the PAR model (Figure 4), where (a) hazard is portrayed as having a level of dynamic complexity similar to vulnerability, and (b) hazard and vulnerability are linked through box 1 (endogenous root causes). An example of a common root cause is "economic systems and development," which can result in environmental degradation that makes many hazards worse, but that also creates systems of critical infrastructure that lack resilience when short-term profit-making is emphasized. Exogenous causes that are natural in origin are categorized into a separate box at the bottom of the figure. The "Pressure" part of the model is shown by the direction of the arrows, where hazard triggers vulnerability, resulting in a damaging event that may be considered a disaster, depending upon a variety of factors, including cultural filters. The "Release" part of the model comes into play if the arrows related to cause and effect

Reflections on Modeling Disaster, Figure 2 Dominant disaster paradigm.

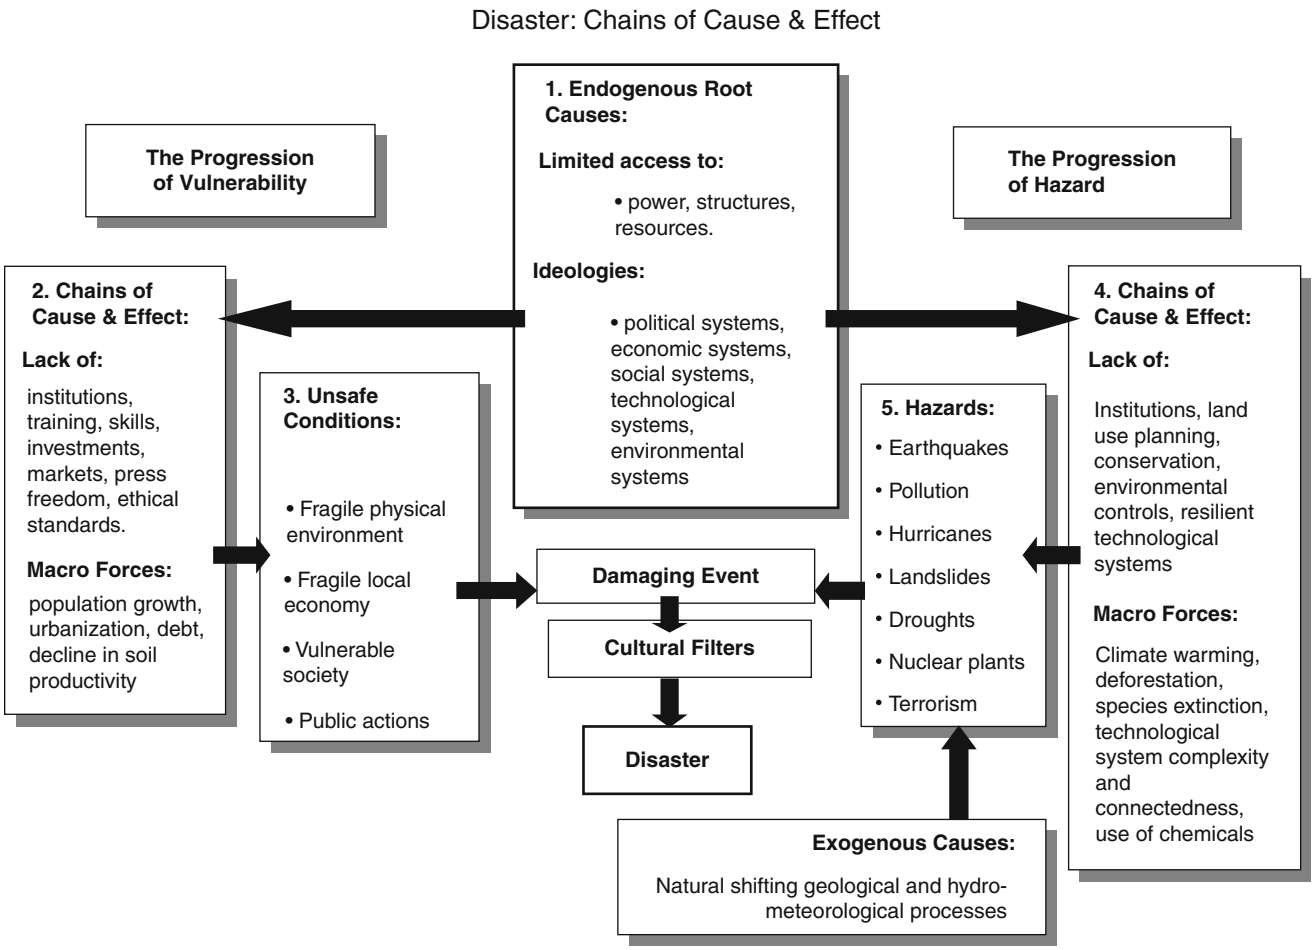
Reflections on Modeling Disaster, Figure 3 Comprehensive disaster/emergency management cycle and the platforms that support it.

reverse direction; by reducing either hazard or vulnerability the "pressure" in the system in lessened.

Though the presentation of Risk as an equation $R = V \times H$ might give the impression that it is quantitative and objective, it is best viewed as being socially constructed. This can be interpreted in two ways: The first is that many aspects of vulnerability are created through sets of social decisions (such as how and where we construct our communities and the systems that support them). The second is that risk is, in part, based upon values and subjective assessments as a result of people's and communities' psychological and cultural filters.

Quantifying risk invariably requires subjective judgments. How, for example, can one combine vulnerability due to gender, income, and other factors in an objective way? Inevitably in such assessments there are subjective decisions regarding about what should be included, and how different factors should be measured and weighted (Slovic, 2000).

CARE model



CARE is a nongovernmental organization involved in humanitarian relief and developmental issues. In contrast to the PAR model that emphasizes a macro-/meso-approach to disaster management, the CARE disaster model focuses on the household level (as embedded within larger scales), and views disasters as one of the many external factors (shocks and stresses) within the context box on the left side of the Figure 5. It was developed "to identify constraints to family and community livelihood security and design grassroots programs to overcome them." (Lindenburg, 2002).

Though its focus on the household level differentiates this from the PAR model, it is structurally and topologically similar in that it uses the notion of cause and effect to understand system constraints, and how people use their resources to cope with hazards. It is less explicit in terms of dynamic processes, which must be inferred. For studies focusing on a micro-level where a rapid community-based assessment is required, it is a very useful alternative to the PAR model (Lindenburg, 2002).

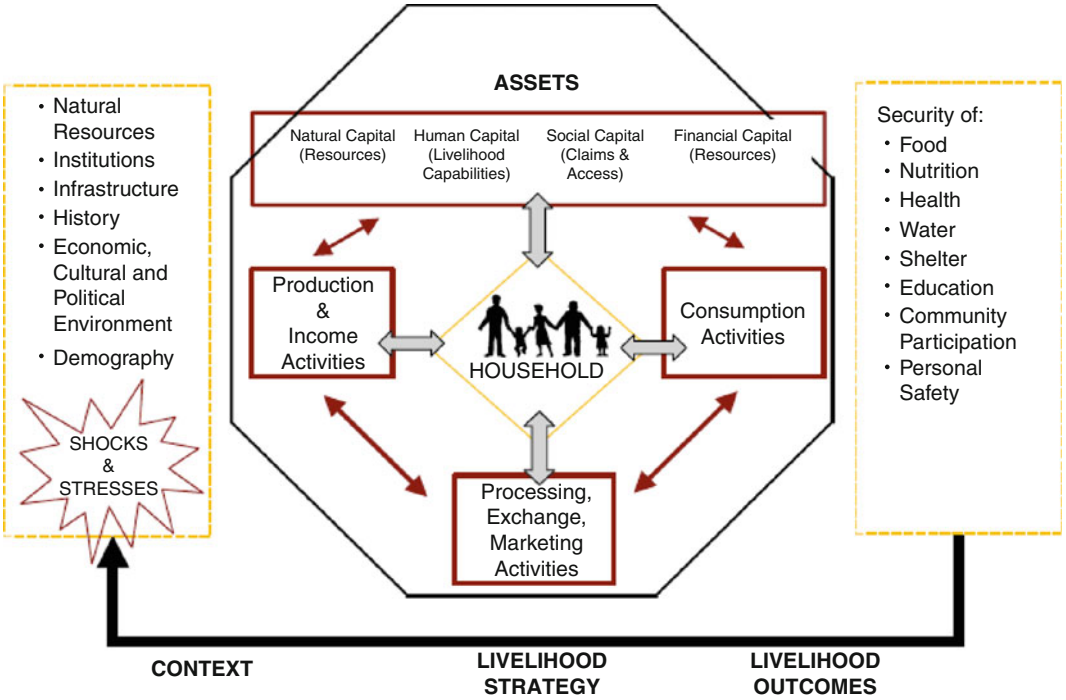
Capacity (in the middle under Assets) and vulnerability are explicit in this model, particularly in the livelihood outcomes box that examines such issues as food security. For more information about this model, readers are referred to CARE (2002).

Risk management model

A typical risk management process, such as the Canadian Standards Association (CSA-Q634-91) can be adapted for disaster management. An example of this is the "Emergency Management Australia Steps in the Emergency Management Process" (Figure 6). This type of linear decision-making model works well when uncertainties are small, hazards and vulnerabilities are well understood and subject to known and available controls, and stakeholder buy-in exists in terms of risk management strategies. A typical risk management strategy that might be used within the "Treat Risks" box (Burton et al., 1993) is shown in Figure 7.

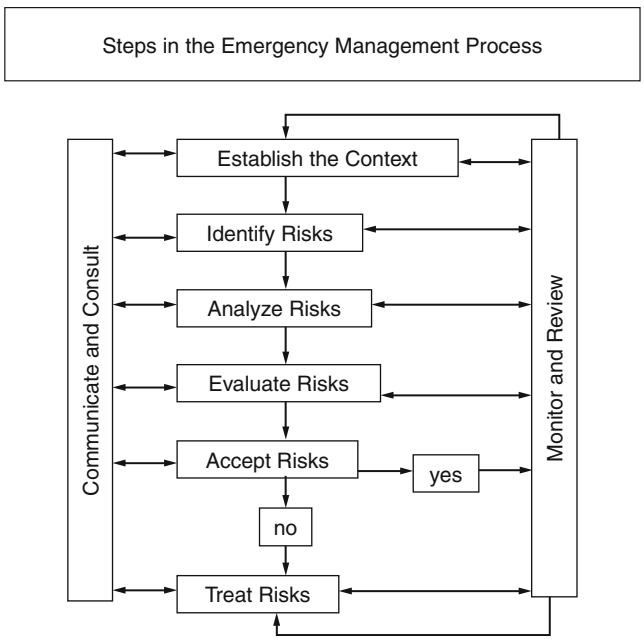
Reflections on Modeling Disaster, Figure 4 Modified pressure and release model (Etkin, 2009).

Readers interested in a critique of this type of risk management process may wish to explore the Garbage Can Model (Cohen et al., 1972).



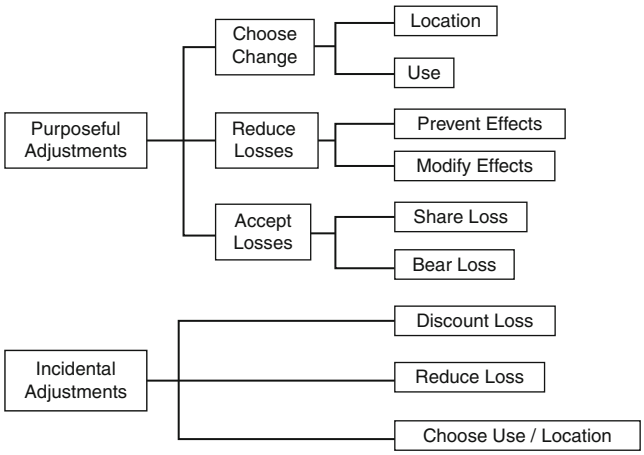
Ecological models

Etkin and Stefanovic (2005) discuss natural disasters from an eco-ethical perspective (Figure 8) emphasizing the interactions and reliance of society on the natural world. This model is, to a large degree, an extension of the work of Burton et al. (1993), which considers the natural environment as both a resource and a hazard, and how mankind's relationships with nature have the potential to increase vulnerability.



Work by Gunderson and Holling (2002) view disaster as part of the evolution of complex systems. Originating from the field of ecology, their work provides a metaphor for any complex system, including society. Figure 9 illustrates their basic model of the pathways that systems move through as they evolve.

An example is the ecology of forest systems. New forests (r) exploit the earth's resources and over time become old forests (K), which are stable. However, as they evolve the potential for fire increases due to increasing amounts of litter on the forest floor and the development of dense canopies. Eventually a trigger (such as lightening or arson) will create a fire that begins the destructive (this is where a disaster may occur) release phase (Ω) after which the system reorganizes itself (α) and the cycle repeats. During the Ω phase, if a critical threshold is passed, a system may flip into a different state, such as a clear lake dominated by fish to a murky one dominated by plankton. In these cases the process can be irreversible.



A complete description of this model is beyond the scope of this entry, and thus far it is not much referred to in the disaster literature, though there is potential for its use at the conceptual if not the applied level. The authors of Panarchy frankly acknowledge that it should be considered as an incomplete metaphor; the greatest advantage of this model may be by broadening perspectives to include issues of instability of complex systems, the significance of cross-scale interactions, and the importance of adaptive change and learning.

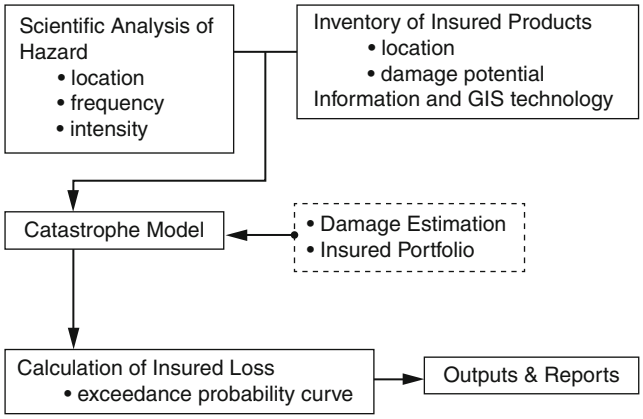
Normal accidents

In 1984, Charles Perrow challenged the way in which large accidents or disasters were viewed (Perrow, 1984). The traditional perspective was that accidents were abnormal, unnecessary events that could be prevented if sufficient management was engendered in the form of training, quality control, and standard operating procedures. This view is called "High Reliability Theory" (La Porte and Consolini, 1991).

Perrow's hypothesis is that in certain types of systems, accidents are a fundamental property of the system and therefore, cannot be totally prevented, with such

Reflections on Modeling Disaster, Figure 8 Ecology of natural disasters.



Reflections on Modeling Disaster, Figure 9 Panarchy model.

events sometimes resulting in disasters. These systems have the characteristics of being complex and tightly coupled. Perrow further argues that some of the methods used to make systems safer (such as redundancy) can actually have the opposite effect, by increasing system complexity. Such systems can reach critical states as they self-organize, where a small perturbation can cause the system to collapse (Per Bak, 1996). Examples of this type of disaster include Three Mile Island and the Challenger explosion. Where the systems are of very high risk, Perrow recommends that those technologies be abandoned. One of the main reasons for this is that complex systems require decentralized management whereas tightly coupled systems require centralized management. When a system is both complex and tightly coupled, a fundamental contradiction exists in terms of how to manage it. In a useful critique of both approaches, Marais et al. (2004) suggest that high-reliability theory "oversimplifies the problems faced by engineers and organizations building safety-critical systems and following some of the recommendations could lead to accidents. Normal accident theory, on the other hand, does recognize the difficulties involved but is unnecessarily pessimistic about the possibility of effectively dealing with them."

Catastrophe models

Partly in response to growing payouts by insurance and reinsurance companies during the 1980s and 1990s,

Reflections on Modeling Disaster, Figure 10 Elements of a catastrophe model (Adapted from Grossi and Kunreuther, 2005).

and particularly due to such events as the case with 11 insurance companies going bankrupt after Hurricane Andrew in 1992, various insurance and private sector companies began to finance the development of catastrophe (CAT) models so that they could better assess their risk posed by disasters. The main proprietary models are AIR Worldwide, EQECAT and RMS, Inc. The US government has developed an open source model called Hazards United States (HAZUS) under the auspices of FEMA. There is an International Society of Catastrophe Managers that promotes this profession within the insurance industry.

The main purpose of these models is to estimate the amount of insured damage that would occur due to a catastrophic event, such as a hurricane, flood, or earthquake. HAZUS estimates include not only physical damage but economic loss and social impacts. These models are based upon meteorology, seismology, engineering, and actuarial science.

The basic structure of the CAT models is shown in Figure 10 (adapted from Grossi and Kunreuther, 2005). Final outputs typically include an exceedance probability curve of financial loss. The main sources of uncertainty relate to a lack of empirical data on hazard and vulnerability, and limited scientific knowledge of hazards and engineering. A deficiency of information with respect to business interruption costs and repair costs affect the accuracy of the loss component of the model (Grossi and Kunreuther, 2005).

Conclusions

Disasters are complex human-centric events that are difficult to define. How they are conceptualized has important consequences in terms of strategies used to manage them. There are a number of conceptual models that are used by academics, professionals, and the public in terms of how they are understood – each has its strengths and weaknesses and can be situationally useful. To some extent these models must be considered perilous, as they can exclude other useful ways of viewing disasters. By not adhering rigidly to one particular model, by analyzing model limitations (sometimes serious ones), and by using them according to their different strengths, the management of disasters can be made more flexible and effective.

RELEASE RATES

Pat E. Rasmussen
Health Canada, University of Ottawa, Ottawa, ON, Canada

Definition

In the context of the natural environment, "release rates" refer to the amount of material that flows through a unit area per unit time.

Discussion

Material is continuously transferred between different components of the Earth System including rocks, soils, plants, waters, and the atmosphere. The rate at which material (such as a metal ion) is transferred from a host component (such as soil) to another component (such as water) depends on how easily it is mobilized, or released, from the host component (Larocque and Rasmussen, 1998). The mobilization of material is controlled partly by the physiochemical conditions existing in the environment, and partly by the characteristics of the material itself.

Knowledge about the release rates of nutrient ions, such as potassium, calcium, and magnesium, as they transfer from bedrock rock to soil, is essential to understanding nutrient cycling in ecosystems (Kolka et al., 1996). Nutrient ions are released by the dissolution of minerals to the overlying soil horizon during bedrock weathering. The rates of release vary depending on the climate, the type of soil, and the type of underlying bedrock.

Release rates are not necessarily constant. For example, the concentration of phosphorus in overland and subsurface water is related to the concentration and release rate of phosphorus in soil. The release of phosphorus from soil occurs simultaneously in two processes: rapid release on contact with solution, and a slower diffusion from inside soil particles (McDowell and Sharpley, 2003).

There are strong seasonal variations in release rates. Measurement of soil carbon dioxide release rates measured in a Chinese fir plantation showed that the rate of carbon dioxide release was higher in the summer than in other seasons. It was found that the soil carbon dioxide release rate increases as air temperature increases within the plantation, and also with increased soil temperature, increased carbon/nitrogen ratios, and increased soil water content (Xi et al., 2005).

Release rates may fluctuate widely over the course of a single day. For example, the release rate of gaseous elemental mercury from mercury-enriched black shale reaches maximum values during the day, depending on sunlight, air and soil temperature, and local meteorological conditions, and decreases to minimum values at night (Rasmussen et al., 2005).

RELIGION AND HAZARDS

Heather Sangster[1], Angus M. Duncan[2], David K. Chester[1]
[1]University of Liverpool, Liverpool, UK
[2]University of Bedfordshire, Luton, UK

Definition

Religious reactions to disasters are to be found within most traditions of faith, across societies located in different parts of the world, and over the long span of human history. In some cases, it is possible to extend the timescale and interpret archaeological evidence to show how prehistoric societies often used theistic frames of reference to make sense of the suffering caused by catastrophic natural events. Geomythology involves the investigation of oral traditions that preserve information on prehistoric geological events, and there is overwhelming evidence that a wide range of theistic responses to disasters have been preserved (Vitaliano, 2007).

The religious interpretations of disasters are neither confined to archaeological examples, nor are they encountered merely as geomyths within oral traditions of faith, but can be found across all the major religions of the world. Within Judaism and Christianity, there have been two prominent models of theodicy: *free-will* (*Augustinian*) and *best-possible worlds* (*Irenaean*). The notion of free-will considers human beings to have freedom and that suffering is not only a result of the operation of free-will, but may also involve sinfulness because a person has acted against God's purpose, with divine punishment sometimes being stressed. The notion of the best-possible world considers that to design a system in nature that does not have the potential to injure unsuspecting humans would be impossible; therefore, God's purpose is to use disasters to enable a greater good to be achieved. In Buddhism, Jainism, Hinduism, and Shinto, there is a common belief that a person's behavior leads irrevocably to an appropriate reward or punishment (Kogen, 1987) and this has often encouraged fatalistic attitudes toward disasters. Present day suffering is frequently believed to be due to *karma* or fate, which is influenced by conduct in former lives. The word Islam means submission to the will of God, and in the *Qur'an*, earthquakes are interpreted within two different yet related frameworks, being perceived as either signs of a future apocalypse or as a punishment of limited duration for a particular group of people (Akasoy, 2009).

Academic scholarship has been highly critical of the influence of religion on the human understanding of disasters (for example, Sigurdsson, 1999). According to a conventional reading of intellectual history, superstition largely replaced the naturalistic explanations of disaster that were embryonic in the classical era and following the Eighteenth Century Enlightenment, religious explanations became less prominent and were progressively replaced by more scientific and social scientific explanations of disasters and their human impacts. Evidence collected by the present authors from disasters that have occurred over the past hundred years (Chester and Duncan, 2008) shows that this is far from being the case and people frequently employ religious frames of reference to explain both extreme natural events and losses caused by them. Indeed religious explanations were apparent following both the Indian Ocean earthquake and tsunami disaster in 2004 and the Haitian earthquake of 2010.

Although there are some examples of people resisting relief efforts due to their religious beliefs, these are exceptions and for most people belief neither inhibits more practical measures being taken to reduce individual or group exposure to hazards, nor does it hinder people accepting help from the civil authorities. Believing at the same time in two mutually incompatible worldviews, or holding one opinion and acting contrary to it, is known in the literature as *parallel practice*, and this has been discussed in detail with reference to countries with a predominant Christian ethos, where it remains a major feature of faith-based responses (Chester and Duncan, 2009), although more detailed research on *parallel practice* in parts of the world where other religions are in the majority is required.

Synonyms

Earth observation

Definition

Remote sensing is a summary term for the instrumentation, techniques, and methods to observe the Earth's surface at a distance and to interpret the images or numerical values obtained to acquire meaningful information concerning the nature or state of the observed features. We distinguish between spaceborne, aerial, and terrestrial remote sensing, each of which offers excellent possibilities to observe and study natural hazards and disasters.

Introduction

To be able to mitigate or effectively respond to disasters, a sound understanding of all relevant aspects is needed: the hazards that may lead to losses when events spatially intersect with elements at risk (EaR; i.e., people, infrastructure, assets), their vulnerability toward the specific hazard at different event magnitudes, and the resulting risk (see *Risk*). Such knowledge allows existing hazards to be effectively monitored and early warnings to be given in case of impending hazardous situations. If a disastrous event does occur, its total losses and damages will not only depend on the severity of the event and the vulnerability of the EaR, but also on how effectively the event is responded to. In the long term, future risk – and renewed disaster occurrences and losses – then depend on lessons learnt from the event, that is, how much risk reduction is incorporated in rehabilitation and reconstruction. This means that disaster risk reduction (DRR) – the ultimate objective – is highly contingent on comprehensive, suitable, timely, and accurate information. All of the above aspects are spatial in nature. By that we mean that they have a certain location and extent, thus can be put in relation with one another, and can be associated with attributes that are linked to a geographic place or area. Therefore, for DRR we require spatial information. The most efficient way to obtain this knowledge, such as on where hazards exist, where people live or their assets are located, where immediate assistance is required after a disaster, or where best to resettle a community after a destructive event, is by using remote sensing (RS), also called Earth observation. This entry explains what RS is, why specifically it is suitable as a basis for DRR, and how we can use it to study the various hazard and disaster aspects. The entry finishes with an assessment of currently promising developments that may facilitate DRR in the coming years.

Overview of remote sensing concepts

RS can be described as the process of making measurements or observations without direct contact with the object under investigation. Thus, while in the context of RS satellites often first come to mind, even amateur photography or similar noncontact measurements made on the ground can be considered RS. It usually results in images, but also includes other measurements, such as of temperature or gravity.

Sensors and platforms

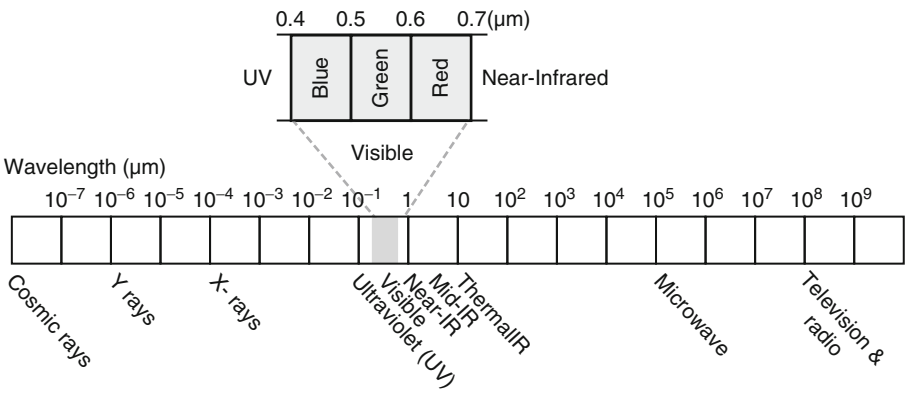
For remote sensing, we normally require a sensor (i.e., a camera or scanner), and also something that carries the device. Such platforms can be airplanes or satellites, but also other devices that allow us to place the sensor in a way that the area or object of interest is exposed, such as balloons or kites. The choice of platform directly affects what we can observe and how. Airplanes and helicopters are flexible in their operation, and with relatively low flying heights provide good spatial detail. However, such surveys can be expensive and regular imaging of the same area thus costly. Satellites fly in a fixed orbit, and are thus less flexible, but can provide data at regular intervals (comparable to trains on a track following a fixed schedule). One platform type are the so-called polar orbiters, where the satellites continuously circle the Earth at an altitude of some 500–900 km, passing over or near the poles. Normally, only a relatively narrow strip of Earth underneath the sensor is observed, depending on the sensor type ranging between less than 10 km and several hundred kilometer in width. Adjacent strips are then visited in subsequent orbital passes. Modern satellites can also point the sensor sideways for greater flexibility. The other class of satellites is positioned in geostationary orbit. This means that the satellite is always directly above a designated place on the equator, moving with the rotating Earth at an altitude of approximately 36,000 km. At that height the sensor can usually observe an entire hemisphere

(the side of the Earth facing it), and provide data at any desired frequency. Many weather and communication satellites fall in this category, while most Earth observation satellites are polar orbiters.

Collecting information

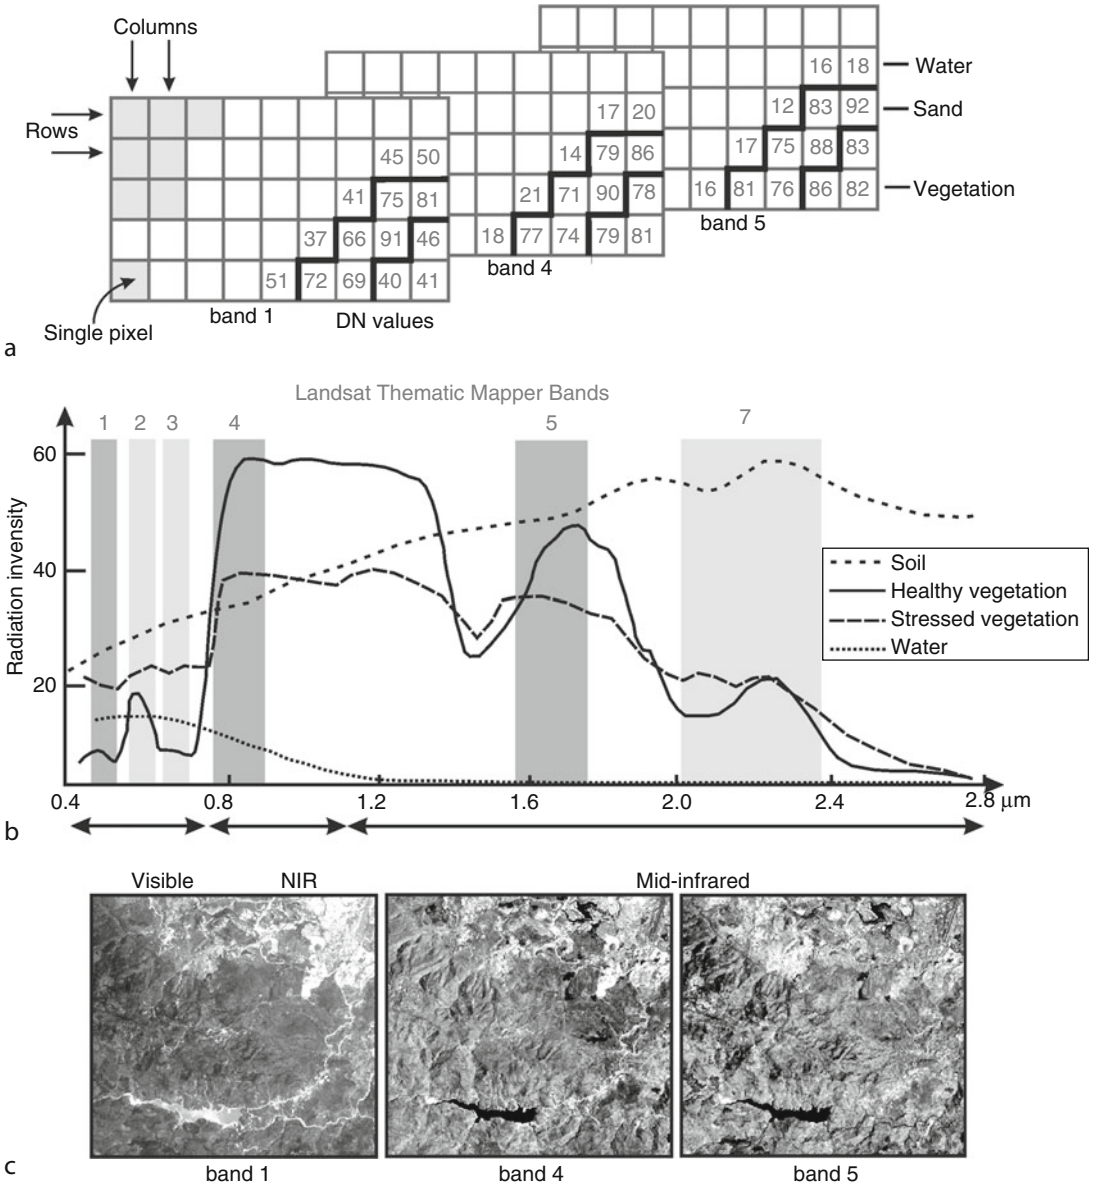
The data obtained depend primarily on the sensor type, just as one might take color or black/white photographs with a film camera. The principle behind collecting different data lies in the electromagnetic energy (EMR; see *Electromagnetic Radiation (EMR)*), which is what the sensors detect. The most common source of energy is reflected sunlight, which contains not only visible light, but also ultraviolet (UV), infrared (IR), thermal, and other energy (Figure 1). Which part of this continuous energy band, also called electromagnetic spectrum, we capture depends on the sensor? While a consumer camera might only capture visible light, other scanner types record UV, IR, thermal, or other energy ranges.

The data



The data recorded by a sensor typically have the form of a grid or raster (Figure 2a), made up of rows and columns that are populated by cells. These cells, also known as picture elements (pixels), contain the information recorded. A sensor can also have several bands, meaning that different sections of the electromagnetic spectrum are imaged. Thus, for the area observed, an image can contain several bands, and the cell corresponding to a small part on the ground will have one data value for each band. The most important point to understand here is that different materials on the ground reflect or emit energy in a characteristic spectral pattern (see *Electromagnetic Radiation (EMR)*, Figure 2b). For example, vegetation is characterized by high energy in the near infrared (NIR), whereas for water the NIR energy is very low. In Figure 2 this results in high values (digital numbers [DN]) for vegetation and low values for water in the band corresponding to the NIR (Figure 3c).

Other factors influencing the data

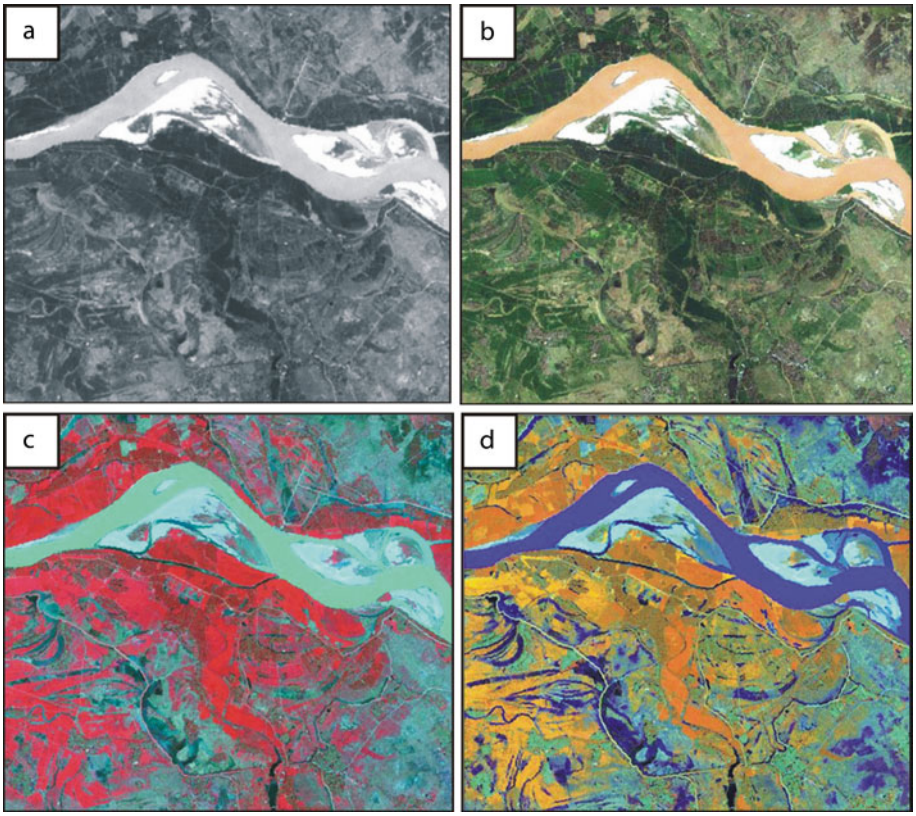


RS data come in many forms, often described by sensor type, as well as their spatial, temporal, and spectral resolution. Sensors recording reflected sunlight or energy emitted by the Earth are called passive sensors. Others emit their own energy, which is reflected by the target and recorded, comparable to a camera flash. These are active sensors, well-known examples being radar or laser scanning. The spatial resolution describes the size of the ground area represented in a single pixel. This largely depends on the distance between the sensor and the object. While aerial photos may have a resolution of a few cm, data from polar orbiters range between about 50 cm and 1 km per pixel. Being very far away, sensors on geostationary platforms, such as weather satellites, typically record data at resolutions of several kilometers. The temporal resolution describes the possible frequency of repeat observations. For aerial surveys, this can be years due to the high cost and logistics involved. With more recent and lower cost devices, such as unmanned drones (see below), near-permanent observation is, in principle, possible. This is especially useful to monitor ongoing events, such as wildfires (Ambrosia et al., 2003). Depending on the type of polar orbiter, currently operational sensors have temporal resolutions varying between approximately 1 and 44 days, whereas modern geostationary sensors record data up to every 15 min. The spectral resolution describes how narrow a slice of the electromagnetic spectrum a sensor band records.

Visual information extraction

The acquired data are only of use if they reveal the required information, which can be extracted by visual assessment or digital image processing. The data can be displayed on a computer monitor using three different color channels (blue, green, red) to generate any color (including black and white). At the simplest level, the data can be displayed one band at a time as a grayscale image (Figures 2c, 3a). Alternatively, the three visual bands (blue, green, and red) can be assigned to their respective monitor colors to create a so-called true-color composite

Remote Sensing of Natural Hazards and Disasters, Figure 1 Electromagnetic spectrum (Modified from Lillesand et al., 2004).



Remote Sensing of Natural Hazards and Disasters, Figure 2 Structure of remote sensing images, where rows and columns form a grid. Images typically have several spectral bands (**a**). Notice how different materials have different spectral values (digital numbers = DN values) that reflect their spectral-signature (**b**). (**c**) shows bands 1, 4, and 5 of a Landsat Thematic Mapper (TM) image, which also illustrate the DN values shown in (**a**). The materials and their DN values shown in (**a**) illustrate what a typical water-sand-vegetation progression, such as at the bottom of (**c**), looks like.

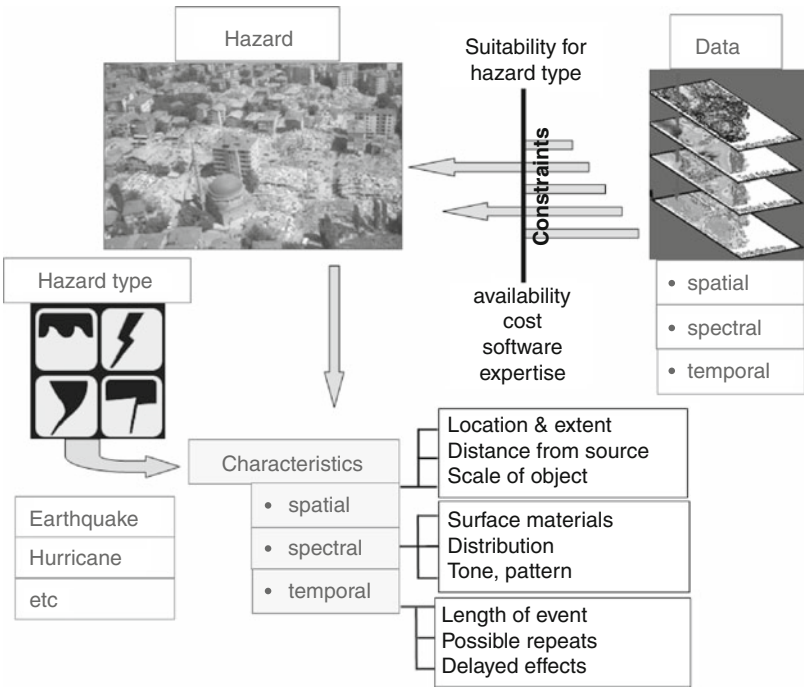
(Figure 3b), similar to what the scene would look like to a human eye from space. However, essentially any band-color combination is possible and can reveal different information about the area observed. A typical combination, called a false-color composite, is shown in Figure 3c, where the information from the NIR band is displayed in red. Since vegetation leads to high DN values in the NIR, a strong vegetation signal leads to a dominant red color wherever there is vigorous vegetation. Figure 3d shows another type of false-color composite.

Remote sensing of natural hazards

Information requirements

The information required to identify or monitor hazards, EaR, or actual disaster damage varies dramatically depending on the hazard type or what are considered features of value that may get affected during an event. Thus, given the diversity of RS data types and observation methods described above, as well as the variable hazard or disaster information needed, an essentially unlimited

Remote Sensing of Natural Hazards and Disasters, Figure 3 Panchromatic Landsat Thematic Mapper image (**a**), true-color composite (**b**), and different false-color composites (**c** and **d**).



number of ways to deploy RS exists. At times, this is easy, for example, earthquake damage in Google Earth pictures tends to be very obvious, similar to the widely discussed damage caused by the 2004 Asian tsunami. However, sound knowledge of both hazard and disaster characteristics, as well as technical image analysis skills, are usually needed, as the difference between identifying broad damage patterns and a specific damage level classification, which is what disaster responders require, is substantial.

RS-based identification of hazards that may lead to disasters is even more complicated, and requires a clear understanding of what information is specifically required, how frequently and at which accuracy levels. Hazards can typically be characterized by a range of features. For example, RS can be deployed to study wildfire hazards by detecting (1) easily combustible vegetation, (2) its water content (i.e., dryness), (3) wind direction and speed, (4) real-time rainfall, or (5) topography, as fires on hill slopes spread more quickly. A sound approach would consider all of the above aspects (Syphard et al., 2008). For other hazards, it is useful not to consider the main hazard type, but the subtypes actually present. For example, *the* volcanic hazard does not exist. Instead, more than a dozen major subhazards can be identified, such as lava flows, pyroclastic flows, gas emissions, glacier melting, crater lake breach, ash clouds (that constitute an aviation hazard but can also circle the Earth, with consequences in other parts of the world), or more local hazards such as fumaroles. Each of these constitutes a hazard in its own right, and has different characteristics in terms of their overall extent, maximum reach, onset time, and duration. With the exception of seismic activity that often precedes or accompanies volcanic activity, essentially all hazard subtypes can be identified or monitored with RS. Because of their highly variable nature, however, each type needs to be well understood to identify a suitable RS strategy, considering also that some can occur simultaneously. For example, a crater lake that is heating due to rising magma can be identified with a thermal scanner (Oppenheimer, 1993). To study quantity and composition of emitted gases, however, observations in another part of the infrared spectrum are needed (Burton et al., 2000). Magma intruding into a volcanic structure can also lead to flank deformation that can be identified with radar observations, such as so-called interferometry that detects cm-scale vertical changes (Massonnet and Feigl, 1998). Alternatively, ground-based RS methods such as electronic distance meters (EDMs) or GPS measurements (see *Global Positioning Systems (GPS) and Natural Hazards*) can also be used (Sturkell et al., 2006).

For some hazards, it is sufficient simply to identify an actual event or ongoing process, such as magma being issued from a crater. More often, however, the above are mere parts of a more complex hazard evaluation that requires multi-data integration and modeling. For example, to understand better the potential area of spatial intersection of hazards and EaR, or to determine hazard magnitude, models are needed. The role of RS then is to provide input to these models. Kerle and Alkema (2012) described how RS is used to model flood hazard. Knowledge of rainfall in an upstream watershed alone is insufficient; more important is how water subsequently infiltrates, accumulates, and moves toward and through exposed areas, in turn a function of local topography and land cover (the material actually covering the ground, such as trees or buildings). While this is done by sophisticated hydrodynamic models, the contribution of RS is varied. It provides land cover information, real-time rainfall estimates (using ground-based radar RS or satellite observations), and the topographic information needed. The latter is also critical in the modeling of local seismic site effects, as ridges amplify seismic waves, leading to higher ground acceleration values than in depressions. Similarly, the spreading of lava or pyroclastic flows can be modeled using digital topographic information.

Selecting an appropriate strategy

Figure 4 illustrates which considerations determine a suitable RS strategy. As explained above, different hazard types, such as earthquakes or hurricanes, have different (1) spatial, (2) spectral, and (3) temporal characteristics, which are briefly evaluated here. (1) A hazard can be very local and spatially confined (e.g., an unstable hill slope), it can be very extensive (e.g., areas affected by tsunamis, hurricanes, or drought), or there can be a large distance between the actual hazard source and the exposed area in question. Examples of that can be earthquakes, where the responsible fault may be a long distance away from areas that may still experience strong shaking during an event, or the breaking of a dam that may lead to flooding far downstream. The data chosen need to reflect those dimensions and the details that need to be seen. The chosen platform type largely determines how extensive an area can be observed, and what spatial resolution the resulting data have. (2) Remote sensing is very sensitive to the surface characteristics of the object or area under investigation, resulting from the different spectral characteristics of different materials (see Figures 1 and 2), and different sensors have been built that are especially suitable for specific surface materials. It was already described how water, gases, or vegetation can be mapped with appropriate sensors. In situations where clouds, smoke, or night-time conditions prevent a clear view on the surface, active sensors, such as radar, can be used. However, here it is particularly important to understand that radar data primarily reflect the surface physics (structure/roughness, moisture, topography), compared to the surface chemistry that optical data correspond to (mineral type, chlorophyll content in leaves, etc.) (Lillesand et al., 2004). Hence, using radar is only useful if it not only

Remote Sensing of Natural Hazards and Disasters, Figure 4 Spatial data suitability depending on hazard or disaster type and their respective spatial, temporal, and spectral characteristics, as well as other constraints that may affect actual availability of the data.

penetrates difficult observing conditions, but also provides the information required. (3) Hazard events can be sudden and brief (e.g., earthquakes or landslides), sudden but of long duration (e.g., a dam break leading to prolonged flooding), but can also show precursory signs (e.g., volcanic activity or hurricanes). Some events, such as earthquakes, may also show a repetitive pattern, where violent aftershocks affect areas already destabilized by the primary event. Some effects may also be delayed, such as disease outbreak after a flood or earthquake. This is also a good example of one hazard type event leading to secondary effects. Others are slope or dam instability caused by earthquakes. A suitable RS strategy reflects the different consequences.

A solid understanding of the hazard(s) in question is thus needed before deciding on a specific analysis type and data that have suitable spatial and temporal characteristics, in case of image data also in the spectral domain. Once suitable data types have been identified, additional constraints have to be considered: data availability and cost, software, and expertise. There can be a large difference between suitable and actually available data, such as historic images taken at different times that may allow hazards to be traced temporally, but that were never acquired. Some sensors are operated by governments, others by private companies, and cost differences for RS data are substantial. As a general trend, costs have been declining, with many current and archive datasets being either free of charge or at a nominal fee (such as Landsat Thematic Mapper [Figures 2 and 3] or ASTER data). However, data from commercial high resolution sensors, such as from IKONOS or Quickbird, cost several thousand US dollars per image. Many software packages exist to process RS data, including a range of powerful open source solutions at zero or low cost. As a general rule, more advanced RS methods, such as radar or laser scanning, require sophisticated processing tools that, like the data, tend to be expensive. In addition, while basic image processing functions, especially applied to optical data, require limited knowledge, the processing of other data types also call for expert knowledge that may not always be available or affordable.

From hazard to risk

To mitigate the consequences of disasters, suitable DRR measures need to be implemented. In addition to knowledge on all hazards present, also information on EaR and their respective vulnerabilities is required. The term EaR includes all elements of value that may suffer damage when exposed to a hazard. As such it not only comprises people, their infrastructure, economic activities and services, but also environmental assets deemed valuable, such as nature reserves or engendered species. RS, in particular high resolution optical imagery, is well suited to identify physical features in direct line of sight of a sensor, such as buildings and other infrastructure (e.g., van Westen et al., 2008). Mapping of infrastructure elements in urban areas has also benefited strongly from increasingly available airborne laser scanning data, another active RS technique. The data collected are characterized by highly accurate and dense measurements that simultaneously allow the actual ground surface (digital terrain model, DTM) and a model that includes all above-ground features such as buildings (digital surface model, DSM) to be generated. This, for example, allows one not only to identify a building (Dash et al., 2004; Rottensteiner, 2003), but via its height also to estimate the number of floors and thus the approximate number of inhabitants. This is an example of how RS-based proxies – building height in this case – can be used to map EaR that are not directly visible. For risk calculation, the monetary value of all EaR should also be considered. For some elements, such as public buildings or infrastructure, such value information may be readily available. In many Western countries similar information also exists for residential buildings. However, there are clear limits to the value information RS can contribute. As no currently operational sensing method can observe the inside of buildings, value information on assets other than the actual building cannot be obtained. Additionally, assigning values to EaR such as human beings or endangered species that can be included in risk equations leads to obvious problems.

While most EaR are physical in nature and thus mappable, assessing vulnerability has always been more difficult. Defined as the susceptibility to suffer loss (see *Vulnerability*), it differs for physical assets, people, and their social structures, and economic and environmental systems, and is strongly dependent on hazard magnitude and event duration. While early risk concepts only considered physical vulnerability, the susceptibility of other critical elements, such as social structures, economic activity, or natural systems, have only gradually become integrated in conceptual risk frameworks, and RS only recently started making a contribution in the assessment of nonphysical vulnerabilities. Using physical proxies such as building type and density, or distance to lifelines, Ebert et al. (2009) showed how social vulnerability can be quantified using high-resolution optical imagery and elevation data derived from laser scanning. A comprehensive conceptualization of how diverse vulnerability types can be included in risk assessment aided by RS was done by Taubenbock et al. (2008). RS data types and processing methods have become increasingly specific to match detailed information needs, and a combination of different methods is typically needed in RS-based risk assessment. For example, while a satellite image may cover large areas, such as the catchment from which a flood might originate, very detailed imagery is needed to map buildings and other structural elements that may be affected by a flood. Since image detail and coverage are usually inversely related (similar to a camera zoom), a multi-data approach may be needed. Assessing vulnerabilities of natural systems or economic processes may also require specific models (Rapicetta and Zanon, 2009; Schmidt-Thome et al., 2006).

Hazard monitoring and early warning

Hazard events can be seen as anomalies in natural processes. The state of such processes can be quasi-binary, that is, have a normal and a non-normal state (e.g., either there is wildfire or not), or the process can follow more or less well-defined patterns. An example for the latter is the annual growing cycle of plants (phenology), whereby a drought condition constitutes an anomaly, one that is plant species-specific. Especially spaceborne RS is ideally suited to provide periodic surveillance to identify such anomalies. However, as in risk assessment a solid understanding of the hazard process in question and its natural variability is essential, as is a suitably matching RS strategy. A number of questions can be asked to guide the development of an appropriate strategy:

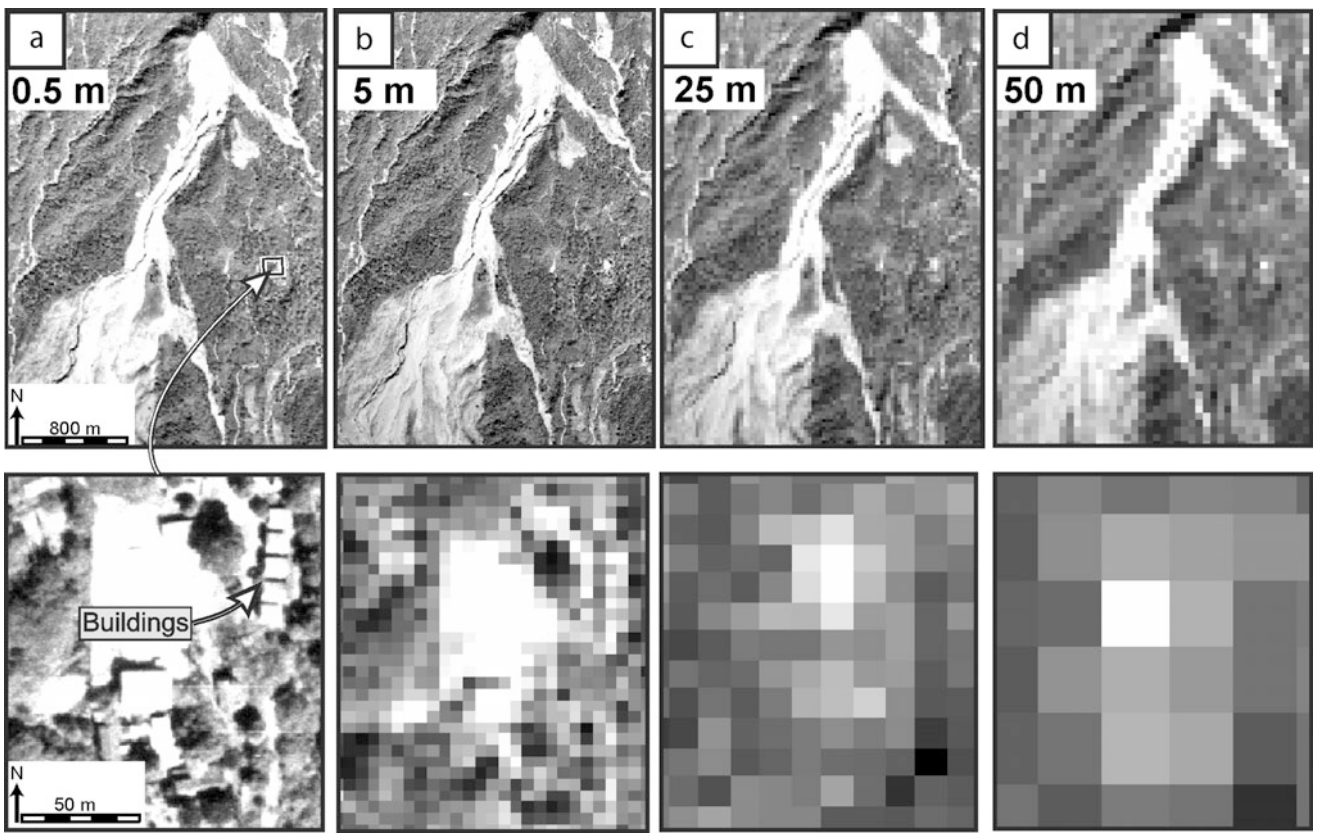
1. Which observable features precede and accompany a hazardous events?
2. What is their spatial extent and detailed expression?
3. What is the speed of onset and evolution, as well as duration?

A good example to illustrate these questions is tropical cyclone forecasting. These weather systems develop over warm ocean stretches during certain times of the year, thus it is clear when and on which areas detection has to focus. Storm systems also have a characteristic shape, often with a central, cloud-free eye. Great spatial detail is not needed, but significant developments, especially around the time of landfall can happen rapidly. Therefore, a suitable RS approach is to use geostationary weather satellites that provide data every 15–30 min for an entire hemisphere. A spatial resolution of 3–5 km is sufficient. The instruments on weather satellites also provide information on cloud top temperatures, atmospheric pressure values, wind speed and direction, and rainfall intensity, thus enough information to assess the strength, evolution, and direction of a storm (Katsaros et al., 2002). This can be coupled with other atmospheric models to provide storm track forecasting.

Tropical storms are easily observed during formation, which is also true for other hazards. Volcanoes heating up or bulging were already mentioned, processes that can occur weeks before an eventual eruption. Other hazardous processes proceed on longer timescales. For example, monitoring of desertification may only require yearly or decadal image acquisition. If the process being observed is only one aspect of a hazard, such as deforestation affecting slope stability, detection of significant changes indicates that previously quantified hazards have to be reassessed. Many hazard types have only short buildup periods and short durations, making early warning difficult, yet still possible if integrated with prior information. For example, if coupled with knowledge of watershed size and runoff behavior, RS-based rainfall detection can provide real-time information on impending floods (Asante et al., 2007), potentially allowing several hours to prepare or evacuate. There are currently no proven RS methods to provide early warnings for earthquakes. A comprehensive assessment of seismic hazard is best done through seismic microzonation, where the potential for different hazards (ground shaking, liquefaction, etc.) is quantified. However, due to the detailed data needed, this is typically done at more local to regional scales (see e.g., Fat-Helbary and Tealb, 2002). Space technology, in the form of GPS (see *Global Positioning Systems (GPS) and Natural Hazards*), can help to identify mm-scale tectonic plate movements, useful to identify areas where seismic stress is building up (Sturkell et al., 2006). Tsunami hazard is one type where RS can contribute little. For tsunamis caused by island flanks sliding into the sea, slope stability monitoring is possible (Puglisi et al., 2005). Monitoring of deep-sea fault lines with RS cannot be done, and real-time observation of tsunamis that propagate at speeds of 600–900 km h^{-1} is only a theoretical, but currently not operational option (Fujii and Satake, 2007). Pressure gauges on the ocean floor, together with an effective international warning system, are a better option.

Existing monitoring systems

A number of satellite-based monitoring systems have been established, such as for drought hazards, volcanic activity, wildfires, tropical storms, and other weather phenomena (already described above). The US National Oceanic and Atmospheric Administration (NOAA) operates a system based on multiple Advanced Very High Resolution Radiometers (AVHRR) that observe all land areas at least twice a day at a resolution of 1.1 km. These data are useful for drought monitoring and even yield estimation for specific crops. The critical aspect of drought is less the actual precipitation amount, but rather its effect on vegetation growth, i.e., more when it rains instead of how much it rains. Hence, products such as rainfall anomalies can be used to assess where water shortages may exist. Even more specific is an assessment of actual vegetation health. This can be done via the Normalized Difference Vegetation Index (NDVI), which measures the chlorophyll content of vegetative matter, and thus its health (Lillesand et al., 2004). This knowledge has to be integrated into a more comprehensive framework that considers local agriculture patterns, regional and national drought and famine mitigation strategies, and relief distribution systems. For example, in Africa, the most famine-affected continent, NOAA collaborates with the USAID/Famine Early Warning System (FEWS, www.fews.net) to provide satellite-based precipitation anomaly and food security information.



A simpler system is used to detect magmatic activity at active volcanoes. A global hotspot detection system based on data from the Moderate Resolution Imagining Spectroradiometer (MODIS) is operated by the Hawai'i Institute of Geophysics and Planetology (HIGP, http://modis.higp.hawaii.edu/) at the University of Hawaii. The HIGP MODIS Thermal Alert System provides worldwide near-real-time information on thermal anomalies, using

the MODVOLC algorithm (Wright et al., 2004). Based on 1 km data, it is not only sensitive to significant heat emissions such as those occurring during magmatic activity, but also wildfires. As part of the Hyogo Framework for Action, it was agreed to set up a Global Multi-Hazard Early Warning System, which also includes a dedicated Global Early Warning System for Wildland Fire that is currently being set up (http://www.fire.uni-freiburg.de/).

Emergency response

RS images are most frequently seen in the public domain following a disaster. Remote sensing, especially space-based monitoring, has proved to be an excellent information source for emergency response at local, regional, and global scales, due to its (1) synoptic (i.e., large area) coverage, (2) frequent and repetitive collection of data of the Earth's surface, (3) diverse spectral, spatial, and potentially three-dimensional information, and (4) relatively low cost for per unit coverage. Hence, often images have already been acquired before ground-based support reaches a disaster site, and can then be used to guide response operations. Until recently, those data were only accessible to select organizations responsible for post-disaster image processing. Beginning with the 2010 Haiti earthquake, high-resolution post-disaster images (although not the individual spectral image bands) were made available in Google Earth shortly after acquisition, making the information accessible to anyone.

As with hazards, the availability and suitability of RS data depend on the disaster type, as is illustrated in Figure 5. To observe the 1998 volcanic mudflow at Casita volcano (Nicaragua), and even to determine principal structural features, even 50 m resolution imagery is sufficient (Figure 5d). However, to identify individual buildings that may have been affected by smaller flows and landslides (Figure 5a), much higher resolution is needed (Kerle et al., 2003). In addition to the many spatial, temporal, and spectral parameters that determine the value of a given dataset, yet more constraints apply in the aftermath of a disaster event. While rapid data acquisition is desirable, space infrastructure is tied to predefined orbital paths, only partly alleviated by the pointability of more recently launched sensors that can increase the temporal resolution, and a gradually growing number of satellites that provide more frequent observation opportunities. To answer the increasingly detailed information demands from the multitude of stakeholders responding to large disaster events, data from high spatial resolution

Remote Sensing of Natural Hazards and Disasters, Figure 5 Aerial photo of the 1998 mudflow at Casita volcano, Nicaragua, progressively degraded from 0.5 m (**a**) to 50 m (**d**). While the flow structure remains well identifiable, individual buildings (**a**) are only recognizable at very high resolution.

sensors are needed. These, however, only cover narrow strips of land, thus several days or weeks can still pass before a larger emergency scene, such as after flooding or an earthquake, is completely imaged at high resolution. Radar remote sensing has proved useful for several disaster response scenarios, such as to detect earthquake damage (Arciniegas et al., 2007), map flood extent (Tralli et al., 2005), or following technological disasters such as oil spills (Brekke and Solberg, 2005). In most other areas, optical data are used, yet those require cloud-free conditions, a further serious constraint on rapid data availability.

Disaster constellations and international disaster support

Individual and largely uncoordinated satellites have limited utility in global emergency response efforts. Similar to GPS (see Global Positioning Systems (GPS) and Natural Hazards), which is based on a network of 24 satellites, a constellation comprising a number of coordinated satellites would thus be more appropriate. Such a solution, the Disaster Monitoring Constellation (DMC), was initially proposed in 1996 and led by Surrey Satellite Technology Ltd (SSTL), UK. The objective of the constellation is daily global imaging capability by means of a network of five low-cost microsatellites (da Silva Curiel et al., 2005). They are owned by Algeria, China, Nigeria, Turkey, and the UK, an unlikely alliance for an international effort. In addition to daily revisits, another substantial strength of the DMC satellites is the large ground coverage in tiles up to 600 km wide, as well as its global reach. For example, NigeriaSat-1 was the first civilian satellite to image the Gulf areas affected by Hurricane Katrina in 2005. However, the price for the large coverage and high temporal resolution is the medium spatial resolution (28–32 m). The initial network has since been expanded to include the Spanish Deimos-1 satellite, while the Turkish instrument failed in 2007. Instead of launching dedicated satellites, the Sentinel Asia program focuses on coordinating the use of existing space infrastructure, together with auxiliary spatial data, for disaster risk management. It is coordinated by JAXA, the Japan Aerospace Exploration Agency.

In addition to technical solutions for improved disaster response, a successful organizational approach also exists. The International Charter "Space and Major Disasters" aims at a more efficient use of existing space technology during a disaster response phase. Initiated by the European and French space agencies (ESA and CNES) in 1999, it became operational in 2000. It provides a unified system of space data acquisition and delivery for a rapid response to natural or man-made disasters. So far, the Canadian Space Agency (CSA), the Indian Space Research Organization (ISRO), the Argentine Space Agency (CONAE), JAXA, the United States Geological Survey (USGS), NOAA, the DMC-operator DMCII, and the China National Space Administration have joined the Charter. Each member agency has committed resources to support the data collection of the Charter to improve the efficiency of data provision for emergency responses globally (www.disasterscharter.org). To date, the Charter has been activated nearly 200 times, responding to a variety of natural and technological emergencies (see e.g., Bessis et al., 2004). Once the Charter is activated, the most suitable and most quickly available space resources of the participating partners are used to obtain imagery of the affected areas. These data are then further processed by Charter partners, such as the German Space Agency (DLR), UNOSAT or SERTIT, who provide map products that are made available via the Global Disaster Alert and Coordination System (GDACS, http://www.gdacs.org/), ReliefWeb (http://www.reliefweb.int) or Reuters's AlertNet (http://www.alertnet.org/). Such organizational improvements are arguably of greater value than the mere launching of more satellites.

Further detailed information on the utility of airborne and spaceborne remote sensing in emergency response is given by Kerle et al. (2008) and Zhang and Kerle (2008), respectively. Examples of how satellite remote sensing has been used for emergency responses are also given by Metternicht et al. (2005) on landslides, and by Tralli et al. (2005) on earthquakes, floods, and other disasters.

Unmanned aerial vehicles (UAV)

Given the dynamics involved in disaster response, permanent monitoring during the emergency response phase is desirable. This, however, can only be provided by geostationary (and low spatial resolution) sensors, or by airborne systems. The latter, in particular, the development of unmanned aerial vehicles (UAV), has seen substantial attention in recent years. UAVs range from the very small (weighing only grams) to full-scale aircraft, and offer substantial potential for hazard monitoring and emergency response applications. Most are tropospheric (i.e., flying at low altitudes below approx. 12 km), whereas others are semiautonomous High Altitude Long Endurance (HALE) UAVs, designed to operate on solar power and allowing autonomous missions of up to several months duration in altitudes of 12–30 km (Baldock and Mokhtarzadeh-Dehghan, 2006). Smaller and less expensive platforms can facilitate rapid scene assessments, while large versions provide a stable platform for multi-instrument surveys. UAVs have become indispensable in fighting of large wildfires, particularly in the USA. While the focus initially was on the detection of hotspots, fire perimeters, and burned ground extent, fire intensity and fuel consumption are now also quantified to aid in the understanding of fire spread behavior. This can only be achieved with detailed and frequent data no other platforms can provide (Ambrosia et al., 2003). The RS instruments carried on those platforms are typically integrated into complete sensing systems with direct satellite or radio link for fast data processing.

Outlook and trends

Natural or industrial hazards and emergencies, with their wide variety of spatiotemporal and damage characteristics, call for an equally diverse arsenal of tools to aid in their mitigation and response. Remote sensing provides an entire suite of sensors and platforms that allow pertinent data to be collected on any given form of hazard and disaster. To that end, relevant sensors can be deployed on the ground, in the air, or in space, and a number of interesting trends and developments can be identified.

- As was pointed out elsewhere the number and sophistication of civilian Earth observation satellites has been increasing, with some 60 currently being operated. They have been characterized by increasing spatial resolution and geometric accuracy, often with stereo observation capability, and improved geolocation of the resulting imagery. Such stability is essential to relate specific pixels unambiguously to the corresponding place on Earth. They also tend to have increased onboard data storage capacity that allows data over longer stretches without data receiving stations to be acquired.
- At the same time, the number, versatility, and reliability of alternative platforms has been increasing, whose cost has also been diminishing. UAVs, including exotic platforms such as ultralite vehicles, kites, blimps, or remote controlled model aircraft, are nowadays frequently used to carry small commercial cameras or other inexpensive sensors, often sufficient to provide the needed information in emergency situations.
- Data availability has become quicker, due to internet-based distribution, repositories such as ReliefWeb or Alertnet, and modern tools such as Google Earth.
- Distributed computing and crowdsourcing is allowing more rapid information processing. For example, several organizations, such as UNOSAT or ImageCat, are experimenting with using a global pool of experts to perform joint image analysis, using a participatory approach with individual image tiles being assigned via a web platform. Google Earth is also increasingly used as a platform for this type of collaboration.
- Ground-based hazard monitoring is experiencing great progress through sensor networks. Those are increasingly composed of small, wireless nodes that carry a multitude of sensors (temperature, humidity, gas analyzers, etc.), that form autonomous, self-configuring, and self-repairing networks. Such a network has, for example, been successfully deployed in a volcanic setting (Werner-Allen et al., 2006; see also Douglas et al., 2008), where its continuous monitoring can well be augmented with the synoptic, but less frequent, data provided by air- or spaceborne instruments. One development trend is toward "smart dust," tiny and cheap sensor chips that can be dropped in large numbers over a hazardous area or disaster scene to self-configure into a sensing network.
- Developments are going on to deploy real-time video cameras on satellites that allow continuous data reception of a disaster area for several minutes, again potentially providing a valuable addition to static data from other RS instruments.

RS-based hazard and disaster monitoring has a very long history, beginning with the first well-documented case in 1906 in San Francisco. A series of kites, the topmost reaching a height of some 600 m, carried a 20 kg camera to map damage following a severe earthquake that destroyed much of the city. In the following decades, aerial photography became the most widely use platform, used for mapping in all parts of the world. Since the 1960s satellite-based solutions have been gaining steady prominence, although the high data quality of aerial imaging, now also largely digital, ensures that the traditional RS type lives on. Hazard and disaster studies have been benefiting tremendously from the data acquired by the many sensor types discussed in this entry, and we are now experiencing a move toward an ever more integrated sensor system that continuously monitors all relevant environmental systems to provide knowledge on hazards, dangerous situations developing, or in case of disastrous events. The Global Earth Observation System of Systems (GEOSS; Hart and Martinez, 2006) embodies such a unified strategy.

RESERVOIR, DAMS, AND SEISMICITY

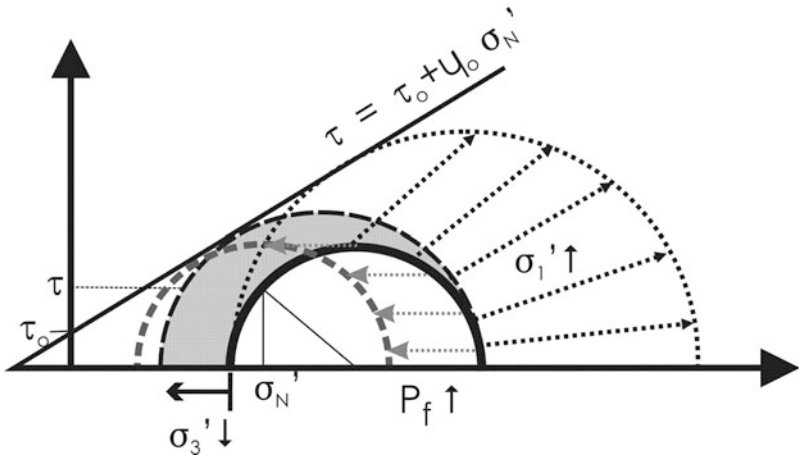
Maurice Lamontagne
Natural Resources Canada, Ottawa, ON, Canada

Synonyms

Anthropogenic seismicity; Reservoir-induced seismicity; Reservoir-triggered seismicity; Stimulated seismicity

Definitions

Reservoir – An artificial pond or lake used for the storage and regulation of water.
Dam – A barrier constructed across a waterway to control the flow or raise the level of water.
Seismicity – Earthquake activity experienced in a given region.



"Reservoir-induced seismicity" (RIS) is the seismic activity recorded in the vicinity of an impounded water reservoir. RIS is caused by stress change comparable in magnitude to the ambient shear stress acting on a fault to cause slip (McGarr et al., 2002). McGarr et al. (2002) define the seismicity around a reservoir as "Reservoir-triggered seismicity" (RTS) if the stress change is only a small fraction of the ambient level. In other words, RIS occurs if the stress perturbations cause an earthquake (it would not have occurred without the perturbation) whereas RTS implies that the perturbations barely "advanced the clock" of a seismic event that would have eventually occurred. Most cases of earthquake activity following reservoir impounding would fall in the RTS category. At least 70 cases of recognized RTS are recognized worldwide (Gupta, 1992) but it is possible that much low level seismicity had escaped detection as one goes back in time. Damaging RTS has occurred at Hsinfengkiang (China), Kariba (Zaire), Kremasti (Greece), Koyna (India), Oroville (USA), and Aswan (Egypt) (Gupta, 1992).

Some characteristics of RTS can be explained by the complicated interactions of a number of rock mechanics factors. Earthquakes are dynamic slip instabilities usually occurring on preexisting sliding surfaces. In a highly fractured intraplate environment subject to deviatoric stresses, fractured rocks can slide abruptly, generating earthquakes. To cause slip on a fracture, the shear stress, induced by the existence of a tectonic stress field, has to overcome friction. The frictional law can be written as the Navier-Coulomb criterion (Figure 1):

$$|\tau| = \tau_o + \mu_o(\sigma_N - P_f) = \tau_o + \mu_o \sigma_N{}'$$

where τ and σ_N are the shear and normal stress acting on the plane of fracture, μ_o denotes the friction coefficient, τ_o is the cohesion, P_f is the pore fluid pressure, and $\sigma_N{}'$ is the effective normal stress. Failure occurs when the shear stress τ exceeds the shear strength of the material. Given the fault orientation, failure can be triggered by changes in $\sigma_N{}'$ which can be brought about by: (1) an increase in σ'_1 (maximum effective compressive stress), (2) a decrease in σ'_3 (minimum effective compressive stress), or an equal decrease in all effective principal stresses, for example, due to an increase in P_f (Saar and Manga, 2003). The first two mechanisms cause failure by increasing the effective differential stress, $\sigma'_1 - \sigma'_3$, and thus the shear stress, τ. The third mechanism induces failure by decreasing the effective strength of the material caused by a decrease in $\sigma_N{}'$, which unlocks the fault and moves the Mohr circle closer to the Mohr-Coulomb failure envelope, while leaving τ unchanged.

Note that RTS involves the complex interaction between all three of the factors τ, σ_N, and P_f. Factors that affect RIS are: ambient stress field conditions, availability of fractures, hydromechanical properties of the underlying rocks, geology of the area, together with reservoir dimensions and the nature of lake-level fluctuations (Talwani, 1997). In real situations, most of these geological factors are poorly determined, notably the permeability of lineaments and fractured zones. Finally, if the mid to upper crust of intraplate areas is in a state of stress close to failure, as is generally assumed, then even small perturbations can trigger seismicity (McGarr et al., 2002).

Reservoir, Dams, and Seismicity, Figure 1 Mohr circle with Mohr-Coulomb failure envelope (diagonal line). τ shear stress, τ_o cohesion, μ_o friction coefficient, $\sigma N'$ effective normal stress, *Pf* pore-fluid pressure. Fault reactivation occurs when the Mohr circle touches the Mohr-Coulomb failure envelope. This can occur by increasing the effective principal stress, decreasing the effective minimum stress or by increasing the pore fluid pressure. For additional description see main text.

Two types of RTS are recognized: "rapid response" and "delayed response" (Simpson et al., 1988; Guha, 2000). Rapid response can be explained by an instantaneous change in the elastic stress following impoundment, leading to elastic compression, which increases the pore-fluid pressure on faults at depth. These induced fluctuations in pore-fluid pressure (P_f), due to an increase in σ_1 (e.g., by the weight of a filling reservoir that contracts the pore space) occur immediately. For this type of RTS, shallow ($\leq$10 km) low-magnitude seismicity in the vicinity of the reservoir follows immediately on first loading. In contrast, delayed response is explained by the diffusion of pore-pressure along fractured zones in a near-failure state caused by reservoir impoundment. This delayed response type is characterized by deep ($\geq$10 km) moderate to large magnitude earthquakes that occur beyond the confines of the reservoir with a significant delay after first filling.

Most cases of RTS are related to the impounding of large reservoirs. Studies have shown that it is not so much the weight of the water that is important as much as the increase of hydrostatic pressure along faults. There is no fixed rule about the timing of this RTS: it can occur at any stage during the impounding or years afterward. Although most RTS is of small magnitude, there have been a few cases of large magnitude RTS, such as the 1967 M 6.3 Koyna reservoir earthquake (Gupta, 1992). The latter example caused damage and casualties. The current accepted number of RTS worldwide is somewhere between 40 and 100 (ICOLD, 2011). Recognizing RTS versus "normal" seismicity is not always evident. To help define the nature of the recorded earthquakes, it is generally recommended that earthquake monitoring with a local network of seismographs starts a few years prior to the beginning of reservoir impounding.

Although no tectonic environment is immune from RTS following reservoir impounding, areas of normal and strike-slip faulting appear most favorable to its occurrence (ICOLD, 2011). RTS in the Canadian Shield (an intraplate environment) is either absent or of small magnitude (maximum magnitude 4.1; Lamontagne et al., 2008). There is no absolute rule to evaluate RTS potential beforehand, it is generally accepted that the potential is greater for reservoirs exceeding 100 m of depth (ICOLD, 2011). The potential for RTS should be included in the design of dams and appurtenants structures for large or deep reservoirs (ICOLD, 2011).

Adaptability; Flexibility; Robustness; Transformability

Definition

In disaster studies, resilience is defined as "the ability of a system, community or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions" (UNISDR, 2009).

Discussion

The concept originated in the field of Ecology: in 1973, Holling defined resilience as a measure of the ability of a system to absorb changes and still persist. Later, he refined this definition, emphasizing that systems, namely complex ones, can evolve toward different states of equilibrium. Therefore, resilience can be interpreted as a measure of the magnitude of disturbance that can be absorbed before a system changes its structure, by changing variables and processes that control its behavior. This approach, labeled as "ecological resilience," contrasts with "engineering resilience" (Holling, 1996), related to the capacity to withstand the external stresses and to the rapidity of restoring previous equilibrium (Pimm, 1984).

Research on complex adaptive systems drove to a widening of the resilience concept – also thanks to the studies carried out by the Resilience Alliance, a multidisciplinary research group established in

1999 – including relevant properties, such as self-organization, learning, and adaptation (Folke et al., 2002).

Starting from the 1990s, resilience has gained prominence in the disaster field: most international reports devoted to risk reduction have emphasized the need for focusing on resilience rather than *Vulnerability*, due to the positive meaning of the former, relative to the negative implications of the latter. Nevertheless, the relation between resilience and vulnerability is still largely debated and at least two different schools of thought can be distinguished:

- Resilience as the opposite of vulnerability (Fortune and Peters, 1995);
- Resilience and vulnerability as independent, or partially overlapping, processes (Paton and Johnston, 2006).

Currently, the main challenge is represented by turning resilience into operational terms. The main features of a system that may induce resilience have been identified (Godschalk, 2003) and some attempts to quantify some of these features have been carried out (Tierney and Bruneau, 2007). Nevertheless, the term is still so vague that "is in danger of becoming a vacuous buzzword from overuse and ambiguity" (Rose, 2007, 384).

RICHTER, CHARLES FRANCIS (1900–1985)

Susan Hough
Southern California Earthquake Center, Pasadena, CA, USA

The one seismologist with global, iconic name recognition was in fact an accidental seismologist with a complicated life story. Charles Francis Richter was born near Hamilton, Ohio, USA on April 26, 1900 and raised by his mother and maternal grandfather. In 1909, the family, including older sister Margaret, moved to Los Angeles, where Richter had his first and not entirely happy experience with formal education. By his teens, Richter had developed a keen interest in astronomy and an abiding passion for the local mountains. Following a year at the University of Southern California, he transferred to Stanford University, earning a degree in physics in 1920. Socially awkward and painfully introspective, Richter's emotional struggles escalated during his college years, landing him back in Los Angeles under the care of a psychiatrist. By 1923, he had regained enough equilibrium to apply to the Ph.D. program at Caltech. Working under Paul Epstein, in 1928, Richter completed his Ph.D. thesis on the spin of hydrogen atom. Around that time, Harry Oscar Wood, head of the Pasadena Seismological Laboratory, asked Caltech head, Robert Millikan, about potential candidates for a position analyzing the seismograms from newly developed instruments. Millikan suggested Richter. Richter accepted the position, viewing it as a temporary assignment until he could move on to a position in the field of physics. In 1928, he married Lillian Brand, a writer and writing teacher. Brand had a son from a previous marriage; she and Richter had no children. The couple shared eclectic interests, including avante garde theater, hiking, writing poetry, and social nudism. As a young assistant in the Seismo Lab, Richter began to analyze recordings of local earthquakes, within a few years tackling the problem of a first-ever scale to measure *Earthquake* size. He borrowed the term "magnitude" from astronomy, and drew on earlier work by Japanese seismologist K. Wadati to develop distance corrections for seismograms recorded by a network of stations. He incorporated Caltech colleague Beno Gutenberg's suggestion to develop a logarithmic scale. The Richter scale is open-ended: Negative magnitudes are possible, and there is no prescribed upper limit. Richter tuned the scale so that magnitude 0 would be the smallest earthquake that he calculated could be recorded under normal conditions. It is not clear if the scale was tuned at the upper end, but in his seminal 1935 publication, Richter wrote that the 1906 San Francisco earthquake "may have been of magnitude 8." In later years, Richter worked in collaboration with Gutenberg to extend the scale beyond southern California, and to better estimate the size of large earthquakes. Many magnitude scales were developed later by others, all designed to follow Richter's original

formulation. Richter's later publications focused on global earthquakes, the magnitude distribution of earthquakes in a given region, and seismotectonics of southern California. The 1933 Long Beach earthquake inspired a lifelong commitment to earthquake hazard and preparedness. Late in his career, Richter was an ardent and vocal skeptic of earthquake prediction research. Charles Richter died of congestive heart failure on September 30, 1985.

RIGHTS AND OBLIGATIONS IN INTERNATIONAL HUMANITARIAN ASSISTANCE

George Kent
University of Hawai'i, Honolulu, HI, USA

Definition

Rights and obligations of different parties in relation to international humanitarian assistance need to be clarified. There are many different issues, in relation to disaster and non-disaster situations, conflict and nonconflict situations, and many other contingencies. There is confusion regarding the rights of those who provide assistance and the rights of the needy to receive assistance.

This contribution describes the current framework regarding international humanitarian assistance and the troubled status of the concept of humanitarian intervention. That is followed by a brief account of the right to assist and the right to assistance. Then a framework is suggested in which rights and obligations of providers and receivers can be related to one another. The conclusion calls for more systematic formulation of rights and obligations regarding international humanitarian assistance, to be established through agreements among all countries, strong and weak.

Framework

International humanitarian assistance may be needed in many different kinds of circumstances. The United Nations International Strategy for Disaster Reduction (ISDR) is the focal point in the UN System to "promote links and synergies between, and the coordination of, disaster reduction activities in the socioeconomic, humanitarian and development fields, as well as to support policy integration." ISDR's definition of disaster is

> A serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources (United Nations. International Strategy for Disaster Reduction, 2006).

There is no distinction here between so-called natural and human-made disasters. Assistance is called for when there is a serious disruption of the community's functioning, regardless of the underlying cause of that disruption.

International human rights law does not explicitly address the right to protection and relief from disasters, but this is clearly implied. Article 3 of the *Universal Declaration of Human Rights* states, "Everyone has the right to life, liberty, and security of person." Article 25 states, "Everyone has the right to a standard of living adequate for the health and well-being of himself and of his family, including food, clothing, housing and medical care and necessary social services, and the right to security in the event of unemployment, sickness, disability, widowhood, or old age or other lack of livelihood in circumstances beyond his control." These rights are further elaborated in subsequent human rights agreements, particularly the *International Covenant on Economic, Social, and Cultural Rights.*

At an international colloquium on rights to humanitarian assistance held at UNESCO in Paris, one participant proposed seven rules that summarize international law relating to rights and duties to humanitarian assistance:

1. States have a *duty* to provide humanitarian assistance to victims in their territory or under their control.
2. States, IGO's [intergovernmental organizations such as UN agencies] and NGO's [nongovernmental organizations] have a *right* to *offer* humanitarian assistance to other States.
3. States, IGO's and NGO's have a *right* to provide humanitarian assistance to victims in other States with the *consent* of these States – in case of disintegration of governmental authority and of civil war – with the consent of the relevant local authorities.
4. States have *no duty* to provide humanitarian assistance to victims in other States but they have a *duty* to *facilitate* humanitarian assistance lent by other States, IGO's or NGO's. If measures of coercion are taken against a particular State, supplies for essential humanitarian needs have to be exempted from them.
5. The Security Council, by virtue of Chapter VII of the Charter, may determine that the magnitude of a human tragedy constitutes a threat to international peace and security and *authorize* States or UN forces to take all measures necessary to bring humanitarian assistance to the victims.
6. States have a *duty* to *admit* humanitarian assistance furnished by other States, IGO's or NGO's in accordance with international law. They may not arbitrarily refuse their consent.

7. Individuals have a *right* against the State under whose control they are to receive humanitarian assistance insofar as this State has a duty to provide humanitarian assistance or to permit its distribution according to rules 3, 4, and 6 (Schindler, 1993).

Thus, states have a right but not a duty to provide international humanitarian assistance. The central argument of this entry is that states should have a duty to provide international humanitarian assistance under some circumstances.

Humanitarian intervention

The idea of inviolable national sovereignty, based on the Peace of Westphalia of 1648, served the international system well from the seventeenth century into the twentieth century. That agreement established the basic principles of the modern nation-state system: countries are sovereign, and thus have no formal authority above them, and they are not permitted to involve themselves in the internal affairs of other countries without the latter's permission. Currently, however, we see violations of human rights. Many now feel that the international community should act to protect those whose rights are violated, at least when there are extensive violations.

One response has been the emergence of the doctrine of humanitarian intervention. Under this doctrine, the traditional Westphalian principle of immunity from outside interference remains in place, but with the qualification that under some extreme circumstances and with appropriate legal processes, the international community may forcibly intervene to protect human rights.

In international law, intervention generally refers to forcible intrusion, usually with military force, into the affairs of nations by outsiders (Haass, 1994; Lyons and Mastanduno, 1994). Despite extensive debate, the doctrine of *humanitarian* intervention remains ill-formed. Some individuals equate humanitarian intervention with any sort of humanitarian assistance in armed conflict. Some use the term to refer to military action to free civilians from situations in which there are serious violations of human rights. Perhaps humanitarian intervention is best understood as *humanitarian assistance provided to people within a nation by outsiders without the consent of the national government*.

Humanitarian intervention occurs when there is a claimed right to deliver humanitarian assistance despite the absence of consent from the government of the receiving nation. A distinction should be made between the simple absence of consent to the delivery of assistance, and the clear refusal of such assistance. In the case of the US-led intervention into Somalia in October 1993, for example, there was neither approval nor refusal. Rather, civil order had collapsed to such a degree that there was no Somali national government in place to grant or deny consent to the delivery of assistance. Perhaps intervention in the absence of consent should have different guiding rules than intervention in the face of clear refusal of consent.

While many individuals define humanitarian intervention as armed intervention into states for humanitarian purposes, it has been argued that this historical understanding "has no place in the system established by the UN." In the legal framework based on the UN Charter, unilateral state intervention is allowed solely for protecting national independence (Sandoz, 1992, 217–218).

The International Commission on Intervention and State Sovereignty tried to address the legitimacy issue by advancing a new doctrine on The Responsibility to Protect, clarifying guidelines for humanitarian intervention. The approach was highlighted in a UN report on *A More Secure World* (High-level Panel, 2004), a UN declaration in 2005, and again in the G8 Summit in 2006. On April 28, 2006, in Resolution 1674, the UN Security Council asserted the right of the international community to provide protection to people whose human rights were being violated. It acknowledged that under some circumstances the international community has a responsibility to provide such protection, but this responsibility was not spelled out.

The responsibility to protect has been viewed mainly as the duty of governments of the countries on the receiving end of the intervention. The terminology could suggest that the countries that do the intervening have specific *obligations* to intervene when necessary for humanitarian purposes, but a careful reading of the discussions indicates that the international community really uses this doctrine to assert its *right* to intervene. The *Guardian* recognized this when it referred to "the UN declaration of a right to protect people from their governments (Williams, 2005)." Similarly, the African Union proclaimed, in its Constitutive Act, "the right of the Union to intervene in a Member State... in respect of grave circumstances, namely war crimes, genocide and crimes against human humanity." It did not speak of a duty to intervene in such circumstances.

The assertion of a right to assist under some circumstances, with no counterpart obligation to assist under any circumstances, implicitly invites the politicization of assistance decisions. The view taken here is that those who provide assistance on humanitarian grounds should not be entirely free to choose who and when they help. Assistance in situations like the genocide in Darfur or the widespread malnutrition in North Korea or Zimbabwe should not be optional, at least so long as they can be undertaken with reasonable safety.

In October 2006, Vaclav Havel, Kjell Magne Bondevik, and Elie Wiesel issued a report arguing that because of the widespread malnutrition and other humanitarian problems in North Korea, "the international community now has an obligation to intervene through regional bodies and the United Nations, up to and including the Security Council (Havel et al., 2006a, b)." Their call for recognition of obligations, and not only rights, on the part of those who would intervene was not well received.

It is not surprising that the providers of assistance tend to emphasize their rights rather than their obligations. However, one would think that if the powerful are going to claim a right to assist under some conditions, they also should have an obligation to assist under some conditions (Kent, 2008, 1–31).

Right to assist versus right to assistance

A right to assistance means that people meeting criteria specified in the law are entitled to receive services specified in the law. For example, in some countries women with children whose incomes fall below a particular level are entitled to monthly stipends calculated according to an established formula. Or children in a particular age bracket and meeting certain residency requirements might be entitled to free immunizations. Entitlements of this form are the basis for human services (welfare) programs in many countries.

If there is a right of those in need to receive assistance under specified conditions, then there must also be an obligation for others to render assistance. These obligations are specific responsibilities for action. Typically, in the area of human rights, individuals have specific rights, and the government has specific obligations to fulfill those rights. When rights are described in the law, the counterpart obligations of government, and the specific agencies responsible for their implementation, ought to be described as well. The rights/obligations nexus can be understood as a kind of contract, explicit or implicit, that establishes who is to do what under what conditions.

Whether within nations or internationally, the challenge is to determine the nature of the contract: who should be entitled to what sort of assistance from whom under what conditions at whose expense? Different sorts of answers would be appropriate for different kinds of situations or needs: poverty, armed conflict, refugees, famine, chronic malnutrition, floods, droughts, terrorism, and so on. Some general principles would apply across broad categories of cases.

Many would agree that there are some extreme situations in which needy people should have a clear right to receive help. In any decent social order, if a child falls down a well, there should be a requirement that the child will be rescued. But the idea of the right to assistance has a very checkered history. For example, the law in the United States is characterized by "the missing language of responsibility (Glendon, 1991, 76–108)." Under the no-duty-to-rescue principle, bystanders are not required to come to the assistance of strangers in peril if they did not cause that peril.

This principle of no-duty-to-rescue is peculiarly American. In contrast, "most European countries do impose a legal duty on individuals to come to the aid of an imperiled person where that can be done without risk of harm to the rescuer. And the constitutions of many other liberal democracies do obligate government to protect the health and safety of citizens (Glendon, 1991, 77)."

In the case of ships in distress on the high seas, there is a well-established international duty to come to the assistance of the needy. Captains failing to meet this obligation have been prosecuted. However, there is no general duty of nations to respond to distress in other nations. The major international human rights instruments are concerned primarily with the responsibilities of States Parties to their own people, not to people elsewhere. They do call for international cooperation in working toward the realization of human rights. For example, the *International Covenant on Economic, Social, and Cultural Rights* requires States Parties "individually and through international cooperation to take the measures needed" to implement the agreement. In practice, however, there is no clear hard duty to provide humanitarian assistance internationally. There is no history of case law with respect to international humanitarian assistance.

The needy are sometimes viewed as having a right to assistance in the limited sense that no third party may interfere with its delivery. This is different from a right to assistance as an entitlement, in which the providers of assistance have an obligation to provide it. Table 1 illustrates the relationship between the concepts.

Providers of humanitarian assistance generally emphasize their right to provide assistance, cell A in the table. Where that right is claimed under the right to protect doctrine, it is implied that governments of receiving countries have an obligation to accept assistance, cell D. This relationship is in the A-D diagonal of the matrix. Little attention has been given to the idea that under some conditions providers might be obligated to give assistance (cell B), because under some conditions others might have a right to receive assistance (cell C). This relationship is in the B-C diagonal.

If a party has a right to receive assistance under some conditions, arguably that party also should accept an obligation to receive assistance under some conditions. And if a party has a right to provide assistance under some conditions, perhaps that party also ought to have the obligation to provide assistance under some conditions. These relationships are in the rows of the table, A-B and C-D.

It can be argued that parties receiving assistance should also recognize obligations to monitor and report on the distribution and impact of that assistance, or at least allow such monitoring and reporting. There have been cases in

Rights and Obligations in International Humanitarian Assistance, Table 1 Rights and obligations of providers and receivers of assistance

	Rights	Obligations
Providers	A. right to provide	B. obligation to provide
Receivers	C. right to receive	D. obligation to receive

which countries receiving assistance did not allow any tracking of it after it arrived in national ports, thus raising suspicions about its possible misuse.

While people of poor countries would be the primary beneficiaries of rights-based international assistance, their governments sometimes resist because of their concern with guarding their sovereignty. They fear that humanitarian intervention might be used against them for political purposes. The governments of weak countries do not want powerful countries, which might have ulterior political motives, intervening without their consent under the pretense of providing assistance.

Why should weak countries accept the idea that outsiders can intervene when they see fit, but not be under any obligation to assist when it is not politically convenient for them? There should be more symmetry in the doctrine. If the international community is to have the right to intervene to provide assistance in some circumstances, there also should be some circumstances in which the international community has an obligation to provide assistance.

Rights of the needy to receive international assistance, as distinguished from rights of outsiders to provide assistance, are rarely discussed. Where the rights of the needy are considered it seems it is mainly to clarify the conditions under which intervention may be undertaken (Guiding Principles, 1993). In 1988 France proposed a General Assembly resolution for disaster relief based on explicit recognition of the rights of the needy to receive assistance, but that aspect disappeared by the time Resolution 43/131 of December 8, 1988 was finalized (Beigbeder, 1991, 354, 380–383).

If it were agreed that the international community had an obligation to assist under some circumstances, the obligation would have to be mitigated in the face of extreme danger, as in armed conflict situations. However, in such situations, consent is often given by the combatants, together with assurances of safe passage, to the International Committee for the Red Cross, UNICEF, and other humanitarian agencies. Indeed, ICRC specializes in obtaining such consent. The key problem in providing international humanitarian assistance in conflict situations is not so much the presence of the conflict as the absence of consent.

There is now no hard duty to provide international assistance based on explicit rights of the needy to receive assistance. There should be not only a right but also an obligation to provide international humanitarian assistance under some circumstances. There should be an obligation on the part of the international community to provide assistance at least when such assistance is welcomed by the receiving nation. The international community could recognize an obligation to *offer* assistance even in conflict situations or other situations in which there are doubts about whether it would be accepted. There would then be an obligation to deliver that assistance if the parties controlling the situation consented and safe passage was assured.

There is a need to create a new global regime of clear rights and obligations for those who provide humanitarian assistance and those who receive it. This would be likely to make the system more effective and more just, and thus contribute to the steady strengthening of overall global governance.

Summary

Currently nations have a right but not a duty to provide international humanitarian assistance. It is argued here that nations should have a duty to provide international humanitarian assistance under some circumstances.

The doctrine of the *responsibility to protect* has been used by the international community to assert its *right* to assist, not as the recognition of a *duty* to assist, in certain circumstances. The assertion of such a right with no counterpart obligation implicitly invites the politicization of decisions to assist. As in the case of domestic emergency services, the provision of assistance should not always be optional. There should be an obligation on the part of the international community to provide assistance at least in some circumstances.

A clear system of rights and obligations for those who provide humanitarian assistance and those who receive it would be likely to make international humanitarian assistance more effective and more just, and thus contribute to the steady strengthening of overall global governance.

RIP CURRENT

Wayne Stephenson
University of Otago, Dunedin, New Zealand

Definition

Rip currents are narrow currents initiated close to the shoreline that flow strongly in a seaward direction through the surf zone and beyond and are an important mechanism for the offshore transport of water and sediment and consequently play a major role in shaping beach morphology.

Discussion

Rip currents are a common occurrence on beaches and are a significant threat to beach users since they are capable of moving bathers offshore into water depths greater than wading depth. Rips should not be confused with the notion of "under tow"; in reality, there are no surf zone processes capable of pulling a person under water. Fatalities from drowning usually result after exhaustion because the panicked swimmer has tried to swim back to shore against the current. If caught in a rip, the best thing to do is relax and go with the flow and wait to be rescued. Stronger swimmers may be able to return to shore once the rip takes them beyond the surf.

Rip currents result from longshore variations in wave heights. Although there are competing theories as to why wave heights vary alongshore. The shoreward transport of water by shoaling waves results in longshore feeder currents flowing from areas of high waves to areas of low waves, at areas of low wave height where two feeder currents converge, water returns seaward as a discrete current. Commonly observed regular spacing of rips is attributed to these longshore variations in wave height. Generally rip spacing increases with wave height and the width of the surf zone. Rip current velocities are commonly 0.5–1.0 m/s but can exceed 2 m/s. There are a number of different types of rips depending largely on wave conditions and surf zone topography. Some beaches exhibit almost fixed rips or persistent rip currents typically controlled by rip channels. The most dangerous rips are "flash rips" that suddenly appear and drain water from the beach face then disappear; such rips are a significant threat to unwary swimmers and present significant challenges to life saving operations. Permanent rips are common on bay head beaches and are usually located at one end of the beach along the embayment wall.

Since 1949, with the advent of record keeping, it is estimated that Australian lifesavers have rescued some 300,000 people from the New South Wales surf, 90% of those rescues were associated with rip currents. Approximately 100 people die from drowning associated with rip currents each year in the USA and 80% of the surf rescues in the USA are as a result of rip currents. Research from the USA also shows that 84% of the fatalities associated with rips were male. In the UK, rip currents were shown to play a role in 71% of incidents occurring within the counties of Devon and Cornwall during the 2005 summer. Rip currents are therefore one of the most significant causes of rescues and drownings on beaches.

Management of rip current hazards involves a two-prong approach, public education about rips, and active patrolling of popular swimming beaches by surf life saving organizations. Public education takes the form of warning signs on beaches and in the media. For example, each summer, Surf Life Saving Australia runs television and print advertisements showing people how to recognize rips, warning never to swim alone and always swim between flags on patrolled beaches. Given the large number of unpatrolled beaches worldwide and ever increasing beach use, rips will remain a significant threat to peoples' safety at the beach.

RISK

Jörn Birkmann
United Nations University, Bonn, Germany

Definition

Risk and risk analysis constitute a multidisciplinary research field. In this context, the term "risk" is defined differently by various disciplines and fields of work. In natural hazard and disaster risk reduction research, *risk* is most commonly defined as the result of the interaction of a hazard (e.g., flood, hurricane, earthquake, etc.) and the vulnerability of the system or element exposed, including the probability of the occurrence of the hazard phenomena (UNDRO, 1980; Cardona, 1990; UN/ISDR, 2004, 2009; Birkmann, 2006b). Risk is estimated by combining the probability of a hazard occurrence, such as the likelihood of a flood (with a specific magnitude or intensity) and the potential scale of consequences (e.g., injury, damage, and loss) that would arise if the event strikes society or exposed elements. The analysis of the potential consequences cannot solely be based on an evaluation of the hazard phenomena. Rather, the vulnerability of the exposed element, e.g., the society at risk, has to be examined. Exposure, susceptibility, or fragility of the system, as well as its coping capacities, are key factors that determine its vulnerability (Birkmann, 2006b). While *risk* is a continuum, a disaster is one of its many "moments" or "materializations" (ICSU-LAC, 2009). However, risk and vulnerability are dynamic; hence, they may differ before, during, and after a disaster (IPCC 2012).

Introduction

Interest in the issue of risk can be traced back to Babylonian times. The development of modern risk analysis was closely linked to the establishment of scientific methodologies for assessing causal links between different types of hazardous events and adverse health effects and the mathematical theories of probability (Covello and Mumpower, 1985, pp. 33–36). Today, risk and its analysis constitute a multidisciplinary research field. In this regard, definitions of risk vary between specific disciplines such as social science, geography, engineering, environmental science, mathematics (risk/loss calculations), as well as between different fields of work, such as disaster management, risk insurance, climate change adaptation, environmental management, and disaster medicine – to name just a few (see, e.g., overview in Thywissen, 2006 and, e.g., different risk definitions in ADRC, 2005; Alexander, 2000; Alwang et al., 2001; Cardona et al., 2003; Crichton, 1999; Disaster Recovery Journal, 2005; Einstein, 1988; Garatwa and Bollin, 2002; Hori et al., 2002; *Journal of Prehospital and Disaster Medicine*, 2004; Natural Disaster Risk Management, 2001; Rashed and Weeks, 2003; Schneiderbauer and Ehrlich, 2004; Shrestha, 2002; Swiss, 2005; Tiedemann, 1992; UNDP, 2004; UNEP, 2002; Burton et al., 1993; Banse, 1996; Greiving, 2002; as well as Stewart and Melchers, 1997; Renn 1992, 2008; Cardona et al., 2003, Wisner et al., 2004, IPCC 2012).

Within the broad field of risk research related to natural or technological hazards and climate change, two major schools of thought can be differentiated that represent larger streams of discussion and discourses. The first school of thought views risk as a product of the interaction of a hazard and vulnerability – which is widely represented within disaster risk reduction research (e.g. UN/ISDR 2004). In contrast, the second school of thought views risk primarily within the broader context of decision and game theory. Consequently, risk is seen as closely linked to decisions (decision options) that could lead to loss or harm, in the light of a hazard event. These two schools of thought will be presented and discussed.

The first school of thought: risk as a product of hazard and vulnerability

The first school of thought, applied by the majority of disaster risk researchers, defines *risk* as a result of the interaction of hazard phenomena and the vulnerability of the exposed elements. This includes the probability of the hazard occurrence and the interaction with the society or elements exposed (see, e.g., UN/ISDR, 2004). Hence, risk is linked to the potential occurrence of negative consequences, in terms of physical, social, economic, and environmental losses, in a given area over a period of time, resulting from interactions between physical events and vulnerable conditions of a society or socio-ecological system.

The report of the United Nations Disaster Relief Organization (UNDRO, 1980) marks an important milestone in this context. The report defines risk as a product of hazard (H) and vulnerability (V) as they affect a series of elements (E) exposed. Examples of such elements could be different social groups and their livelihoods, properties, economic sectors, and public services as well as services of critical infrastructures. Key publications, such as the report "Living with Risk" of the United Nations International Strategy for Disaster Reduction (UN/ISDR), promote this notion of risk. The report presents the formula of *risk* being a function of hazard and vulnerability (Risk = Hazard × Vulnerability) (UN/ISDR, 2004, p. 36). Compared to this formula, some researchers incorporate

exposure as an own element and view risk as a function of hazard, exposure, and vulnerability (see, e.g., ADRC, 2005). In addition the IPCC Special Report SREX also underscores that risks are a product of the complex interaction between hazards, such as climate or weather events, on the one hand and the vulnerability and exposure of societies on the other (IPCC 2012, p. 4). Despite differences in terminology, particularly with regard to the definition of exposure, key components of the term "risk" remain the same in nearly all formulas and so-called equations. Hence, the first school of thought and the respective formulas of risk underline, that risk is determined by both, the hazard event (and its magnitude) and the vulnerability of the exposed elements. The Hyogo Framework for Action 2005–2015 – the key document of the World Conference for Disaster Risk Reduction – stresses the starting point for reducing disaster risk and promoting a culture of disaster resilience lies in the knowledge of hazards and of the physical, social, economic, and environmental vulnerabilities most societies face, in addition to the ways in which hazards and vulnerabilities are changing in the short and long term, followed by action taken on the basis of that knowledge (UN, 2005).

Overall, risks related to natural hazards and climate change are not autonomous or externally generated circumstances to which society reacts, adapts, or responds. They are, rather, the result of the interaction of society and the natural or built environment. Consequently, effective risk management essentially requires an improved understanding of this relationship, and the factors influencing it (Susman et al., 1983; Renn, 1992; Vogel and O'Brien, 2004; Birkmann, 2006a, b, c). Understanding the various types of relationships and interactions between nature and society is, therefore, key for better understanding risk. In this context, the "Science Plan for Integrated Research on Disaster Risk" of the International Council for Science (ICSU, 2008) formulates that:

> Risk depends not only on hazards but also on exposure and vulnerability to these hazards, making risk an inherently interdisciplinary issue. In order to reduce risk, there needs to be integrated risk analysis, including consideration of relevant human behaviour, its motivations, constraints and consequences, and decision-making processes in face of risks. This inevitably requires that natural scientists and engineers work together with social or behavioural scientists in promoting relevant decision-making in the risk management area. Moreover, the understanding of risk patterns and risk-management decisions and their promotion require the integration and consideration of scales that go from the local through to the international level. (ICSU, 2008, p. 14)

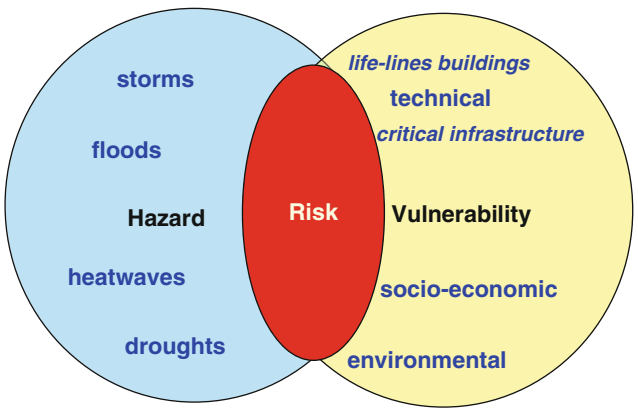
The second school of thought: risk from a sociological perspective

The second major school of thought evolved in sociological and behavioral science. According to this school of thought, *risk* is defined as an inherent characteristic of decisions, in the light of hazardous events (see Luhmann, 2003; Renn et al., 2007; Renn, 2008). Luhmann, a key authority within the sociological risk community, defined risk related to a decision of an individual or a collective to act in such a way that the outcome of these decisions can be harmful or could, in case of an event (e.g., hazard event), lead to losses and harm (Luhmann, 2003, p. 25). Consequently, *risk* is seen as an inherent element of a decision-making process particularly resulting from having options to decide in one way or another. In other words, if an individual or collective has the opportunity to decide, in the light of adverse consequences, the related decision-making process implies taking a risk. The aforementioned definitions and perspectives link risk and its theoretical and conceptual basis with the broader context of decision and game theory. According to Luhmann (1991), the term "risk" can be solely used, if a decision can be identified that could lead to loss or harm. Furthermore, he differentiated the terms "risk" and "threats." While *risk* exists if loss and harm can be linked to an outcome of a decision, *threats*, in contrast, represent loss and harm that are externally caused, without a decision of an individual or a collective (Luhmann, 1991, p. 31)

Additionally, important impulses for the risk discussion also emerged from Beck, particularly his books "Risk Society" (1986, 1992) and "World Risk Society" (2008). From the perspective of modernization processes in developed countries, Beck underscores that societies are transforming mainly due to their complex and rapid technological developments from industrial societies towards risk societies. Hence, he argues that technology and respective development pathways of societies are increasingly leading to more threats and insecurities induced and introduced by modernization itself (Beck, 1992, p. 21). Many of these new risks can no longer be directly experienced. Rather, they are inherent threats closely embedded within societal development processes. Furthermore, some of these risks involve lifestyle (choices), whereas others encompass risks of unknown statistical probability, such as Severe Acute Respiratory Syndrome (SARS) or terrorist attacks (see, in detail, Beck, 1992). In this regard, Beck calls for a reflexive modernity, an institutionalized activity and state-of-mind, involving constant monitoring and reflections upon and confrontation with these risk phenomena. The idea of a reflexive modernization can be linked to some extend to the broader discussion of root causes of risk within disaster risk reduction research (see, e.g., Wisner et al., 2004, p. 18).

The outline of the two major schools of thought regarding *risk* underlines the different viewpoints of what constitutes and defines risk. Although these schools cannot be merged, it is interesting to note that a certain overlap can be identified, particularly when dealing with new phenomena of climate change. In terms of adaptation strategies, sea level rise and other phenomena, linked to climate change, might imply both, risks, in terms of the potential interaction of a hazard event and a vulnerable society, as well as the inherent risk of different decision options that could lead to harm or losses. Consequently,

the dichotomy between the first and second school of thought might melt in the light of natural hazards and decision-making processes, related to climate change and extreme events, as well as irreversible changes.



In the following sections, further facets of risk will be explored, particularly regarding different risk formulas used within the first school of thought and the issue of timescales. Finally, challenges for improving our understanding of risk will be outlined.

Risk formulas

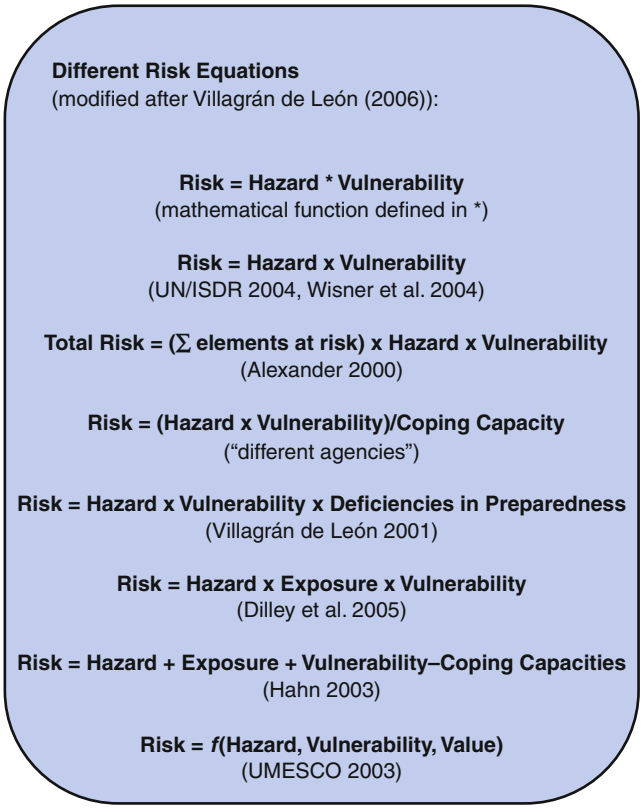
With regard to the first school of thought – represented particularly by the disaster risk reduction research community – different formulas of risk and its factors have been developed. According to UNDRO (1980), the specific risk of an element exposed (e.g., human life, house, infrastructure services, etc.) is seen as a product of the interaction of a hazard (e.g., floods, landslides, etc.) – including its probability and magnitude – and the vulnerability of the element exposed. In this regard, risk represents the potential damages and losses, such as the number of lives likely to be lost, the persons injured, damage to property, and disruption to activities caused by a particular natural phenomenon (UNDRO, 1980).

Overall, risk is expressed – in many publications of the disaster risk research community – by the formula *Risk = Hazard(s) x Vulnerability* (UN/ISDR, 2004). Some authors also include the concept of exposure to refer particularly to the physical aspects of vulnerability or to an own component that is situated in between the nexus of hazards and vulnerability (see e.g., IPCC 2012). Villagrán de Leon (2006) shows different *risk equations* that underline similarities and differences of the respective definitions of risk (see Figure 1).

Important differences in these equations center around the notions of societal response capacities, expressed, e.g., as coping capacities or deficiencies in preparedness.

Risk, Figure 1 Risk as a product of the interaction of hazard(s) and vulnerability (Source: Birkmann, 2008, p. 10).

Additionally, some equations explicitly differentiate exposure from vulnerability, whereas others view exposure as a subcategory of vulnerability itself (see Turner et al., 2003). Despite these differences, the overall understanding that risk and disaster risk are a complex function of the interplay of hazards (e.g., weather and climate events) and vulnerability can be seen as a kind of basic consensus. Regarding different risk equations, UN/ISDR (2004) underlines the importance to also consider the social contexts in which risks occur, as people do not necessarily share the same perceptions of risk, nor their underlying causes. The framing of the societal response capacities remains a difficult task. This cannot be discussed here in detail; however, it might be necessary to further address the potential differences of coping, preparedness, and adaptation linked to risk to natural hazards and climate change within the scientific community. These and related questions are addressed within the IPCC special report on "Managing the Risk of Extreme Events and Disasters to Advance Climate Change Adaptation," published in March 2012.



Timescales

Timescales are an important issue, when dealing with risk and its dynamics. In terms of different hazards, e.g., low-frequency hazards (e.g., earthquakes) occur on a different timescale than high frequency hazards (e.g., floods). Thus, information required to detect and evaluate the different hazard types might need to consider different timescales. Likewise, the identification of vulnerability has to deal with various timescales with regard to different vulnerability patterns and processes. Even if the hazard profile and intensity remains the same, over a period of time, the vulnerability of a society or community – as one of the key components of risk – differs if the analysis focuses on a certain point in time or on a time period, since particularly the social conditions such as susceptibility are likely to change over time (see Kienberger 2010, IPCC 2012).

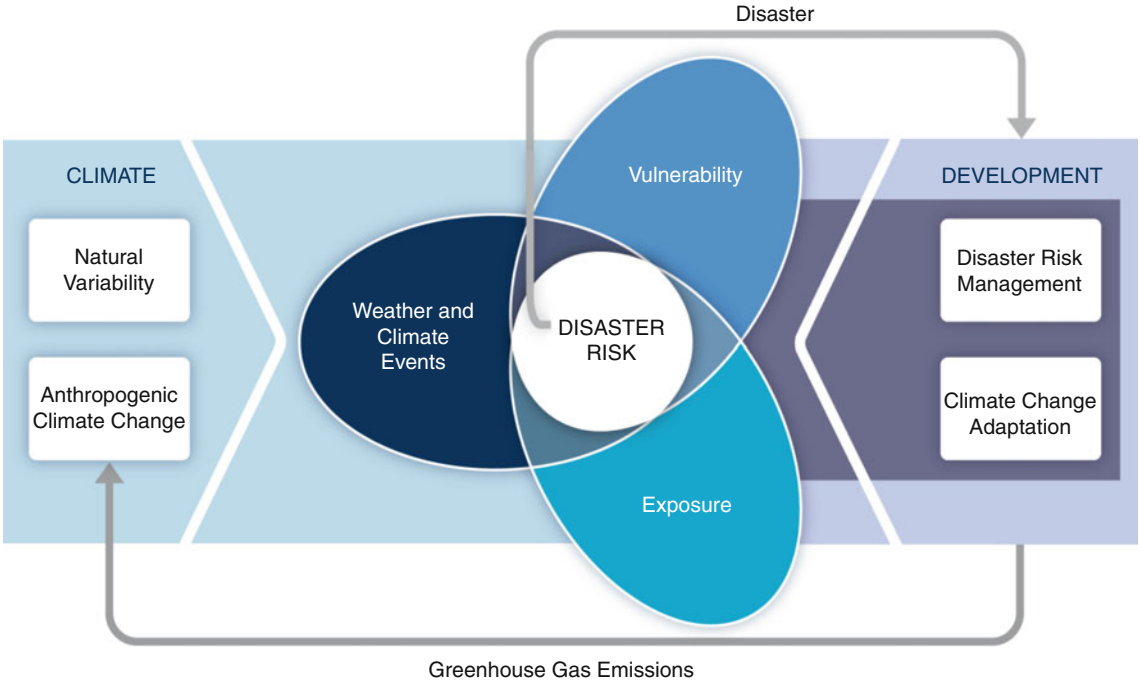
Overall, it is essential to consider the dynamic nature of risk and vulnerability (IPCC 2012). Considering timescales and aspects in risk definitions and risk analysis requires, first and foremost, addressing these issues explicitly in respective definitions and risk assessments (Figure 3).

Probability

The probability of a hazard event to occur is another important aspect that should be addressed when dealing with risk in the context of natural hazards. The probability of a hazard (hazard event) to occur is often estimated by using the frequency of past similar events or by event-tree methods. However, probabilities for rare events may be difficult to estimate, if an event tree cannot be formulated. The exact identification of the frequency of tsunamis is still a challenge, particularly in regions where they occur very rarely. Likewise, creeping natural hazards and

Risk, Figure 2 Different risk formulas (Source: Villagran de Leon, 2006).

irreversible changes, in the light of climate change, such as sea level rise, as well as man-made hazards, such as terrorist attacks, pose problems to the traditional hazard frequency-probability relation. Also, the cascading hazard in March 2011 in Japan that was triggered by an earthquake followed by a tsunami and an accident in a nuclear power plant (Fukushima) shows that new approaches are needed that go beyond a single hazard probability function. Therefore, irreversible changes might have to be characterized differently. Some probability functions also focus on loss or harm, in other words, the probability of loss of human life. These calculations, however, need to be carefully conducted, when dealing with low-frequency and very specific hazard phenomena (e.g., cascading hazards).



Future challenges: improving our understanding of risk

Understanding risk requires an improved understanding of risk factors, underlying vulnerabilities, and societal coping and response capacities, as well as changes in hazard phenomena and cascades. This includes acknowledging issues such as complexity, nonlinearity, uncertainty, and limits of knowledge, that risk to natural hazards and climate change imply (see, e.g., ICSU-LAC, 2009, p. 15; Birkmann et al., 2009; Renn, 2008, p. 289; Bohle and Glade, 2008; Patt et al., 2005). Additionally, factors that influence and determine risk perceptions, such as beliefs, values, and norms, need to be better understood, in terms of improving knowledge on the social construction of risk (see, e.g., Adger et al., 2009).

Overall, appropriate information and knowledge are essential prerequisites for promoting a culture of risk reduction and resilience. Specific information must first be collected on the dynamic interactions of exposed and vulnerable elements, e.g., persons, their livelihoods and critical infrastructures, and potentially damaging hazard events, such as extreme weather events or potential irreversible changes as sea level rise. In this context, understanding risks related to natural hazards and climate change requires among other aspects:

- Knowledge of the processes and driving forces by which persons, livelihoods, property, infrastructure, goods, and the environment itself are exposed to potentially damaging events, e.g., understanding exposure in its spatial and temporal dimensions.
- Knowledge of the factors and processes which influence and determine the vulnerability of persons and their livelihoods or of socio-ecological systems; Understanding the increases or decreases in susceptibility and societal response capacity, including the role of governance.
- Knowledge on how environmental and climate change impacts are transformed into hazards, particularly regarding processes by which human activities in the natural environment or changes in socio-ecological systems lead to the creation of new hazards (e.g., natural-technical hazards, NaTech), irreversible changes (e.g., undermining supporting ecosystem services), or increasing probabilities of hazard occurrence.
- Knowledge regarding different tools, methodologies, and sources of knowledge (e.g., expert and scientific knowledge, local or indigenous knowledge) that allow capturing new hazards, risk and vulnerability profiles, as well as different risk perceptions. In this context, new tools and methodologies are needed that enable the evaluation, e.g., of current and planned adaptation and risk reduction strategies.
- Knowledge on how risks and vulnerabilities – and, in part, also hazard phenomena – can be modified through forms of governance, particularly risk governance – encompassing formal and informal rule systems and actor-networks at various levels. Furthermore, it is essential to improve knowledge on how to promote adaptive governance within the framework of risk assessment and risk management.

(ICSU-LAC, 2009, p. 15; Birkmann et al., 2008, 2009, Birkmann and Fernando, 2008; Cutter and Finch, 2008; Renn, 2008, p. 289; Bohle and Glade, 2008; Biermann, 2007; Biermann et al., 2009; Füssel, 2007; Renn and Graham, 2006; Patt et al., 2005; Cardona et al., 2005; and Kasperson et al., 2005).

Risk, Figure 3 Systematization of disaster risk, vulnerability and weather and climate events (hazards) according to the new IPCC special report SREX (Source: IPCC 2012, p. 4).

Future research, as well as strategies for improving our understanding of risk, should encompass at least six knowledge demands:

1. Identification of (new) hazards and irreversible changes, as well as changes in known hazards
2. Examination of vulnerability and its core components
3. Identification of risk, as a product of the interaction of a hazardous event (including the probability of occurrence), and vulnerability
4. Risk perception (particularly regarding "unexperienced" hazards such as sea level rise)
5. Evaluation and assessment methodologies and tools, that for example capture actual and (potential) future dynamics of vulnerability and hazard phenomena
6. Risk management and adaptive governance

These knowledge demands also underline that expertise from various disciplines will be needed to address the challenges in a systematic and integrative way in order to improve the knowledge of risk to natural hazards. Additionally, both schools of thought, in terms of risk definitions, can contribute to these challenges and demands within their specific perspectives.

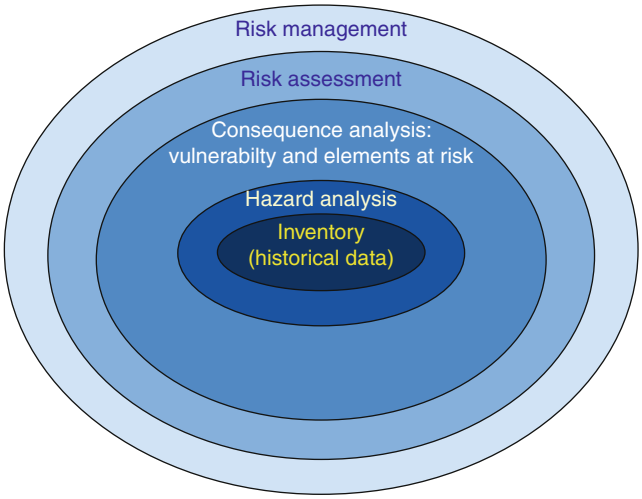
RISK ASSESSMENT

Suzanne Lacasse
Norwegian Geotechnical Institute, Oslo, Norway

Synonyms

Risk analysis; Risk analysis process; Risk qualification; Risk quantification



Definition

Risk assessment is a process of comprehending the nature of risk and determining its level. The risk is assessed by analyzing the potential hazards and evaluating the conditions of vulnerability of the elements potentially at risk from these hazards, including exposed people, property, services and infrastructure, livelihood, culture, quality of life, environment, and even potential loss of reputation.

Risk assessment

To determine the nature and extent of the risk, the risk assessment methodology includes: (1) the analysis of the characteristics of the hazard(s) such as location, intensity, frequency, and probability of occurrence, and (2) the analysis of exposure and vulnerability including the physical, social, health, economical, environmental, and perception dimensions and the assessment of the coping capacities to likely scenarios of occurrence.

Risk is obtained from the probability of failure weighted by the consequence of such failure. The risk assessment can be done in a qualitative or quantitative manner. Risk assessment is part of an integrated risk management process. Figure 1 illustrates such integrated process for the assessment and management of the risk associated with a landslide. The risk management process starts with an inventory of landslides, for example, at the location of interest, and then considers the following:

Risk Assessment, Figure 1 Integrated risk management process including risk assessment, starting with inventory of landslides at a location.

1. What can cause harm? (i.e., danger identification)
2. How often can it happen or how likely is the danger to happen? (i.e., estimation of frequency of occurrence)
3. What can go wrong? (i.e., evaluation of loss based on assessment of vulnerability of all elements at risk)
4. How bad are the consequences? (i.e., assessment of severity of consequences)
5. What should be done about the risks, that is, the hazard and vulnerability? (risk management, including comparison with acceptable and/or tolerable levels of risk and risk mitigation)

One typically assesses risk based on a number of plausible scenarios. In the case of a landslide, the following steps would be used: (1) Define scenarios for triggering the landslide and evaluate its probability of occurrence. (2) Compute the run-out distance, volume, and extent of the landslide for each scenario. (3) Estimate the losses for all elements at risk for each scenario. (4) Estimate the risk.

Hazard analysis

A landslide hazard analysis, for example, includes characterizing the danger of a slide in terms of type, size, velocity, location, travel distance, pre-failure deformations and failure mechanism and their frequency. A landslide hazard analysis usually involves an analysis of the likelihood that a slide will occur within a given period of time based on the geology, slope, gradient, elevation, geotechnical properties, vegetation cover, weathering, and drainage pattern.

Vulnerability analysis

The analysis of the vulnerability considers the propensity of the human, social, physical, economical, environmental, cultural, institutional, and political assets to suffer damage from hazardous events. The vulnerable assets use quantities such as loss of life, moneys involved, environmental damage, etc., of the elements at risk.

Risk

Risk is expressed as the product of the probability of a hazard occurring and the potential for adverse consequences, loss, harm, or detriment. Risk can be presented in terms of curves of cumulative frequencies of harmful events causing increasing level of losses, using so-called F-N curves. On these curves, the annual cumulative frequency, F, of events causing N or more losses is shown. The losses can be expressed as number of fatalities, monetary units of damage, level of pollution, time loss, etc. Both axes are usually plotted on logarithmic scales. As part of the risk management, one can use F-N curves to compare the risk level associated with a danger with risk acceptance and tolerability criteria.

RISK GOVERNANCE

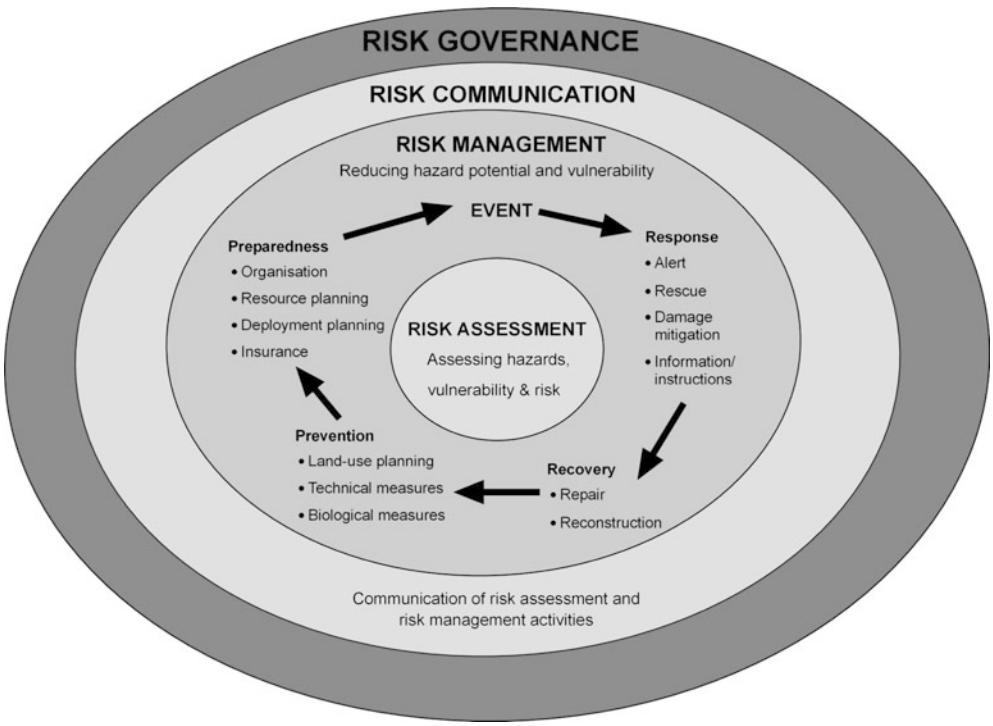
Stefan Greiving[1], Thomas Glade[2]
[1]TU Dortmund University, Dortmund, Germany
[2]University of Vienna, Vienna, Austria

Definition

Modern social systems are characterized by complex patterns of interdependencies between actors, institutions, functional activities, and spatial organizations. Controlling, managing, or even steering the complex, fragmented, and often competing societal interests is beyond the capacity of the state as an agent of authority. This is important

for dealing with risks, in particular in cases of high uncertainty and ambiguity (Klinke and Renn, 2002).

The term "governance" in its widest sense can be understood as the following. At the national level, it characterizes the structure and processes for collective decision making involving governmental and non-governmental actors (Nye and Donahue, 2000). At the global level, "governance embodies a horizontally organized structure of functional self-regulation encompassing state and non-state actors bringing about collectively binding decision without superior authority" (see Rosenau, 1992; Wolf, 2002).



This understanding can also be applied in the area of "risk." "Risk governance" aims to enhance the disaster resilience of a society (or a region) and includes "the totality of actors, rules, conventions, processes, and mechanisms concerned with how relevant risk information is collected, analysed and communicated and management decisions are taken" (IRGC, 2005). This definition points at three elements of risk governance: risk assessment and risk management that have to be embedded in a risk communication process among scientists, politicians, and the public (public and private stakeholders) as shown by the following Figure 1.

Aiming at the development of integrative models and concepts that link the different phases of risk governance mentioned before, attention has to be paid to the given differences in characteristics of the several risk types, both on the collective level and the individual perception of risk (see, e.g., IRGC, 2005). These factors might contribute in each single case in a different manner to the perception and estimation of risk. In addition, they are strongly interlinked with more collective social-political factors (WBGU, 2000). Moreover, differences in the individual perception and estimation of risks should be considered (Dubreuil et al., 2002).

Relevance for natural hazards

The limitation of research, which is fragmented and isolated, i.e., between natural sciences and engineering disciplines on the one hand and social sciences on the other hand, the importance and difficulty of maintaining trust, and the complex, socio-political nature of risk call for more comprehensive approaches.

Actually the successful management of risks is limited. The interactions between individual sectors, disciplines, locations, levels of decision-making and cultures are not known or not considered. Similarly, the linkages between the natural processes posing a threat to society are often not well understood, or considered. For example, a forest fire might demolish the trees on a slope. The next rainstorm event will trigger debris flows which will consequently enter the streams. These might be blocked, with consequent danger of breakout floods, or might be additionally loaded with vast amounts of debris with consequent damage farther downstream. To even enhance this problem: such interactions can, but might not, act within a single storm event. These interactions can also been temporally distributed over some days, months, or even years.

Risk Governance, Figure 1 Communication and the disaster cycle (Adapted from Greiving et al. (2006, p. 11).

Therefore, required societal responses to environmental changes are manifold and need careful assessments.

Additionally current risk management research and practice is fragmented by subject and by level of decision making (IRGC, 2005; Greiving et al., 2006). Inadequate information about risks in terms of societal and natural dimensions, incomprehensible procedural steps as well as insufficient involvement of the public in the risk-related decision-making process lead to severe criticism and distrust regarding relevant decisions with regard to a specific risk.

The tremendous increase in annual losses, caused by extreme events, indicates the urgency of inclusiveness. It is noteworthy, however, that this increase is not automatically caused by the increase of occurrences of the hazards. This increase might also be purely attributed to the extension of the societal usage of an area, for example, increase of house values, suburbanization, more expensive – and often vulnerable – infrastructure, etc. The insurability of economic assets becomes more and more questionable, if the so-called probable maximum loss (PML), the insurance industry is able to deal with, would be exceeded due to global change. Global change is herein understood as changes in both the social dimension with all its economic, political, and administrative changes and the natural dimension with the widely discussed climate change, but also vegetation change, changes in the hydrological regimes through water reservoirs, extensive ground water usage, etc.

Often assessed criteria are primarily relevant for climate change and those natural hazards which are triggered by meteorological conditions such as floods, droughts, forest fires, landslides, but also creeping change processes like the loss of biodiversity, soil erosion, or water pollution, to name a few.

Decisions in the area of so-called traditional risks like flooding, taken mainly on the basis of engineering expertise, are normally based on probabilities because they are past-oriented and informed by statistics. However, analyzed data are only available for a specific period – and are thus not representative for longer periods. It is important to recognize that such calculated return periods cannot be easily extended over longer periods. For example, a river changes its flow behavior dramatically, if internal thresholds are exceeded (e.g., changes of bed roughness, different flow dynamics with overtopping riverbanks, etc.). Nearly all natural systems show such nonlinear behavior and consequently, it is most important to determine and identify the limits, within which the analysis is valid, and for which not. This principle problem is also enlarged by observed climate changes. Related effects on temperature and precipitation will certainly lead to new uncertainties, because past events might not be representative anymore. Similarly, changes in the catchments (e.g., deforestation, surface sealing through suburban development, etc.) will lead to high uncertainties. Here, the perspective changes from probabilities to just possibilities. With public decision making not having any precise information at hand, restrictions for private property rights are probably no longer legally justifiable. Hereby, justification of actions and consensus about thresholds and response actions becomes more important, which calls naturally for inclusiveness.

Within the global change debate, the field of climate change in general, but particularly as a triggering factor for many natural hazards, is of special importance for Europe with its dominant existing settlement structures, cultural landscapes, and infrastructures which have been developed over centuries. Prevention actions, carried out by spatial planning, are under these circumstances less effective than in countries which are still growing rapidly in terms of population and the built environment. Here, disaster-prone areas can be kept free from further development whereas most of these areas are in Europe already built up. However, this calls for authorities with risk awareness and means to mitigate this problem. And in the developing countries with high potential to avoid the adverse effects, strong authorities with the required power are needed – and this is often not available in such countries.

Moreover, measures, based on mandatory decisions of public administration as well as measures which are in the responsibility of private owners, need to be accepted widely for their implementation. This is clearly visible when looking at evacuation orders, building protection measures to be taken by private households, risk awareness, etc. Having these facts in mind, the "active involvement," propagated, e.g., by the European Communities Flood Management Directive (European Communities, 2007), has to be seen as crucial for the success of the Directive's main objective: the reduction of flood risks. Within the European Community, it has also been recognized that the risk approach has also to be applied to other natural hazards such as coastal hazards or soil erosion and landslide hazards (e.g., Soil Thematic Strategy, 2006).

This makes clear that risk governance has become increasingly politicized and contentious. The main reasons are controversies concerning risk that are not about science versus misguided public perceptions of science, where the public needs to be educated about "real" risks (Armaş and Avram, 2009). Rather, risk controversies are disputes about *who* will define risk in view of existing ambiguity. Technology policy discourse is not about who is correct about assessment of danger but whose assumptions about political, social, and economic conditions as well as natural or technological forces win in the risk assessment debate. Thus, the hazard is real, but risk is socially constructed.

This understanding of risk used here is different than the definition within engineering and natural sciences. Herein, risk is not understood as socially constructed, but "real" – real in terms of potential monetary losses. All these approaches try to quantify the risk in terms of determination of the expected frequency and magnitude of the relevant hazard (e.g., earthquake, flood, landslide) and the elements at risk (e.g., infrastructure, buildings, etc.). The degree of

expected damage as a consequence from a specific event magnitude is herein expressed as vulnerability, and various vulnerability functions exist (e.g., Fuchs et al., 2007). The overall and ultimate aim of natural and engineering science–based approaches is always to provide "objective," reliable, repeatable and comparable information on both hazard and potential consequences.

Scientific literacy and public education are important but not central to risk controversies. Emotional response by stakeholders to issues of risk is truly influenced by distrust in public risk assessment as well as management. Due to this fact, those who manage and communicate risks to the public need to start with an understanding of emotional responses toward risk. It is a matter of the definition of risk how risk policy is carried out. Moreover, defining risk is an expression of power. Slovic (1999) thereby argues that whoever controls the definition of risk controls technology policy.

Within the communication strategies in all approaches, trust can be seen as a central term in this respect. The regressiveness of trust of public in for example, policy makers appears to be related to "a number of factors, including social alienation; a lack of social capital; higher levels of education and greater availability of information resulting in a more sceptical public; increased scientific pluralism leading to confusing messages; cronyism in government; growth of citizen activism in an era of complex and uncertain risks and multiple messengers; regulatory scandals [...] and a hyper-critical media" (Löfstedt, 2005).

Further, public decision making that is based only on the factual "scientific" dimension of risk, not taking into account the "sociocultural" dimension, which includes how a particular risk is viewed when values and emotions are concerned leads to distrust (e.g., whether a risk is judged acceptable, tolerable or intolerable by society is partly influenced by the way it is perceived to intrude upon the value system of society). Regarding this, Löfstedt (2005) summarizes three present distinct problems for risk regulators as following: "(a) it is easier to lose or destroy trust than to gain it; (b) in an 'era of distrust', the public will turn to other sources of information and (in many cases) believe this information more than that provided by the public risk managers, even when the latter may be more accurate; (c) when the public has access to many more sources of information, such as the Internet and 24-h television, they are no longer dependent on policy-makers or risk managers for information. The result is a more knowledgeable but more skeptical public."

Trust has a key role in dealing with risks and should be regarded as fundamental for risk interpretation of the public between "real" and "perceived" risks. (Interpretations of "risk" differ according to individual and social contexts.) Especially "trust is particularly relevant in conditions of ignorance or uncertainty with respect to unknown or unknowable actions of others. [...] In this respect, trust concerns not future actions in general, but all future actions which condition our present decisions" (Gambetta, 2000).

Consequently, ensuring a stakeholder-focused process means consulting and involving stakeholders. In this regard, research on risk governance has to be understood as cooperative research: a form of research process, which involves both researchers and non-researchers in close cooperative engagement. This also meets the demand of the White Paper on European Governance (European Commission, 2001) where a better involvement and more openness as well as better policies, regulation, and delivery have been identified as key objectives of "good governance." Strong stakeholder-oriented elements have also been integrated in recent disaster management strategies like the United Nations International Strategy for Disaster Reduction (ISDR, 2005). The risk governance approach has recently been regarded as important by the new Territorial Agenda of the EC, launched in 2007 in Leipzig, Germany, by the Member States Ministers for Spatial Planning as part of the priority 5 "Promoting Trans-European Risk Management" (European Commission, 2007).

Distrust makes institutional settings vulnerable as it lowers the efficiency and effectiveness of management actions. The whole disaster cycle from mitigation, preparedness, response to recovery is embedded in an institutional system. Institutional vulnerability can in principle be understood as the lack of ability to involve all relevant stakeholders and effectively coordinate them right from the beginning of the decision-making process. It refers to both organizational and functional form as well as guiding legal and cultural rules.

Generally speaking, a good institution design leads to effectiveness, equality, and resilience. Narrow social networks and relations increase the possibility of social learning and adaptation through cooperation and communication. Besides the accurate assessment(s) of the hazard(s), the relevance of informal social networks, local institutions and authorities (traditional and administrative), and local-based organizations is a prerequisite for the reduction of impacts of the disaster.

Existing approaches for assessing good/bad risk governance

The development of integrative models and concepts that link the elements of risk governance (risk assessment, management and communication), from an interdisciplinary perspective can be interpreted as the overall objective for integrative approaches to risk governance. Therefore, it is important to use a methodology that overbears the mentioned tendency to insularity between disciplines, to find a proper way to deal with uncertainty and ambiguity and to create resilient communities as well as reduce the institutional vulnerability.

The elaborated approach is a comprehensive risk governance concept which aims – as already mentioned in literature (Löfstedt, 2005) – at a broad and active involvement

of decision makers at the relevant political and administrative levels and/or of stakeholders. In addition it offers a better understanding and acceptance of research by society and vice versa bringing the legitimate interests of society and single stakeholders into research and decision making. The concept is supported by a tool that is able to monitor the performance of a risk governance process and consists of an "indicator system" as a methodological concept that brings together the state-of-the-art concepts in risk governance with methodological and procedural needs, identified by those who are close to the daily practice in risk communication. In addition, an "interest analysis" is useful being a practical method for preparing stakeholder involvement processes.

The concept is based on a comprehensive investigation on the state of the art of knowledge and methodologies applied for risk governance, having analyzed existing risk governance concepts with a special focus on Europe and some input for non-European settings. Accordingly, 14 risk resilience projects and initiatives were analyzed to develop a comprehensive and inclusive framework and indicators for governance of risk resilience, sustainability and performance.

This number and range of the analyzed projects and initiatives was satisfactory because all important elements of risk governance were covered. Furthermore, the multitude of analyzed projects/initiatives was characterized by a diversity of addressed risks which was of great relevance for the project in order to guarantee the transferability to various risk settings. Originally 35 risk governance principles, derived from a first literature screening, had been used for this analysis that was based on two parts (Wanczura et al., 2007):

1. Overall information like, for example, description of the risk governance approach; characterization of the risk governance approach and conclusions.
2. Detailed table where 35 principles/indicators were checked if they were covered in the analyzed approaches. These principles were grouped under five perspectives: Basic/Content, Procedure, Stakeholder, Resources, and Expertise. They allow a better general observation if important aspects were considered appropriately. Additionally, each of the indicators had clarifying questions to reach a better understanding of the indicator and its aim.

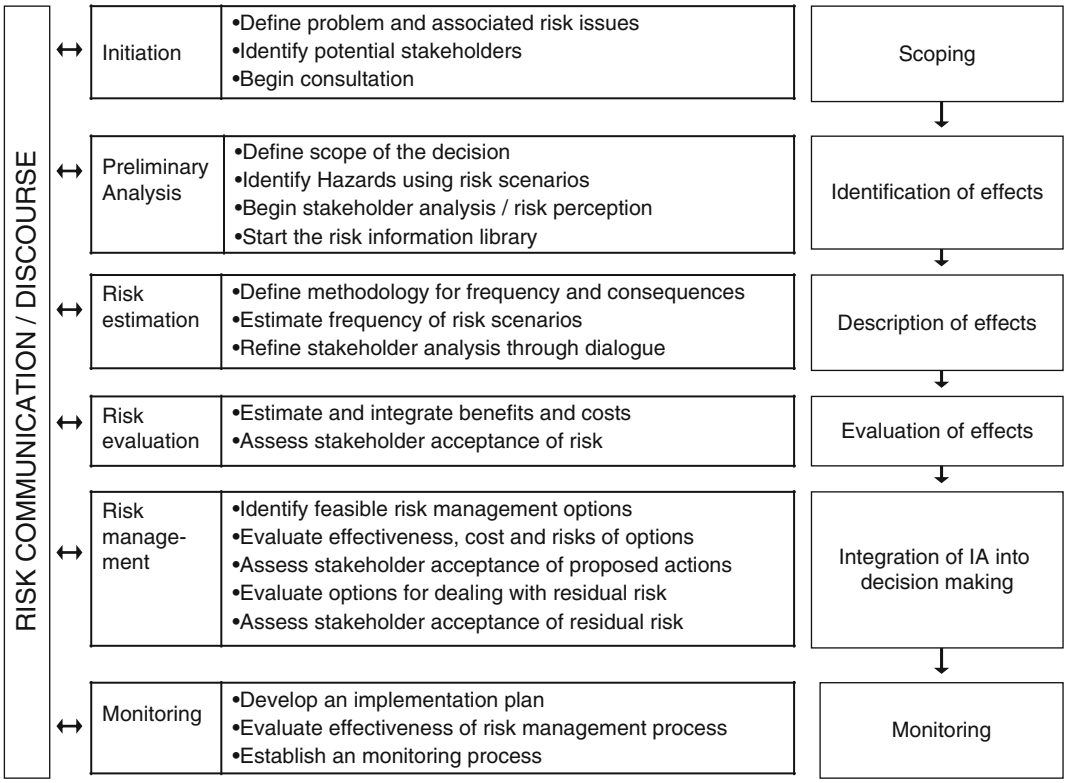
The elaboration of the key aspects was enabled by means of a literature research, a set of interviews, and a scientific colloquium. It has to be pointed out that the hazard itself was of minor importance herein. The societal and administrative settings were the focus in this survey. Thus, the aim was to list all significant indicators for a risk governance process in order to enable a detailed description as well as a comparison between them in consideration of existing standards (see Audit Commission, 2000). In addition, it allowed the development of a balanced set of indicators. Nevertheless, it was not feasible to consider all indicators which were available due to the difficulty of handling such a variety and quantity. Especially concerning stakeholder-communication, the number of indicators should be low. Scientific literature proposes only few (approximately 20 indicators) aggregated and comprehensible indicators (Weiland, 1999). Consequently, a core set of the 12 mostly accepted principles/indicators were chosen ("Key Performance Indicators"; KPI), representing the resilience framework (see Table 1).

Indicators are used especially by decision-making stakeholders in order to justify and improve their decisions as well as to improve their impact/implementation of concepts and benchmark the given performance of risk management systems in terms of the attention they paid to the above-listed governance principles. Therefore, such a system is able to assess the progress of management setting over time, but also benchmarking different organizations at a certain point of time.

Old wine in new glasses?

Risk governance can be understood as a holistic way of understanding and dealing with risk. Consequently, it might be just "old wine in new glasses" if a risk assessment and management process is embedded into a comprehensive communication and stakeholder involvement process. However, today's risk management practice is often not inclusive at all, i.e., in the context of traditional risks where natural as well as technological hazards are causing factors. At the same time, the experts of the hazard analysis define what is right and wrong for the affected party involved. The quality of the hazard analysis and assessment is not questioned here. Light is thrown on the way, how the respective results are presented. For example, the experts often require specific management actions in terms of technical measurement, etc., which are sometimes not at all in line with the needs of the affected parties. Here, it belongs to the duties of social sciences to develop proper ways for applying inclusiveness in risk management practices where the role of the affected public is wholly neglected. For that purpose, the concept of risk governance makes inclusiveness more explicit.

It should be kept in mind that different addressees have different attitudes/interests which are relevant when spreading inclusiveness: other scientists (i.e., geoscientists, engineers), politicians, mass media, public, and affected individuals. There is also a question how to communicate inclusiveness to a wider community. Social networking through ICT/WEB technologies and modern visualization tools (i.e., Geo Information Systems, GIS) are quite helpful for target group–oriented communication. Any pedagogy of inclusive risk governance should be designed for different target groups (for instance, pupils) and calls for an adequate language to achieve a mutual understanding. Indeed, further research is necessary to accommodate the different needs and expectations of involved parties.



Risk Governance, Table 1 Definition of risk governance indicators for the integrative approach

Perspective	Keyword	Key question	Objective	Key performance indicator
Basic/content	*Principles*	What are the guiding principles?	Definition of guiding principles and a consistent "target system"	Degree of operationalization of the guiding principles
	Trust	How far is attention paid to relevance of an atmosphere of mutual respect and trust?	Between all relevant stakeholders and decision makers, an atmosphere of mutual respect and trust exists	Reflection of trust concerning people/institutions
	Objectives	What are the concrete protection goals for subjects of the protection?	Definition of a comprehensive and obligatory understanding of the damage-protection relation	Degree of obligation concerning the protection goals for the subjects of the protection
Procedure	*Accountability principle*	How far is accountability defined at each level (process, each risk)?	Each actor knows his responsibilities and acts accordingly	Definition of the responsibility
	Justification	How far is the activity concerning the management of existing risks justified?	Justification of action in the area of risk management	Definition and agreement on a justification concerning the exposure to risk
Stakeholder	*Representation*	How far are all relevant social groups (and their representatives, stakeholder, respectively) and their expectations known?	Identification of all relevant social groups and their expectations	Degree of high profile of all social groups and their expectations
	Access to information	How far is information for all stakeholders accessible?	Access for all stakeholders to the relevant information	Degree of the availability and understandability of the relevant information for stakeholders
	Tolerance process & outcome	How far do the stakeholders tolerate/accept the risk governance process and its outcomes?	All involved stakeholder tolerate/ accept the risk governance process and its outcomes	Degree of the tolerance/ acceptance on the part of involved stakeholder
	Dialogue	To what extent is a constructive dialogue with the relevant stakeholders available or conducted?	Establishment of custom discourse-processes concerning risk topics	Quality of discourse-processes with relevant stakeholders (i.e., public or private representatives)
Resources	*Financial resources*	To what extent do the available financial resources meet the requirements of the defined Risk Governance Process?	Allocation of sufficient financial resources for a successful risk governance process	Degree of realization of a financial concept
	Staff resources	To what extent do the staff resources (technical qualification and number of people) meet the requirements of the defined Risk Governance Process?	Allocation of adequate staff resources	Realization of a staff assignment concept
Expertise	*Role*	How far has the role of experts been defined?	If experts are involved, their role within the decision-making process has to be defined	Degree of definition and agreement concerning the role of experts

Source: own elaboration

The Strategic Environmental Assessment (SEA) offers a suitable procedural frame for implementing a risk governance approach (European Communities, 2001). Damage potential as a key term in the definition of risk can be understood as a relevant issue, covered by SEA issues of human health, material assets, and cultural heritage (See Annex I, Directive 2001/42/EC). Moreover, EU Directive 2001/42/EC in Annex II points out the characteristics of the effects and the areas likely to be affected. Projects that have to obtain a permit from a certain plan or program might have significant effects on the environment because of specific consequences, for example, increasing damage potential regarding certain hazards that threaten the area where the project is planned.

When looking at the EU directive 2007/60/EC on the assessment and management of flood risks, it becomes obvious, how important risk governance principles are for today's EU policy. Art 10 § 2 states: "Member States shall encourage active involvement of interested parties in the production, review and updating of the flood risk

Risk Governance, Figure 2 Integration of stakeholder into the process of assessing and managing risks (Source: own table).

management plans." This underlines the proposed active stakeholder involvement from the early beginning as outlined more in detail by the following Figure 2.

Conclusions

Risk governance becomes more important the more a risk setting is complex, characterized by uncertainty and ambiguity, or when many stakes have to be balanced/weighted up. This includes the proper assessment of hazards, independent of whether we are dealing with natural, technological, or traffic hazards, to name a few. Herein, the major future challenge is the incorporation of the dynamics in all developments, and how to include these dynamics properly into the risk governance cycle. For tackling institutional weaknesses, the procedural approach of risk governance has to be linked with a defined material goal stakeholders are in line with as a process does not end in itself. Here, resilience and therefore proactivity come into play, because resilience is determined by the degree to which the social system is capable of organizing itself to increase its capacity for learning from past events for better future protection and to improve proactively risk reduction measures. The material goal "resilience" can be seen as a widely accepted strategy within the natural disaster community (e.g., Fuchs, 2009; Paton et al., 2001). On the contrary, the more procedural approach "risk governance" has been created and adapted first in the area of new emerging, mostly man-made risks. The usage of both terms in the same context has to be seen as an innovative approach to combining an appropriate path (risk governance – including identification, assessment, management, and communication of risk) toward the material goal of creating resilient communities, able to deal with the whole range of risks, nature-made as well as man-made ones. A fully adopted "risk governance" strategy will indeed cause more work, discussion, and even contradiction during the assessment, but is then accepted by the parties involved and designed for a successful and long-lasting strategy which might support more sustainable communities.

RISK PERCEPTION AND COMMUNICATION

Michael K. Lindell
Texas A&M University, College Station, TX, USA

Definitions

Risk perception – the result of an informal personal assessment of adverse consequences that could be caused by extreme environmental events.
Risk assessment – the result of a formal scientific analysis that systematically identifies the causes and consequences of environmental extremes.
Risk – the likelihood that an event of a given magnitude will occur at a given location within a given time period, with that event's associated casualties and damage, as well as its psychological, demographic, economic, and political impacts.
Risk communication – a process by which stakeholders provide (one-way) or exchange (two-way) information about hazards.
Hazard adjustments – mitigation actions such as land use and building construction practices that reduce vulnerability, emergency preparedness actions such as emergency plans that facilitate emergency response, and recovery preparedness actions such as insurance purchase that redistribute losses.

Introduction

Some people, because of their access to data or their specialized expertise in interpreting those data, have scientific risk assessments of environmental hazards and specialized knowledge of ways in which those risks can be managed. These risk analysts engage in risk communication to convey their assessments to decision makers, such as government officials and risk-area residents, whose risk perceptions might or might not be consistent with the analysts' risk assessments. Decision makers often have limited knowledge about what actions to take in response to the environmental risks, so it is important for analysts to communicate information about emergency response actions or long-term hazard adjustments that are both effective and feasible. Finally, people's acceptance of analysts' risk assessments depends on their perceptions of the sources of that information, so it is important for risk analysts to ensure that they establish and maintain credibility with their audiences.

Perception of environmental hazards

The essential dimensions of risk are probability and consequences, but some well-known approaches to perceived risk include qualitative "outrage factors," such as *dread* and *unknown* risks (Slovic et al., 2001). These additional dimensions of perceived personal risk appear to be useful in explaining people's responses to technological hazards, but it is unclear if they are related to the perception of, and response to, natural hazards. Most research on natural hazards has defined perceived risk in terms of people's expectations about the probability of personally experiencing the adverse physical and social impacts that an extreme environmental event causes (Lindell and Perry, 2004). Thus, these studies have typically defined risk perception in terms of specific consequences, such as death, injury, property damage, and disruption to daily activities (work, school, shopping, etc.). Moreover, most research on natural hazards risk perception has examined the ability of risk perception to predict warning responses such as evacuation (Sorensen, 2000) and long-term hazard adjustment such as insurance purchase (Zahran et al., 2009). This research has studied earthquakes (Lindell and Perry, 2000), hurricanes and other storms (Dash and Gladwin 2007), floods (Terpstra and Gutteling, 2008), and volcanic eruptions (Perry and Lindell, 2008).

Perceived personal risk is related to the recency, frequency, and intensity of people's personal experience with hazard events (Weinstein 1989). Such experience can involve casualties or damage experienced by the respondent himself/herself, by members of the immediate or extended family, or by friends, neighbors, or coworkers (Lindell and Prater, 2000). Hazard experience is a function of the annual probability of the occurrence of a major event and the number of years of exposure (past tenure at that location).

Perceived personal risk also is related to proximity to earthquake (Palm et al., 1990), hurricane (Peacock et al., 2005), and flood (Preston et al., 1983) sources. The relation between hazard proximity and personal risk is determined by a perceived risk gradient that relates increasing distance to decreased risk (Lindell and Earle, 1983). However, in addition to abstract beliefs about risk gradients, people who are farther away from hazard sources are also less likely to have direct experience with hazard impacts and, thus, have lower levels of perceived personal risk for this reason. Specifically, those who are closer to a hazard source are likely to observe environmental cues of the hazard (Preston et al., 1983). Finally, risk perception is significantly related to some demographic characteristics. These include lower education and income (Fothergill and Peek, 2004), female gender (Fothergill, 1996), and ethnic minority status (Fothergill et al., 1999).

Risk perception also is influenced by social communication because social groups, such as authorities, news media, and peers, can serve as sources of hazard information (Lindell and Perry, 2004). However, hazard information is not distributed uniformly over the entire population. Authorities, in particular, have limited resources, so they tend to focus on those at greatest risk (Baker, 1991; Lindell et al., 2005). This tendency is compounded by the tendency for those at greater risk to be more likely to recognize the relevance of such information and, thus, pay greater attention to it.

Perceptions of hazard adjustments

A substantial amount of research has focused on people's perceptions of natural *hazards*, but Lindell and Perry (2000) called attention to the need for also studying their perceptions of natural *hazard adjustments*. Such studies are needed because the theory of reasoned action (Fishbein and Ajzen, 1975) posits that one's attitude toward an object (e.g., seismic hazard) is less predictive of behavior than one's attitude toward an act (seismic hazard adjustments) relevant to that object. Thus, to understand the adoption of hazard adjustments, it is just as important to understand the perceived attributes of the hazard adjustments as the perceived attributes of the hazard itself.

The identity of these perceived attributes can be surmised from studies on the adoption of hazard adjustments, which have found support for attributes such as effectiveness (Mulilis and Duval, 1995), cost (Peacock, 2003), required knowledge (Davis, 1989), and utility for other purposes (Russell et al., 1995). These are consistent with the protective action decision model (Lindell and Perry, 2004), which proposes that hazard adjustments can be defined by *hazard-related* and *resource-related* attributes. Hazard-related attributes, such as efficacy in protecting people and property and usefulness for other purposes, have been found to be significantly correlated with adoption intention and actual adjustment (Lindell and Whitney, 2000; Lindell and Prater, 2002). However, resource-related attributes (cost, knowledge and skill requirements, time requirements, effort requirements, and required cooperation with others) generally have the predicted negative correlations with both adoption intention and actual adjustment, but these are small and nonsignificant. The hazard adjustments that have been studied to date have generally had small resource requirements, so it is unclear if the lack of support for the significance of these attributes is due to this factor (Lindell et al., 2009).

Perceptions of information sources

Previous research has characterized stakeholders as authorities (federal, state, and local government), evaluators (scientists, medical professionals, universities) watchdogs (news media, citizens' and environmental groups), industry/employers, and households (Drabek, 1986; Pijawka and Mushkatel, 1991; Lang and Hallman, 2005). The interrelationships among stakeholders can be defined by the power they wield over each other's decisions to adopt protective actions and hazard adjustments. French and Raven (1959, Raven 1965) posited that power

relationships can be defined in terms of six bases – reward, coercive, expert, information, referent, and legitimate power. Reward and coercive power are the principal bases of regulatory approaches, but Raven (1993) noted these require continuing surveillance to ensure rewards are received only for compliance and punishment will follow noncompliance. Unfortunately, many state mandates are hampered by a lack of formal reporting or review by state officials, and limited or no penalties for failing to enforce their provisions (Burby et al., 1998). Consequently, there is a need to better understand the ways in which households can be influenced by bases of power other than reward and coercion. French and Raven's conception of expert (i.e., understanding of cause-and-effect relationships in the environment) and information (i.e., knowledge about states of the environment) power suggests assessing perceptions of stakeholders' hazard *expertise*. French and Raven's conception of referent power is defined by a person's sense of shared identity with another (Eagly and Chaiken, 1993), which is related to that person's *trustworthiness*. Although trust has been defined many different ways (see Arlikatti et al., 2007 for a review), fairness, unbiasedness, willingness to tell the whole story, and accuracy are central (Meyer, 1988).

French and Raven (1959) defined legitimate power by the rights and responsibilities associated with each role in a social network, which raises questions about what households consider to be the responsibility of different stakeholders for protecting them from seismic hazard. This is reinforced by research on stakeholders' perceived *protection responsibility*, which dates from Jackson's (1981) research that attributed low rates of seismic adjustment adoption to respondents' beliefs that the federal government was the stakeholder most responsible for coping with earthquakes. Much later, Garcia (1989) found respondents had come to believe earthquake preparedness was an individual's responsibility. Her conclusion that a perception of personal protection responsibility leads to a higher level of seismic adjustment adoption is supported by similar findings on tornado adjustment adoption (Mulilis and Duval, 1997). Recent research has found that these perceived stakeholder characteristics (expertise, trustworthiness, and protection responsibility) have significant positive correlations with hazard adjustment intentions and actual adjustment adoption (Lindell and Whitney, 2000; Arlikatti et al., 2007).

Risk communication

Based on an extensive review of research on risk perception, hazard adjustment perception, stakeholder perception, and risk communication, Lindell and Perry (2004) proposed that risk communication should be a process by which stakeholders *share* information about hazards affecting a community. Communication among stakeholders can be analyzed in terms of who (source) says what (message), via what medium (channel), to whom (receiver), and directed at what kind of change (effect). As noted earlier, sources are perceived primarily in terms of expertise, trustworthiness, and protection responsibility. Messages vary in their content – especially their information about a hazard, its characteristics (e.g., magnitude, location, and time of impact), alternative protective actions and their attributes (efficacy; cost; safety; requirements for time and effort, knowledge and skill, tools and equipment; and cooperation from others), as well as contacts for further information and assistance.

The primary information channels available for use include print media such as newspapers, magazines, and brochures; electronic media such as television, radio, telephone, and the internet; and face-to-face interaction through personal conversations and public meetings. However, other channels are available for emergency response (e.g., sirens and tone alert radios, see Lindell and Prater, 2010). The distinctions among these information channels are important because they differ in the ways in which they accommodate the information processing activities of the receivers. For example, orally presented information is ephemeral and is easily lost unless otherwise recorded, whereas written information inherently provides a record that can be referred to at a later time. Receivers differ in many respects, but the most important of these are their perceptions of source credibility, access to communication channels, prior beliefs about hazards and protective actions, ability to understand and remember message content, and access to resources needed to implement protective action. Message effects include attention, comprehension, acceptance, retention, and action.

Finally, feedback is an important component of the communication model because some attempts are unidirectional, whereas others are interactive. Unidirectional communications appeal to many hazard managers because they appear to be less time consuming, and sometimes, this actually is the case. Frequently, however, interactive communication is needed for receivers to indicate that they have not comprehended the message that was sent or that the message sent by the source did not satisfy their information needs. It is important to recognize that risk information is transmitted through informal social networks (Lindell et al., 2007), so a warning message is likely to be relayed from the original source (e.g., an authority) through an intermediary (e.g., a risk-area resident) to an ultimate receiver (e.g., a peer such as a friend, relative, neighbor, or coworker) in addition to – or even instead of – being transmitted directly from the original source to the ultimate receiver.

There are six basic functions that should be addressed in a community risk communication program (Lindell and Perry, 2004). These are strategic analysis, operational analysis, resource mobilization, program development, program implementation for the continuing hazard phase, and program implementation for the escalating crisis and emergency response phases. The first function, strategic analysis, lays the foundation for later risk communication activities. Thus, the strategic analysis involves conducting analyses to identify hazards and locations at risk as well as

examining the community to identify important characteristics such as its ethnic composition and communication channels. In addition, hazard managers should work with community agencies to identify the community's prevailing perceptions of environmental hazards and hazard adjustments and set appropriate goals for the risk communication program.

Operational analysis seeks to identify appropriate hazard adjustments for community households and businesses and to work with the community agencies to encourage these hazard adjustments. Hazard managers should also work with community agencies to identify available risk communication sources and channels in the community as well as to identify the differences among audience segments in terms of their access to and preferences for different types of media (e.g., radio) and specific channels (e.g., specific radio stations) within each medium.

During resource mobilization, hazard managers should obtain the support of senior management by "selling" the importance of assessing community hazard vulnerability and identifying hazard mitigation, emergency preparedness, emergency response, and disaster recovery as effective solutions. They should also enlist the participation of government agencies, businesses, and nongovernmental organizations in a collaborative strategy to coordinate all of the community's risk communication programs. Hazard managers should also work with these organizations to develop collaborative relationships with the news media and with neighborhood associations and service organizations.

During program development for all phases, hazard managers should staff, train, and exercise a crisis communications team and establish procedures for maintaining an effective communication flow in an escalating crisis and during emergency response. Hazard managers should also work with community organizations to develop a comprehensive risk communication program that presents information about hazards and hazard adjustments in a form that attracts attention and is easily understood and retained. They should also encourage these organizations to use informal communication networks in the community. Hazard managers should also establish procedures for obtaining feedback from the news media and the public.

Program implementation for the continuing hazard phase involves building source credibility by increasing perceptions of expertise and trustworthiness and using a variety of channels to disseminate hazard information. Hazard managers should also describe community-level hazard adjustments being planned or implemented – such as land use regulations or building codes. They should also work with local organizations to describe feasible household hazard adjustments risk-area residents can take to protect themselves. Finally, hazard managers should evaluate risk communication program effectiveness by measuring the degree to which the program has achieved its objectives.

Program implementation for the escalating crisis and emergency response phases involves working with community officials to classify the situation in terms of its severity and activate the crisis communication team promptly so that its members can make all appropriate contacts. Hazard managers should determine the appropriate time to release sensitive information by developing procedures that define when information is to be released and select the communication channels appropriate to the situation. Hazard managers also need to provide timely and accurate news releases for the public that are supplemented by fact sheets containing basic background information that is appropriate to any incident. Hazard managers should maintain source credibility with the news media and the public by being honest about what is and is not known and state that they do not know the answer to a question when this is the case. However, they should make a commitment to answer any unresolved questions at a later time. Last, they should evaluate performance through post-incident critiques involving all members of the crisis communication team.

Summary

Risk perception is the result of people's informal assessment of the adverse personal consequences – such as death, injury, illness, and property damage – that could be caused by extreme environmental events. Perceived personal risk is related to the recency, frequency, and intensity of people's experience with hazard events. It also is influenced by social communication because social groups, such as authorities, news media, and peers, can serve as sources of hazard information. Thus, to understand people's risk perceptions, it is necessary to understand their interpretations of their own hazard experiences and their perceptions of information sources. In addition, to understand people's protective responses to their risk perceptions, it is also important to understand the perceived attributes of those protective actions. These attributes include hazard-related attributes, such as efficacy in protecting people and property and usefulness for other purposes, as well as resource-related attributes (cost, knowledge and skill requirements, time requirements, effort requirements, and required cooperation with others). To be most effective, risk communication programs should engage a process in which stakeholders *share* information about hazards affecting a community. Such programs should address six basic functions – strategic analysis, operational analysis, resource mobilization, program development, program implementation for the continuing hazard phase, and program implementation for the escalating crisis and emergency response phases.

ROCK AVALANCHE (STURZSTROM)

Reginald L. Hermanns
Geological Survey of Norway, Trondheim, Norway

Synonyms

Rock avalanche; Rock-fall avalanche; Rock-fall generated debris stream; Sturzstrom

Definition

Rock avalanche (sturzstrom) were defined by Hsü (1975) based on Heim's (1932) description of phenomena described with the German terms "Bergsturz," "Trümmerstrom," "Sturzstrom" as a stream of very rapidly moving debris derived from the disintegration of a fallen rock mass of very large size; the speed of a rock avalanche often exceeds 100 km/h, and its volume is commonly greater than 1×10^6 m^3.

Discussion

Rock avalanches are among the most hazardous *landslides* phenomena due to the speed, size, and run-out distance. Rock avalanches have destroyed entire villages and killed thousands. The run-out distance of a rock avalanche often exceeds several kilometers and the mobility becomes visible by the run up on opposite valley slopes, which is related to the volume of the initial rock failure (Scheidegger, 1973) and the morphology of the flow path (Nicoletti and Sorriso Valvo, 1991) but can also be influenced by the entrainment of saturated soil material or ice along the flow path (Hungr and Evans, 2004).

Systematic regional analyses of the temporal spatial distribution of rock avalanches have shown that rock avalanches do not distribute randomly but occur along lithologically, structurally preconditioned mountain fronts during climatic phases of higher run off or following deglaciation (e.g., Hermanns et al., 2006a, Blikra et al., 2006). Due to post failure slope deformation, rock avalanches often occur repeatedly at the same location with short recurrence intervals while neighboring slopes remain stable (Hermanns et al., 2006b). In addition, in tectonically active mountain regions, rock avalanches are often triggered by *earthquake*s and cause the formation of *landslide dams* adding to the *Disasters* (e.g., Petley et al., 2007).

Rock avalanche *Hazard* assessment involves characterizing potentially unstable slopes followed by *Slope Stability* analyses of the slope and run-out modeling of the rock avalanche. Due to the enormous energy released during the event, rock avalanches cannot be mitigated, and unstable rock slopes, which might form rock avalanches, can rarely be prevented from failure (e.g., artificial draining of slope). If a potential failure is imminent, complete *Evacuation* of the potentially affected run-out area is the only *Disaster Risk Management* measure.

ROCKFALL

Fausto Guzzetti
CNR – IRPI, Perugia, Italy

Synonyms

Rock fall

Definition

A rockfall is a type of fast-moving landslide common in mountain areas worldwide (Cruden and Varnes, 1996).

Discussion

An individual rockfall is a fragment of rock detached from the bedrock along new or preexisting discontinuities (e.g., bedding, joints, fractures, cleavage, foliation) by creeping, toppling, sliding, or falling, that falls along a cliff, proceeds down slope by bouncing, flying, tumbling, or rolling. A rockfall stops when it has lost enough energy through impacts or by friction (Fig. 1) (Dorren, 2003; Guzzetti and Reichenbach, 2010).

Creeping is limited to the pre-failure stage of a rockfall. Toppling consists of the outward or sideway rotation from the slope of a single or multiple adjacent blocks. Sliding occurs in the initial stage of a rockfall or at impact, with significant loss of energy due to high friction. Driven by gravity, free fall occurs along ballistic trajectories at high velocity. In nature, the motion of a boulder is most often by tumbling (a rapid sequence of short, low flying parabolas), and rolling is rarely observed. Irregularities in the shape of the block or the terrain facilitate impact and bouncing, and prevent or interrupt rolling. At impact, energy is lost and the direction of motion of the rockfall changes. Upon impact, a block can break into multiple fragments that proceed along separate trajectories. In forests, collisions against trees can deflect or stop rocks.

For primary rockfalls, the fall immediately follows detachment. For secondary failures, the time and trigger of the fall are different from those of the detachment. A rockfall can involve single or multiple blocks. When multiple blocks are involved in a failure, there is little or no interaction among the individual fragments. Rockfalls travel at speeds ranging from a few to tens of meters per second, and range in size from small cobbles to large boulders hundreds of cubic meters in size. The statistics of rock fall volume obey the behavior of a negative power law.

Natural triggers of rockfalls include earthquakes, freeze–thaw cycles of water, melting of snow or permafrost, temperature changes, intense or prolonged rainfall, stress relief following deglaciation, volcanic activity, and root penetration and wedging. Human-induced causes of rockfalls include undercutting of rock slopes, mining activities, pipe leakage, inefficient drainage, and vibrations caused by excavations, blasting, or traffic. Due to their high mobility, rockfalls are a particularly destructive type of failure, and in several areas, they represent the primary cause of landslide fatalities. A good predictor of rockfall occurrence in an area is the evidence of previous rockfalls.

ROGUE WAVE

Norm Catto
Memorial University, St. John's, NL, Canada

Synonyms

Anomalous wave; Extreme wave; Freak wave; Killer wave

Definition

A relatively large wave, often not directly associated with immediate weather conditions, which occurs as an isolated, anomalous event.

Discussion

Rogue waves are distinguished both by their height and the relatively unexpected nature of their occurrence. Heights in excess of 30 m have been recorded offshore. At sea, a wave is considered rogue if it has a minimum height of twice the mean significant wave height, defined as the mean of the largest 33% of wave heights recorded for a specific area. In addition, a rogue wave is a single large wave in isolation, not accompanied by a prolonged period of similar waves or wave train. Rogue waves thus can occur during relatively calm conditions, and are not always directly associated with storm activity. They can be generated in both deep, open ocean, or in coastal waters. Rogue waves, locally in excess of 10 m in height, have struck confined coastal embayments directly facing the open ocean, causing damage and loss of life.

Although well known by mariners and in coastal communities for centuries, scientific investigation of rogue waves began relatively recently. Postulated causes for individual events vary, indicating the anomalous nature of the phenomenon. Most explanations involve the focusing and combination of individual smaller waves, generated by normal wind activity or marine swell, into large features. Focusing may be triggered by diffraction of smaller waves from adjacent coastlines, possibly accounting for coastal events; interaction between waves traveling in one direction and an opposing current; or nonlinear addition of smaller clapotis waves in offshore areas, responsible for deep-water events. Rogue waves formed from combinations of storm-induced wind waves may develop some days after the triggering event.

Rogue waves pose hazards for vessels at sea, fixed offshore infrastructure (such as oil-drilling platforms), and coastal communities located in confined embayments. The unpredictable, anomalous nature of the phenomenon, and the lack of detailed explanations linking specific meteorological conditions to genesis, hinders efforts to reduce the hazard posed by rogue waves.

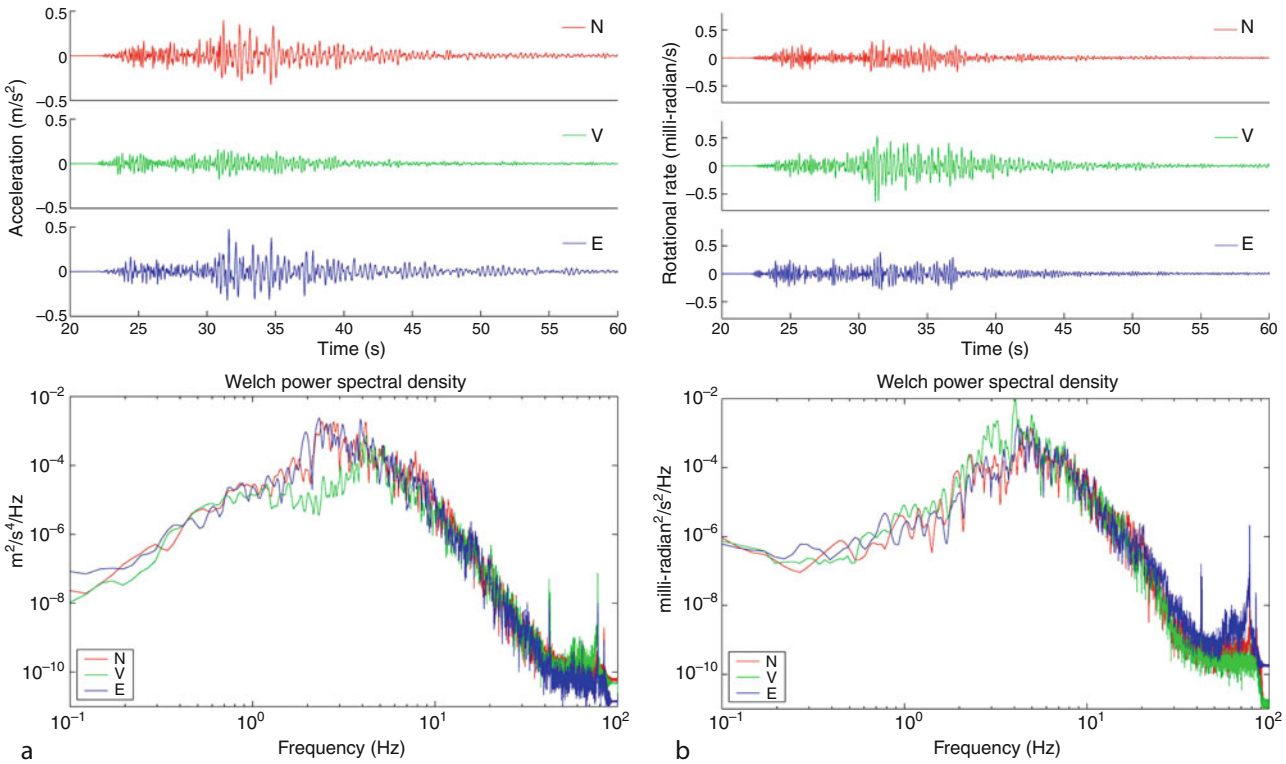
ROTATIONAL SEISMOLOGY

William H. K. Lee
U.S. Geological Survey, Menlo Park, CA, USA



Definition

Rotational seismology is an emerging study of all aspects of rotational motions induced by earthquakes, explosions, and ambient vibrations. It is of interest to several disciplines, including seismology, earthquake engineering, geodesy, and earth-based detection of Einstein's gravitation waves.

Rotational effects of seismic waves, together with rotations caused by soil–structure interaction, have been observed for centuries (e.g., rotated chimneys, monuments, and tombstones). Figure 1a shows the rotated monument to George Inglis observed after the 1897 Great Shillong earthquake. This monument had the form of an obelisk rising over 19 metres high from a 4 metre base.

Rotational Seismology, Figure 1 (**a**) Rotation of the monument to George Inglis (erected in 1850 at Chatak, India) observed after the 1897 Great Shillong earthquake. (**b**) Coordinate system for translational velocity. (**c**) Coordinate system for rotational rate.

Rotational Seismology, Figure 2 (**a**) Recorded translational acceleration (*top*) and its spectra (*bottom*) from an M_W 5.1 earthquake in Taiwan on July 23, 2007. (**b**) Recorded rotational rate (*top*) and the corresponding spectra (*bottom*) from the same earthquake. E, N, and Z refer to orthogonal sensor orientations.

During the earthquake, the top part broke off and the remnant of some 6 metres rotated about 15° relative to the base. The study of rotational seismology began only recently when sensitive rotational sensors became available due to advances in aeronautical and astronomical instrumentations.

Rotational ground motions

The general motion of a particle or a small volume in a solid body can be divided into three parts: translation along and rotation about the orthogonal *X*-, *Y*-, and *Z*-axes, and strain. Figure 1b shows the axes in a Cartesian coordinate system for *translational velocity* measured by the traditional seismometers, and Figure 1c shows the corresponding axes of *rotation rate* measured by rotational sensors.

Rotational ground motions can be measured directly by gyroscopic sensors, or inferred indirectly from an array of translational sensors. In recent years, rotational motions from small local earthquakes to large teleseisms were successfully recorded by sensitive rotational sensors in several countries. Observations in Japan and Taiwan show that the amplitudes of rotations can be one to two orders of magnitude greater than expected from the classical elasticity theory. Figure 2a and b shows, respectively, the amplitudes and spectra of translational acceleration and of rotational rate recorded 51 km away from an M_W 5.1 earthquake in Taiwan.

Relation to traditional seismology

Seismology is traditionally based on classical elasticity theory under infinitesimal strain. Rotation is then defined as the curl of the displacement field, and the rotational components of motion are contained in the S-waves (Lee et al., 2009b). However, modern elasticity theories, for example, that of the Cosserat brothers incorporates local rotation and couple stress (a torque per unit area). Applications of modern elasticity theories to rotational seismology began only recently.

Seismic networks traditionally deploy only translational seismometers. To improve our understanding of damaging earthquakes, rotational sensors must also be deployed, particularly in the *near field* where rotational motions are expected to be the largest. A first step towards such extensive seismic instrumentation has been taken in southwestern Taiwan, where two 32-element arrays of both translational and rotational instruments with station spacing of tens of meters have been deployed.

SACKUNG

Michael J. Bovis
University of British Columbia, Vancouver, BC, Canada

Synonyms

Deep-seated gravitational deformation; Gravitational spreading; Slope sagging

Definition

Sackung is a German term denoting slow, deep-seated gravitational deformation of slopes.

Discussion

Sackung-type movements have typical surface expression as uphill-facing (antislope) scarps, tension cracks, grabens, and anomalous ridge-top depressions running roughly parallel to the contours in steep mountain topography. Individual scarps, grabens, and cracks (collectively referred to here as "linears") have a typical relief of 1–10 m and may be traced over distances of 100 m to more than 3 km. Linears may be arranged subparallel to one another, or en echelon, and comprise slope-movement complexes covering areas of 1–10 km^2 that are clearly visible on air photographs (Figure 1).

Material properties and movement mechanisms

Sackung features were first recognized in the European Alps, but have since been recognized in many other mountain areas. Hürlimann et al. (2006) provide a comprehensive citation of papers from the past 40 years. Linears occur over a wide range of rock types, ranging from ductile sedimentary rocks to hard jointed intrusive and metamorphic rocks, but often are best displayed and preserved in hard rocks with closely spaced discontinuities dipping steeply into a slope. This structure favors flexural toppling, likely an important mechanism for development of many antislope scarps. The feasibility of flexural toppling may be assessed kinematically for joint poles, α, falling outside a friction circle drawn ϕ degrees flatter than the slope angle β, where ϕ is the friction angle along the through-going discontinuities, i.e., $\alpha < (\beta - \phi)$ (Bovis and Evans, 1996, Nicol et al., 2002).

Numerical modeling of large-scale sackung movements is now fairly common, using both distinctive-element and continuum methods (Nicol et al., 2002; Eberhardt, 2008). Modeled ground-motion vectors agree fairly well with long-term measured ground movements. Such 2-D modeling also shows that sackung movements are sensitive to water pressure fluctuations and to slope steepening by either Neoglacial or fluvial undercutting of slopes (Bovis and Stewart, 1998; Ambrosi and Crosta, 2006).

Hazard implications

Sackung linears have been reported adjacent to many *Rock Avalanche* detachment zones, which has provoked discussion of a probable connection between slow, ductile sackung-type movements and sudden rock avalanche detachments. Some linears probably developed in response to an abrupt change in longitudinal stress as the avalanche detached, but in many cases, the morphology and degree of weathering of linears indicate a far greater age than the rock avalanche. This implies that sackung linears are an expression of premonitory movements in stressed slopes, some of which fail catastrophically, though Hewitt et al. (2008) caution that sackung movements are not a necessary precursor for all catastrophic detachments. Where minimal erosion of linears has occurred since their development, cosmogenic ^{10}Be dating may be used to establish very long-term stability for some sackung slopes, which therefore constitute a minimal hazard at present (Hippolyte et al., 2009).

Sackung, Figure 1 Vertical air photograph of a sackung slope, Affliction Creek, British Columbia, Canada. Note glacial undercutting of the slope. Tension cracks and grabens shown by dashed lines. Antislope scarps shown by dotted lines.

Some sackung linears have been mapped as neotectonic faults, but detailed field investigations supplemented by numerical modeling show that many of these features represent sackung movements controlled by much older tectonic features (Ambrosi and Crosta, 2006).

SAFFIR–SIMPSON HURRICANE INTENSITY SCALE

Ilan Kelman
Center for International Climate and Environmental Research – Oslo (CICERO), Oslo, Norway

Synonyms

Hurricane classification scale

Definition

The Saffir–Simpson Hurricane Scale rates the danger and damage potential from hurricanes.

Discussion

The Saffir–Simpson Hurricane Intensity Scale rates the danger and damage potential from tropical cyclones for the Atlantic, Caribbean, and Northeast Pacific. In those regions, tropical cyclones are called hurricanes. Historically, the scale has reported wind speed, storm surge depth, and barometric pressure. Revisions in 2009 focused the renamed Saffir–Simpson Hurricane Wind Scale on wind speed only, reporting the maximum sustained surface wind speed as the peak one-minute wind at a height of ten meters above ground. Hurricane categories, focusing on infrastructure in the USA, are:

- Category 1: 119–153 km/h. Damage to poorly constructed or poorly anchored buildings and other infrastructure such as signs. Loose items can become lethal projectiles.
- Category 2: 154–177 km/h. Additionally, damage to roofs, doors, and windows.
- Category 3: 178–209 km/h. Additionally, wall failures will occur and trees will be broken or uprooted.
- Category 4: 210–249 km/h. Complete destruction of some buildings along with other infrastructure such as signs and lines for electricity and communications.

Most trees are blown down. Extensive windborne debris contributes to damage, deaths, and injuries.
- Category 5: over 249 km/h. Additionally, many buildings and most other infrastructure suffer complete destruction.

The shorthand "Cat." is frequently used for "Category". Sometimes, the scale includes Tropical Storms defined as having winds of 63–118 km/h. Some media commentators suggest adding Category 6, cutting Category 5 off within the range of 280–290 km/h. This change is not necessarily helpful because Category 5 already suggests widespread destruction, so a further category adds little.

This Saffir–Simpson Scale was invented by an American consulting engineer, Herbert Saffir, in 1969, focusing on wind speed. Over the following years, with the then director of the USA's National Hurricane Center, Bob Simpson, the scale was expanded to include storm surge height and barometric pressure.

Pressure and storm surge have now been phased out of the scale due to concerns about the accuracy and usefulness of the information. In particular, storm surge height on land depends on factors such as near-shore bathymetry and topography. As well, in places with large tidal variations, a storm surge peaking at low tide can be the same as a high tide whereas the same storm surge at high tide can yield devastating flooding. Similarly, the Saffir–Simpson scale does not fully reflect the possibilities for hurricane-related inland flooding. During hurricanes, flooding from rainfall or storm surge has historically caused the majority of fatalities, rather than wind speed, although the statistics have been changing as messages about hurricane-related flooding have become more prominent. The scale should therefore be interpreted as an indicator of wind-related destruction only, not of all dangers from a hurricane.

SAN ANDREAS FAULT

William A. Bryant
California Geological Survey, Sacramento, CA, USA

Definition

The 1,100-km-long San Andreas Fault is the principal element of the San Andreas Fault System, a network of faults with dextral strike-slip displacement that collectively accommodates the majority of relative northwest-southeast transform motion between the North American and Pacific crustal plates. This major transform *Fault* extends along western California from the Salton Trough near the California-Mexico border northwest to its complex junction with the Mendocino Fault Zone near Punta Gorda.

Discussion

Andrew Lawson first mapped the fault in northern California in 1893. Lawson identified the fault as the San Andreas rift, based on its expression in the San Andreas Valley in San Mateo County. Schuyler (1896–1897) described parts of the fault in southern California and referred to the fault not as the San Andreas but as the "great earthquake crack," referring to surface displacement associated with the Mw ~7.9 1857 Fort Tejon earthquake. The fault first gained international scientific attention following the Mw 7.8 1906 San Francisco earthquake (Lawson, 1908). Lawson's 1908 report summarizing the investigation of the *Earthquake* contained the first integrated description of the San Andreas Fault and formed the underlying basis for modern studies of paleoseismology and earthquake geology (Prentice, 1999).

Noble (1926) was the first to suggest a large amount of dextral slip (38 km) along the San Andreas Fault. Stanley (1987) documented 325–330 km of post-late Oligocene dextral slip. The fastest, generally accepted Holocene dextral slip rate of 33.9 ± 2.9 mm/yr for the San Andreas Fault has been documented along the Cholame-Carrizo Section, which lies in the central portion of the fault zone (Sieh and Jahns, 1984). Average recurrence intervals of large magnitude earthquakes, in general, range from a little more than 100 years to as much as 450 years (Bryant and Lundberg, 2002).

Fault creep as high as 32 mm/yr characterizes the San Andreas Fault along the 132-km-long Creeping Section in central California. The northwestern and southeastern ends of the Creeping Section are transitional to the surface-rupture termination points of the 1906 earthquake to the northwest and 1857 earthquake to the southeast. Creep up to 4 mm/yr also has been measured near the southern end of the fault east of the Salton Sea.

CASE STUDY

SANTORINI, ERUPTION

Yuri Gorokhovich
Lehman College, City University of New York, Bronx, NY, USA

Introduction

The volcanic island of Santorini is both an ancient and a modern legend. Its history is linked with ancient maritime life of the Mediterranean Sea, the Minoan civilization on Crete and Greek mythology. But the most dramatic page of Santorini's history is directly tied to the volcanic explosion of the ancient island of Thera between 1627 and 1600 B.C.E. (Friedrich et al., 2006) that changed its entire shape after one of the strongest explosions that mankind has ever witnessed. Modern Santorini is a remnant of that explosion, a mighty monument to the grandiose forces of nature.

The formation of the Santorini volcanic complex we see today began after the explosion of Thera which coincided with social and political changes on the nearby island of Crete during the Late Bronze Age. Many historians have long believed that, since Santorini is less than 100 km from Crete, the explosion of Thera triggered the end of the Minoan civilization in the Late Bronze Age (Marinatos, 1939). Thus, the eruption of Thera is also known in human history as the Minoan eruption. Although widely disputed, this point of view still prevails in media documentaries and popular history. Scientific data from models and field observations are ambiguous and do not provide an unequivocal answer.

Many references to the Santorini complex can be found in ancient literature. Its two islands, Thera and Therasia were mentioned in works of Strabo (66 B.C.E.–46 A.D.), Herodotus (c. 484–425 B.C.E.), Pliny (24–79 A.D.), Seneca and many other ancient writers, geographers, historians, and philosophers (Fouquè, 1879). The Pythian Ode of Pindar (522–441 B.C.E.) mentions Thera in verse 10 and Calliste (the ancient name of Santorini) in verse 258 (Friedrich, 2000). During the fourteenth century Venetian period in the Mediterranean region, merchants from Venice built a chapel of Santa Erene (Saint Irene) on the main island of Thera. Since that time, the island complex has come to be known as Santorini.

According to ancient texts, Santorini hosted Argonauts, Phoenicians, Lacedemonians, and Dorians. In Ptolemy's "Dialogs," it was suggested as a potential location of the mysterious Atlantis. It minted its own coins beginning in 635 B.C.E. Due to its central geographic location, Santorini played an important role in Mediterranean maritime trading. It thrived through the Roman period and the early Christianity era, and eventually was owned by the Venetian family Crispo until 1537 and then by the Ottoman Empire until the Greek War of Independence in 1821, when it became a Greek territory.

An abundance of rich volcanic soil and volcanic tuff (which was used as construction material) provided jobs and income for Santorini's inhabitants. Hydraulic (i.e., water resistant) cement, a strong mixture of volcanic ash and lime, was manufactured from Santorini's highly siliceous volcanic ash, called pozzolana (from Pozzuoli, a village near Naples where ancient Romans started mixing volcanic ash and lime). The island's rich volcanic soil helps Santorini's farming sector to produce wines, grapes, vegetables, and fruits for export. The island is also a prime destination for tourists, who are lured by the dramatic geologic features formed by volcanic eruptions in the 1950s, the discovery of the ancient city of Akrotiri and its splendid frescoes in the 1960s, and its mysterious link to the story of Atlantis.

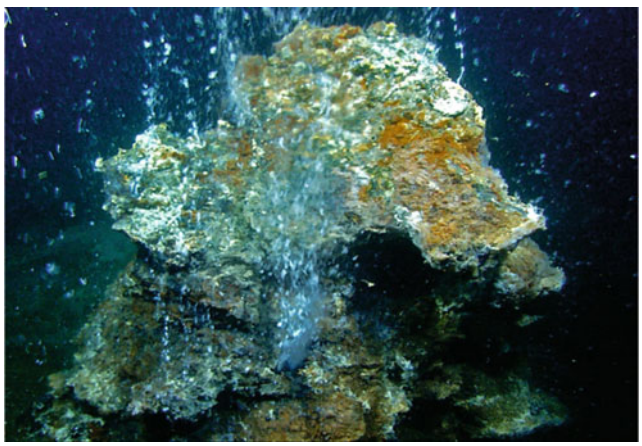
Geographic settings

The Theran (Minoan) eruption in seventeenth century B.C.E. left four separate islands: Thera, Therasia, Aspronisi, and Paleo Kameni (Figure 1). The fifth volcanic island known as Neo Kameni appeared in the eighteenth century CE. Thera, Therasia, and Aspronisi are remnants of the rim of the former volcanic caldera. Paleo and Neo Kameni are small volcanic islands that occupy the center of the caldera. The largest island Thera forms the eastern section of Santorini. Its highest elevation is Mt. Profitis Elias (708 m a.s.l.). The western section of Santorini is the island of Therasia (or *little Thera*, gr.), a volcanic rock complex with elevation of 295 m. a.s.l. Aspronisi (*white island*, gr.) forms the southwestern section of the Santorini complex.

The highest elevations of the caldera walls reach 300 m a.s.l. where the largest towns of the island (Oia and Fira) stretch along the rim and provide picturesque views of

Santorini, Eruption, Figure 1 Santorini volcanic complex.

the surrounding sea and volcanic islands of Nea Kameni and Palea Kameni. Many houses, shops, hotels, restaurants, and even swimming pools are perched on the inner slopes of caldera to provide even more breathtaking views to tourists.



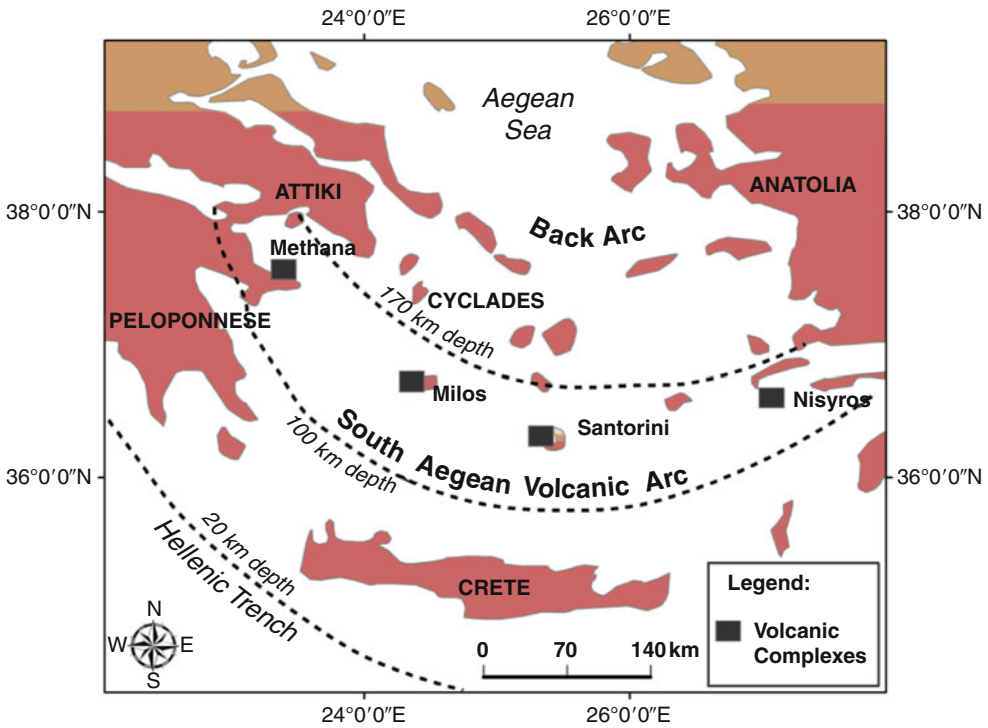
In addition to the main Santorini volcanic complex there is also another volcanic feature, an underwater volcanic cone called Kolumbo, described as a "parasitic cone on a flank of a mass of Santorini" by Fouquè (1879). It is located 7 km northeast from Santorini (Figure 1) at the depth of 500 m. This volcanic complex was studied in 2006 by Robert Ballard and Haraldur Sigurdsson (Gramling, 2007) who used underwater remotely operated vehicles (ROV). They found that this small cone is active with hydrothermal springs and fumaroles (Figure 2). The last explosion of Kolumbo occurred in 1950.

The soils of Santorini were derived from the parental volcanic rocks and according to earlier studies were classified as andisols (Misopolinos et al., 1994). The latest study by Moustakas and Georgoulias (2005) define Santorini soil type as Eentisols due to the very slow rate of weathering, restricted leaching, the longevity of the dry season, and high pH. Rich in nutrients, Santorini soils support approximately 550 taxa of ferns and flowering plants (Biel, 2005).

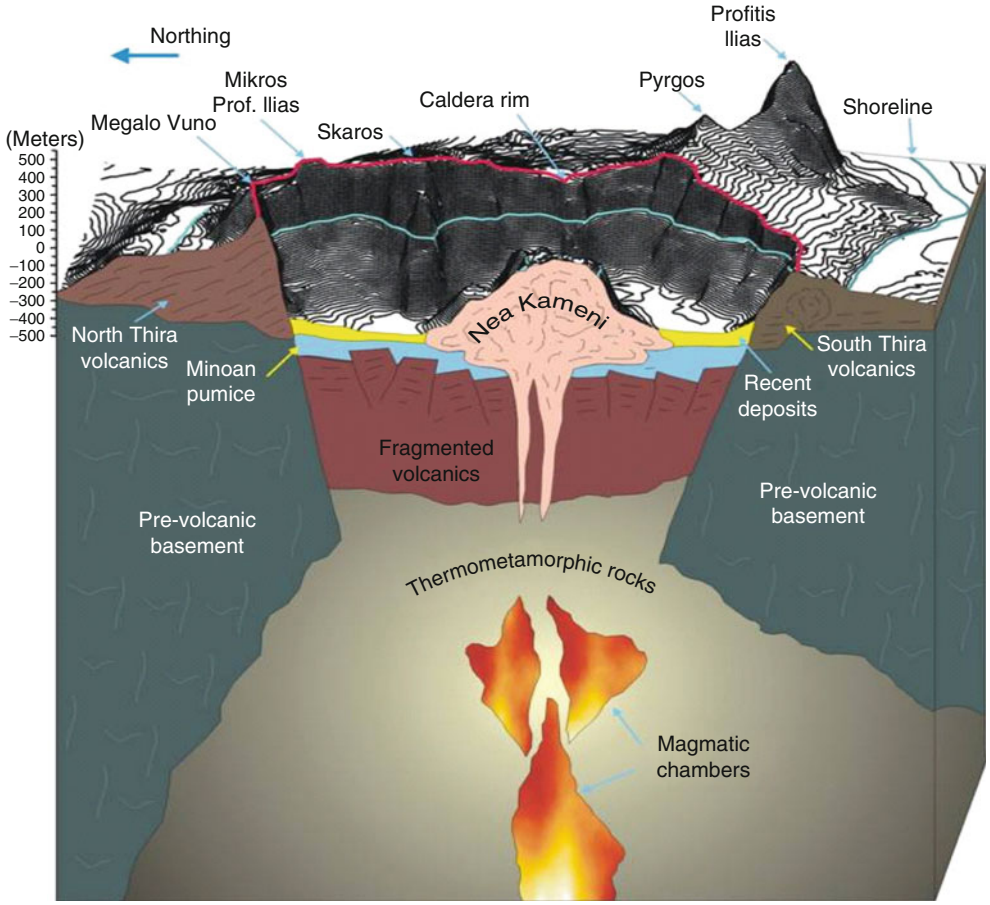
Geological settings of Santorini

The geological settings of Santorini are tightly coupled with the plate tectonics structure of the Mediterranean region. The northeastern motion of the African plate toward Greece created a convergent ocean-continental margin with corresponding volcanic arc complex, deep-sea

trenches and associated with them volcanism and earthquakes with epicenters located between 100 and 170 km below the land surface. This margin where Santorini is located is known as the South Aegean Volcanic Arc (Figure 3). Modern Santorini consists mostly of volcanic rocks such as dacites, andesites, ignimbrites, basalts, tephra, and tuffs among others. The island also has igneous and metamorphic rocks, mostly granites, schists, quartzites, scarns, and marble.



Santorini, Eruption, Figure 2 Hydrothermal activity near Kolumbo (Courtesy of the Institute for the Study and Monitoring of Santorini Volcano (ISMOSAV)).



Santorini is not the only one volcanic complex in the Aegean Sea. There are three other large volcanic complexes: Methana, Milos, and Nisyros (Figure 3, see from NW to SE). These complexes are active and create potential hazards for the region. According to Vougioukalakis and Fytikos (2005) all volcanic complexes present low hazard risk except Nisyros. Figure 4 shows the main geologic elements of the Santorini volcanic complex: magma chambers, pre-volcanic rock complex, current caldera rim, and the fractured zone (fragmented volcanics) under the Nea Kameni.

Santorini hazards

The Santorini complex is a source of three main geological hazards: (1) Volcanic; (2) Earthquakes; (3) Tsunamis. However, the volcanic hazard of Santorini induces both, earthquake and tsunami hazards. During previous volcanic eruptions inhabitants of Santorini felt multiple tremors before and after eruptions, most likely due to the magma movements. The historic tsunami effects were described by the Jesuit priest Francois Richard (Fouquè, 1879) in his recollection of the volcanic explosion of Kolumbo in 1680. Historical hazards and disasters on Santorini are known from both various texts and geological findings. Contemporary hazards

Santorini, Eruption, Figure 3 Elements of the South Agean Active Arc (Adapted from Pe-Piper and Piper, 2005). *Dashed line* with corresponding numbers show depths of earthquake epicenters.

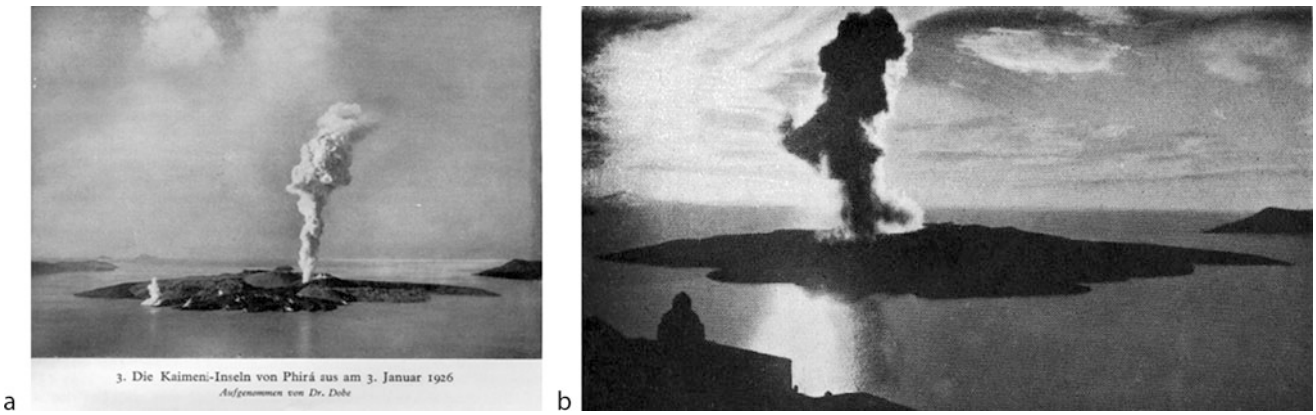
Santorini, Eruption, Figure 4 Schematic diagram showing current structure of Santorini volcanic complex (Courtesy of the ISMOSAV, 2008).

are documented by observations, monitoring, and measurements.

Volcanic hazards caused many disastrous events (Table 1) on Santorini in the past. Combined with recent geologic data these events help scientists to evaluate possible occurrences of similar eruptions. Pyle (1997) suggests periodicity of several such eruptions per thousand years. According to McCoy and Heiken (2000a) a recurrence interval for explosive eruption on Santorini similar to the Minoan is 20,000 years with smaller explosive eruptions every 5,000 years. Eruptions in the twentieth century were recorded on photos (Figure 5) and documented by scientific measurements.

Volcanic eruption of Thera (aka Minoan or Late Bronze Age eruption)

Among many eruptions during the history of Santorini the most outstanding by force and its place in human history was the eruption of Thera during the Late Bronze Age. That period in the Mediterranean was characterized also by intensive earthquake activity (Monaco and Tortorici, 2004; Nur and Cline, 2000). The latest C^{14} analysis of organic material from an olive branch defines the date of the Minoan eruption as 1627–1600 B.C.E. with 95.4% probability (Friedrich et al., 2006). Data from Egyptian medical papyrus collection provides an earlier and more exact date of August 1603 B.C.E. (Trevisanto, 2007).



The multi-hazardous character of Thera's eruption manifested itself in geological and archaeological findings. While recovering remnants of the ancient city Akrotiri that survived Thera's eruption, archaeologists found a damaged staircase with visible effects of the compressive force (Figure 6) from the earthquake (seismic) wave.

Many walls of the dwellings in Akrotiri collapsed due to the earthquake effects and the excessive weight of the volcanic ash on the roofs.

Despite the abundance of discussions and scientific studies, the destructive effect of the volcanic ash from the Thera eruption on the demise of Minoan civilization on nearby Crete is not supported by field data (Vitaliano and Vitaliano, 1974). Earlier, Ninkovitch and Heezen

Santorini, Eruption, Table 1 Historical eruptions on Santorini (Summarized from Friedrich, 2000)

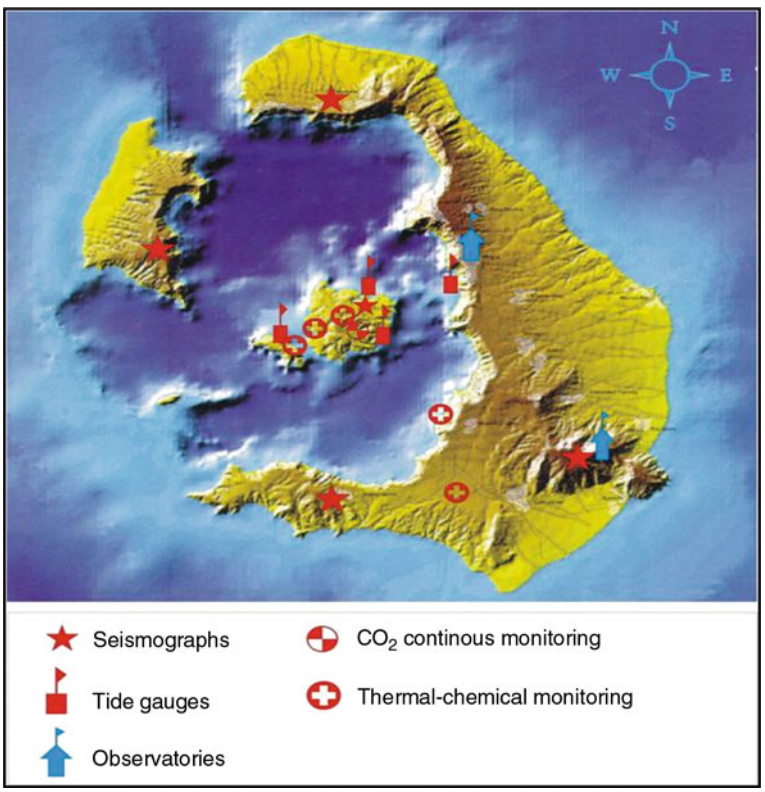
Volcanic event	Description	Source
Approx. 1,640 B.C.E.	Original round volcanic island (Stroghyle) experienced phreatic eruption that created the rim of the modern Santorini	Geologic interpretation
Approx. 197 B.C.E.	New island Hiera was formed as the result of the eruption	Strabo (Geography, 1.3.16)
Approx. 46 A.D.	Island of Theia appeared	Seneca, Cassiodorus (468–562 A.D.)
Approx. 726 A.D.	New island appeared next to Hiera. Ash from this volcanic eruption reached the Straits of Dardanelles, coast of Asia Minor, and Macedonia	Nicephoros (758–828 A.D.) and Theophanes (752–818 A.D.)
Approx. 1457–1458	New island appeared between Thirasia and Thera	Buondelmonte (1465–1466), Athanasius Kircher (1665)
1570–1573	New island Mikra Kameni was formed 4 km northeast of Paleo Kameni	Athanasius Kircher (on account of the Jesuit priest Ricardus)
Sept. 27, 1650	Eruption of Kolumbo, an underwater volcano, northeast from Thera. After 4 months Kolumbo disappeared under the water. "Fifty persons died from the harmful effects of the volcanic gas and more than a thousand animals died that way" (Fouquè, 1879)	Jesuit priests Francois Richard (1657) and Father Goree (1712)
1707–1711	New island (Neo Kameni) appeared west of Mikra Kameni. Sulfurous springs appeared	Father Goree (1712), Barskii (1745)
1866–1870	Neo Kameni and Micro Kameni were joined by newly formed lava that filled out the space between them. The process accompanied by ash eruption and explosions. Gas and fumaroles were formed	Reiss, Stubel, Schmidt, Fouquè, Karl Von Seebach
1925–1928	Increase of sea water temperature, steam, appearance of lava, phreatic eruption, formation of large lava field across Neo Kameni (Figure 5)	Reck (1936)
1939–1941	New vents, two domes, and lava field appeared on Nea Kameni	
1950	Phreatic explosions and extrusion of lava	Georgalas (1959)

Santorini, Eruption, Figure 5 (**a**) Historical eruption on Nea Kameni in 1926. (**b**) Eruption on Paleo Kameni, 1950.

(1965) used core analysis of sea-floor sediments that showed that distribution of volcanic material (tephra) from the Thera eruption was not uniform and that its majority was ejected toward the Turkey. Sullivan (1988) reported finding of tephra in Turkish lakes, Francaviglia (1990) reported finding tephra on Turkish coastal beaches, and Guichard et al. (1993) reported findings of Santorini tephra in sediments of the Black Sea.

The analogy between the Thera eruption and the volcanic eruption of Krakatau in Sunda Straight (Indonesia) on August 26, 1883, prompted a hypothesis of the disastrous effect of tsunami waves on Minoan civilization on Crete (Marinatos, 1939). Later, the findings of concave walls in one of the late Minoan houses near Amnissos supported this hypothesis (Marinatos, 1968). Recent studies by Minoura et al. (2000), Koenig (2001), and Dominey-Howes (2004) do not support the disastrous effects of tsunami generated by the Thera eruption on Crete.

At the same time the archaeological study in Gouves (Vallianou, 1996), an analysis of the tsunami on Santorini (McCoy and Heiken, 2000b) and the surrounding area and geological findings of potential tsunami deposits from Thera eruption near Minoan palace Palaikastro (Bruins et al., 2007) and coast of Israel (Goodman-Tchernov et al., 2009) support the conclusion on tsunami

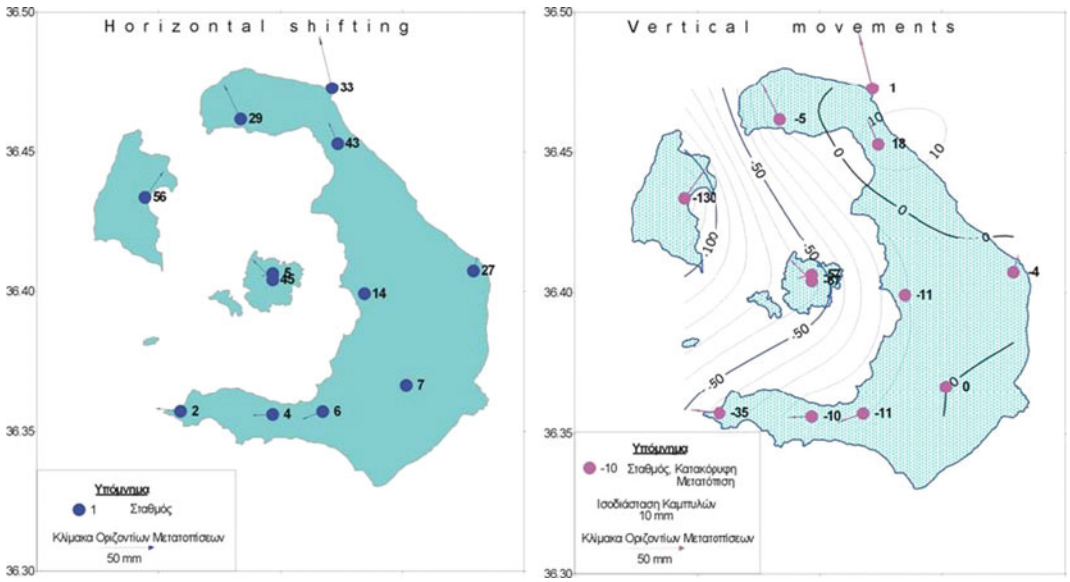


distribution and consequent inundation of the coastal areas of Crete and Aegean within several hundred meters (Minoura et al., 2000). Still this evidence does not yet explain the demise of the Minoan civilization on Crete.

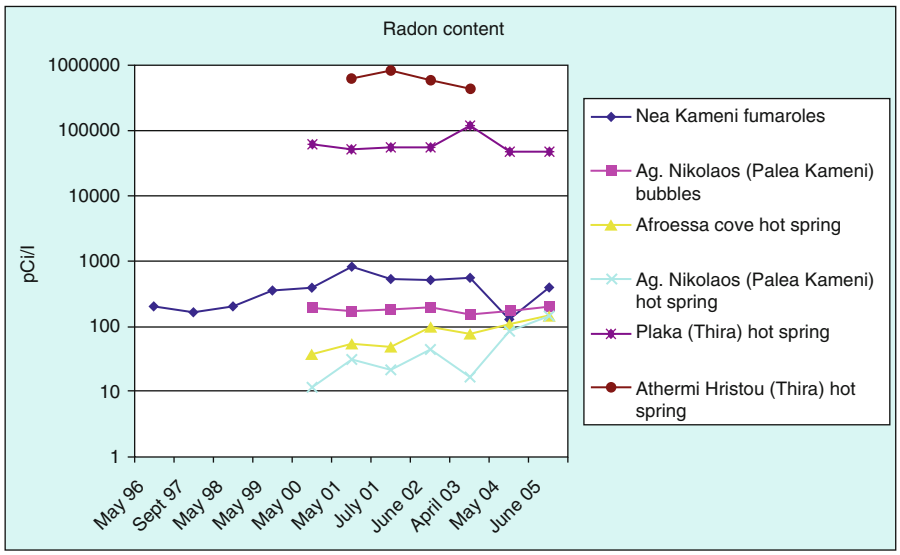
It is also hard to assess the impact of the Thera eruption on the local Theran population since only one excavation at Akrotiri (Figure 1) revealed remnants of the ancient town buried under the volcanic ash. Though no skeletons or human remains were found (Doumas, 1990) in the excavated ruins and only one precious object (golden ibex figurine) was discovered (Pantazis et al., 2002). On a global scale Pyle (1997) argues that the Thera eruption was not a catastrophe "unparalleled in all of history" and that its erupted volume and intensity was lower in comparison with the eruption of Tambora (Indonesia) in 1815 CE. The study also argues that the contribution of sulfur emissions and climatic effects from the Thera eruption was even lower than during the Tambora and Mt. Pinatubo (Philippines, 1991) eruptions.

Three important conclusions from the archaeological and geological studies of the Thera eruption help to assess the consequences of this disaster on the ancient population: (1) No human and animal skeletons and no considerable valuables have been found in the excavated ruins of the ancient city of Akrotiri; (2) Distribution of ash and volcanic debris from the Thera eruption was directed toward the Turkish and eastern Mediterranean coast; (3) While the tsunami and inundation of coastal areas most probably occurred, they did not have a disastrous effect on the population and even more, on the collapse of the Minoan civilization on Crete. Apparently the ancient population of Thera was able to react to the early warning from the initial volcanic tremors and leave the island safely.

Santorini, Eruption, Figure 6 Broken staircase in Akrotiri.

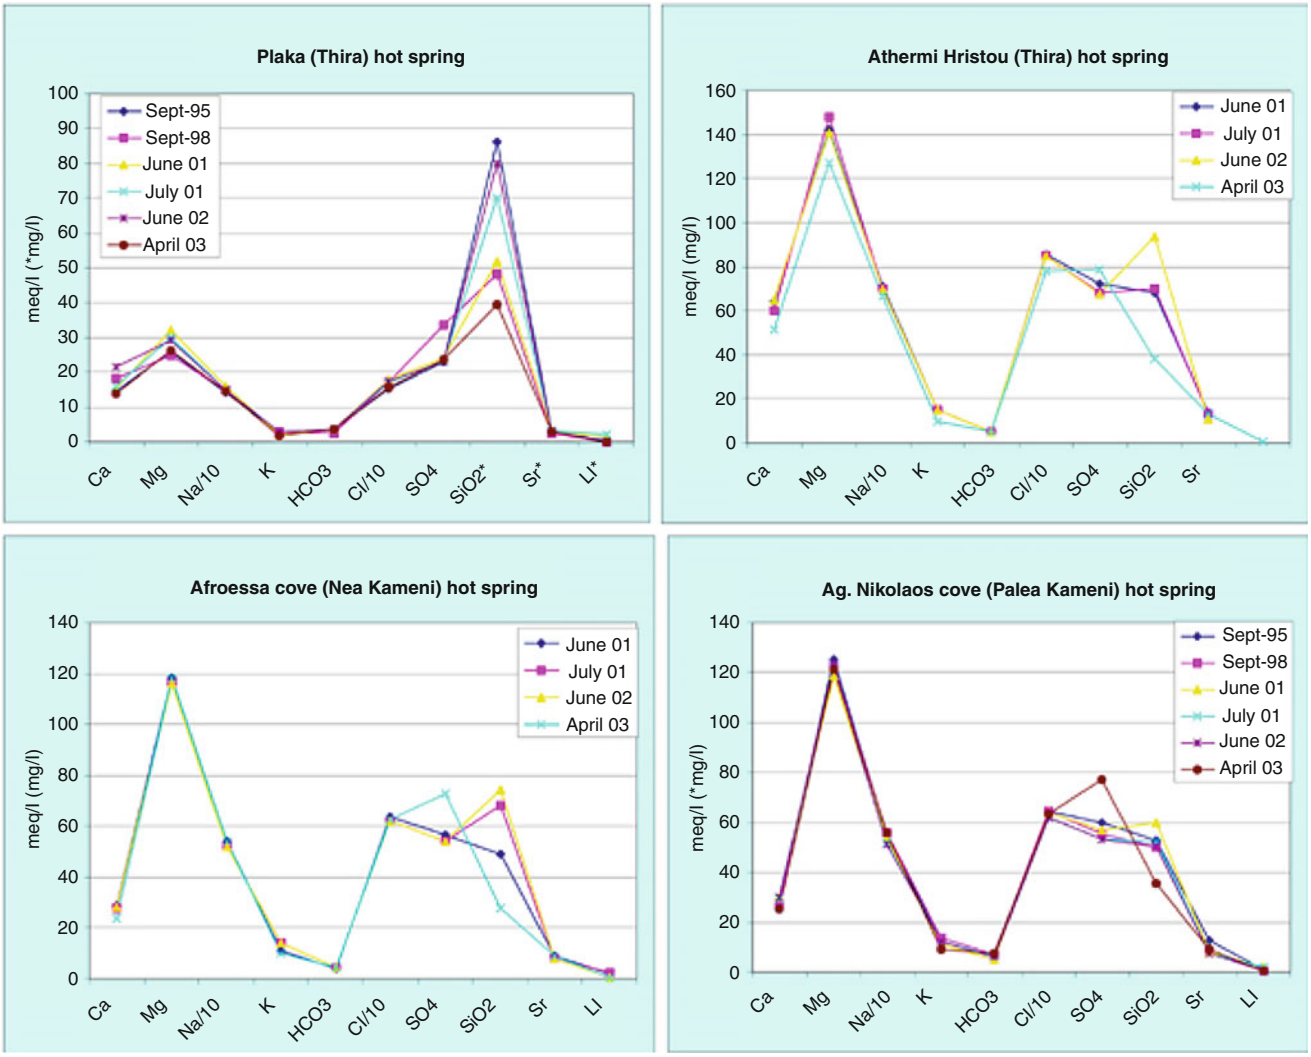


Santorini, Eruption, Figure 7 Monitoring stations and types of observations (Courtesy of ISMOSAV, 2008).



Volcano monitoring

The current geological state of the island is being monitored by the Institute for The Study and Monitoring of Santorini Volcano (ISMOSAV) founded in 1996. Figure 7 shows the locations of various monitoring stations and associated types of measurements.

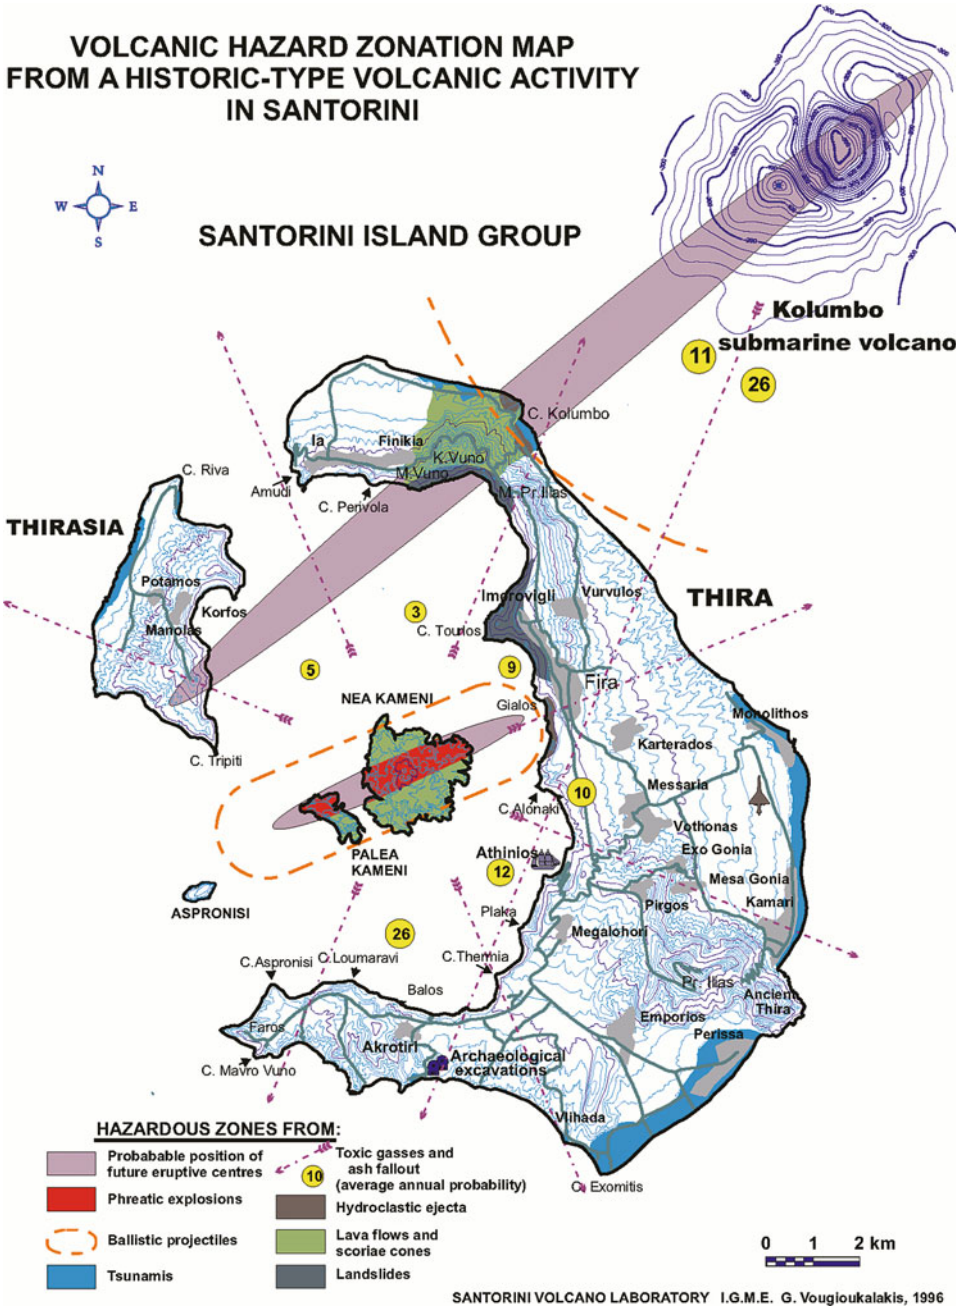


Ground deformations due to the rising magma in magmatic chambers (Figure 4) are primary indicators of volcanic activity. Ground deformations are usually measured by electronic distance meters (EDM) to detect the slightest inflation of magma with accuracy of up to a few millimeters. EDM devices receive and send electromagnetic signals to established benchmarks on the volcanic surface within the range of 10–50 km. An EDM monitoring system on Santorini was established in 1994. Measurements between 1994 and 2003 revealed gradual inflation (up to 10 cm) of the area between Nea Kameni and Therasia (Stiros et al., 2005). Other areas of the Santorini complex do not show any significant changes. The latest data from ISMOSAV (Figure 8) show the highest vertical (130 mm) and horizontal (56 mm) movements recorded on Therasia.

Santorini, Eruption, Figure 8 Map of horizontal and vertical deformations (Courtesy of ISMOSAV, 2008).

Santorini, Eruption, Figure 9 Changes in radon concentration, 1996–2005 (Courtesy ISMOSAV, 2008).

Santorini, Eruption, Figure 10 Chemical composition of hot springs (Courtesy ISMOSAV, 2008).



Seismic activity on the island is monitored by five permanent and four temporary stations (Dimitriadis et al., 2005). For the period 1994–2002 these stations recorded multiple earthquakes with maximum magnitude of 5.0. Most seismic activity occurred at the center of the Santorini complex (i.e., Paleo Kameni) and the northern part near Kolumbo volcanic cone. These locations are associated with two main faults. However, according to authors of the study available data are still limited to explain this activity.

The thermal-chemical monitoring of Santorini volcano consists of the following measurements:

- Hot fluids composition
- Gas composition
- Temperatures
- Radon content in hot gasses and waters
- CO_2 flux

These measurements represent the five main parameters of volcanic activity. The goal of thermal-chemical monitoring is to find fluctuations in measured values and associate them with periods of activity or repose of volcanic processes. For example, in relation to CO_2 flux, ISMOSAV (2008) reported that the main flux values per day range between 5 and 50 ppm/s, whereas the maximum registered values did not exceed the 150 ppm/s. According to ISMOSAV this fluctuation is considered characteristic for the repose time period of the volcano. During the volcano reactivation the magnitude of CO_2 flux will increase and might serve as an early warning sign.

Radon content is another indicator of earthquake and volcanic activity. For the period 1996–2005 radon concentration increased in the Afroessa cove (Nea Kameni) and the Ag. Nikolaos (Palea Kameni) hot springs (Figure 9).

Santorini, Eruption, Figure 11 Volcanic hazard zonation map (Vougioukalakis and Fytikas, 2005).

The maximum registered temperature fluctuation on Nea Kameni fumaroles is about 3°C (94°C ~ 97°C). The same fluctuation was measured on Palea Kameni. Nea Kameni fumaroles consist mainly of heated atmospheric air and CO_2 with minor concentrations of CH_4, H_2, and CO. Palea Kameni gasses consist mainly of CO_2 (99.9 vol.%) with minor concentrations of N_2, O_2, CH_4, and CO. Their fluctuations since 1995 are not significant (Figure 10).

According to ISMOSAV (2008) findings there are no significant fluctuations in the chemical composition of hot gasses and waters, which could indicate any deep feeding process inside the magma chamber and possible eruption. They also suggest that the decrease of the total gas outflow and the minor gas constituents measured during the last 2 years could indicate ongoing self-sealing processes for the uppermost Kameni area.

While monitoring of geochemical parameters is necessary for the short-term (in geologic sense) analysis and hazard assessment, its use for predicting earthquake and volcanic activity does not appear to be feasible

(Thomas, 1988). Seismic and geodetic components of ongoing monitoring help to acquire additional clues and complement overall conclusions.

Hazard assessment and zonation

Hazard assessment of the Santorini complex is based on historical records, geological studies, and results from current monitoring. Trends in seismic, temperature, gas, and ground deformation data help to make short-term predictions and recognize early warning signs of volcanic activity. Analysis of historical and geological records helps to predict the most probable scenario and map potentially vulnerable areas of ash fallout, zones of inundation and landslides, etc.

The assessment of volcanic hazard is important for Santorini because approximately 70% of tourist establishments are in Oia and Fira (Fytikas et al., 1998). At the same time there is no emergency plan and coordination between departments responsible for emergency measures (Dominey-Howes and Minos-Minopoulos, 2004). With the total number of local population close to 13,600 and an additional 1,000,000 population of tourists during the year (Vougioukalakis and Fytikas, 2005), the absence of the emergency plan reduces the resilience of the Santorini population and makes future disaster management uncertain and potentially ineffective.

According to Vougioukalakis and Fytikas (2005), the most probable volcanic eruption scenario on Santorini will be similar to ones that occurred during the last millennia. The eruption with maximum possible effect will follow the path of the Minoan eruption. In their analysis authors consider a 20,000-year lag between maximum possible events in Santorini history, the number apparently taken from (McCoy and Heiken 2000a). This makes the probability of eruption similar to the one that occurred in Minoan time low. In addition, an eruption of that type will make the island completely obsolete and, therefore, there is no need for a relevant volcanic hazard map.

In case of the most probable eruption scenario, the analysis of historical eruptions and their effects, combined with recently obtained geologic and monitoring data allows drafting a potential hazard zonation map (Figure 11). This zonation includes the following hazard zones:

- Probable position of the future eruptive centers
- Phreatic explosions
- Ballistic ejecta
- Tsunamis
- Toxic gasses and ash fallout
- Hydroclastic ejecta
- Lava flows and scoriae cones
- Landslides

Summary

The Santorini volcanic complex is known for its strong historic and modern volcanic eruptions. While the probability of strong eruption, similar to the Minoan event is low, it is possible to expect less disastrous events, analogous to the post-Minoan eruptions during the CE period with low human and property losses. Current data from the existing monitoring network show relatively stable geochemical trends, clustering of seismic activity along two existing faults and strong ground deformations in the northern part of the Santorini volcanic complex between Nea Kameni and Therasia.

Archaeologic and historic data suggest that during the Minoan eruption the population of Thera was able to leave the island safely and timely. Most likely the early signs of volcanic activity triggered prompt evacuation of the Theran people. The absence of human and animal skeletons and valuable objects in Akrotiri might be a sign of organized and controlled retreat from the island. These are lessons from the ancient past that we need to respect. Although the size of affected population and its distribution on the island is not known because Akrotiri is the only excavated Minoan settlement found on Santorini.

The absence of an emergency plan and lack of coordination between departments responsible for emergency measures weakens the resilience of the modern day Santorini population approaching 14,000 people. Considering the influx of tourists in the amount of 1,000,000 people annually, even the probable volcanic event with low impact can bring the havoc and disorientation of people seeking shelter and safety. More importantly, the absence of a coordinated governmental action plan prevents now any kind of pre-disaster education of potential actors and building strong local capacity of Santorini population to cope with potential disaster.

Acknowledgments

This work would be incomplete without the help of Mr. Ioannis Kotiadis (ISMOSAV) who maintains the monitoring network on Santorini and provided valuable graphs and images for this paper.

SEA LEVEL CHANGE

Peter J. Hawkes
HR Wallingford Limited, Wallingford, Oxfordshire, UK

Definitions

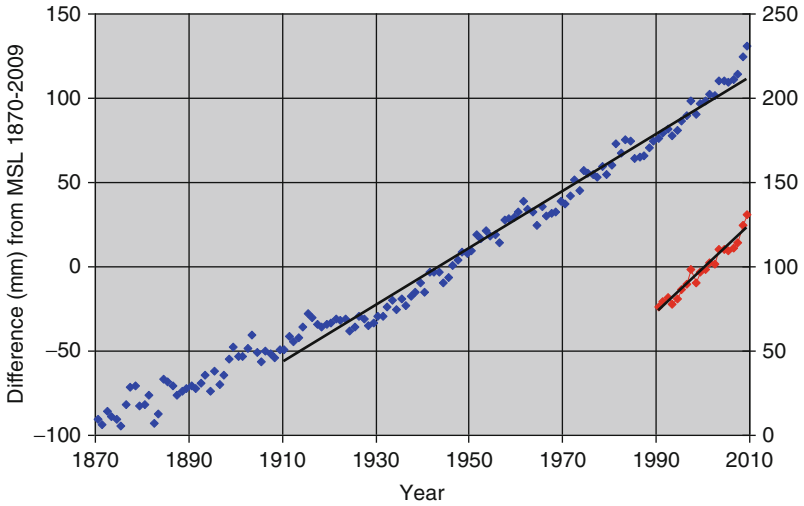
Mean sea level (MSL). An oceanographic term, referring to sea surface level, possibly averaged over an area or a period of time, but with short-period variations such as waves filtered out.
Monthly mean sea level. Average sea surface level, usually at a single location, preferably taken over an integer number of tidal cycles, averaged over a period of about one calendar month.
Global mean sea level. Average sea level, averaged over all sea areas.
Sea level change. Referring to the long-term trend in mean sea level, which may be calculated from a single location or across a region. One can distinguish between *absolute* sea level change and *relative* (to the local land level) sea level change.
Projection. Extrapolation to what would happen under given starting conditions, for given changes and given physical assumptions. Climate change projections are often expressed relative to a particular time period, presently usually 1961–1990.

Introduction

The sea surface is constantly changing, on several different time and length scales. Each type of sea level change results from a range of forcing factors, and in turn produces its own risks to people and property.

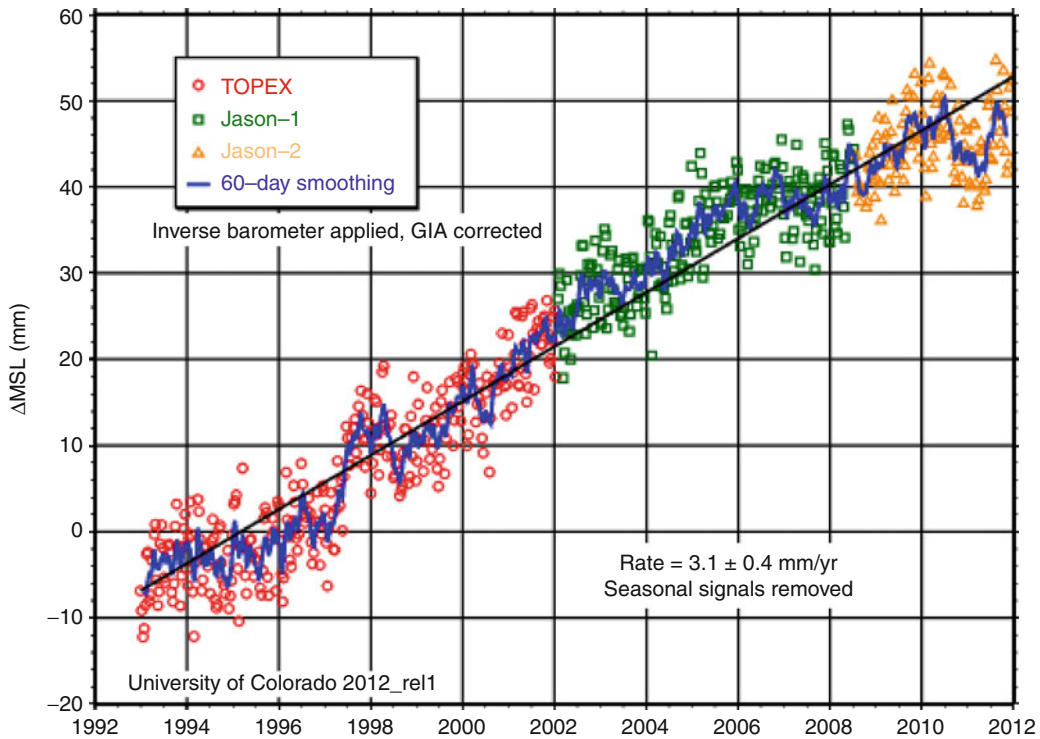
Waves produce the largest and most rapid changes to the sea surface level, on a scale of meters of change in a few seconds, threatening ships, sea defenses, and offshore structures. Tides and surges are also on scale of meters of change, but over a few hours. Tides and surges alone (i.e., without waves) tend not to cause damage, but if flooding does occur, there is an almost unlimited source of water, so flooding may be widespread in low-lying areas. Tidal processes are driven by the interactions of the Sun-Earth-Moon system on large water bodies, whereas surges result from atmospheric low pressure cells. A tsunami is a rare event, on a scale of meters on land in an extreme case, occurring over a period of minutes, but sometimes causing widespread damage because it cannot be forecast and has not been planned for. In many parts of the world there is a seasonal variation in mean sea level, meaning that the mean level at one time of the year may be up to about one quarter of a meter higher than at another time of year.

The issue of most interest here is mean sea level rise, an extremely slow increase in the global mean sea level undetectable by eye but measurable over a period of years. Centimeters or even tens of centimeters rise in mean sea level might appear to be unimportant in the face of tides and waves which cause meters of variation. However, a gradual rise in mean sea level means that, over a long period of time, the same tides and waves act at a slightly higher elevation at the coastline and therefore are more likely to cause damage to people and property.



Causes of mean sea level change

The causes of mean sea level change can be divided into two main types (see, e.g., Sect. 5.5 of IPCC, 2007). One is thermal expansion, under which water volume increases very slightly with increase in water temperature (see, e.g., Ishii et al., 2006). This thermosteric effect can be calculated based on ocean volume and change in temperature, although ocean temperature change is not easy to estimate and is not closely related to air temperature change. The other cause of mean sea level change is the exchange of water between oceans (including floating ice) and land reservoirs (including glaciers, ice caps, ice sheets, and lakes). This can be estimated based on observations of increasing or decreasing ice extent and depth (see, e.g., Dyurgerov and Meier, 2005) but again prediction of what will happen in the future is highly uncertain.



At the end of the last ice age, sea level would have been about 120 m lower than it is today (Gornitz, 2009). If all the remaining ice on land (mainly in Greenland and Antarctica) were to melt and join the oceans, then mean sea level would be about 65 m higher than today (Permanent Service for Mean Sea Level website: Frequently Asked Questions and Answers).

Tide gauge and satellite measurements of mean sea level change

The Permanent Service for Mean Sea Level (PSMSL) has monthly mean sea level data (http://www.psmsl.org/data/obtaining) from hundreds of tide gauges around the world, some going back over a century. Individual tide gauge records should be treated with some caution where, for example, there is a break in the record, or the tide gauge has been moved during the record, or the land level is known to be moving. The PSMSL website gives access to best estimates of annual global mean sea levels by Church and White (2011). These are plotted in Figure 1, with linear trend lines for 1910–2009

Sea Level Change, Figure 1 Global annual mean sea level 1870–2009 (From tide gauge data available via the PSMSL website).

Sea Level Change, Figure 2 Global mean sea level (in millimeters relative to the average level 1993–1999) from satellite measurements (From the University of Colorado Sea Level Research Group website).

(blue dots and left-hand scale, 1.7 mm/year) and for 1990–2009 (red dots and right-hand scale, 2.6 mm/year).

Figure 2, from the University of Colorado Sea Level Research Group website, shows global mean sea level 1993–2011 based on satellite measurements, indicating an upward trend of 3.1 mm/year.

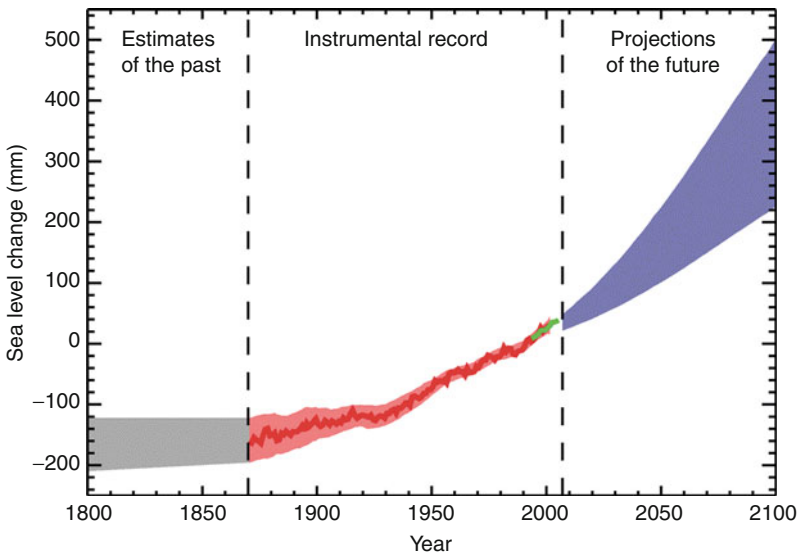
The intergovernmental panel on climate change

The Intergovernmental Panel on Climate Change (IPCC) is the largest international group looking at evidence of climate change and projections of potential future climate change and impacts. The last major revision of its

position was published in 2007, and the next update is expected in 2013 and 2014. The reports are available at http://www.ipcc.ch/.

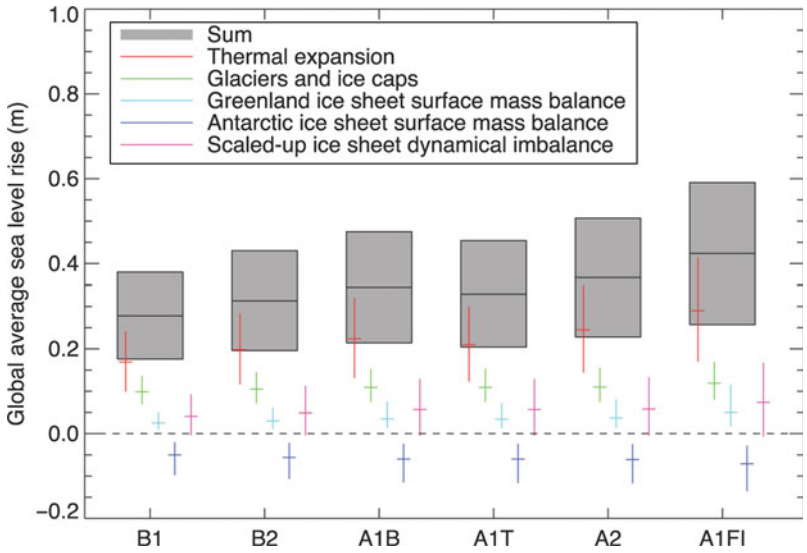
Of all the metocean variables, including temperature, mean sea level probably shows the best evidence of past change, because a number of different geological, biological, and instrumental records are available, and continued sea level rise in the future might be considered a prediction rather than a projection. The report of Working Group 1, the Physical Science Basis (IPCC, 2007) is the most relevant of the IPCC reports for the study of mean sea level change. Its Sect. 5.5 discusses the evidence for and causes of mean sea level change, including regional variations.

Section 11.3.1 of IPCC (2001) notes that "for the past 3,000–5,000 years oscillations in global sea level on time-scales of 100–1,000 years are unlikely to have exceeded 0.3–0.5 m" and "the rate over the past 3,000 years was only about 0.1–0.2 mm/year". Section 5.5.2.1 of IPCC (2007) notes 15–20 cm rise in global mean sea level during the twentieth century.



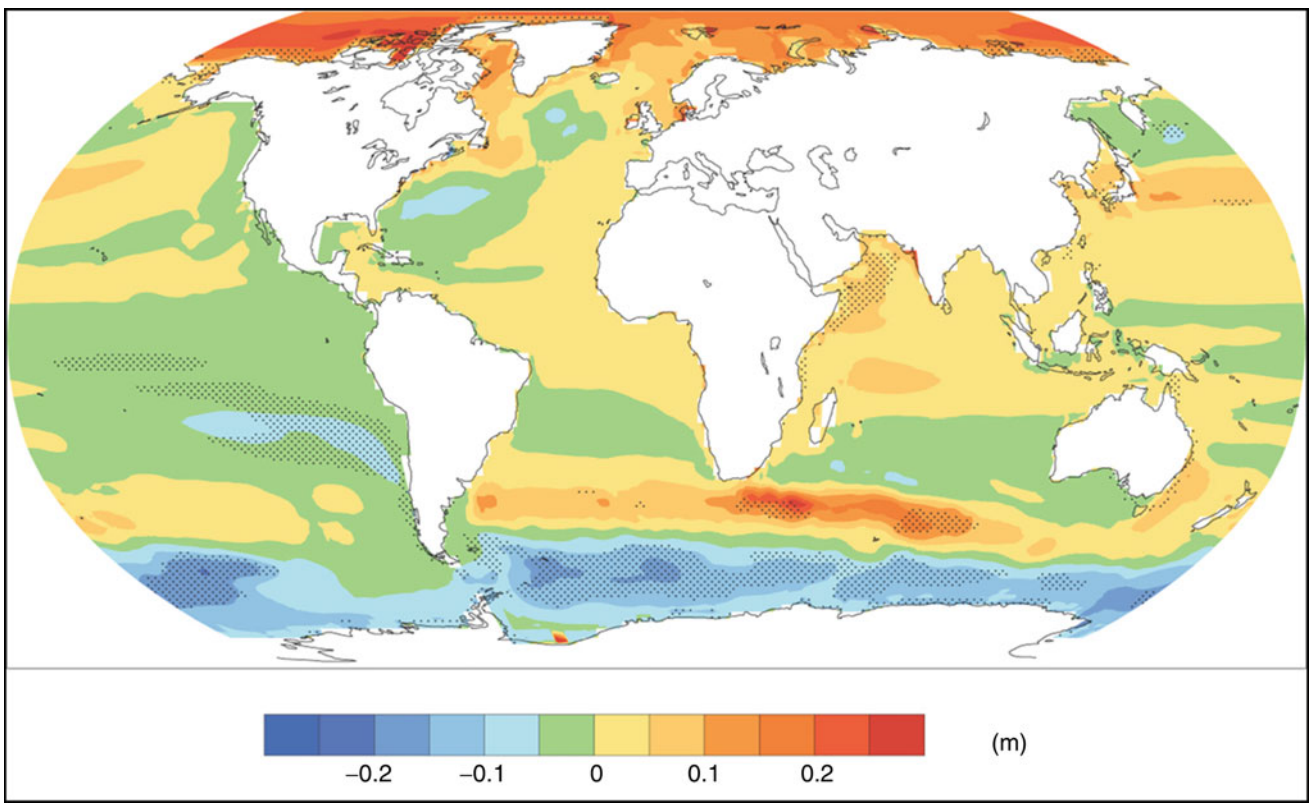
IPCC projection of future mean sea level change

IPCC (2007) concludes that global mean sea level rose at an average rate of about 1.7 ± 0.5 mm/year during the twentieth century and that the rate has been slightly higher over the period 1961–2003. Climate model projections in IPCC (2007) suggest that the global average rate of rise over the twenty-first century will be 2–5 mm/year, meaning that mean sea level will be 0.2–0.5 m higher in 2,100 than in 2000 (see Figure 3). These figures primarily relate to the thermal expansion of the oceans, excluding rapid dynamic changes such as any contribution from the Antarctic and Greenland ice sheets.



Estimates of future sea level rise by 2100, including an uncertain allowance for ice melt based on present-day melting rates, are given in Figure 4, and are in the range 0.2–0.6 m. The diagram shows thermal expansion of existing sea water (red bar) as the largest contribution to sea level rise, and the Antarctic (dark blue bar) as a negative contribution, meaning that it is projected to increase its ice content.

The projected sea level rise in Figure 4 assumes that the part of the present-day ice sheet mass imbalance that is due to recent ice flow acceleration will persist unchanged. This is probably the greatest uncertainty and several more recent papers have projected higher rates of sea level rise in the twenty-first century caused by higher assumed rates of ice melt. Some researchers argue that uncertainty in the ice melt effect means that there could be over 1 m increase in sea level by 2100: for example, Rahmstorf (2007) projects 0.5–1.4 m rise, Horton et al. (2008) up to 1 m rise, Jevrejeva et al. (2010) 0.6–1.6 m rise, and Pfeffer et al. (2008) 0.8–2.0 m rise.



In combination with other factors, such as subsidence and glacial rebound, sea level rise relative to the land could be slightly different from place to place. Modeling reported in IPCC (2007) indicates some global variation in the projected future rate of mean sea level rise, suggesting (see Figure 5) a lower than global average rate of rise around the Antarctic and a higher than average rise in the Arctic. At mid-latitudes, the mean sea level rise will be generally higher than in the equatorial area due to changes in ocean density distribution (steric sea level rise).

Sea Level Change, Figure 3 Projections of future mean sea level rise due mainly to thermal expansion (Reproduced from Fig. FAQ 5.1 of IPCC, 2007).

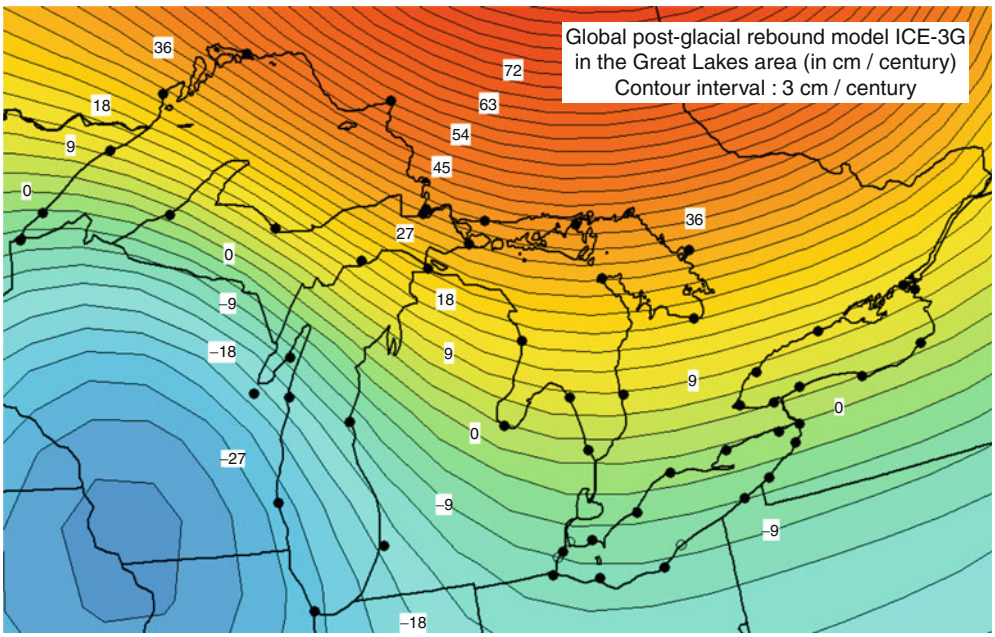
Sea Level Change, Figure 4 Projections and uncertainties (5–95% ranges) of global average sea level rise and its components in 2090–2099, relative to 1980–1999, based on six different emissions scenarios (Reproduced from Fig. 10.33 of IPCC, 2007).

Sea Level Change, Figure 5 Local mean sea level change relative to the global average change projected to 2100 (Reproduced from Fig. 10.32 of IPCC, 2007).

Relative (to the local land level) mean sea level change

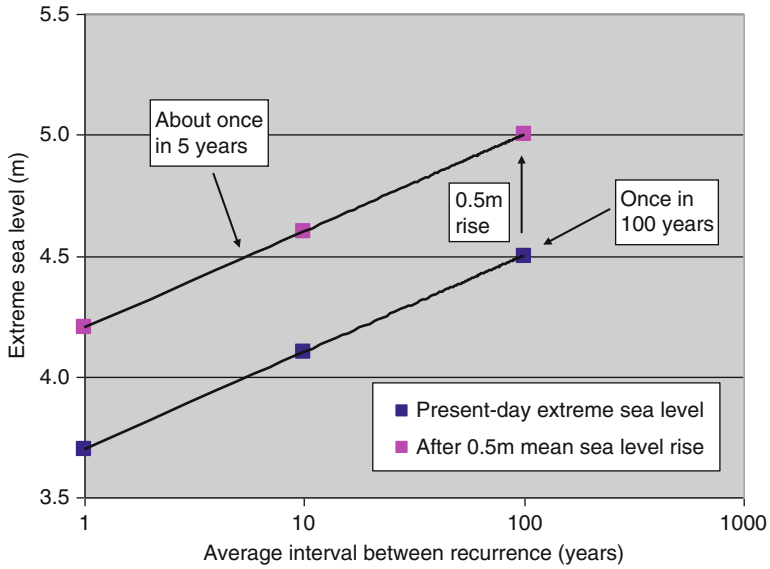
Locally, the concern is likely to be with relative, rather than absolute, mean sea level change, that is to say the change in mean sea level relative to the local land level. In combination with other factors, like subsidence and glacial isostatic adjustment, sea level rise relative to the land will vary regionally. Venice, for example, would be particularly vulnerable to mean sea level rise, because the local land level is dropping slowly, creating a larger than average relative mean sea level rise. However, in Upper Canada, glacial rebound is up to about a meter a century (see Figure 6) meaning that the land is rising faster than the sea level.

Impacts



Sea level change is of obvious interest to those living near the coast or on low-lying islands. Without investment in improved sea defenses, the probability of flooding would increase with sea level rise, and the damage done when flooding occurs is also likely to increase.

An increase in mean sea level would mean a reduction in the distance between the sea level and the level at which flooding and/or damage may begin to occur, but this alone would be unlikely to cause flooding. Significant impacts of mean sea level rise, for example, involving loss of life or property, would tend to occur on extreme (very high sea level) events rather than under average conditions. As an illustration of this (see Figure 7) consider extreme sea levels for a location on the south coast of England. At the present-day mean sea level, an extreme level of 3.7 m above mean sea level is expected to occur once, on average, per year; 4.1 m once in 10 years; and 4.5 m once in 100 years. If there is a significant flood risk when sea level reaches 4.5 m above present-day mean level, then this risk will occur once, on average, in 100 years. If mean sea level rises by, say, half a meter over the next 100 years, and the extreme levels are assumed to rise by the same amount, then the present-day flood risk level would occur about once, on average, in 5 years. This is a fairly typical result that, if no change is made to sea defenses, the probability of the coastal flood threshold being reached is around twenty times higher following a century of projected future mean sea level rise.



Mitigation

The obvious methods of mitigation are to build higher and stronger sea defenses, and/or move people and assets to higher ground, possibly abandoning very low-lying areas where it is not cost effective to protect them. For the magnitude and very low rate of mean sea level rise that has occurred in recent centuries, these approaches have been adequate and there has been time enough to apply them. If sea level rise continues for several more centuries, possibly at an increasing rate, the meters of rise that may occur may mean abandonment of large areas of low-lying land.

Stabilization of global mean air temperature by limiting carbon emissions would offer only a partial solution, as sea water would continue warming and expanding for some time even if air temperature did not increase further. If and when sea level rise begins to become a more serious and widespread problem, technology may find a way of putting water from the sea back into the land-ice reservoirs of Antarctica and Greenland, for example, through weather controls.

Sea Level Change, Figure 6 Postglacial rebound in the Great Lakes area, shown as contours of centimeters per century (Reproduced from Fig. 3.2 of PIANC, 2008).

Sea Level Change, Figure 7 Illustration of the effect of mean sea level rise on the frequency at which a flood threshold may be exceeded.

Summary

Sea level change is a natural process that has occurred throughout history and prehistory. Over the last century, the 15 cm increase in global mean sea level was small enough to have had little impact on humans, but steady enough to make it probably the most reliably documented of any climate-related trend.

Future climate projections suggest an increased rate of rise in mean sea level, likely to cause about 0.5 m rise in total over the coming century. This would require considerable coastal defense expenditure to prevent the present frequency of coastal flooding from increasing, possibly leading to abandonment of some areas of very low-lying land. Although the rate of sea level rise is very low, it is cumulative, perhaps amounting to a few meters over several centuries – potentially a huge problem for our distant descendants.

SECONDARY WAVE (S-WAVE)

Allison Bent
Natural Resources Canada, Ottawa, ON, Canada

Synonyms

S wave; Shear wave; Transverse wave

Definition

Secondary waves are elastic shear waves that travel through the Earth.

Discussion

S waves are seismic body waves meaning they travel through the Earth's interior. Their velocity is slower than that of P waves, and they are normally the second major phase to be observed on a seismogram, and are therefore also referred to as secondary waves. In the Earth's crust, S wave velocities are typically 3–4 km/s. S waves are usually larger in amplitude than P waves and may cause strong shaking and/or damage. The particle motion associated with S waves is perpendicular to the direction of propagation. S waves can be subdivided into two groups: SV waves, which are recorded by seismographs on the vertical and radial components; and SH waves, which appear on the tangential component. S waves cannot propagate through liquids or gases, the knowledge of which helped lead to the discovery that the outer core was liquid.

SEDIMENTATION OF RESERVOIRS

Anton J. Schleiss
Ecole polytechnique fédérale de Lausanne (EPFL), Lausanne, Switzerland

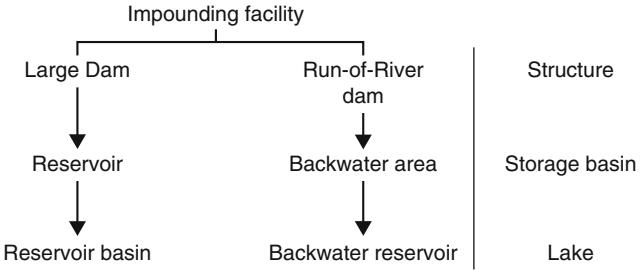
Synonyms

Filling up of reservoirs by sediments; Reservoir sedimentation; Siltation of reservoir

Definition

Process of filling up of reservoirs by sediments, which are transported by rivers or overland flows.

Introduction



Sedimentation is known as the process which fills up natural lakes and man-made reservoirs by sediments to become the end land again. The main reason for this process is the sediment yield transported by the rivers as suspended or bed load into the reservoirs. Bed and suspended sediment load originate from soil and rock erosion in the catchment area of the reservoir. Suspended fine sediments are also the result of surface erosion as well as of crashing and abrasion of coarser sediments transported by rivers. When entering lakes and reservoirs, the coarser sediments such as sand and gravel settle down and form a delta. The finer suspended sediments are deposited over the whole reservoir. During floods, they are periodically transported as turbidity currents like an underwater avalanche directly from the delta along the reservoir to the deepest point in front of the dam.

Today, the worldwide yearly loss of storage capacity due to sedimentation is already higher than the increase of capacity by the construction of new reservoirs for irrigation, drinking water, and hydropower. In Asia, for example, 80% of the useful storage capacity for hydropower production will be lost by 2035. Thus, the sustainable use of the reservoirs is not guaranteed in long term. In the case of deep and long reservoirs, the sedimentation rate is much below the world mean value. Nevertheless, the sedimentation threatens also these reservoirs since the mentioned turbidity currents are sporadically transporting large volumes of sediments down to the dam. There, the concentrated deposits are hindering the safe operation of the outlet structures as intakes and bottom outlets. Thus, after only 30–40 years of operation, sedimentation has become a serious problem in many reservoirs located even in catchment areas with moderate surface erosion as in the Alps.

The problem of reservoir sedimentation

Reservoir sedimentation is a problem that will keep those responsible for water resources management occupied more than usual during the decades to come. All sorts of impounding structures are concerned: large dams, in the form of fill or concrete dams, as well as river barrages comprising weirs, power plants, locks, impounding dams, and dykes (Figure 1). Impounding facilities are always costly, but this is justified by their various potential uses.

Although the aim behind the efforts to create reservoirs is storing water, other substances are carried along by the water and are usually deposited there as well. This is a result of dam construction, dramatically altering the flow behavior and leading to transformations in the fluvial process with deposition of solid particles transported by the flow. Each reservoir created on natural rivers, independent of its use (water supply, irrigation, energy, or flood control), can have its capacity decreased due to deposition over the years. In an extreme case, this may result in the reservoir becoming filled up with sediments, and the river flows over land again.

Sedimentation of Reservoirs, Figure 1 Classification of impounding facilities.

A reservoir, like a natural lake, silts up more or less rapidly. In actual fact, reservoirs may completely fill with sediments even within just a few years, whereas natural lakes, for example, in the Alpine foreland, may remain as stable features of the landscape for as much as 10,000–20,000 years after they were formed during the last Ice Age.

Reservoir sedimentation reduces the value of or even nullifies the dam construction investment. The use for which a reservoir was built can be sustainable or represent a renewable source of energy only where sedimentation is controlled by adequate management and suitable mitigation measures. Lasting use of reservoirs in terms of water resources management involves the need for reduction of sediment yield and sediment removal.

The planning and design of a reservoir require the accurate prediction of erosion, sediment transport, and deposition in the reservoir. For existing reservoirs, more and wider knowledge is still needed to better understand and solve the sedimentation problem and hence improve reservoir operation.

Consequences of reservoir sedimentation

The accumulating sediments successively reduce the water storage capacity (Fan and Morris, 1992). Consequently, at long term, the reservoir operates only at reduced functional efficiency. Declining storage volume reduces and eventually eliminates the capacity for flow regulation and with it all water supply, energy and flood control benefits (Graf, 1984; International Committee on Large Dams (ICOLD), 1989). Reservoir sedimentation can even lead to a perturbation of the operating intake and to sediment entrainment in waterway systems and hydropower schemes. Depending on the degree of sediment accumulation, the outlet works may be clogged by the sediments. Blockage of intake and bottom outlet structures or damage to gates that are not designed for sediment passage is also a severe security problem. Other consequences are sediments reaching intakes and greatly accelerating abrasion of hydraulic machinery, decreasing their efficiency and increasing maintenance costs.

Sedimentation rate

The worldwide installed capacity of all reservoirs is about 7,000 km^3, whereas 4,000 km^3 can be used for energy production, irrigation, and water supply. (Basson, 2009). The average age of existing reservoirs is about 30–40 years. It is estimated that about 0.8% of the worldwide storage capacity is lost annually by sedimentation. The highest average sedimentation rate is found in arid regions as in the Middle East, Australia, and Oceania as well as Africa (Table 1). A detailed collection of sedimentation rates in regions all over the world can be found in Batuca and Jordaan (2000).

Sedimentation of Reservoirs, Table 1 Average sedimentation rates in different regions (Basson, 2009)

Region	Average sedimentation rate (%/year)
Africa	0.85
Asia	0.79
Australia and Oceania	0.94
Central America	0.74
Europe	0.73
Middle East	1.02
North America	0.68
South America	0.75

Sedimentation of Reservoirs, Table 2 Dates when 80% of the useful reservoir volumes for hydropower production are lost by sedimentation and 70% of the reservoirs for other uses (Basson, 2009), respectively

Region	Hydropower dams: Date when 80% filled with sediment	Non-hydropower dams: Date when 70% filled with sediment
Africa	2,100	2,090
Asia	2,035	2,025
Australasia	2,070	2,080
Central America	2,060	2,040
Europe and Russia	2,080	2,060
Middle East	2,060	2,030
North America	2,060	2,070
South America	2,080	2,060

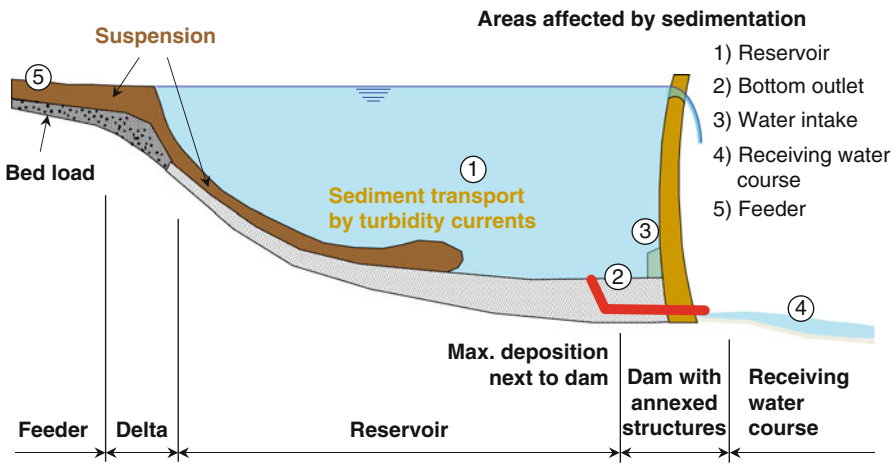
In Table 2, the date prediction is given when 80% of the useful reservoir volumes for hydropower production are lost by sedimentation and 70% of the reservoirs for other uses (Basson, 2009), respectively. It may be seen that in Asia, for example, 80% of the useful storage capacity for hydropower production will be lost in 2035. In view of the increasing energy demand, this is a serious problem; 70% of the storage volumes, used for irrigation, will be filled up by sediments already in 2025. This will be the case in the Middle East in 2030 and in Central America in 2040. This underlines that reservoir sedimentations endanger the sustainable energy and food production in many regions in the world.

The sedimentation rate of each particular reservoir is very variable. It depends more particularly on the climatic

situation, the geomorphology, and the conception of the reservoir including its outlet works.

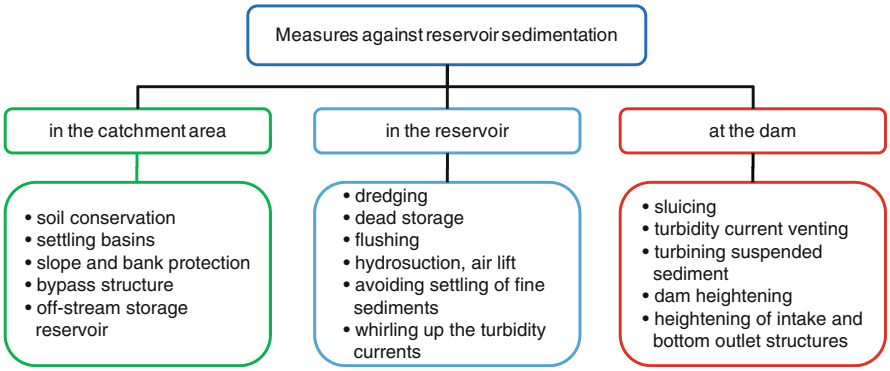
Reservoir sedimentation by turbidity currents

In long, deep, narrow reservoirs, turbidity currents are often the governing process in reservoir sedimentation by transporting fine materials in high concentrations (Jenzer Althaus et al., 2009). The erosion of the soil within a catchment area is at the origin of the material transported by a river. The erosion process starts in the high mountainous regions and continues in the highlands and plains and ends in the lakes or in the sea respectively where it comes – due to the decreasing flow velocity – to sedimentation. Depending upon the sediment supply from the watershed and flow intensity in terms of velocity and turbulence, rivers usually carry sediment particles within a wide range of sizes. During flood events, the fraction of sediments smaller than sand reaches 80–90 % of the total sediment carried by the river (Alam, 1999), and the total sediment discharge is usually significant. If the sediment concentration is high enough, it may come to turbidity current.



The turbidity currents belong to the family of sediment gravity currents. These are flows of water laden with sediment that move downslope in otherwise still waters like oceans, lakes, and reservoirs. Their driving force is gained from the suspended matter (fine solid material), which renders the flowing turbid water heavier than the clear water above. When a sediment-laden river flows into a large reservoir, the coarser particles deposit gradually and form a delta in the headwater area of the reservoir that extends farther into the reservoir as deposition continues (Figure 2). Finer particles, being suspended, flow through the delta stream and pass the lip point of the delta. If after the lip point of the delta, the difference in density between the lake water and inflowing water is high enough, it may cause the flow to plunge, and turbidity current can be induced. During the passage of the reservoir, the turbidity current may unload or even resuspend granular material. Subsequently, the sediments are deposited along the path due to a decrease in flow velocity caused by the increased cross-sectional area. Fine sediments (clay and silt sizes) are usually the only sediments that remain in suspension long enough, following over long distances the reservoir bottom along the thalweg through the impoundment down to the deepest point in the lake normally near the dam, to reach the outlets. At the dam, the sediments settle out.

Measures against reservoir sedimentation



Over the years, several measures against reservoir sedimentation have been proposed (Schleiss and Oehy, 2002). But not all of them are sustainable, efficient, and affordable. For example, raising the height dams and outlet works does not provide a long-term and sustainable solution.

There is a strong need to limit sediment accumulation in reservoirs in order to ensure their sustainable use. Management of sedimentation in Alpine reservoirs cannot be apprehended by a standard generalized rule or procedure. Furthermore, sediment management is not limited to the reservoir itself, it begins in the catchment areas and extends to the downstream river. Every situation has to be analyzed for itself in order to determine the best combination of solutions to be applied. The possible measures are summarized in Figure 3 and grouped according to the areas where they can be applied.

An integrated approach to sediment management that includes all feasible strategies is required to balance the sediment budget across reservoirs (Morris, 1995). Integrated sediment management includes analysis of the complete sediment problem and application of the range of sediment strategies as appropriate to the site. It implies that the dam and the impoundment are operated in a manner consistent with the preservation of sustainable long-term benefits, rather than the present strategy of developing and operating a reservoir as a nonsustainable

Sedimentation of Reservoirs, Figure 2 Areas affected by sedimentation in the surroundings of a reservoir (De Cesare et al., 2001).

Sedimentation of Reservoirs, Figure 3 Inventory of possible measures for sediment management (Schleiss and Oehy, 2002).

source of water supply (Morris, 1996). A sustainable sediment strategy should also include the downstream reaches; therefore, monitoring data should also include downstream impacts as well as sedimentation processes in the reservoir (Morris and Fan, 1997).

The known remedial measures can be subdivided in those taken in the catchment area, in the reservoir, and at the dam itself as shown in Figure 3. Oehy (2003) and Oehy and Schleiss (2007) proposed and studied several technical measures against turbidity currents. Turbidity currents may be stopped and forced to settle by obstacles situated in the upper part of the reservoir in order to keep the outlet structures free of sediments. They can also be whirled up near the dam and intakes and kept in suspension, which allows a continuous evacuation through the turbines (Jenzer Althaus, 2011). In certain cases, fully venting of turbidity currents through outlet structures is possible.

Summary

Today, the worldwide yearly mean loss of storage capacity due to sedimentation is already higher than the increase of capacity by the construction of new reservoirs for irrigation, drinking water, and hydropower. Thus, the sustainable use of the reservoirs is not guaranteed in long term. In the case of alpine reservoirs, the sedimentation rate is much below the world mean value. Nevertheless, sedimentation threatens also these reservoirs since turbidity currents are sporadically transporting large volumes of sediments like an underwater avalanche down to the dam. There, the concentrated deposits are hindering the safe operation of the outlet structures as intakes and bottom outlets. Many possible measures against sedimentation are known from practice, but they are strongly depending on the local conditions. For reservoirs in rather narrow valleys, technical measures, which can govern turbidity currents, are of special interest. The problematic of sedimentation and sediment management should be considered in the early stage of the design of the reservoir in order to obtain sustainable solutions. Although methods for erosion volume estimation and empirical relationships for trap efficiency estimation are available, this is still not the case for many reservoirs built recently all over the world.

SEICHE

Giovanni Cuomo
Hydraulics Applied Research & Engineering Consulting (HAREC) s.r.l, Rome, Italy

Synonyms

Harbor wave; Long period waves; Tidal wave

Definition

A seiche is a standing wave in an enclosed or partially enclosed body of water. Seiches have been observed in lakes, harbors, reservoirs, swimming pools, bays and seas.

Discussion

The word originates in a Swiss French dialect word that means "to sway back and forth" and was first used by the Swiss hydrologist François-Alphonse Forel in 1890, to make scientific observation of the seiches occurring in Lake Geneva, Switzerland.

Seiches can be caused by meteorological forcing (wind and atmospheric pressure variations), wind waves and swells, seismic activity, landslides, and tsunamis.

Once originated, the wave is reflected from the ends and the water surface oscillates around its rest (horizontal) position. Repeated reflections produce standing waves whose shape corresponds to one of the natural modes of oscillation of the water body, as a function of its geometry.

For a rectangular basin of length L, width W, and depth h, the period of each mode can be evaluated using the generalized Merian's formula:

$$T_{mn} = \frac{2L}{\sqrt{gh}}(\alpha^2 m^2 + n^2)$$

where $\sqrt{gh}$ is the speed of a shallow water wave, $\alpha = L/W$ and m and n define the harmonic nodes in the transverse and longitudinal directions.

Generally, the motion of the water body develops as a combination of the natural modes of the basin. If the forcing is impulsive (i.e., tsunamis or pressure front), the disturbed body of water tends to return at rest after dissipating its energy within a number of free oscillations; if the forcing is periodic, with a frequency close to that of one or more of the natural frequencies of the basin, the body of water can resonate locally amplifying the amplitude of the seiche.

Seiches are often imperceptible to the naked eye due to their usually small amplitude and long wavelength, resulting in a small steepness of the water surface. Small amplitude seiches are almost always present on large lakes; harbors, bays, and estuaries are often prone to seiches with amplitudes of a few centimeters and periods of a few minutes. Seiches can also form in semi-enclosed seas. For instance, in the Adriatic Sea and the Baltic Sea, they contribute to flooding of Venice and St. Petersburg, respectively.

Tsunami can also excite seiches in bays and harbors, and these can in turn be amplified due to the interaction of consecutive tsunami waves with local bathymetric and topographic features, originating very large waves. For instance, the tsunami that struck Hawaii in 1946 had a 15-min interval between wave fronts; since the natural period of oscillation of Hilo Bay is about 30 min, consecutive waves were in phase with the motion of Hilo Bay, and excited a resonant seiche in the bay, which reached a height of up to 26 ft (8 m circa), killing 96 people in the city alone.

Harbors are usually prone to wave-induced seiching (Los Angeles and Long Beach, Rotterdam, Barbers Point and Marina di Carrara) with standing wave patterns resulting in strong localized currents at the nodes (points that experience no vertical motion) reducing the operability of berths and eventually inducing breakage of mooring lines.

Earthquake forecasting; Seismic potential

Definition

Seismic Gap. A segment of an active plate boundary that, relative to rest of the boundary, has not recently ruptured and is considered to be more likely to produce an *Earthquake* in the future.

The seismic gap theory (for a summary of early work in this field see McCann et al., 1979) states that a segment of a plate boundary that has not ruptured recently has the greatest chance of rupturing in the future (relative to other segments that have experienced large earthquakes). This is based on the recognition that tectonic plates move relative to one another at an approximately constant speed and the assumption that the slip of plate boundary faults occurs primarily during major (magnitude 7 or greater) earthquakes. There are clear applications of this method to the estimation of earthquake hazards and to "earthquake forecasting" (e.g., McCann et al., 1979). However, there are questions about the applicability of this method (e.g., see Kagan and Jackson, 1991, 1995). Some variables that affect this hypothesis include the possibility of aseismic slip, an incomplete earthquake record, distribution of slip along several faults on a plate boundary (e.g., the San Andreas/Hayward fault systems in the San Francisco area), earthquake triggering and clustering, and the uncertainty in the recurrence interval for large earthquakes along plate boundaries. In recent years, Global Positioning Satellite (GPS) data and *Paleoseismology* (that provides a better record of the earthquake history) have been used to better understand plate boundaries, plate motions, fault segmentation, and the possibility of aseismic slip. Some recent examples of the applications of earthquake forecasting include:

1. Using the earthquake catalog of Chile and recent GPS measurements, Ruegg et al. (2009) identified the Concepción–Constitución region of central Chile as a mature seismic gap. In their article published in June 2009, they concluded, "a worst-case scenario of a magnitude 8–8.5 earthquake should it happen in the near future." Eight months after that article was published, a magnitude 8.8 subduction earthquake occurred in this seismic gap and ruptured nearly 700 km of the plate boundary. Madariaga et al. (2010) summarize research on this seismic gap and the subsequent earthquake.
2. Using GPS data, detailed geological information from faults, paleoseismology, and *Seismology*, a 59% probability in the next 30 years for one of more magnitude 6.7 or greater earthquakes on the San Andreas Fault in southern California has been calculated by the 2007 Working Group on California Earthquake Probabilities (2008).

With improved seismic, GPS, and paleoseismological data, and better earthquake catalogs and understanding of fault interaction, earthquake triggering, and rupture, we can expect to see improvements in the area of understanding "seismic gaps" and forecasting the location of future large earthquakes. This, in turn, should lead to improved earthquake hazard estimations and may help focus earthquake preparedness and mitigation efforts.

SEISMOGRAPH/SEISMOMETER

Allison Bent
Natural Resources Canada, Ottawa, ON, Canada

Definition

A seismograph is an instrument used to detect and record ground motion caused by seismic waves.

Discussion

A seismograph typically consists of three components – a sensor (seismometer), an amplifier or digitizer, and a recording device. Although seismographs have evolved over the years, all operate on the same basic principles by measuring ground motion relative to something that remains fixed or unaffected by the shaking. Early seismographs usually consisted of a mass suspended by a spring within a case. The mass would remain still while the case shook. The relative movement was usually recorded on paper by a pen or light source. In most modern seismographs, the mass has been replaced by a permanent magnet. Ground shaking causes the magnet to generate electric signals in the wires that are wound tightly in the surrounding case. The ground motions are digitally recorded and either stored on site or transmitted to another site for archiving. The record showing the recorded waveform is referred to as a seismogram.

Some seismographs are designed for use over a narrow range of frequencies but broadband instruments, which detect and record signals over the full range of frequencies of interest to seismologists are becoming more commonly used. Typically a seismograph station will host three seismographs to detect ground motion in three orthogonal directions – vertical and two horizontal directions, most commonly north–south and east–west – although there are some stations that have only a vertical seismograph. Seismographs can detect ground motions much smaller than that can be felt by a human. Although designed principally for recording ground motions caused by earthquakes, seismographs record seismic waves triggered by other sources, such as underground explosions.

Definition

Seismology is a branch of geophysics dealing with earthquakes and other Earth's vibrations, with the sources that generate the vibrations, with seismic wave propagation, and with the structures through which they propagate.

Discussion

Seismology can be considered as a tool for exploring the Earth's interior, and it is deeply rooted in continuum and fracture mechanics, theoretical physics, applied mathematics, and statistics. Seismology has a remarkable diversity of applications in natural hazard research including seismic hazard assessment, *Earthquake* forecasting, volcano and *Tsunami* warning systems, and detections of sudden movements of glaciers and ice sheets.

There are several geophysical disciplines to explore the Earth's interior, including studies of gravity, magnetic and electric properties of the planet, but seismology is perhaps the most powerful and informative, especially in studies of the deep mantle and core. Seismologists study the internal structure of the Earth by recording and analyzing the signals arising from natural (e.g., earthquakes) and human-made (e.g., explosions) energy sources. Such seismic signals contain a wealth of information that enables scientists to quantify active wave sources and to reveal structures in the planetary interior associated with dynamic processes that occurred in the geological past and are now active. Additionally, if an earthquake is of sufficient magnitude, the Earth as a whole may be set into oscillations of various modes, and the periods of these free oscillations can yield useful information.

Earthquakes occur as a sudden release of stresses. When an earthquake occurs, part of the released energy generates elastic waves propagating through the Earth. These waves can be detected by a seismograph that measures and records the ground motion. There are two principal types of elastic waves: body waves, which travel through the body of the

Earth, and surface waves, which are guided along and near the surface of the Earth (e.g., Stein and Wysession, 2003).

Seismology can be divided into several sub-disciplines including earthquake seismology, *Paleoseismology* (studies of past large earthquakes by analyzing near-surface sediments and rocks), statistical seismology (statistical analysis and modeling of earthquake occurrence in time and space), and computational seismology (e.g., quantitative modeling of seismic wave propagation, earthquake occurrences, and other seismological phenomena).

Although the origin of seismology dates back to the East Han Dynasty in China, it is misleading to pretend that state-of-the-art seismology is a well-developed branch of science. To the contrary, most of the seismologists clearly understand the grand challenges for seismology. Several important questions still remain pressing, including: How do faults slip? How do magmas ascend? How does the near-surface environment affect natural hazards? (Forsyth et al., 2009). The fundamental difficulty in answering these questions comes from the fact that no earthquake or magma ascent from its chamber has ever been observed directly and just a few of them were subject to an in situ verification of their physical parameters.

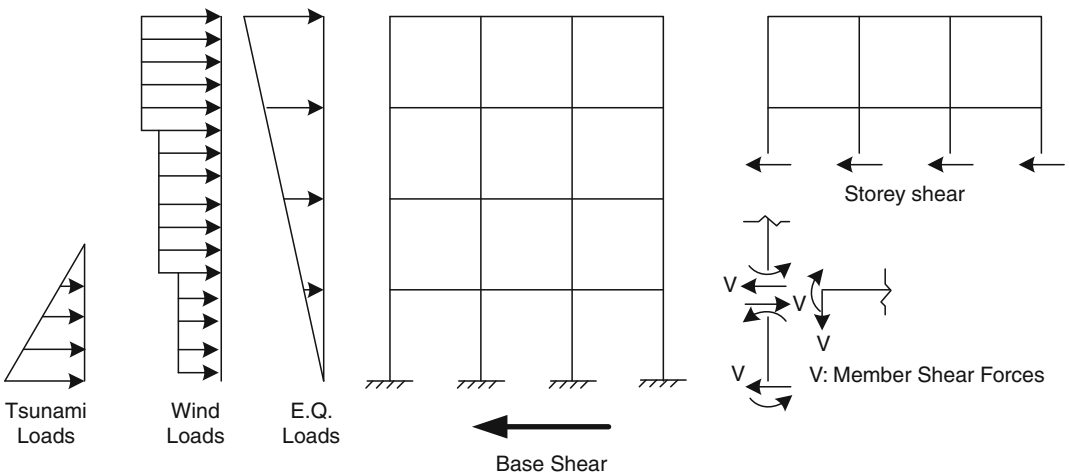
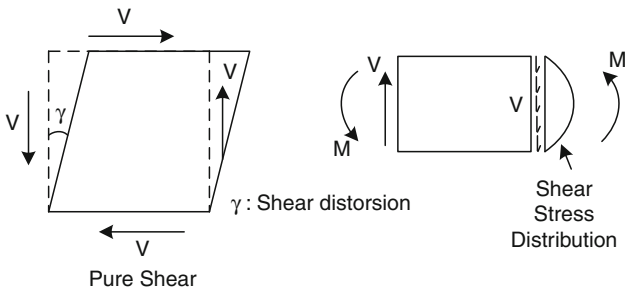
SHEAR



Murat Saatcioglu
University of Ottawa, Ottawa, ON, Canada

Definition

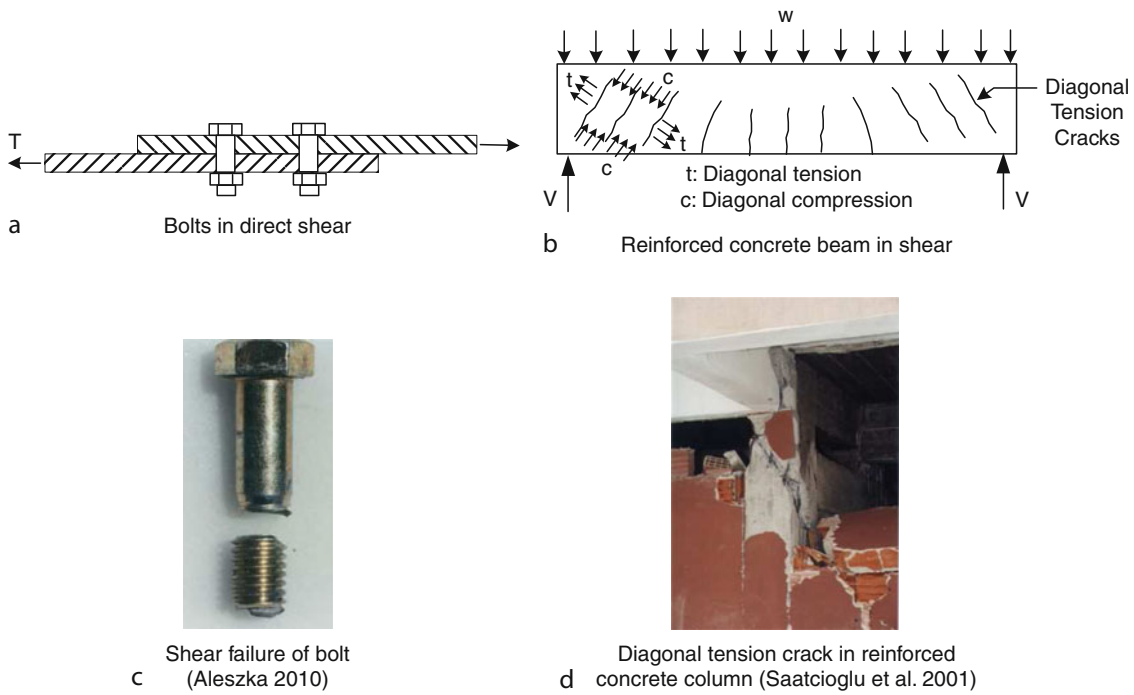
Shear is force applied parallel to, or in the plane of a cross section of a structural member. Shear stresses are typically computed across a section that is perpendicular to the member length. Therefore, shear forces used in structural design are often perpendicular (transverse) to member length.



Discussion

Shear forces generated by a natural hazard can occur in horizontal or vertical directions depending on the type of hazard. Earthquake-induced inertia forces are generated from accelerations that occur during seismic excitations. Although seismic shear forces on structures can be developed in any direction, it is generally accepted that they are more critical in the horizontal direction.

Shear, Figure 1 Examples of base shear, story shear, and member shear forces.



Therefore, structures are routinely analyzed using horizontal (lateral) forces in two orthogonal directions of structural plan. These forces are obtained either from dynamic analysis or equivalent static load analysis. Equivalent static loads are computed by distributing "base shear force" computed from the code of practice. "Story shear" is computed by accumulating lateral seismic forces above the story level. Vertical seismic excitations also contribute to member shear. Shear forces associated with vertical earthquake accelerations are considered to be a fraction of those generated by horizontal accelerations, though very large vertical accelerations have been recorded during previous earthquakes. Shear usually occurs in combination with flexure (bending), and sometimes in combination with axial load. Shear forces either produce flexural (bending), or they are produced by flexure. Typical shear forces caused by natural hazards are illustrated in Figure 1.

Shear, Figure 2 Shear distortions and shear stress distribution.

Tsunami-induced hydraulic bores, storm surges, and floods generate shear forces primarily in the horizontal direction. These shear forces may be caused by hydrostatic and hydrodynamic water pressures, impulsive hydraulic bores, and/or impacting debris. Tsunamis and floods can also result in vertical uplift (buoyant) forces, generating vertical shear forces in horizontal elements. Shear created by these forces are computed in much the same manner as those shown in Figure 1. Similarly, shear forces generated by wind pressures associated with windstorms and other extreme wind hazards are primarily applied in the horizontal direction. These forces are calculated by multiplying external wind pressures and suctions on windward and leeward surfaces by applicable surface areas over which they act, generating story shears as shown in Figure 1.

Shear forces generate shear stresses and shear distortions, as illustrated in Figure 2. Shear stress distribution across a section is parabolic within the elastic range of materials. Shear capacity of a member is dictated either by its direct shear capacity parallel to the direction of shear force, as in the case of bolts connecting two plates, or by principal tensile or compressive stresses that develop from shear along an inclined plane, as in the case of reinforced concrete elements. Structural members often fail in shear due to diagonal tension or compression. This is illustrated in Figure 3.

Shear, Figure 3 Direct shear versus diagonal tension and compression caused by shear.

SHIELD VOLCANO

Raphaël Paris
Clermont University, Clermont-Ferrand, France

Definition

A shield volcano is a low-angle volcano formed principally by accumulation of low viscosity lava flows (mostly basaltic lavas). The name "shield" derives from "Skjalbreidhur" (broad shield) volcano in Iceland, which displays a warrior's shield-like profile. Nevertheless, this latter volcano is a small-scale monogenetic edifice, and the "shield volcano" mostly refers to larger polygenetic edifices. With volumes between 3,000 and 80,000 km³ (Mauna Loa, Hawaii), oceanic shields are the world's largest volcanoes.

Hazards directly or indirectly related to volcanic activity can be listed as follows:

Lava flows: Devastation of populated areas, communication networks, forest fires (sometimes in natural reserves of the biosphere). In the case of lava flows entering seawater or lakes, small phreatic explosions and unusual waves due to collapse of the coastal lava bench may occur. Risk assessment studies mostly consider the spatial distribution of vents and lava flows, their recurrence in time (Trusdell, 1995), distribution of human activities, and preparedness of communities (Gregg et al., 2004).

Gas emissions: Nasal, throat, or lung irritation or more serious breathing diseases. Possibility of lethal concentrations of CO_2 and H_2S, depending on the type of activity and local topography. Pollution of atmosphere (acid rain) and of water resources (e.g., Canary Islands, where 70% of water resources are groundwater; areas where rainwater is collected in outdoor tanks).

Earthquakes: Seismicity of shield volcanoes is usually low compared to stratovolcanoes, except for some volcano-tectonic events such as caldera collapse or flank landslides (M 7.2 in Nov. 1975 at Kilauea during a volcano-tectonic event of the south flank; $M > 5$ during a caldera collapse in Fernadina volcano, Galapagos). These events can cause significant damage with strong shaking, mass landsliding, and destructive tsunamis (e.g., Kalapana earthquake in 1975).

Explosive eruptions, when magma interacts with groundwater: Less frequent than effusive eruptions, but critical for hazard assessment and not yet well understood. In May 1924, the drain out of the Halemaumau lava lake at Kilauea volcano was accompanied by hundreds of steam explosions (Jaggar and Finch, 1924). A photographer was killed by falling rocks and hot mud. The previous explosive event at Kilauea, in 1790, was even larger (VEI 4) and killed at least 80 people. Phreatic and phreatomagmatic explosions are also reported for shield volcanoes in the Indian Ocean (e.g., June 1791 and February 1860 at Piton de la Fournaise, July 1991 at Karthala) and Atlantic Ocean (e.g., Caldera de Bandama, Canary Islands). The large extent of pyroclastic deposits observed at Kilauea (Uwekahuna Ash Member, 2800–2100 BP: Dzurisin et al., 1995) and Piton de la Fournaise volcanoes (Bellecombe Ash Member, 4700 BP: Mohamed-Abchir et al., 1998) suggests that large explosive eruptions (VEI 5) can occur at shield volcanoes.

Caldera collapse, formed by emptying of a magma chamber and ensuing roof collapse during large eruptions or subsurface withdrawal. In June 1968, the caldera floor of Fernandina volcano (Galápagos) subsided an estimated 1–2 km³ after a small effusive flank eruption, increasing seismicity and explosive activity (Simkin and Howard, 1970). The smaller caldera collapse that occurred at Piton de la Fournaise in April 2007 (90×10^6 m³: Staudacher et al., 2009) was also preceded by increasing seismicity, but no explosive activity was reported and voluminous lava flows (130×10^6 m³).

Massive flank failures: Most shield volcanoes exhibit evidence for mass-wasting during their growth. These catastrophic failures involve volumes between 25 and 500 km³, thus representing very-high-magnitude but very-low-frequency hazards (e.g., 47 events identified in La Réunion during the last 2 Myrs: Oehler et al., 2004). Tsunami deposits up to 188 m a.s.l. were described on the west coast of Gran Canaria and interpreted as the result of a huge collapse on the eastern flanks of Tenerife Island ca. 830 ka (Pérez Torrado et al., 2006). Ongoing studies on flank failures focus on

possible precursors. A large eastward (seaward) ground displacement was recorded by InSAR monitoring during the April 2007 eruption at Piton de la Fournaise (Augier et al., 2009).

Summary

Shield volcanoes are usually considered as weakly hazardous volcanoes since casualties directly due to their activity remain rare. However, destructive lava flows can involve great economic loss, and volcanic explosions up to VEI 5 are quite frequent. Massive flank failures generating megatsunami are very-high-magnitude/very-low-frequency events that have to be included in hazards evaluations.

Definition

Sinkholes are closed depressions generated by karstification that occur naturally on the surface of the ground.

Discussion

Sinkholes are usually circular or subcircular, and range in size from one to several hundred meters in diameter and up to several tens of meters in depth. The inclination of the slopes varies from vertical to gentle. Sinkholes can appear on karst rocks (mainly carbonates and evaporites), non-karst rocks and also on detrital sediments.

Collapses caused by human activity are sometimes categorized as sinkholes, as well as depressions where streams sink underground. The term sinkhole, equivalent to doline, is more common among engineers and researchers in North America (Ford and Williams, 2007) but is becoming more frequent in European literature.

The main mechanisms involved in sinkhole development are dissolution, collapse, and suffosion. Usually, more than one of these mechanisms are involved in sinkhole generation and they also condition its morphology.

1. Dissolution of carbonate or evaporite rocks occurs through fissures. More material is removed from the center than from the edges of the depression. This is the main mechanism that triggers the other processes. Sinkholes generated in this way have gentle slopes (Figure 1).

Sinkhole, Figure 1 Several solution sinkholes developed on limestones in the Sinkhole Plain (Mammoth area) in Kentucky (USA). Some of them contain water.

Sinkhole, Figure 2 Collapse sinkhole located in Chichén Itzá (Mexico) Locally named *cenotes*.

2. Collapse of the roof of a cavern or conduit is propagated upward until reaching the surface. Consolidated rocks (Figure 2) and unconsolidated cover (Figure 3) can be affected. The slopes of the collapse sinkhole are vertical, but its later evolution generates funnel and even basin morphologies.
3. Suffosion is the evacuation of unconsolidated sediments through solution conduits. Such sinkholes have varying slopes.

There are genetic classifications of sinkholes (Williams, 2003; Waltham et al., 2005) that basically consider the type of mechanism involved and the type of material affected. As an example, caprock collapse sinkhole indicates that the upward propagation of collapse affects non-karst rocks.

The occurrence of sinkholes is worldwide: examples can be found in the USA, Canada, Mexico, Cuba, Italy, Great Britain, Spain, Israel, Turkey, the Russian

Sinkhole, Figure 3 Cover collapse sinkhole in the Ebro Basin (Spain) caused by dissolution of evaporite rocks.

Federation, Iran, and elsewhere. They can cause severe economic problems in populated areas.

Specific terms include cenote (collapse sinkhole flooded with water) and blue holes (large collapse flooded with seawater).

SLIDE AND SLUMP

Lionel E. Jackson, Jr.
Geological Survey of Canada, Vancouver, BC, Canada

Definitions

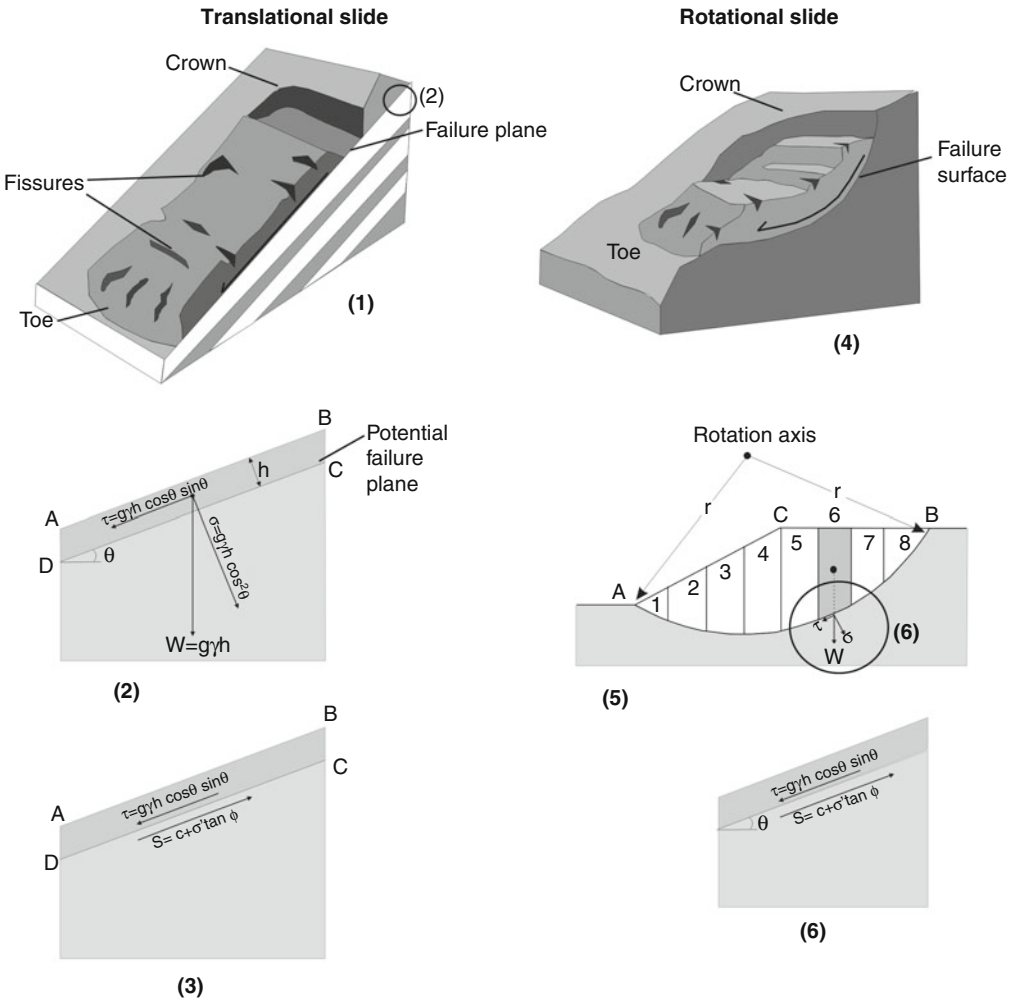
Slide A slide is the displacement of a rigid or semi-rigid mass of soil or rock so that it descends along a distinct underlying failure surface under the influence of gravity. If the failure surface is planar, it is referred to as a *translational slide*.

Slump. A slump is the name given to a *slide* when the underlying failure surface is curved rather than planar. The motion of a slump is rotational, so that portions of the slide drop and rise with respect to the adjacent stable slopes. It is more properly referred to as a *rotational slide*.

Introduction

Slides and rotational slides (slumps) include downward and horizontal displacement of rigid or semi-rigid masses of soil (earth and debris), or rock under the influence of gravity. This includes movements of land and the sea bottom. It differs from a *collapse* where displacement is entirely vertical. Landslides are classified according to the type of material that is moving or has moved, the type of movement involved, and the velocity of movement (Cruden and Varnes, 1996; Multinational Andean Project, 2009). In slides, rigid or semi-rigid masses are displaced vertically and horizontally along well-defined underlying failure surfaces. This is in contrast to flow-type failures where earth material behaves like a liquid (Hungr et al., 2001) or failures called *topples* or *falls* that involve transport in part by free fall (Cruden and Varnes, 1996). Movements of slides are further subdivided based upon the geometry of the underlying failure surface (Table 1). If it approximates a plane (Figure 1, diagram 1, Figure 2), it is classified as a *translational slide*. If it approximates a curved surface (Figure 1, diagrams 4, 5; Figure 3), it is classified as a *rotational slide*. The latter is commonly referred to as a *slump*. Although the failure plain of a rotational slide is seldom directly observable, its curved geometry is inferred in the field on the basis of rotational movement in the landslide. The upper portion of the landslide drops below the level of the adjacent land surface whereas the middle or lower part of the landslide rises above its pre-failure level (Figure 3). Velocities of translational and rotational landslides can range from very slow (millimeters/year) to very rapid (meters/second). Translational and rotational slides are further subdivided based upon the material involved (Tables 1, 2).

In order for earth or debris to move as a semirigid mass, water content must be below the plastic limit so that the mass behaves as a solid. With increasing water content beyond the plastic limit or remolding of earth and debris (which contain fine particles) by landslide movement, translational and rotational slides become increasingly



Slide and Slump, Table 1 Classification of translational and rotational slides (After Cruden and Varnes, 1996)

Movement type	Subtype based upon material
Slide (translational)	Rock slide, debris slide, earth slide, rock wedge failure
Slide (rotational)	Rotational rock slide, rotational debris slide, rotational earth slide

plastic in behavior. They can eventually grade into flow-type landslides such as *earth flows* and *debris avalanches*. Translational or rotational failures of steep rock slopes can transition into *rock avalanches*.

Mechanics of translational slides and environments conducive to them

In rock, failure planes underlying translational slides are typically preexisting natural planes of weakness. They

Slide and Slump, Figure 1 Diagrams illustrating translational and rotational slides and forces determining stability within the geologic and geomorphologic environments in which they occur. *Diagram 1* depicts a translational slide in bedded sedimentary rock. The slide has occurred along a bedding plane dipping at an angle, θ. *Diagram 2* summarizes gravitational forces acting on polygon A-B-C-D. The *dot* indicates its center of mass. *W* is the gravitational force acting on the polygon as a whole; shear stress (τ) is the component acting parallel to potential failure plane C-D; and σ is the normal stress acting normal to C-D. *Diagram 3* shows the opposed forces of shear strength (*S*) and shear stress (τ). The ratio of the two is the *factor of safety* which must be >1 if it is to remain stable. *Diagram 4* depicts a rotation slide. Arc A-B in *diagram 5* is a potential failure surface in a homogenous earth material such as thick marine clay or mudstone. For the sake of explanation, A-B is the potential failure surface where shear stress is a maximum for slope A-C. The stability of the slope can be determined by dividing it into elements (*Diagrams 5 and 6*) and totaling shear strength and shear stress.

include bedding planes in sedimentary rocks (Figure 2), foliation (parallel orientation of the long axes of minerals) and cleavage planes in metamorphic rocks, and joints and faults in rocks of all types. Where two or more planes of weakness intersect in steep rock slopes, failure of part or all of the mass defined by their intersection is a *wedge failure* (Figure 4). Unconsolidated sediments, such as colluvium, till (boulder clay), and tephra, commonly fail as translational slides where they overlie rock. Forces involved in translational slides in rock or overburden on rock for an idealized slope are summarized in Figure 1, diagrams 1–3 (modified from Ritter, 1986).

Slide and Slump, Figure 2 Failure surface of the Qianjiangping landslide, Three Gorges Reservoir, China, December, 2009. The failure surface is a bedding plane (see Wang et al., 2004; Photo by Lionel Jackson, Geological Survey of Canada).

In Figure 1, diagram 2, polygon A-B-C-D (light gray) represents a mass of rock or sediment overlying rock (dark gray) along potential failure plane C-D (sedimentary contact, bedding plane, joint, etc.). The black dot represents its center of mass. It has a thickness h (m), a unit mass γ (kg/m^3). C-D is inclined at an angle θ. Gravity (g) pulls the slope vertically toward the center of the earth with a force, W (in Newtons (N)):

$$W = g\gamma h \tag{1}$$

For the purpose of calculating forces that drive and resist translational slides, W (Equation 1) can be resolved into the force acting parallel to the potential failure plane in a descending direction (shear stress (τ)) and the force normal to it (normal stress (σ)) so that:

$$\tau = g\gamma h \cos\theta \sin\theta \tag{2}$$

and

$$\sigma = g\gamma h \cos^2\theta \tag{3}$$

Normal stress across C-D (σ) in Equation 3 assumes absence of water in the slope. However, water is

Slide and Slump, Figure 3 Large rotational slides, Yocarhuaya, Bolivia, March, 2009 (defined by *dashed lines*). The slides occur in massive landslide colluvium at the toe of a 5-km-long earthflow complex. *Arrows* show relative vertical movement. Movement of the upper slide caused abandonment of part of the Yocarhuaya community (between the *upper set of arrows*). The church steeple (S) is about 8 m in height. (Photo by Lionel Jackson, Geological Survey of Canada.)

Slide and Slump, Table 2 Definition of Landslide Materials (After Varnes, 1978 and Couture, 2011)

Rock	Material made up of strongly bonded minerals or cemented aggregations of rock fragments and mineral material. In soil engineering practice, rock is commonly differentiated from debris and earth in that it cannot be ripped or ripped with difficulty by earth-moving machinery in its unfailed state and usually requires blasting if it is to be excavated
Soil	Aggregate of solid, typically inorganic particles that was either transported or formed *in situ* by weathering of rock; subdivided into *earth and debris* *Earth*: Generally unconsolidated material dominated by sand and finer sediments. It usually exhibits low plasticity. Earth is usually the breakdown product of silt-and-clay-rich sedimentary rocks such as shale and mudstone and igneous or metamorphic rocks prone to chemical breakdown *Debris*: Disordered mixtures of fragments of rock and sediment (sand and finer sized particles). Colluvium (product of rock breakdown), glacial sediments, volcanic ejecta, and former landslide material are types of debris. It can also include a significant content of organic detritus such as logs and organic-rich soil

Slide and Slump, Figure 4 Scar created by a wedge failure in a bedrock slope, Vancouver Island, British Columbia, Canada. The failure occurred at the intersection of two joint systems *A* and *B* in plutonic rock. Instrument in foreground is approximately 30 cm across. (Photo courtesy of Marc-Andre Brideau, Simon Fraser University.)

universally present in slopes from trace amounts to total saturation. It is referred to as *pore pressure* (μ). It may be positive when the slope is saturated or negative when water is held in pores by capillary attraction. Pore pressure is an important factor in many slides. Thus, σ must be adjusted for it because μ can reduce or increase it. The term *effective normal stress* is used and its symbol is σ':

$$\sigma' = \sigma - \mu \tag{4}$$

A component of the effective normal stress is not the only force acting to resist τ. There are frictional and cohesive forces that act along the failure plane. Cohesion (c) can be thought of as molecular attractive forces between soil and rock particles along the potential failure plane. These have to be overcome in order for translational movement to begin. Movement must also overcome frictional forces between grains in rock or sediment. This is referred to as *internal friction* which is expressed as an angle φ which is determined by testing in soil or rock mechanics laboratories. The total resistance to shear stress (τ) is called shear strength (S). Shear strength is related to cohesion, effective stress, and internal friction:

$$S = c + \sigma' tan\ \varphi \tag{5}$$

Equation 5 is known as the *Coulomb equation*. Shear strength acts in opposition to shear stress and is depicted in Figure 1, diagram 3. The ratio of shear stress and shear strength along a failure plane is called the *factor of safety* (F). F must be >1 or the slide begins to move:

$$F = \frac{\text{Shear strength}}{\text{Shear stress}} \tag{6}$$

Translational slides are among the largest in mountain regions. Once in motion, these may continue to travel slowly as a broken slab like the Downie slide in British Columbia (Piteau et al., 1978), or transition into rapidly moving, fluid-like rock avalanches like the 1903 Frank Slide in Alberta, Canada (Cruden and Krahn, 1978). Over time, various processes work to reduce the factors that act together to produce shear strength (Equation 5). This is why mountain and hill slopes can remain stable for thousands of years and then fail as translational slides or other types of landslides. For example, weathering processes may slowly alter the minerals that cement or provide cohesion along bedding planes, faults, and joints. Such alteration can reduce cohesion or the angle of internal friction, reducing shear strength. Hydrothermal alteration can also be a factor in reducing shear strength in volcanic (Siebert, 2002) and nonvolcanic settings (Piteau et al., 1978). With time, the combination of long-term reduction in these factors and transient reduction in effective stress due to high pore pressure (e.g., prolonged or heavy rainfall or snow melt) can reduce F to 1 causing failure. Similar processes occur with time in unconsolidated sediments on bedrock. Shear stress τ can also increase naturally with time. Tectonic movements or erosion at the base of slopes can steepen slopes (increase θ). These act to increase τ and decrease effective stress σ', thus reducing shear strength S (Equations 2, 3, 4). In regions prone to earthquakes, acceleration of slopes due to seismic shaking can trigger slides by increasing τ or decreasing σ' so that the factor of safety F drops to 1 on normally stable slopes (Keefer, 1984). Lastly, slopes can be loaded from above by landslides up-slope. Such loading increases τ. Poorly sited artificial fills on slopes can have similar effects.

Mechanics of rotational slides (slumps) and environments conducive to them

Rotational slides (Figure 1, diagram 4) typically occur in thick, relatively homogenous sediments such as clay, silt, and artificial fills. They also occur in massive and weak sedimentary rocks such as mudstone or claystone. In such slopes, a semicircular or curved surface defines a potential surface of failure where shear stress is at a maximum relative to shear strength. The successive rotational slides in Figure 3 occur in landslide colluvium of a 5-km-long landslide complex. The landslide colluvium is many tens of meters in thickness.

In reality, there is a continuum between translational and rotational slides. Rotational slides can have relatively planar segments interspersed with curved segments and still display rotational movement at the surface. Rotational slide colluvium is commonly remolded as a result of slide movement. This remolding can weaken and raise pore pressure within the slide colluvium so that it begins to flow. Transformation of rotational slides into *earthflows* or *debris flows* is common.

Rotational slides are triggered when the ratio of shear strength to shear stress along a critical curved surface approaches 1 (Figure 1, diagrams 4–6). Because the failure occurs along a curved surface (A-B), movement approximates rotation around an axis with a radius r. Sophisticated numerical approaches are used to locate and evaluate potential failure surfaces (e.g., U.S. Army Corps of Engineers, 2003). These subdivide slopes into elements and compute forces acting on them. In Figure 1, diagrams 5 and 6 illustrate the general principle (modified from Terzaghi and Peck (1967) and Krynine and Judd (1957)). The potential slide in diagram 5 is subdivided into elements (1–8 in the example). In element 6, the dot represents the center of mass of this element and W, τ, and σ vectors are shown at the base of the element similar to diagram 2 since it is assimilated to a planar failure surface. To compute the factor of safety for the slope, shear strength and shear stress are evaluated for each element. Because of the curved surface, the shear stresses of some elements are opposed to other elements. Elements 1–3 would tend to rotate the mass to the right (up-slope) whereas elements 5–8 would rotate it to the left (down-slope). Element 4 straddles the lowest part of the curve: Shear stresses in it cancel themselves. The factor of safety F is the sum of the shear strength for all the elements over the sum of the shear stress for all the elements.

Natural processes discussed with respect to translational slides can alter shear strength and shear stress in slopes subject to rotational slides.

Human activities and translational and rotational slides

Human activities can trigger new translational and rotational slides, or reactivate dormant or inactive ones. Timber harvesting and conversion of forest to pasture or other vegetation types are probably the most widespread human activities responsible for creating new or aggravating existing translational and rotational slides. The roots of trees anchor unconsolidated overburden to underlying rock, thus adding to shear strength S at the overburden rock contact. Within a few years after timber harvesting, roots decomposed and lose their strength. A significant increase in translational landslide activity follows (Swanson and Dryness, 1975; Sidle, 2005; Figure 5). This is particularly significant in steep areas where translational sliding quickly accelerates to form debris avalanches (Rollerson et al., 2005). The transpiration

Slide and Slump, Figure 5 Soil slides following logging and haul road construction on a mountainside on Vancouver Island, British Columbia, Canada. Glacial till and colluvium overlie bedrock and failure occurred along the overburden/bedrock contact (Photo courtesy of Brent Ward, Simon Fraser University).

of trees also acts to lower the water table in slopes thus increasing effective stress (σ'). Rising water tables is a factor in reactivating inactive or dormant landslides where their tree cover is removed (Sidle, 2005). Logging also requires the construction of a road network. In hilly or mountainous areas, road cuts must be made across slopes as well as the emplacement of fills across valleys. Road cuts reduce resisting forces on natural hillslopes: This can be visualized by removing elements 1–3 in Figure 1, diagram 5. Poorly engineered fills commonly fail in rotational slides or load underlying slopes causing them to fail. The combined effect of poor road construction, logging, and vegetation conversions in upland areas is a significant factor in increasing landslide and related disasters in the developing world (Fisher and Vasseur, 2000; Sidle, 2005; Mora, 2009).

Increasing pore water pressure through the creation of artificial reservoirs is another prominent way in which human activities can trigger translational and rotational slides, sometimes with disastrous results. The raising and lowering the reservoir behind the Vaiont Dam, Italian Alps, in 1963, destabilized adjacent slopes and triggered a rapidly moving translational slide with a volume of 2.7×10^8 m^3. It crossed the reservoir creating a wave that overtopped the dam and killed nearly 2,000 people downstream (Kiersch, 1964). At present, translational and rotational slides are a major problem associated with the flooding of the Three Gorges Reservoir, China. The Qianjiangping landslide (Figure 2) was triggered during the initial flooding of the reservoir to the 134 m level on July 13, 2003. The landslide was a translational slide that failed along a bedding plane in sandstone of Jurassic age. It had an estimated volume of 2.4×10^7 m^3 (Wang et al., 2004). Direct impact by the landslide and the displacement wave that it generated in the reservoir killed 24 people and left 1,100 people homeless. The level of the Three Gorges Reservoir will fluctuate 30 m seasonally in order to control flood flows of the Yangtze River. The fluctuation of the reservoir has proven to accelerate or reactivate large, creeping translational or rotational slides. New cities such as Wushan with populations of hundreds of thousands are situated on landslide complexes that experience movement with reservoir level fluctuations and require constant monitoring (Wang et al., 2009).

Summary

In a slide, a rigid or semi-rigid mass of soil or rock is displaced so that it descends vertically and horizontally along a distinct underlying failure surface under the influence of gravity. If the failure surface is planar, it is referred to as a translational slide; if it approximates a curved surface, it is classified as a rotational slide that is commonly referred to as a *slump*. Translational and rotational slides are further subdivided based upon the material involved. The failure surfaces underlying translational slides usually follow preexisting planes of weakness such as bedding planes, faults, joints, and foliation or contacts between overburden and bedrock. Rotational slides typically occur in massive rock or sediments where a curved surface defines maximum values of shear stress. Shear strength that resists shear stress is a function of cohesion, internal friction, and effective stress. Effective stress is the component of force operating normally to a potential failure surface minus pore water pressure. The ratio of shear strength to shear stress, called the *factor of safety*, must be greater than 1 for a slide to be stable. Natural geomorphic processes may act to reduce shear strength and increase shear stress with time. Human activities can induce translational and rotational slides by reducing shear strength through steepening slopes by excavation (road cuts, excavations, logging, and vegetation conversion), raising pore pressure (impounding reservoirs, removing trees), or increasing shear stress (placing fills on slopes).

SLOPE STABILITY

Kaare Høeg
Norwegian Geotechnical Institute, Oslo, Norway

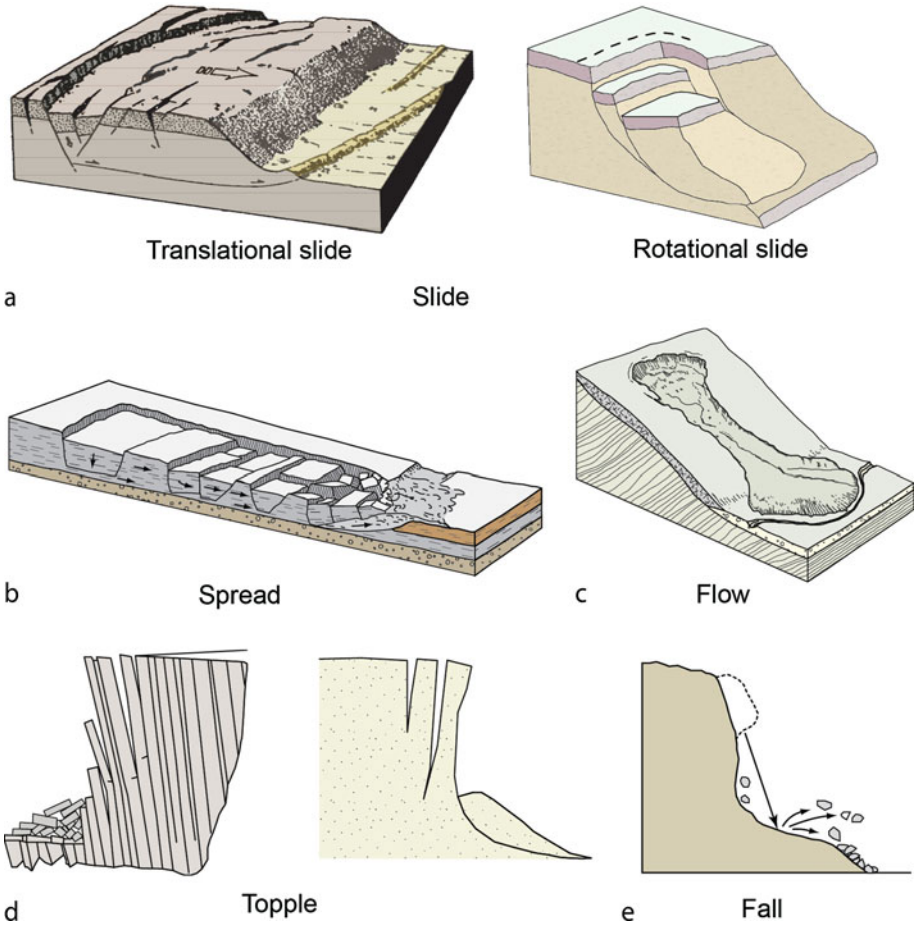
Definition

In sloping terrain *landslides* (downhill mass movements) may be triggered by a number of different factors, natural as well as man-made. To prevent landslides from occurring or to mitigate potential consequences, *slope stability* analyses are required.

Slope failure mechanisms

The general term "landslide" is used to describe any type of downslope movement of soil and rock under the effects of gravity. There are many different types of mass movements (*landslide; mass movement; avalanche; debris avalanche*) in clay, silt, sand, gravel, rock, and snow slopes. However, internationally, it has been agreed to classify the different mass movements into five main categories as illustrated in Figure 1 (e.g., Cruden and Varnes, 1996; Turner and Schuster, 1996; Highland and Bobrowsky, 2008): (a) slide; (b) spread; (c) flow; (d) toppling; (e) fall.

Sliding may occur as a translational movement along a fairly plane sliding surface or as a rotational movement along a spoon-shaped failure surface (*slump and slide*). Combined mass movements also occur with both translation and rotation. The mass moving above the sliding surface is commonly referred to as the sliding body (Figure 1a).



Spread (*lateral spreading*) is a special form of sliding and has therefore been given a specific term. The sliding body slides on a plane of weakness most often caused by high pore-water pressures (*pore-water pressure).* Earthquakes commonly cause landslides of this type. Often, the sliding body will split into separate smaller blocks and spread out during the mass movement (Figure 1b).

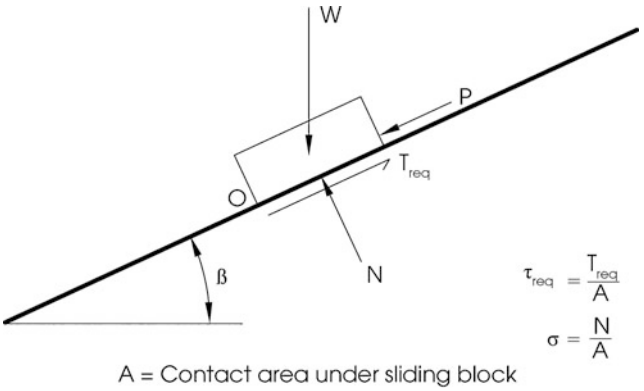
A flow will often start as a slide or spread with a limited mass movement, but if the soil or rock mass is broken down (degrades/disintegrates) during the initial motion and deformation, the sliding mass will gradually be transformed into a flowing mass that can attain a very high velocity and travel a long distance (run-out). As an example, after an initial slide has been triggered in a sensitive and brittle clay (*quick clay*), the clay will lose its strength, turn into a thick fluid, and flow even in rather flat terrain (Figure 1c). There are many other examples of dramatic flows (*debris flow; debris avalanche; lahar; liquefaction; mudflow; quick sand.*) Flows also occur in dry masses where the air pressure between soil and rock particles and collisions among particles cause dynamic motions and very long run-out distances.

Toppling, rather than sliding, may develop in masses of rock or cemented soils if subvertical cracks or joints have developed in the ground (Figure 1d). The depth of the cracks and the distance between them will govern whether failure will occur by sliding or toppling.

Fall often starts as the sliding or toppling of a block of rock in a very steep slope, followed by free fall and bouncing down the valley side until it stops on flatter ground (Figure 1e). A fall of several rocks at the same time may cause such a large impact and induced vibrations and pore-water pressures that a more extensive landslide is triggered (*impact triggered landslides*).

The most dangerous and damaging snow avalanches are denoted as sheet failures and consist of an extensive snow cover which is released almost all at once along a weak layer in the snow pack or along the ground surface. This type of mass movement belongs to the category of slide or spread and is transformed to a flow with high velocity and high air pressures inside and in front of the avalanche (*avalanches*).

Slope Stability, Figure 1 Different types of mass movements classified in five main categories (Modified after Cruden and Varnes, 1996).



In general, a mass movement is better and more fully described by combining terms from the five main landslide categories shown in Figure 1. For instance, a mass movement should be described by combining the terms "slide" and "flow" into "soil slide-debris flow," when the failure starts as a slide of an intact sliding soil body, but is broken down during the initial shear displacement and internal deformations and is transformed into a disaggregated flowing mass.

In some geologic materials which exhibit brittle deformation properties, e.g., quick clay or stiff, fissured clay, initial small slides may develop into extensive landslides due to a gradual retrogressive failure mechanism which causes the back scarp to gradually move upslope until firm ground is reached.

Evaluating slope stability

The stability of a slope is evaluated by considering the force equilibrium of the assumed sliding, spreading, or toppling body (Figure 1). The following description refers to the likelihood of initiating/triggering slope instability, not the subsequent development of mass movements. Usually, there is considerable uncertainty with respect to the prediction of the critical failure mechanism and volume of mass that may initially fail. Several analyses must be performed to make sure that one has considered the most critical situation. The slope will find the path of least resistance to failure, and the stability computations must include that situation, otherwise the analyses will be misleading. Figure 2 shows a simplified sketch of a translational slide. The vertical gravitational force, W, of the sliding body has a component along the sliding plane, i.e., a destabilizing force. In addition, there may be other destabilizing forces, as, for instance, water pressure in a crack in the back of the slope or additional loads from buildings constructed on the slope. The resistance against sliding, i.e., the stabilizing forces, consists of the shear resistance between the sliding block plus the resistance of any man-made supporting structure or anchorage that may have been provided to prevent sliding. In Figure 2 it is assumed that there is a resulting destabilizing force, P, along the sliding plane. Thus, the shear force between the sliding plane and the block required to prevent sliding (T_{req}) is:

$$T_{req} = W\sin\beta + P \quad (1)$$

Slope Stability, Figure 2 Principle sketch for the situation of translational sliding.

If T_{req} is larger than the shear resistance that may be mobilized (T_f), instability and sliding will take place. The subscript "f" indicates failure. In engineering computations one tends to use shear stress (τ) rather than shear force, where $\tau = T/A$, and A is the area over which the shear force acts. In Figure 2 that is the contact area between the sliding block and the sliding plane.

The shear stress at failure, τ_f, is called the shear strength. In slope stability evaluations the most important and difficult task is reliable determination or estimate of the shear strength of the rock, soil, or snow involved in the slope stability analysis. This aspect is discussed under a subsequent subheading. In addition to material properties, the magnitude of the normal stress ($\sigma = N/A$) minus the water pressure between the block and the sliding plane determines the value of the shear strength, τ_f

As shown in Figure 1a, for many slopes a rotational slide may be more critical than a translational slide. In a cross section through the sliding body in Figure 1a, the sliding surface may be approximated by a circular arc. The slope stability evaluation consists of comparing the destabilizing moment with the stabilizing moment around an axis of rotation through the center of the circle. The destabilizing moment is caused by the gravitational force, W, of the sliding mass and any applied loads toward the top of the slope. The stabilizing moment is created by the shear forces along the sliding surface opposing any rotational motion as well as any man-made retaining structure at the toe of the slide or anchorage into firm ground behind the sliding surface. The forces normal to a circular sliding surface have no moment arm and therefore cause no moment around the axis of rotation.

Thus, as for the translational slide in Figure 2, the stability evaluation for the rotational slide consists of comparing the average shear stress required for equilibrium, τ_{req}, with the average τ_f along the sliding surface. In advance, one does not know the location of the center of the circle or the radius of the critical circle, and all conceivable combinations must be considered to find the critical sliding surface.

In general, the sliding surface does not consist of a plane or a circular arc but is composed of a more complex surface combining translation and rotation accounting for any existing planes of weakness in the ground. The stability computations then become more complicated and laborious, but the limit equilibrium principle outlined above still holds by comparing τ_{req} to the maximum available average τ_f along the sliding surface.

If the sliding block on the plane in Figure 2 is high compared to the width, the critical failure mechanism is toppling (Figure 1d) rather than sliding. Then one has to compare the stabilizing moment with the destabilizing moment, for instance, around an axis through the point 0.

Definition of safety factor and probability of failure

A commonly used measure for evaluating the safety of a slope is the term "safety factor," $F = \tau_f/\tau_{req}$ which must be larger than unity to have a stable situation. This equation may also be written as $\tau_{req} = \tau_f/F$, which says that the shear strength may be reduced by the factor F before instability occurs and a slide is triggered. It emphasizes the importance of being able to determine shear strength. The safety margin (SM) is expressed as: $SM = F - 1$.

If the safety factor could be computed with great accuracy and reliability, a value of, for instance, 1.05 may be considered satisfactory. However, there are uncertainties associated with all factors that enter into the stability analyses; the properties of the soil or rock, pore-water pressures in the ground, intensity, and duration of future rainfall and snow melts, location of any planes of weakness and cracks in the ground, magnitude of destabilizing loads, and other factors described under a separate subheading below. The probability (likelihood) of failure may be estimated if the uncertainties in the different parameters may be quantified. By using the computational model for the stability evaluation and by introducing the uncertainties in the different parameters, one may find the combined effect of all the uncertainties and a probability of failure. Reliability index (RI), rather than safety factor, is a term that gradually is being more used to reflect the uncertainties in slope stability evaluations. It is defined as: $RI = (F_{avg} - 1)/SD_F$, where F_{avg} = most probable value of F; SD_F = standard deviation of F. The reliability index may be directly related to the probability of failure.

Determination of shear strength

The process to determine shear strength of soils, rock, and snow, respectively, has many similarities and common features. The basic linear Mohr-Coulomb equation is used as a first approximation:

$$\tau_f = c' + \sigma'_f \tan\phi' \quad (2)$$

where

τ_f = shear strength (on the failure plane)
c' = cohesion (shear strength parameter)

ϕ' = angle of shearing resistance (friction angle) (shear strength parameter)
$\tan\phi'$ = friction coefficient
σ'_f = effective normal stress on failure plane; $\sigma'_f = \sigma_f - u_f$
σ_f = total stress on failure plane to satisfy force equilibrium
u_f = pore-water pressure on failure plane

Soils (sediments) that have some cementation between particles have a c'-parameter larger than zero. The magnitude depends on chemical reactions that may have occurred in the ground and on earlier preloading by sediments which later have been eroded away (*erosion*) or by overlying glaciers that later have melted. Sediment that has been preloaded in this way is termed *overconsolidated*, because earlier in its geologic history it has carried higher vertical effective stresses than those existing at present. Sediment that has not been preloaded is called *normally consolidated.* It is in general much more compressible and has lower shear strength than an *overconsolidated* sediment of the same mineral composition at the same effective stress level.

The product of effective normal stress and the friction coefficient $\tan\phi'$ provides the frictional resistance along the sliding surface (failure surface). It is essential to note that it is not the total stress but the effective normal stress, defined as $\sigma'_f = \sigma_f - u_f$, that contributes to shear strength which points out the importance of pore-water pressures on slope stability. It is difficult to accurately estimate the value of u_f, especially in relatively impervious soils like clays, where the pore pressure may consist of a stationary as well as a nonstationary component caused by a change in loads acting on the slope (*pore-water pressure*). Field measurements are required to determine reliable values.

Capillary pressures in the pore water above the ground water level are lower than atmospheric pressure (i.e., under-pressure). The capillary pressures therefore cause an increase in effective stresses and thereby an increase in strength and soil stability. They give the impression that the sediment has significant cohesion. However, this is termed apparent cohesion as it disappears when the capillary under-pressures disappear during precipitation. Thus, the shear strength is reduced, and slope instability may occur.

The magnitude of the angle of shearing resistance (ϕ') depends on the type of soil (clay, silt, sand, gravel), how densely packed the soil is, degree of overconsolidation, grain size distribution, mineralogy, chemical weathering, and many other factors. Laboratory and/or field testing is required to determine this parameter.

To be able to mobilize the maximum shear resistance (shear strength τ_f), some shear deformation along the sliding surface must take place. Many types of soils and joints in rock masses exhibit reduced shear resistance after the peak in a shear stress vs. shear displacement diagram is passed, and the shear resistance is reduced from the value τ_f to a value τ_r. The residual strength (τ_r) is expressed in the same way as peak strength:

$$\tau_r = c'_r + s'_r \tan\phi'_r \quad (3)$$

However, the strength parameter c'_r is usually zero because any cementation between particles is broken during the previous shear deformations beyond the peak level, and ϕ_r' may be significantly smaller than ϕ' at peak resistance. In many slopes there are layers or seams of soils that already have been subjected to large shear deformations due to previous movements of over-riding glaciers, due to slope deformations during a previous period when the slope geometry was different, or movements caused by creep or freezing/thawing cycles (*creep; solifluction*). The shear strength along these potential sliding surfaces may therefore be closer to τ_r than τ_f. The stability of many slopes has been incorrectly analyzed by failing to understand the geologic history, geomorphology, and engineering geology of the site under consideration, and unexpected landslides have occurred.

Most rock slopes contain planes of weakness (e.g., joints, cracks, shears, faults) (*shear; fault*), and it is the shear strength along such planes that governs the slope stability. The shear strength is determined by a nonlinear form of the Mohr-Coulomb, because the friction angle is a function of the magnitude of effective stress on the plane (e.g., Barton and Choubey, 1977). The friction angle is primarily governed by the roughness of the joint, and as shear deformations take place, the roughness is worn down and reduced, and so is the friction angle. There is a significant difference between the friction angle at peak strength and at residual strength. The determination of joint roughness, the degree of weathering in the joint, and the type and thickness of infill material (clay and silt) is essential to the estimation of the shear strength of the plane of weakness (sliding plane).

Causes of slope instability and main triggering factors

Slope instability occurs when the stabilizing forces are reduced, the destabilizing forces are increased, or a combination thereof. After a landslide has taken place it is usually very difficult to pinpoint just one triggering factor. Water, for instance, affects the stability of slopes in many different ways.

Reduction of stabilizing forces by a reduction in shear strength

– Increase in pore-water pressure (or in water pressure in a rock joint) and thus reduction of effective normal stress. This may be caused by heavy precipitation, snowmelt, blockage of drainage paths (for instance, due to frost), or leakage from a water main. Earthquake vibrations (*earthquake*) lead to a temporary increase in pore-water pressure. This is particularly significant for loosely deposited silts and sands which may liquefy (*liquefaction*) and lose most of their strength. Even thin layers (seams) of saturated silts and sands in clay slopes

may create planes of weakness and cause slope instability during or shortly after an earthquake.
- Opening of cracks in the extension zone at the top of the slope allows ingress of water. When water enters into the fissures of stiff, overconsolidated clays, swelling occurs, and there may be a significant reduction in shear strength. Smectitic clays in a rock joint may swell considerably and reduce the shear strength and stability of the joint.
- Chemical changes in the pore water can lead to weakening of chemical and electrostatic forces between soil particles. A classic example is that the ductile behavior of a marine clay deposited in salt water may turn into a brittle quick clay (*quick clay*) when fresh water flow leaches out the salt ions.
- Reduction of shear strength from peak value down to residual strength due to large shear deformations. This may imply reduction of friction angle from, for instance, 30° to 10° and a complete loss of cohesion. Gradual downslope creep deformations (*creep; solifluction*) caused by shear stresses, freeze/thaw cycles, and swell/shrink cycles (*expansive soils and clays*) may cause deformations large enough to reduce the peak strength down to residual strength.

Reduction of stabilizing forces by erosion and excavation at toe of slope

- Erosion at the toe of the slope due to flowing water leads to undermining, loss of toe support, and instability. For many submarine slopes, such erosion is the main cause of instability (*marine hazards).* In a brittle material like quick clay, river or brook erosion at the toe may lead to a small initial slide that can start a retrogressive development in the back of the initial slope failure, and a large quick clay flow may develop. Similarly, excavation at the toe of a slope for the construction of a road or railway without providing other means of slope support may trigger a landslide.

Increase in destabilizing forces

- Loading the top part of the slope by placing landfills, buildings, or other structures. Submarine slopes, in areas of rapid deposition of sediments near river outlets, often become unstable due to such sediment loading. The situation is worsened by the fact that fine-grained sediments have very low permeability and excess pore-water pressures build up in the slope (*marine hazards*).
- Buildup of water pressure in cracks developed in the extension zone in the top part of the slope. The water pressure tends to push the slope downhill, and if the cracks remain filled with water for a long time, destabilizing seepage forces develop in the slope.
- When it rains the ground becomes saturated, and there may be a significant increase in density of the slope material and the destabilizing forces. This factor comes in addition to the increase in pore-water pressures caused by the precipitation.
- Forces developed due to expansion when water freezes in cracks in the extension zone. A similar phenomenon occurs when tree roots grow into joints and cracks of rock masses. This has been the cause of many rock slides, topples, and falls.
- Lowering of external water level against a slope extending into a lake or reservoir can trigger instability. The external water pressure against the lower part of the slope constitutes a stabilizing force, and if the water level is lowered, the safety factor against instability is reduced. Furthermore, if the lowering takes place rapidly such that the pore-water pressures inside the slope along the potential failure surface have no time to drain (dissipate), the destabilizing effect of the external water level lowering is even more detrimental.
- Earthquake vibrations cause dynamic destabilizing forces which come in addition to the already existing static forces. Even if the dynamic loads may not cause slope instability, they can cause an accumulation of downhill movements during the earthquake, the opening of cracks, and a reduction of the peak strength toward residual strength. In addition, as described above, the earthquake vibrations may cause a buildup of pore-water pressures.

Landslides triggered by volcanic activity result in some of the most devastating types of failure (Highland and Bobrowsky, 2008). Volcanic lava melts snow quickly, which can form a deluge of ash, soil, rock, and water that accelerates rapidly on the steep slopes of the volcano. These volcanic debris flows are known as lahars (*lahar*). Volcanic edifices are young and geologically weak structures that in many cases can collapse and cause rock and soil slides which may develop into debris avalanches (*debris avalanche*) (Devoli et al., 2009).

Soil slope instability after forest fires is a fairly common occurrence. When the vegetation disappears, the tree roots no longer prevent shallow slides from being triggered, water penetrates into the ground, and debris flows may develop more easily (Turner, 1996).

Summary

Various types of landslides and slope failure mechanisms are described. The evaluation of slope stability is commonly done by performing limit equilibrium analyses. The result is presented in the form of a computed factor of safety against instability or a probability of failure considering all the uncertainties in the evaluation. The main uncertainty usually lies in the determination of shear strength of the material in the slope, whether it consists of soil/sediment, jointed rock, or snow. Instability occurs when the stabilizing forces are reduced, the destabilizing forces are increased, or a combination thereof. Many examples of potential triggering factors are described. After a landslide has taken place, it is usually very difficult to pinpoint just one triggering factor. Water, for instance, affects slope stability in many different ways.

SNOWSTORM AND BLIZZARD

Thomas W. Schmidlin
Kent State University, Kent, OH, USA

Synonyms

White-out

Definition

Snowstorm. An atmospheric disturbance that produces snowfall of sufficient intensity or depth to cause disruption to society. An accumulation of 15 cm of snow in 24 h is generally sufficient to be considered a snowstorm, although lesser thresholds may apply early and late in the snow season or in locations where snowfall is rare.

Blizzard. An extreme snowstorm with strong winds and blowing or drifting snow that obscure visibility, obstruct travel, and create a hazardous environment to people and animals. The definition of a blizzard varies. In the USA, the National Weather Service defines a blizzard as winds over 35 miles h^{-1}, falling or blowing snow reducing visibility to ¼ mile or less, for a duration of at least 3 h. A blizzard in Canada is defined as wind speed over 40 km h^{-1}, a wind chill greater than 1,600 W m^{-2}, and visibility less than 1 km in snow, lasting for at least 4 h. The U.K. Met Office defines a blizzard as wind speed over 56 km h^{-1} causing blowing and drifting snow reducing visibility to 200 m (Wild, 1997). The term "blizzard" was first used by Henry Ellis along Hudson Bay in 1746, although Ellis's meaning at the time was ambiguous (Wild, 1997). It was used in South Dakota, USA, by 1867 and the term was in general use by the 1880s (Wild, 1997).

Discussion

Snow is frozen precipitation that originates as an ice crystal and grows as a snowflake through deposition, accretion, or aggregation. Snow is a winter feature of most of the Earth's middle and high latitudes. Snow occurs year around in portions of the Arctic and Antarctic and at high elevations. Snow covers about 78 million square kilometers of the Earth's land area each year, including about one half of the land in the northern hemisphere. Snow is an important component of the energy and water balances, in plant and animal ecology, and in human recreation. A large accumulation of snow within a short time causes disruption to human activities and is called a snowstorm. A severe snowstorm with strong winds and reduced visibility is a blizzard.

Snowstorms and blizzards originate as an area of low atmospheric pressure, typically a mid-latitude cyclone with associated fronts and other mesoscale features. Heavy snowfall rates result from uplift and a supply of moist air that produce condensation and snowfall. Uplift may result from orographic lift over terrain, warm air advection, an upper-level jet streak, diabatic processes, and cyclogenetic lift (Mote et al., 1997). Local areas of intense snowfall (5–15 cm h^{-1}) within the snowstorm may result from mesoscale processes in the atmosphere. These mesoscale bands of intense snowfall are associated with sharp temperature gradients, frontogenesis at the 700 hPa pressure level (~3 km height), and a deep layer of negative equivalent potential vorticity (Nicosia and Grumm, 1999). The resulting upward motion and convection may even include lightning and thunder along with the snowfall. Most snowstorms are large and affect a long swath across tens of thousands of square kilometers. Other snowstorms may be quite localized and affect

just a few hundred square kilometers. These may occur as convective bands of snowfall downwind of large lakes or bays (e.g., Laird et al., 2009).

Blizzards with their extreme winds and reduced visibility often occur along a band within the larger snowstorm. The strong wind that accompanies a blizzard requires a sharp pressure gradient and extreme low atmospheric pressure in a mid-latitude cyclone. An ordinary winter storm intensifies into a blizzard when the favorable conditions exist in the atmosphere. These include interaction of the surface cyclone with upper-level short-wave troughs and jet streaks and rapid amplification of upper-level (~5.5 km height) troughs (Kocin et al., 1995).

The average area affected by blizzards in the USA is 150,000 km^2 although the 24–27 January 1978 Midwest Blizzard covered over 1 million square kilometers (Schwartz and Schmidlin, 2002). The USA (excluding Alaska) averages about 11 blizzards annually with an average population of 2.5 million in the area affected by each blizzard. The March 1993 Superstorm had blizzard conditions across a large region of the eastern United States with a population of 72 million people.

Snowstorm records

The deepest snowfalls occur in the moist mountainous regions of the middle and high latitudes. The greatest 24-h snowfall in North America was 193 cm (76 in.) at Silver Lake, Colorado, at 3,115 m elevation on 14–15 April 1921 (Krause and Flood, 1997). Most other North American snowstorm records were set at Thompson Pass at 855 m elevation in the Chugach Range of southern Alaska. A snowstorm there in December 1955 gave 306 cm in 2 days, 373 cm in 3 days, and 414 cm in 4 days. A 7-day snowstorm in February 1959 produced 480 cm of snow at Mt. Shasta Ski Bowl, California, at 1,084 m elevation. Bessans, France, at 1,710 m elevation in the Alps recorded 172 cm of snowfall in just 19 h on 5 April 1959 (Krause and Flood, 1997). Canada's deepest 1-day snowstorm was 118 cm at Lakelse Lake, British Columbia, on 17 January 1974. Similar extreme snowfalls occur in the mountains of Norway and northwestern Japan.

Societal impacts

Snowstorms create slippery surfaces and loss of roadway friction along with low visibility to limit surface transportation by automobile, truck, bus, and train (Changnon et al., 2006). Vehicle accidents occur on the snowy and icy surfaces. Air travel is also disrupted by poor visibility and traction at airports. Deep snow simply restricts movement. Deep snowfalls can lead to medical emergencies when people in need of assistance cannot travel to hospitals. Social functions, such as school, churches, athletic events, concerts, and other businesses, may close or restrict functions during and after snowstorms. Electricity may be disrupted during snowstorms by collapsed poles or wires or by fallen trees due to high winds or the weight of snow. Removal of snow from transportation routes is a costly endeavor for individuals, businesses, and governments. The weight of snow can cause the collapse of structures and trees. Deep snowfalls on sloping surfaces can result in avalanches of snow onto buildings or transportation routes. Rapid snowmelt after large snowstorms may result in flooding. Persons are injured during and after snowstorms in vehicle accidents and by falling on snow or ice, they suffer heart attacks from exertion in snow removal, and are injured by collapsed structures or fallen trees. Delays in transportation lead to losses of perishable products. Most retail sales, business, and tourism are diminished during and after snowstorms. Among positive impacts, snowstorms may bring needed moisture in watersheds and agricultural landscapes. Some businesses, such as winter recreation, snow removal, and the sales of winter-related household, auto, or recreational goods, may benefit from snowstorms (Schmidlin, 1993).

The impacts of snowstorms have been quantified by combining the snowfall depth with the area and population affected by the snowstorm with an emphasis on the urban northeastern United States (Kocin and Uccellini, 2004). By this system, the 12–14 March 1993 blizzard was the most extreme snowstorm on record.

Summary

Snowstorms with 15 cm or more of snow in 1 day cause societal disruptions and may create hazardous situations. They are also an important part of the winter environment for much of the northern middle and high latitudes of earth. Blizzards are extreme forms of snowstorms that result from very intense mid-latitude cyclones. They paralyze transportation and pose extreme risks to persons outdoors.

SOCIAL–ECOLOGICAL SYSTEMS

Fabrice G. Renaud
United Nations University, UN Campus, Bonn, Germany

Synonyms

Human–environment systems; Social-environmental systems; Socio-ecological systems

Definition

Social–ecological systems are complex, integrated systems where human activities and environmental processes are inter-dependent, co-evolving, and linked through various feedback loops.

Discussion

Social–ecological systems are composed of a diversity of agents such as microbes, plants and humans, a set of actions related to their physical or behavioral characteristics, and a physical substrate (Anderies et al., 2006). These systems are highly dynamic and are characterized by the mutual interactions between the societal and ecological subsystems (Gallopín, 2006). The interactions between elements of the system are typically stochastic and nonlinear.

The coupling of the two systems emanates from the fact that the delineation between social and biophysical systems is artificial and subjective since human action and ecological structures are closely linked and dependent on each other. It is therefore considered more relevant to consider the subsystems within a common analytical framework where the interactions, regulations, and feedback mechanisms are captured at various spatial and temporal scales (e.g., Turner et al., 2003a). The systems can be defined at various spatial scales ranging from the local, such as communities and their immediate environment, to global. Because the systems are highly dynamic and processes within them operate at various speeds, several temporal scales have to be considered to characterize them.

Social–ecological systems are an element of analysis in resilience theory and in sustainability science and are increasingly considered in the context of vulnerability and risk assessment linked to natural hazards and climate change (Turner et al., 2003b; Walker and Meyers, 2004; Renaud et al., 2010).

SOCIOLOGY OF DISASTER

Alison Herring
University of North Texas, Denton, TX, USA

Introduction

Disasters are viewed as an ever-present threat in our lives and appear to be on the rise; the past few decades have seen a growth in the number of disasters and the devastation caused by disasters (Mileti, 1999; Quarantelli, 1998; Waugh, 2007). The past decade alone has seen multiple disasters around the world: the 2004 South Asian tsunami which killed an estimated 230,000 people (Stern, 2007); Hurricane Katrina which hit the Gulf Coast in August, 2005 killed an estimated 1,325 people (Bullard and Wright, 2009); the 2005 northern Pakistan earthquake killed an estimated 80,000 people, and the more recent Japanese earthquake of 2011, killed an estimated 15,835 people (Saito and Kunimitsu, 2011). While these disasters are seen as having had a natural physical trigger, there are a variety of man-made disasters with comparable fatality rates, such as Chernobyl which occurred in the Ukraine in 1986 where the release of radiation reportedly affected

50,000 people, and the World Trade Center Bombings in New York in 2001 that killed an estimated 2,996 people (Ai et al., 2005).

Disasters are not only measured in terms of death rates but also in monetary costs which have been escalating in the USA (Mileti, 1999). Between 1950 and 1959, the USA experienced 20 disasters costing roughly $38 billion (1998 value), whereas between 1990 and 1999 the USA experienced 82 disasters costing an estimated $535 billion (Perrow, 2007). The cost of Hurricane Katrina is estimated at $200 billion (Burby, 2006), and is the first disaster in which the government has paid out more $100 billion for damages (Sylves, 2006). There are several reasons which may contribute to this increase in disasters; a population explosion has resulted in greater concentrations of urbanization in places where hazards are prevalent (Dash, 2010; Phillips and Fordham, 2010), both in the Western World and the developing world; and a reliance on technology to solve problems in our environment may increase the likelihood of failure down the road, as evidenced by the catastrophic failure of the levees during Hurricane Katrina (Bullard and Wright, 2009; Burby, 2006; Campanella, 2008; White, 1975).

While the agent of the disaster may be appealing to study, it is not the only aspect of disasters which is important. Disaster research has become a growing field resulting in interdisciplinary study with researchers from other fields such as geography, political science, engineering, psychology, international affairs, and others all seeking to add their knowledge to the overall picture of disasters.

Sociology of disaster investigates the social aspects of disaster, specifically issues related to how people perceive disasters, how they are able or unable to prepare for, respond, and recover from disasters. Topics which sociologists study range from how race, class, gender, and age may influence our risks to disaster, our survival chances, and our response to disaster; whether we evacuate in the event of an impending disaster, how we evacuate, and why we may not be able or willing to evacuate; how popular culture influences our perceptions of disaster, and the myths that prevail about disasters in our culture. The importance of sociology to the study of disasters is significant not only in terms of understanding human behavior in situations where no social norms exist, but also in an applied perspective where emergency management professionals may use the information to make better planning decisions to prepare for the disaster and its anticipated outcomes with the limited resources they have at their disposal.

Definitions and paradigms

The first acknowledged disaster research study was conducted by Samuel Henry Prince in 1917, following an explosion in the Halifax Harbor when a French munitions ship collided with a Belgium ship in the harbor (Perry, 2007; Scanlon, 1996). An estimated 1,963 people were killed and 9,000 people injured in the vicinity. Prince's observations of people at the scene, which included people trying to get to family members, rumors beginning shortly after the hazard, the fear of looting, the lack of preparation by the city, and resources converging upon the scene, still hold true today and form the basis for many sociological studies (Drabek and Key, 1976; Fitzpatrick and Mileti, 1991; Kendra and Wachtendorf, 2003; Neal, 1994).

It was not until the 1950s and the Cold War era that disaster research began in earnest when the military approached researchers to study possible civilian reactions to a nuclear attack. The prevailing belief of the military held that civilians would be traumatized by disasters that would inevitably make them prone to psychological breakdowns and lead to social control issues following the event. This assumption was the cornerstone of the military's command and control model, which was prevalent in emergency management offices (Quarantelli, 1987). As researchers were unable to conduct experiments in bombing the population, it was determined that natural disasters would provide a means of studying people's reactions and behaviors to adverse conditions which would provide suitable knowledge that could be used in the event of war (Quarantelli, 1987). Since many of the disaster researchers at the time came from the field of collective behavior, analysis of people's behavior in disaster situations was more often than not interpreted through symbolic interactionist theories (Quarantelli, 1987, 2002). The military's concentration on fast-onset, single event disasters coupled with the researchers focus on collective, or group dynamics, within a disaster concentration can be clearly seen in the definition of disaster produced by Fritz (1961, 655) at the time

> actual or threatened or uncontrollable events that are concentrated in time and space, in which a society, or a relatively self-sufficient subdivision of a society undergoes severe danger, and incurs such losses to its members and physical appurtenances that the social structure is disrupted and the fulfillment of all or some of the essential functions of the society, or its subdivision, is prevented.

The criticism now leveled against this definition is that it assumes disaster events as being limited in terms of time and space, thus disaster research focused on hazards such as hurricanes, tornadoes, and earthquakes, while not applying to other types of hazards such as famine or drought (Kroll-Smith and Gunter, 1998). Albeit more recent definitions of disaster do still focus on the "event" perspective defined by Fritz, qualifiers have been introduced to emphasize social processes (Perry, 2007). For example McEntire (2007, 2) states that "[d]isasters are the deadly, destructive, and/or disruptive events that occur whenever a hazard (or multiple hazards) interact with vulnerability." A disaster may be viewed then, as the actual impact of an external hazard upon the social environment and the consequences that result (Hewitt, 1998; Oliver-Smith, 2002). The key is the resulting disruption to the social structure that a hazard causes (Bullard, 2008; Wisner et al., 2004).

Though many researchers tend to believe that there is a functionalist bias in the early disaster research studies (Hewitt, 1998), no specific sociological theory emerged from the studies due to the focus on the external hazard. This focus was partly because of the military's concentration on the response phase of disaster due to the need to plan for contingencies, and partly because the application of disaster research led to the development of paradigms rather than theories (Quarantelli, 1987, 1994, 2002; Stallings, 2002). Paradigms are based more on abstract reasoning produced via discourse than from empirical study and, therefore, tend to be consensus-driven and are seen as a reflection of the inductive nature of much of disaster research to date (Perry, 2007). Paradigms are useful however as they focus on "what should be studied, [and] what questions should be asked" (Ritzer, 1979, p. 26). Several paradigms have emerged over the years of disaster research; these are the hazards paradigm, the social vulnerability paradigm, and the sociopolitical ecology perspective.

Hazards paradigm

The hazards paradigm developed during the 1950s has formed the dominant approach to disaster research since its emergence. This dominant perspective views the hazard, often a natural trigger, as an extreme, separate, and external force acting upon a population (Phillips and Fordham, 2010). Thus, the focus of the paradigm is on the external agent that is capable of destroying and killing, while the affected population is treated as an homogenous entity passive in the wake of the hazard they are unable to control (Perry, 2007; Phillips and Fordham, 2010; Tobin and Montz, 1997). Each hazard under this perspective, while a part of the normal environmental processes, warrants its own area of study, resulting in the proliferation of hurricane centers, earthquake centers, etc. Studying each hazard separately emphasized the idea that natural disasters are an unfortunate accident which disrupts our normal daily lives and for which the survivors are not at fault.

However, as the basis of sociology is the study of behavior in society, it was soon recognized that the external hazard, or trigger, is unimportant; instead the focus of disaster researchers is on people's behavior and adaptation to the event. Quarantelli (1981) called for an All-Hazards approach which would focus research on society and societal norms after the impact from a hazard. This not only permitted the study of disasters where the originating source was not readily apparent, such as in famines and droughts, but also began to demonstrate that environmental risks were not the only element of disasters.

Social vulnerability

The social vulnerability paradigm emerged in the 1980s as research on the impact of disasters began to show that it was not necessarily living in a risky environment that constituted the most risk from a disaster, but rather the social characteristics of a population. There are specific locations in our environment that are more prone to hazards than other locations: the Gulf Coast and the Eastern Seaboard of America are prone to hurricanes, the West Coast of California is prone to earthquakes as it lies on the San Andreas Fault, and the Mid-West is more prone to tornadoes (Hewitt, 1997). These hazards are not a problem until they come into contact with human populations (Hoffman and Oliver-Smith, 1999; Kendra, 2007; Wisner et al., 2004). In fact, whether a population faced a disaster was not as simple as being in the wrong place at the wrong time. Rather, research showed that disasters "were more properly viewed as primarily the result of human actions; that while hazards are natural, disasters are not" (Bolin and Bolton, 1986).

Social vulnerability stems from the interaction of the environment with social structures which are, themselves, affected by political structures (Peacock and Ragsdale, 1997; Oliver-Smith, 1998). The political aspect is important because it defines those who are already vulnerable prior to the hazard, and analyzes how the hazard exacerbates those social structures already in place (Oliver-Smith, 2002). "Social systems generate unequal exposure to risk by making some people more prone to disaster than others and these inequalities are largely a function of the power relations (class, age, gender, and ethnicity among others) operative in society" (Bankoff, 2006). Vulnerable populations within society have a reduced "capacity to anticipate, cope with, resist and recover from the impacts of a natural hazard" (Boyce, 2000; Cutter et al., 2003; Wisner et al., 2004, p. 11). Disaster risk is, therefore, contingent upon a host of intersecting factors not simply geographical location in proximity to a hazard, or frequency or intensity of the hazard but also the temporal context of an individuals' position within society governed by social structures of stratification (Cutter et al., 2003). Disaster vulnerability is, therefore, often deeply rooted in people's history.

Research in this paradigm seeks "to understand how social, economic, and political relations influence, create, worsen, or can potentially reduce hazards in a given location." This paradigm investigates the lack of access to resources, the lack of political voice, the age and condition of the building stock within the region, the dynamics of the population, the degree of urbanization, and the number of social networks and infrastructure. Over the past 2 decades, significant research has been undertaken within this paradigm in order to understand and define the vulnerabilities that may exist and identify the known groups in order to build capacity, promote empowerment, and increase resiliency of these groups in the event of a disaster (Cutter et al., 2003: Dash, 2010; Phillips and Fordham, 2010).

Though the approach tends to focus on specific populations in terms of their potential vulnerabilities, the reality is that people are often seated within several categories. Being a member of one category tends to result in being a member of another. For example being an

elderly, black female will seat the individual within three categories of vulnerability: age, race, and gender.

Class

Class is a significant concept for analysis by sociologists in general as class refers to the socioeconomic status of an individual. This status is made up not only of a person's wealth but their level of income, level of education, and type of occupation, which greatly affects resources that may, or may not be, at their disposal, such as knowledge, skills, and social and familial connections which a person is able to draw upon as well as the power that they may, or may not hold, in society (Dash et al., 2010). Significantly, for disaster researchers, socioeconomic class plays a key role in determining whereabouts a person may live, what resources they may have at their disposal, and how likely they are to be able to survive a hazard.

The most significant aspect of class is the wealth that people may have. Wealth has several important aspects when we look at disasters and how people are influenced by disaster situations. Contrary to popular belief, resources are concentrated in the hands of only a relatively few number of people; Wolff (2007) contends that 17% of the American population has no wealth at all and 30% have less than $10,000. Albeit some members of society may be able to choose to locate in a hazard prone area; such as building a multimillion dollar ocean front home for the view for others there is no choice but to live in more hazardous and marginal conditions (Dash, 2010; Grenier and Morrow, 1997; Hewitt, 1998; Phillips and Fordham, 2010). This population tends to be more likely to live in floodplains where land is cheaper, thus more likely to have their homes flooded. While those with greater wealth may be able to afford to mitigate risk to their homes by building homes to stricter building codes that are more likely to survive excessive winds and seismic activity, those with very limited resources are less able to live in homes that have such protection. Those with few resources are more likely to live in buildings that are old, or substandard, and less likely to survive a natural hazard. This group is more likely to rent than to own property and, therefore, less likely to be able to upgrade the building in order to mitigate their risk (Blinn-Pike, 2010; Burkle, 2006; Mileti, 1999; Peacock and Girard, 1997).

Income also becomes an important factor in our social class. In 2010, the official poverty rate was 15.1% meaning that 46.2 million people in the USA lived on less than $10,890 per year according to the Department of Health and Human Services. This means that those with disposable funds have available resources to fall back upon when unforeseen hazards occur, whereas those who are barely making ends meet have nothing to fall back on and are at a higher risk and less likely to be able to recover. While many people presume that insurance will cover the costs of a disaster, for some people insurance is a luxury which may cost them as much as three quarters of their household income (Dash, 2010). That is assuming that insurance companies will insure homes; although redlining is illegal, Peacock and Girard (1997) found certain areas within Miami that were not covered by the three largest insurance companies. This means that residents must use local, smaller companies who may not only be more expensive but because of their small size and concentrated clientele are also more likely to go bankrupt in the event of a major disaster as they do not have the resources to cover such huge losses.

Neighborhoods reflect the social class of the individual residents located in the area. Poor neighborhoods have fewer resources, degrading infrastructure, fewer employment opportunities, and more people dependent upon public transportation (Burkle, 2006). A significant problem, not only for individuals, but also for emergency managers is when preparing for an evacuation, as happened in New Orleans with Hurricane Katrina (Bourque et al., 2006). A quarter of the population of New Orleans lived in poverty prior to the storm in 2005 most in inner city areas (Branshaw and Trainer, 2007; Brezina and Kaufman, 2008; Comfort, 2006; Drier, 2006). This had significant repercussions especially for evacuation prior to the storm as a quarter of the population did not own, or have access to, an automobile and therefore had no means of evacuating (Bullard, 2008; Drier, 2006; Miller and Rivera, 2006) (Figures 1 and 2).

Sociology of Disaster, Figure 1 Two residents wade through chest-deep water after finding bread and soda from a local grocery store after Hurricane Katrina came through the area in New Orleans, Louisiana (AFP/Getty Images/Chris Graythen).

Sociology of Disaster, Figure 2 A young man walks through chest deep water after looting a grocery store in New Orleans on Tuesday, August 30, 2005. Flood waters continue to rise in New Orleans after Hurricane Katrina did extensive damage when it made landfall on Monday (AP Photo/Dave Martin).

Coupled with exposure to more environmental hazards and related health issues, educational attainment is often lower than in wealthier areas and job prospects limited by knowledge and skill levels. Fewer resources are available for education in these areas than is the case in more wealthy areas. Traditionally, the poor are more likely to accept low-paid unskilled labor which is hourly paid and more often than not without benefits (Johnson, 2008). This means that many people will not evacuate at all, or in time, because of fear of losing not only their pay but also their jobs in a market that can easily replace unskilled labor. When a disaster hits, their jobs are frequently the first to be lost and the last to be replaced. Five years after Hurricane Katrina hit New Orleans it is estimated that only 85% of the pre-Katrina jobs have been recreated (Louisiana Workforce Commission, 2010). In comparison, the wealthier members of society are more likely to have salaried positions, with benefits, are less likely to lose that income in the event of a disaster and thus have more resources available to use.

The poorer populations are more constrained by their environment and typically stay close to their roots (Dash et al., 2010). This has an adverse effect on evacuation for this population. For the wealthier populations, moving away from family in search of jobs means that there are family members outside of the region of the disaster who can provide support and aid in recovery; a resource that is not as available to poorer members of society who live around their family (Freudenburg et al., 2009). The social networks that are available to the lower socioeconomic classes during normal daily activity cannot be accessed during a disaster situation when everyone is in the same boat (Bourdieu, 2005; Bourque et al., 2006; Elliot et al., 2010).

After a disaster, housing is often in short supply and the demand is high, not only from those displaced by the disaster and having nowhere else to stay, but by the influx of construction workers who can afford to pay higher rents. Rents inevitably increase to such a point that the poor are forced out of the area. It is estimated that, after hurricane Katrina, an estimated 58% of renters were paying more than 35% of their pre-tax income on rent and utilities, an increase of 43% since 2004. Paradoxically, the number of homes classified as vacant rose to 25% of all residential units. This is, in part, due to the classification of a housing unit as having a roof, doors and windows, which many of the severely damaged homes in New Orleans did, but they were still uninhabitable from water damage and boarded up by residents unable to afford to repair them (Louisiana Workforce Commission, 2010).

In general, the lower socioeconomic classes are less likely to have the resources prior to the disaster to be able to mitigate the effects of the disaster and subsequently have fewer resources after the disaster to be able to recover (Blaikie et al., 1994). The majority of the costs of a disaster are borne by the victims of the disaster and disproportionately by low income groups (Beatley, 1989; Cutter et al., 2003; Dash, 2010; Mileti, 1999).

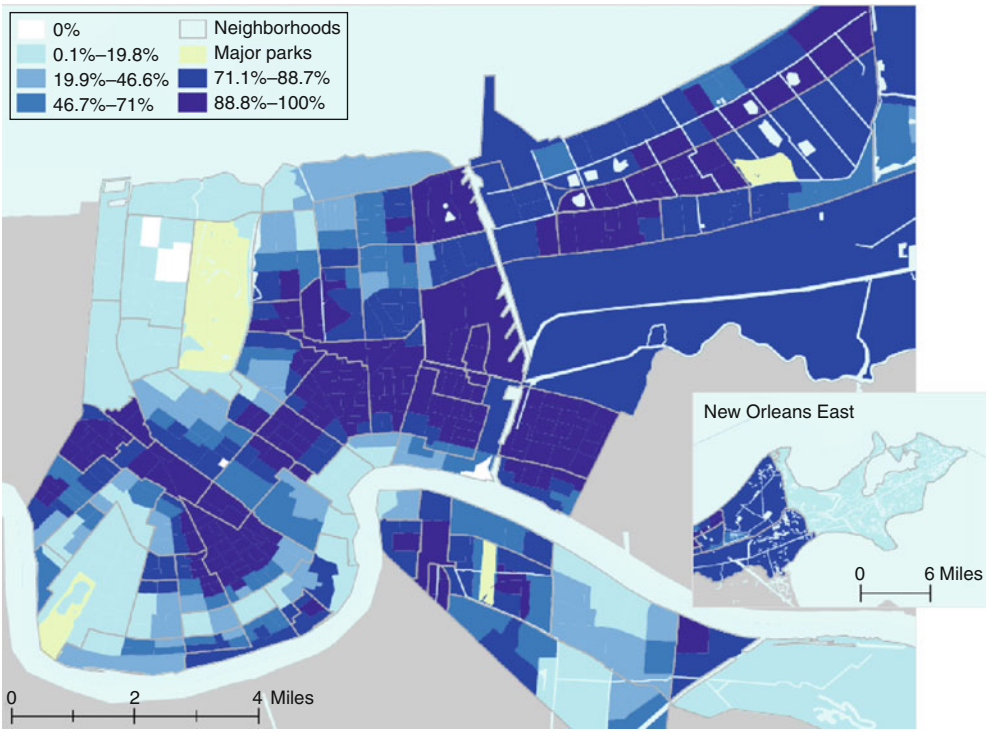
Gender

Sociological research in the field of disasters has shown that men and women experience disasters differently due to the differing roles and responsibilities expected of them. Women are more likely to live longer, but have less secure incomes throughout their lives, whereas men are more likely to be homeless and experience higher levels of violence (Enarson, 2010). These types of inequalities have large impacts on the ways in which gender experiences disasters, especially as women are less likely to have access to much needed resources. During any phase of the disaster, women are more likely to experience a dramatic expansion of their caregiver roles regardless of whether they are married or single. For example, women are more likely to heed any warnings that they hear and take preventive action, especially if they have children (Enarson, 2010; Gladwin and Peacock, 1997). Men on the other hand, are more likely to be risk tolerant and therefore less likely to take action to protect themselves (Enarson, 2010).

Women are more likely to live in poverty, live in single female head of households, and so lack access to resources when a disaster strikes. In New Orleans, at the time Hurricane Katrina struck in 2005, one in four women lived in poverty (Comfort, 2006; Drier, 2006; Enarson, 2010; Morrow and Enarson, 1996). This translates to women being less able to take mitigative action and more likely to experience higher death and injury rates than men regardless of the fact that they are more likely to heed the warnings (Enarson, 2010).

Recovery from a disaster is also experienced differently by gender. Divorce rates and spousal abuse tend to increase dramatically after a disaster often leaving women in charge of the children (Enarson, 2010). At the time of Hurricane Katrina, more than a half (56%) of families with children were headed by women and two fifths of these

lived in poverty. This population not only found it difficult to recover from the effects of Katrina but was disadvantaged in trying to negotiate through a bureaucratic system which did not recognize their head of household status when multiple families lived in one housing unit (Enarson, 2010; Morrow, 1997).



Gender is not alone in how it shapes an individual's experience, nor does it guarantee that all women, or all men, will experience the same thing. As stated earlier, individuals are a conglomerate of several characteristics of which gender and race/ethnicity are master statuses. That is, they often define the individual regardless of the achievements of that individual.

Race/ethnicity

Racial stereotypes allow us to categorize people into groups, often based on false assumptions, and allow an "us" and "them" attitude, which limits the power given to "them." This trend often shows up dramatically in disaster situations. New Orleans, a predominantly African American city, had an African-American population of 67% prior to the storm (Johnson, 2008) and was one of the poorest cities in the USA ranking third in the nation (Drier, 2006) with a poverty rate twice the national average (Bourque et al., 2006). Over a third of African-American women in New Orleans were officially poor prior to the storm (Enarson, 2010).

As a consequence of racial stereotyping and discrimination, minorities tend to live in more hazardous areas either from natural hazard, or man-made hazardous sites, where they trade safety for employment (Dash, 2010). Their perception of risk due to the presence of the nearby hazard, or working within the hazard site may actually raise their tolerance for risk, and thus, they are less likely to evacuate in the event of an impending disaster (Bullard, 2008). In terms of New Orleans, although African-Americans represented over two thirds of the population they only comprised a fifth of the urban population being situated in the surrounding high flood risk, low-lying areas (Drier, 2006).

The map below shows the percentage of African-Americans living in census blocks in New Orleans Parish: The higher the percentage of African-Americans in the block the darker the shade of blue. From this map it can clearly be seen that African-Americans are not concentrated on the high land near the banks of the Mississippi, but are in fact positioned farther back from the river in the lower lying swamp areas. As this was the area that sustained most damage from the flooding, it can be appreciated that in the aftermath of a disaster, the damage patterns are often directly related to ethnic/racial boundaries within the environment, which highlights the social vulnerability of certain groups (Bolin and Bolton, 1986; Sharkey, 2007) (Figure 3).

Sociology of Disaster, Figure 3 Percent African-American by Census block group in Orleans Parish (Adapted from Census 2000 and compiled by Greater New Orleans Community Data Center (GNOCDC, 2011)).

Although there are obvious disadvantages to belonging to certain groups, there are some less obvious aspects of group membership which also have significant consequences in disaster situations. For example, minorities do not always "hear" the warnings given by emergency managers, partly because of language barriers, but also because minorities tend to view "official warnings" differently (Dash, 2010). Hispanics, for example, are more likely to seek confirmation from other familial groups rather than from official channels and more likely to decide what they should do as a group. Many minorities reside within the same area as their family, and so are more likely to need the use of shelters in the event of an evacuation should they evacuate especially given that people will evacuate as families rather than as individuals (Dash, 2010; Drabek and Key, 1976; Fitzpatrick and Mileti, 1991).

Cultural patterns may also result in a higher degree of resiliency. For example, research conducted by Klinenberg (2003) on the 1995 Chicago heat wave showed that the elderly Latino population was protected from the effects of the heat wave by cultural reverence that holds elders as valuable resources enmeshed within the family system. This is in sharp contrast to African-American and white cultures where the elderly lived alone and isolated from family and neighbors, and consequently resulted in the large number of deaths in this group.

Sociopolitical ecology perspective

This perspective goes beyond just examining the impact of the disaster and the social structures in society. Sociopolitical ecology seeks to take into account the cultural and organizational components that make up communities and the social networks within them (Peacock and Ragsdale, 1997). Communities are an amalgamation of preexisting social structures and complex relationship networks. In a disaster event, those structures and networks can aid or hinder an individual's response and recovery to a disaster. Those same networks extend outside of the community into the larger political sphere and, subsequently, become a resource or deterrent outside of their local effect. Individuals and communities are seen as competing for scarce resources such as food, temporary shelter, and recovery funds. Those with power will be able to garner these resources and recover faster and more thoroughly to the detriment of those with less power who will have more difficulty in recovering. Thus, recovery is not a homogeneous experience within the community.

This brings stratification systems within the community into play. For example, in Hurricane Andrew the Anglos and the Cubans were able to recover much quicker than any other population in the community because they had more power, resources, and networks. It was found in the aftermath of Hurricane Andrew that Florida City, a mainly poor minority neighborhood, which had a weak local government, was ultimately unable to recover from the effects of the hurricane as it had so few resources and no political voice. However, an adjoining neighborhood, Homestead, which was comprised of more middle-class families had more resources and a stronger local government. Because of their political power, the Homestead community was able to acquire funds from the federal government in order to help recovery of the neighborhood (Dash et al., 1997).

By analyzing social structures prior to a disaster, researchers using the sociopolitical ecology or social vulnerability perspective are able to identify the groups of people within an area who will be more likely to be severely impacted by a disaster, and are thus able to advise local governments and emergency managers.

As sociologists we are interested in all aspects of social behavior related to disasters, thus, we also focus on aspects of popular culture such as the media and how the media has influenced the popular perception of disasters and created the myths that abound about disasters.

Media and popular culture in disasters

Researchers have studied popular culture within disasters (Bahk and Neuwirth, 2000; Couch, 2000; Webb et al., 2000). In fact, an entire issue of the *International Journal of Mass Emergencies and Disasters*, March 2000 Volume 18(1), was devoted to popular culture in disaster. These researchers look at how a culture represents the disasters that they have been a part of. After a disaster has struck we often see considerable graffiti, much of which "mocks" the hazard that passed through. For example "Remodeled by Andrew" was found on a nearly destroyed house after Hurricane Andrew had passed through the area. Popular culture can also be seen in merchandized items; for example, after Hurricane Katrina many t-shirts were produced with logos that represented resentment toward FEMA or the belief that looting had been widespread after the event. American culture also tends to remember the anniversaries of the disasters. These dates are usually memorialized for a number of years after the event by people revisiting the site on the day and reconnecting with others and producing some way of remembering that date. It is not known how long such dates will be remembered; after the first 5 years, the tenth anniversary is remembered. Hurricane Andrew did celebrate its 15th anniversary. However, there are usually fewer and fewer people at each succeeding anniversary as the event becomes a memory and people move on with their lives.

The sociological focus on behavior in disasters rather than attitudes has led to considerable understanding about human behavior, even showing that a hazard does not necessarily need to be present in reality for people to perceive its danger. One case in point was the reaction to the Three Mile Island incident in 1979. Response to the incident at

the nuclear power plant was more intense and fearful because of the release of *The China Syndrome* a few weeks prior. The premise of the movie concerned the meltdown of a nuclear power plant including people's reactions to the meltdown and the efforts of authorities to avert the crisis (Wills, 2006). The influence of the media has inevitably become a significant topic of research amongst sociologists concerned with how the public perceive and react to disasters (Scanlon, 2007; Tierney et al., 2006).

Disaster movies have been analyzed by numerous researchers (Wenger et al., 1975; Jones, 1993; Fischer, 1998; Mitchell et al., 2000) for the myths that, invariably, are proven to be false by researchers. For instance, disaster movies tend to show that people will panic when they realize the danger they are in; research shows that panic is very rare. In fact, even though the authority figures in the movies tend to stress the need to wait to inform the public so as not to cause panic, in reality it is very hard to get people to evacuate even when they are asked to do so.

Death tolls are used by the movie industry to provide the extent of the disaster by focusing on high numbers of casualties. However, in reality, since the Galveston Hurricane of 1900 which killed 8,000, death tolls in America have been very low in most disaster situations (Mitchell et al., 2000), until hurricane Katrina in 2005 (Brunkard et al., 2008; Sharkey, 2007). However, even in real news programs, the death statistics reported at the beginning of the event will be drastically overstated. As the days pass, the statistics get substantially lower as more and more people are accounted for. Disaster movies focus on the pre-impact and impact stages of the disaster, and the lives of various characters throughout these stages, showing high energy small events which happen to them so as to keep audience's attention. Little attention is paid to the post-impact and recovery stages of disaster, thus ignoring the lingering consequences of disasters that continue well after the encounter with a hazard. The need for the audience to connect with characters in the movie also places emphasis on certain characteristics within the scene which are unrealistic. For example, the Director of FEMA, or the head of the local emergency management office, single-handedly saving the region from catastrophe as in the movie *Volcano*, or *Category 6*, when in reality he would be directing and coordinating the response and recovery efforts from a secure location.

Some researchers have focused on the news media and their disaster coverage showing that reporters tend to believe the disaster myths too (Scanlon, 2006). Many reporters believe that looting will occur in a disaster and will report either that it is occurring as did happen in hurricane Katrina, as evidenced by footage, or they will report the lack of looting. Interestingly, the perception of "looting" changes with race/ethnicity emphasizing the disparities and prejudices of the population. The two photos shown here were found in the Associated Press a day or two after Hurricane Katrina.

With the advancement in technology, the news media are able to provide coverage from the affected site almost immediately. During hurricanes, reporters actively enter the area where it is most likely to hit and report on the situation. Although this act is an attempt to show how bad the situation is their televised presence often has the reverse effect. People will not evacuate presuming that since the media is there then they can ride it out as well while shaking their heads at the weatherman holding onto to the palm tree with both hands to prevent himself being blown away. The convergence of the media into a disaster zone also puts pressure on local resources which are already stretched thin by the disaster and subsequently increases the risk to emergency workers (Kendra and Wachtendorf, 2003). The rate at which new technology and social media is advancing also means that live action video is now making its way immediately out of the disaster-stricken area. This will have significant impact not only on being able to respond to the populations affected but, hopefully, will also begin to allay some of the disaster myths.

SOLAR FLARES

David H. Boteler
Earth Science Sector, Natural Resources Canada, Ottawa, ON, Canada

Definition

Solar flares are a burst of electromagnetic radiation from the Sun.

Discussion

The first flare was observed in 1859 when Richard Carrington, while making sunspot drawings, saw a sudden brightening. Now, with modern instruments, we know that the burst of radiation from a solar flare lasts from a few minutes to several hours and spans the entire electromagnetic spectrum. The intensity of a flare is classified according to the X-ray flux, F, in the 0.1–0.8-nm [1–8 Å] wavelength range measured on the GOES satellite (see Table 1). The size of a flare is given by the flux value, using the classification letter as a multiplier: For example, a X4.5 flare has a peak flux of 4.5×10^{-4} W m^{-2}.

Solar flares are often thought to be the cause of a wide range of space weather effects. The radiation from solar flares is directly responsible for increased ionization on the dayside of the Earth that interferes with radio communications. However, other effects, such as magnetic storms, are due to associated phenomena like coronal mass ejections. Nevertheless, observations of solar flares continue to be a valuable precursor of such phenomena for space weather forecasting.

Solar Flares, Table 1 Solar flare classification

Class	X-ray flux (W.m^{-2})
X	$F \geq 10^{-4}$
M	$10^{-5} \geq F > 10^{-4}$
C	$10^{-6} \geq F > 10^{-5}$

SOLIFLUCTION

Piotr Migoń
University of Wrocław, Wrocław, Poland

Synonyms

Gelifluction; Soil flow

Definition

Solifluction, literally "soil flow," is a category of shallow mass movement, which affects saturated unconsolidated deposits and results from reduction of internal friction and cohesion due to excess water.

Discussion

Precise definition of solifluction has not been agreed upon, and three views can be found in the literature: (1) solifluction is a laminar flow of soil in any environment, soil saturation being an essential prerequisite; (2) solifluction is a specific cold-climate phenomenon and involves soil flow of water-saturated active layer above the permafrost table. Others call this type of movement "gelifluction" and consider it a variant of solifluction; (3) solifluction is again a cold-climate phenomenon and involves two mechanisms: gelifluction (understood as in (2) above) and slow soil creep due to volume changes imposed by alternating freezing and thawing. In addition, sliding of soil on a frozen substrate is included in solifluction. The final definition (3) is most widely accepted today (Matsuoka, 2001; French, 2007).

Solifluction is usually associated with periglacial environments of high latitudes and high altitudes, particularly with permafrost terrain, and concerns downslope movement of seasonally unfrozen ground of the active layer. The rates of solifluction vary with slope gradient, water content in soil, and climatic conditions. In frigid, polar regions, it occurs at a rate of <5 cm $year^{-1}$, whereas in alpine environments, yearly displacements may exceed 1 m. Solifluction is present on slopes as gentle as $\sim 2°$. The thickness of deposit affected by solifluction is usually <1 m, but

lower hill slopes may carry composite solifluction sheets a few meters thick. Lobes and terraces, ending with distinct risers 0.2–1.5 m high, are landforms indicative of solifluction. However, under more severe climatic conditions rather uniform sheets develop.

Hazards associated with solifluction need to be considered in respect to active and relict solifluction. Active solifluction poses little hazard in the short term, and its negative impacts are easy to mitigate. Insertion of piles into perennially frozen ground to support building foundations or other constructions makes near-surface solifluction practically harmless. More hazardous are relict solifluction sheets and lobes in the former periglacial terrains of Europe or North America. They are often degraded, vegetated, and subdued in appearance, hence not easy to recognize and map. Nevertheless, relict shear planes may be present in solifluction slope deposits, especially if these are clayey, and are capable of reactivation. Slope undercutting or extra load disturbs the state of equilibrium and may lead to renewed sliding or flow, particularly if water content in the soil is high. Examples are known where reactivation of Late Pleistocene solifluction lobes caused considerable engineering problems during road and dam constructions, including the necessity of relocation of structures (Hutchinson, 1991).

SPACE WEATHER

David H. Boteler
Earth Science Sector Natural Resources Canada, Ottawa, ON, Canada

Definition

Space weather is the chain of processes from eruptions on the Sun, their passage through interplanetary space, and the interaction with the Earth's magnetic field that leads to disturbances in the Earth's magnetosphere, ionosphere, and on the ground that represent a hazard to man-made technology and human life.

Introduction

Space weather starts at the Sun. As well as the heat and light that the Sun provides to sustain life on Earth, the Sun occasionally emits bursts of electromagnetic radiation and high-energy particles that impact the Earth. The particles can damage satellite electronics and present a hazard for manned space flight. Disturbances produced in the ionosphere disrupt radio communication and satellite navigation systems, and magnetic disturbances on the ground interfere with aeromagnetic surveys and directional drilling and are a threat to power systems and pipelines.

Space weather processes

A typical space weather event would start with a sunspot group crossing the Sun's disk. Energy buildup associated with the sunspots is released in a solar flare and associated solar energetic particles, and often a coronal mass ejection. The radiation travels at the speed of light and reaches the Earth 8 min later, solar energetic particles travel at a significant fraction of the speed of light, and start arriving an hour later, whereas the particles in coronal mass ejections and high speed streams travel at speeds from 500 to 2,000 km/s and take 1–4 days to travel the 149 million kilometers to Earth. At other times coronal holes, sometimes lasting for months, produce streams of high-speed particles that sweep past the Earth with every solar rotation (Schwenn, 2006).

At the Earth the solar radiation and particles produce effects extending from the space environment down through the ionosphere to the ground. The electromagnetic radiation from solar flares produces extra ionization on the dayside of the Earth. Solar energetic particles are shielded by the Earth's magnetic field (Smart et al., 2006) from entry to the upper atmosphere except at high latitudes where the magnetic field lines are nearly vertical. Particles from coronal mass ejections and high speed streams interact with the Earth's magnetic field causing a worldwide depression of the field strength (a magnetic storm) lasting 1–2 days and short-lived (15–60 min) magnetic excursions (magnetic substorms) at high latitudes. Substorm particles also enter the upper atmosphere creating extra ionization and causing the atoms to emit light (the aurora) (Pulkkinen, 2007).

Magnetic effects

Magnetic disturbances have long been identified by the deflections they cause to compass needles. Modern electronic compasses are still used for navigation and applications like directional drilling where magnetic disturbances can cause errors. Magnetic disturbances also create magnetic field variations that interfere with aeromagnetic surveys.

Magnetic field variations also induce electric fields in the Earth and in electrical conductors at the Earth's surface. The telegraph was the first system using long conductors and magnetically induced voltage created false signals that prevented messages being sent. Following the solar flare observed by Carrington in 1859, the magnetic storm caused worldwide disruption to the operation of the telegraph system (Boteler, 2006). As technology evolved and new cable communication systems were introduced, magnetically induced voltages were found to affect both land cables and undersea cables (Lanzerotti, 2001). Pipelines also experience magnetically induced voltage swings that interfere with corrosion protection of the pipeline.

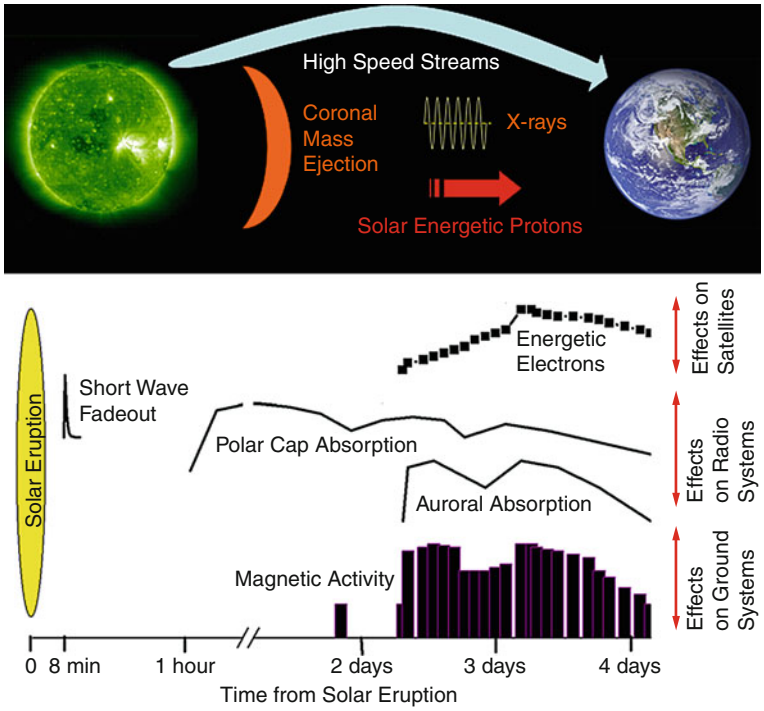
Power transmission networks are another system using long conductors that are exposed to magnetic disturbances. Geomagnetically induced currents (GIC) in transmission lines flow to ground at substations where they interfere with operation of the power transformers (Kappenman, 1996, Pirjola, 2007). Extra harmonics are generated that can cause misoperation of protective relays, increased reactive power demand causes voltage dips, and overheating can damage transformers. In March 1989, a magnetic storm caused widespread power system problems including a blackout in Quebec and transformers burnt out in the USA and UK. Modern power systems are more heavily loaded than in 1989; so, there is concern that a similar size magnetic disturbance could produce widespread power system problems.

Ionospheric effects

The ionosphere affects the propagation of radio waves: both those reflected by the ionosphere and those passing through it. Radio signals travel in straight lines and the curvature of the Earth's surface would restrict radio communication to short distances if it was not for the signals being reflected by the ionosphere. It was the presence of this reflecting layer at the top of the atmosphere that made possible Marconi's transatlantic radio transmissions and all subsequent long-distance high-frequency (HF) radio communication.

Solar illumination of the atmosphere creates the normal ionosphere. This consists of the E and F regions that reflect radio waves and the D region that absorbs radio waves. The amount of reflection or absorption depends on the electron density of the region and the frequency of the radio wave. At high enough frequencies the radio signal passes right through the ionosphere and these frequencies are used for satellite communication and navigation systems.

All phases of a space weather event create ionospheric disturbances that impact radio communications (Goodman, 2005). X rays emitted during solar flares create extra ionization in the dayside D region causing increased absorption and a shortwave fade-out (SWF) of HF radio communications. Solar energetic particles penetrate into the ionosphere at high latitudes, creating polar cap absorption (PCA) that can block HF radio communications for days. During geomagnetic storms, precipitation of auroral particles creates absorption in the auroral zone that sporadically blocks HF radio communication. Disturbances in the E and F regions can also change the reflecting properties of the ionosphere making it difficult for radio operators to know which frequencies to use or making HF communications impossible.



At frequencies above 500 MHz which are used for satellite communications and positioning systems, ionospheric absorption is small, so the signal is not lost; however, signals are slowed going through the ionosphere, so for global navigation satellite systems (GNSS) that rely on signal timing the extra delays can lead to positioning errors during space weather events. Patches of ionization mean that signals may travel different paths to reach a receiver. Destructive and constructive interference between these signals can cause scintillation of the signal at the receiver causing loss of lock of GNSS receivers and loss or degradation of satellite communication links. Because of local characteristics of the ionosphere, scintillation is a particular problem in equatorial and auroral regions.

Space environment effects

The energetic particles in the space environment around the Earth and in interplanetary space can be a hazard to spacecraft and manned spaceflight. In interplanetary space, spacecrafts are directly exposed to the "solar wind" particles streaming from the Sun and the bursts of particles associated with coronal mass ejections. Close to the Earth the geomagnetic field acts as a shield against these particles (Smart et al., 2006), creating a cavity in the solar wind called the magnetosphere. However, inside the magnetosphere, particles magnetically trapped in the radiation belts can be energized to levels where they present a hazard. Satellites in high altitude orbits are exposed to these trapped particles. Satellites in low altitude orbits are below the radiation belts except when they cross the South Atlantic Anomaly, a region of low magnetic field strength that allows the radiation belt particles to come down to lower altitudes.

Satellites are affected by the space environment in a variety of ways (Tribble, 2003). Energetic particles from solar events and in the radiation belts can penetrate the walls of a spacecraft damaging components inside. Sometimes the deposited charge does not cause damage but is enough to change the state of memory levels, leading to false signals known as Single Event Upsets. Energetic electrons can penetrate into the dielectrics of electrical circuits inside the spacecraft. This "deep dielectric charging" can build up to a point where a sudden electrical discharge occurs that damages the satellite electronic systems. These energetic particles can also damage human tissue, so presenting a danger for manned spaceflight, particularly during activities like spacewalks that are outside the shielding of the spacecraft.

Satellites in low earth orbit also experience drag from the upper reaches of the atmosphere. This is something that is routinely taken into account in managing the orbit. However, during geomagnetic storms the particles

Space Weather, Figure 1 Solar eruptions produce electromagnetic and particle radiation which cause disturbances at different times on the Earth that affect a variety of technologies.

deposited into the ionosphere produce extra heating that causes the atmosphere to expand. This causes extra drag on the low altitude satellites. In some cases, this can cause premature de-orbiting of spacecraft: a notable example being when Skylab descended earlier than planned. The connection with space weather was recognized and led to headlines such as "Skylab coming down, sunspots to blame." Thus, space weather can affect satellite operations from interplanetary space all the way down to the top of the atmosphere. Energetic particles penetrating into the atmosphere in polar regions are also being recognized as a possible hazard for aircraft electronics and frequent fliers on high altitude flights.

Mitigation and forecasting

Modern systems, because of greater sophistication or reduced operating margins, are becoming more vulnerable to space weather. Engineering solutions to make systems immune to the problems are difficult or not cost effective. For example, satellite electronics could be protected from energetic particles by adding more shielding to the satellite but the added weight increases the launch costs. With space weather phenomena, like many natural hazards, the more extreme events occur less frequently, so the optimum solution is a careful assessment of the probability of occurrence and a decision made to protect against an event that could reasonably be expected to occur within the lifetime of the system. Where systems cannot be protected special operating procedures are used to put the system into "safe" mode when major space weather events are forecast. Forecasting space weather is a major scientific challenge and is the focus of considerable research work around the world. Operational space weather services are coordinated by the International Space Environment Service. Consult their web site (www.ises-spaceweather.org) for links to the ISES Regional Warning Centres providing space weather services around the world.

Conclusions

Space weather is a natural hazard of the technological age. The hazards originate with disturbances on the Sun that travel through space to impact the Earth. A range of systems are affected: power systems, pipelines, radio communications and satellite positioning systems, and satellites and manned space missions. As society places greater reliance on these systems, there is an increasing requirement for forecasts of space weather so that action can be taken to protect affected systems.

Definition

A storm surge is a rise of water above (1) the predicted astronomical sea tide or (2) a typical lake level. Storm surges occur because of severe hydrometeorological conditions associated with storms and tropical cyclones.

Discussion

Synonym

"Storm tide" refers to a rise of seawater above a reference altitude, thus including the astronomical tide.

Processes involved

Storm surges are primarily caused by:

(a) Reduced atmospheric pressure: This process is known as the "inverse barometric effect," by which a reduction of 1 hPa of pressure causes 1-cm water level elevation in stationary conditions.
(b) Strong winds that may push water coastward, by creating currents that accumulate waters in shallow areas.
(c) Strong waves that create a mean sea level rise as they are breaking (waves setup).

Typically, atmospheric forcing due to pressure and wind dominates for the large continental shelf, whereas wave setup becomes more important for steep submarine slopes.

Storm surges are gravity waves, and are thus affected by the rotation of the Earth:

(d) The Coriolis effect creates an acceleration of water currents to the right in the Northern Hemisphere, thus contributing to sea level rise when the coast is to the right of a storm surge track.

As they hit the coast, storm surge intensity also interacts with:

(e) Boundary water level, including water level in estuaries and coastal swamps and lowlands, often affected by storm precipitations.

While these processes and coastal patterns control the elevation of a timely averaged sea level above astronomical tide, coastal engineers also need to take into account the instantaneous sea level change caused by waves (swash), in order to estimate, e.g., how much water runs on (run-up), or over (overtopping) a natural or man-made protection.

Related hazards

Storm surges can cause: (1) coastal flooding of low-lying areas by simple submersion of the shoreline, dunes overwash, or dikes overflowing; (2) wave impacts on infrastructures, by the collection of debris between them, by scouring (i.e., submersion waters carrying debris behind the coastal protections and destroy their foundations), or, in high latitudes, by the involvement of ice; (3) rapid erosion of the shoreline and damages or destruction of assets or defenses located on eroded areas; and (4) salinization of coastal lowland.

Storm surge impact

Storm surges effects are most damaging when they occur at high tide. Storm surges are considered by NOAA as the most deadly coastal hazard associated to hurricanes: Hurricane Katrina, which affected the New-Orleans in 2005 (see section Cross-references) caused more than 1,800 deaths. More than 300,000 people lost their lives during the Bhola cyclone in 1970 primarily because of the storm surges it caused. With respect to extra-tropical storms, the 1953 North Sea storm caused more than 2,000 deaths in the Netherlands, England, and Belgium, also causing damages to infrastructures in France.

STORMS

Norm Catto
Memorial University of Newfoundland,
St. John's, NL, Canada

Synonyms

Abrupt; Severe weather events

Definition

Types of storms include tropical cyclones (hurricanes, typhoons); mid-latitude cyclones; extratropical storms; thunderstorms (including lightning and hail storms), tornadoes, dust storms, blizzards (snowstorms), and ice storms (verglas).

Tropical cyclones include hurricanes in the Atlantic and eastern Pacific Oceans, typhoons in the western Pacific Ocean and along the coasts of Southeast Asia, and cyclones in the Indian Ocean and along the coasts of Australia. They are responsible for large death tolls in heavily populated, less economically developed countries, particularly in Southeast Asia, Eastern Africa, Central America, and the Caribbean. They are also costly in financial terms. Including indirect and ongoing recovery costs, Hurricane Katrina in 2005 cost the USA in excess of $500 billion.

Mid-latitude cyclones can affect any mid-latitude area between 30° and 70° latitude. Mid-latitude cyclones develop by frontal movement, and can occur at any time of the year. Although many follow the trajectory of the Jet Stream, others do not, moving along the varying frontal systems that exist at the time. They thus differ from tropical cyclones in their location, track direction, and the method of formation. Mid-latitude cyclones can generate winds as strong as tropical cyclones. In coastal areas, they can create storm surges capable of causing damage. Their effects are widespread in interior areas. Because they do not depend on warm water as a source of energy, they do not dissipate as they cross land. In Atlantic Canada and New England (USA), strong autumn and winter mid-latitude cyclones are common. Extratropical storms, which form when weakening hurricanes interact with mid-latitude cyclones and other weather systems, also can cause severe flooding.

Thunderstorms form as unstable, warm, and moist air rapidly rises into colder air and condenses. They are generated by several mechanisms, including convection, frontal activity, and uplift due to orographic effects. In coastal areas, thunderstorms can form when moist air is heated, either over warmer land or over warm ocean waters.

The hazard from lightning strikes largely depends on the number of thunderstorms. In the USA, between 70 and 80 people are killed each year. Lightning strikes cost the insurance industry more than $5 billion annually. In the past 10 years, the value of personal computers destroyed by electrical surges from lightning strikes has exceeded $200 million annually in the USA. Throughout North America, hail causes more than $3 billion in annual damages to cars, roofs, crops, and livestock.

Although tornadoes can occur in several countries, more than 90% are developed in the USA and adjacent southern Canada. Tornadoes are the most significant natural hazard in much of the midwestern United States. However, other areas are not immune. The most deadly tornado in the last 100 years, causing 922 deaths, occurred in Bangladesh in 1969.

Blizzards, ice storms, and other hazards of winter can affect more than one billion people each year. Although winter hazards do not always receive the attention devoted to volcanic eruptions or earthquakes, humans die from exposure and hypothermia every year. For people unaccustomed to winter hazards, a snowfall may come as a profound shock and pose difficulties for citizens and public services.

Hazards posed by storms have been greatly reduced, although not eliminated, by improvements in meteorological forecasting, particularly involving remote sensing. However, storms continue to kill people and cause significant property damage throughout the world.

STRATOVOLCANOES

Shane J. Cronin
Massey University, Palmerston North, New Zealand

Synonyms

Composite volcano; Stratocone

Stratovolcanoes, Figure 1 Mt. Taranaki, New Zealand, 2,518 m above sea level, is a classic stratovolcano with a construction of lava flows and pyroclastic fragmental deposits. Its steep upper slopes are only a few thousand years old, whereas the low outermost slopes contain mass flow and volcanic ash deposits dating back over 200,000 years.

Stratovolcanoes, Figure 2 Mt. St. Helens, Washington State, USA, site of a massive eruption in May 1980 generated when a huge part of the volcano's flank collapsed outward in a debris avalanche, unleashing a supersonic volcanic blast that devastated the surrounding landscape and took over 60 lives. The scar left by the landslide collapse is slowly healing with the growth of a lava dome.

Definition

A volcanic construct, built up into the form of a tall mountain over thousands to hundreds of thousands of years by accumulation of successive layers (=strata) of lava, pyroclastic deposits (from explosive eruptions), and related mass-flow deposits (Davidson and DeSilva, 2000; Schmincke, 2004). In their simplest form, these are conical-shaped mountains with steep upper slopes curving gradually down into low-sloping outer flanks (Figure 1). Older examples may show complex morphologies with irregular edifices being scarred by several generations of partial collapses (Figure 2). Their wide bases pass outward into overlapping fans of volcano-sedimentary deposits that may join to form a radiating ring-plain around the edifice (Cotton, 1944). Stratovolcanoes may vary greatly in volume between 10 and 500 km^3, with surrounding ringplains containing up to 80% of the erupted volume of long-lived examples (Zernack et al., 2009).

Introduction

Stratovolcanoes or composite volcanoes are the most recognizable of volcanic landforms. These distinctive and very high mountains are often picturesque and snow capped. Despite their fairy-tale appearances, stratovolcanoes have a destructive and unpredictable side to their character, matched in violence by few other volcano types. This dark side is well demonstrated by disasters resulting from widely different types and scales of eruptions from these volcanoes around the world. Stratovolcanoes have collectively killed >200,000 people since AD 1783 (Tanguy et al., 1998) and make up eight out of the top-ten killer volcanoes over the twentieth century (Witham, 2005).

Occurrence

Stratovolcanoes are one of the most common volcano types on Earth, with at least 700 recognized as being active (Simkin and Siebert, 1994). Long chains of stratovolcanoes, separated by 50–100 km, occur along volcanic arcs and continental margins. One of the most extensive chains wraps around the entire Pacific Ocean from the Aleutians through the Americas, and from Kamchatka through Southeast Asia, the Southwest Pacific Islands, and into New Zealand. They are common to all zones of tectonic plate subduction and are also formed occasionally in other settings, including intraplate localities (e.g., Nyiragongo, Congo).

Construction and magmatic systems

As their name indicates, stratovolcanoes are composite features, built up gradually from repetitively stacked beds of eruption products that accumulate around a single vent system (Figure 1). These volcanic mountains contain a range of volcanic deposits, including explosively produced pyroclastic fall units (tephra), pyroclastic density current deposits (pyroclastic surge or flow units), along with lava flows, lava domes, and a large range of reworked volcanic deposits (volcaniclastic sediments). The diversity of these eruptive products is characteristic for stratovolcanoes, engendering both variation in the mountain shapes and a bewildering array of volcanic hazard processes. They may also undergo several phases of growth, weathering, collapse, and rebirth, with active vents migrating and occasionally multiple vents developing (Davidson and DeSilva, 2000).

Stratovolcanoes are most commonly produced by andesitic magmas derived from the process of subduction (Gill, 1981). Cold and water-saturated subducted lithospheric crust descends into the Earth's mantle beneath convergent margins, releasing volatiles (mainly water) as temperatures increase. The volatiles rise into the mantle wedge above the subducting slab, promoting its partial melting, and magmas form, accumulate, and rise due to the effects of buoyancy (McKenzie, 1985). Complex assimilation, fractionation, and mixing processes undergo these typically basaltic melts as they rise from the mantle through the crust (e.g., Grove et al., 2002). In general terms, melts often pond at the base of the lithospheric crust, anywhere between 15 and 35 km below the volcano (Annen et al., 2006). Upon further evolution to lower densities, melts from this zone rise and may pond higher within the crust, where they again reach neutral buoyancy, often between 9 and 14 km below the volcano (Carmichael, 2002; Devine et al., 2003). Here magmas continue to fractionate (forming crystals that separate out due to density differences) and assimilate (melt and incorporate) surrounding rock, possibly also mixing with other magma batches (Price et al., 1999). Eruption-triggering processes may involve tectonic motion, injection of further heat/magma from below, and crystallization of rising magma (Blundy et al., 2006). These complex magmatic roots produce a range of erupted compositions, dominantly in the andesitic range. If a volcano mainly erupts low-viscosity magmas, a shield-like form will result from stacked lava flows, whereas high-viscosity magmas generally produce caldera volcanoes or lava dome complexes. The volumes and compositions of andesitic magmas favor explosive eruptions; but these are generally not powerful enough to distribute the bulk of their products very far; hence, they build up around the vent and a composite mountain forms.

Why are stratovolcanoes so hazardous?

There are a number of reasons why stratovolcanoes have repeatedly proven deadly to populations that surround them. First, they typically spend the majority of their life span in periods of dormancy, lasting years, decades, or several centuries. An old adage is that a volcano is ready to strike, once the memory of the last event has faded. Volcanoes with long periods of dormancy slip from public attention, and especially when written records in many parts of the world are <200 years old, many volcanoes are never recognized as being a source of threat (e.g., Mt Pinatubo prior to its 1991 eruption; Newhall and Punongbayan, 1996).

A second cause for stratovolcano-induced disasters is that human populations are naturally drawn to living on and near such structures. Especially during dormant periods, pyroclastic deposits from stratovolcanoes engender extremely fertile, friable, and well-drained soils. The edifices also host high-quality and plentiful water supplies and may have other economic value in terms of building aggregate, hot springs, mineral deposits, and forest/wildlife resources (Schmincke, 2004).

Stratovolcanoes, Figure 3 Gunung Merapi, Central Java, Indonesia, in the aftermath of the 2006 eruption where the summit lava dome partially collapsed down the southern volcano flanks, generating a dense pyroclastic density current that filled the Kali Gendol valley, spilling out to devastate the village in this area, 5 km from the summit.

The third major risk factor of stratovolcanoes is their unpredictability. In some cases, where magma flux is high, this variability is limited and eruption magnitudes and types are relatively uniform for long periods (e.g., historic activity at Merapi Volcano, Java, Indonesia; Voight et al., 2000; Figure 3). However, typical variations in the complex magma generation mechanisms throughout a volcano's lifespan, along with environmental factors, including the height, saturation, and stability of the volcanic edifice, combine to produce a huge array in magnitude, composition, and style of eruptions from any single stratovolcano (e.g., Vesuvius; Andronico and Cioni, 2002). This means that populations preparing for the next eruption based only on the last event could be in for an unfortunate surprise.

The final major basis for society's vulnerability to stratovolcanoes is their height and inherent instability. Even small eruptions of these volcanoes are capable of generating destructive mass flows, because they have so much gravitational potential energy when generated 2–4 km above communities at risk. In addition, because stratovolcanoes are formed from a variety of solid (lava) and loose strata, the latter layers are easily saturated and weakened. With increasing height and hydrothermal alteration, mountain volcanoes become very unstable. In addition, snow and glacier ice caps, along with crater lakes, provide ready sources of water to rapidly magnify mass flows (e.g., Cronin et al., 1996; Figure 4). Small magmatic intrusions, earthquakes, and major rainstorms may readily trigger massive collapses, generating lahars and debris avalanches that obliterate everything in their paths with little warning (e.g., Lowe et al., 1986).

Stratovolcanoes, Figure 4 Ruapehu Volcano, New Zealand, a typical snow-capped stratovolcano showing also a crater lake over its active vent. Explosions through this lake frequently generate devastating lahars that build up with snow and sediment to flow over 200 km to the sea. The black material surrounding the lake and forming the stripe down the glacier is the remains of pyroclastic density currents and lahars from the September 2007 eruption.

Volcanic processes, hazard impacts, and hazard evaluation at stratovolcanoes

Hazard maps for stratovolcanoes are often complex and contain a range of diverse information due to the large range in volcanic processes associated with such volcanoes. The main threats posed by stratovolcanoes include:

Pyroclastic fall (ashfall or tephra fall): Stratovolcanoes typically produce eruptions that are intermediate in magnitude between caldera volcanoes and scoria cones, involving <1 km^3 of magma and typically only a tenth to a hundredth of this. Despite their moderate volume, stratovolcanoes may produce sustained and unstable eruption plumes of up to 35-km high. Being such high mountains, their eruption columns may efficiently reach high into the atmosphere and wind typically disperses ash over several hundred square kilometers (Carey and Sparks, 1986). Ashfall impacts are typically defined via mapping the dispersal, thickness, and grain size of products of past eruptions and determining the prevailing wind directions and strength conditions that may affect future eruptions (e.g., Pyle, 1989). Hazard zones may be based on this mapping along with numerical simulations that combine particle settling and wind/climate models (Bonadonna, 2006). These zones are normally ellipsoidal, stretched along the main axis of ash dispersal. Ashfalls can be heavy enough to cause building collapse and smother crops. Even light falls may disrupt air and road transport, electricity lines and cause human and animal health problems (Cronin et al., 2003). Under ashfall, visibility is extremely low and the ash is a hard, abrasive, and an extreme irritant to breathing. Adsorbed volcanic gases commonly adhere to volcanic ash, including some poisonous compounds, such as sulfuric, hydrochloric, and hydrofluoric acid (Hansell et al., 2006).

Pyroclastic density currents: They are rapidly moving hot mixtures of volcanic gas and particles (Branney and Kokelaar, 2002), generated by a number of mechanisms on andesitic stratovolcanoes. These are by far the greatest cause of casualties from volcanic eruptions (Witham, 2005). Due to erupting magmas of lower-viscosity and higher density than rhyolitic eruptions, andesitic eruption columns are often less stable, with frequent partial collapses generating localized pyroclastic density currents. Even small eruption columns that collapse on the upper volcano flanks may efficiently travel long distances as they descend the steep volcanic slopes (Lacroix, 1904). Further cascading hazards of huge potential consequence are generated when pyroclastic flows travel across snow- and glacier-capped areas. Andesitic pyroclastic flows are also often generated from the collapse or explosion of lava domes (Abdurachman et al., 2000). These viscous bodies of magma ooze slowly out at the summit or upper flanks of many andesitic volcanoes, becoming very unstable as they grow and build up internal magmatic gas pressure (Voight and Elsworth, 2000). These types of pyroclastic flow hug the ground and remain concentrated in the valleys over a runout of 5–15 km from source. Pyroclastic density currents sweep away, bury, or burn most objects in their paths, with the famous AD79 eruption of Vesuvius claiming most of its victims with a combination of repeated pyroclastic flows and heavy ashfalls (Sigurdsson et al., 1982). Mont Peleé in Martinique extinguished 29,000 lives in a matter of hours in May 1902 with a series of pyroclastic flows and directed blasts that destroyed the town of St Pierre, eerily leaving most of the buildings standing (Lacroix, 1904). Typically, pyroclastic flow hazard zones are drawn concentrically around a central volcanic edifice, although recognizing that these flows are strongly topographically controlled on stratovolcanoes, higher-level hazard zones may be concentrated along major valley systems.

Directed blasts: These are a special type of pyroclastic density current that are characterized by extremely highly energetic explosions that expel country rock and fresh pyroclasts radially at supersonic velocities. They are usually generated when there is a major collapse of a volcano's flank or large lava dome (Siebert et al., 1987). At Mt. St. Helens in 1980, the flank collapse and subsequent blast were among the most violent natural events that modern volcanologists have ever witnessed. These swept over forests in an area of 600 km^2, killing over 60 people and tossing heavy machinery around like children's toys (Lipman and Mullineaux, 1981).

Lahars: These fast-flowing mixtures of water and rock debris (also called mudflows, debris flows, and hyperconcentrated flows) are ubiquitous to stratovolcanoes and are a natural consequence of eruptions at high elevations where there is often snow cover, crater lakes, or simply just unstable and saturated lithologies (Vallance, 2000).

Appearing like flowing concrete with huge boulders, lahars extend the deadly range of stratovolcanoes well beyond that typically affected by any other process except ashfall. They can flow for so long in cases (>300 km) that people in the river valleys where lahars are focused may be taken by surprise without knowing even if the volcano has erupted (Neall, 1996). This tragic circumstance occurred in the town of Amero in Colombia, where 23,000 people were swept away and buried in their houses overnight by huge lahars (Voight, 1990). The lahars were produced 73 km away by small pyroclastic flows traveling across a glacier on the summit of Nevado del Ruiz Volcano. The eruption was so small, and the alarms too late for the residents to be warned of these huge flows of mud and rock. Lahars also occur after major eruptions as rainstorms trigger sudden remobilization of loose and unstable pyroclastic deposits high on the flanks of mountain volcanoes or if crater lakes break out from their impoundments (Manville and Cronin, 2007). Lahars have killed thousands of people from eruptions of Mts. Merapi, Kelut, and Semeru in Indonesia, along with devastating large areas of the Philippines following the 1991 eruption of Mt. Pinatubo (Newhall and Punongbayan, 1996).

Debris avalanches: These are major "dry" collapses of volcanic slopes, usually resulting from the failure of unstable flank areas of the edifice. These sweep aside and bury everything in their path and may change the landscape irrevocably, by leaving behind major amphitheater like holes and scarps on the edifice and filling valleys and lowland areas with deposits tens of meters thick (Siebert, 1996). In extreme cases, over half the volume of a stratovolcano may collapse and cover hundreds of square kilometers with several cubic kilometers of deposit. The fact that stratovolcanoes are built so high with both strong (lava) and weak (volcaniclastic and pyroclastic breccias) strata making up their flanks makes them vulnerable to collapse. In most areas of the world, these edifices also act like large sponges, soaking up rainwater that at times can be heated by geothermal activity below to gradually soften and weaken the volcano's core. Once an edifice becomes too high, intrusion of new magma into it, changes in the hydrothermal system, major earthquakes, or even increasing water pressure within it may trigger catastrophic failure and debris avalanche (McGuire, 2003). The propensity to collapse depends on the dominant lithology of the strata, with some pyroclastic-dominated volcanoes, such as Mt. Taranaki growing and collapsing more than 12 times over a lifespan of >200,000 years (Zernack et al., 2009). The 1980 catastrophic eruption of Mt. St. Helens began with a "small" debris avalanche of only 1 km^3 (Lipman and Mullineaux, 1981).

Tsunami: While these great ocean waves are most commonly generated by large submarine earthquakes, several have been generated by pyroclastic flows, debris avalanches, and major collapses of stratovolcanoes into the sea. Collapse of the Unzen-Dake volcano in Japan in 1792 killed over 6,000 people when the avalanche entered the ocean to generate huge tsunami (Siebert et al., 1987). Similarly, during the massive 1883 Krakatau eruption, part of the stratovolcano collapsed into the sea and a large caldera formed below it, generating huge pyroclastic flows and extremely deadly tsunami that killed over 36,000 people in the surrounding region (Simkin and Fiske, 1983).

Monitoring at stratovolcanoes

A large range of geophysical, remote sensing, and geochemical techniques are employed at stratovolcanoes to detect the signs of unrest preceding eruptions (e.g., Scarpa and Tilling, 1996; Carn and Oppenheimer, 2000; Bonforte et al., 2007; Scott and Travers, 2009). Unfortunately, they are also among the most challenging volcanoes to monitor due to their height, snow cover, and the extreme climates of their upper slopes. The rise of magma below and into stratovolcanoes generates earthquake, gravity, electromagnetic, geodetic, and thermal changes. Hence, the slopes of these edifices are monitored by tilt meters, stationary satellite global-positioning systems, and other surveying techniques to detect swelling of the flanks, such as that preceding the catastrophic Mt. St. Helens eruption. If crater lakes or hot springs are present, temperature and chemical records are carried out. Once unrest is determined, the detection and measurement of gas released from the volcano (especially SO_2) via satellite or ground-based measurements is normally the most reliable means of warning for an imminent eruption (e.g., Lipman and Mullineaux, 1981; Newhall and Punongbayan, 1996).

Current investigations in stratovolcano hazards

Hazards research on stratovolcanoes has historically started with the documentation of past events in order to develop the most rigorous forecast of potential hazard scenarios for the future, such as what was carried out before the major 1980 eruption of Mt. St. Helens (e.g., Crandell and Mullineaux, 1978). The key danger factors for stratovolcanoes can be lessened if they are treated as real hazard sources during dormant periods. This depends on accurate determinations of the length of dormancy periods and developing probabilistic forecasts of scale and types of future eruptions (e.g., Turner et al., 2008). To this end research is ongoing to integrate the latest geochemically based models of magma generation, storage, and ascent processes with eruption outcomes. By combining these theoretical models with geophysical methods for determining rise of magma prior to eruption at stratovolcanoes (e.g., Curilem et al., 2009), more precise forecasts on the likely nature of volcanic eruptions can be made. Several research groups are also working on ways of treating missing data in geological records and developing methods to apply the histories of well-known volcanoes to improving forecasts at those with few known historic or well-dated prehistoric event records. Other areas of ongoing research include the development of numerical models and forecasts of the potential areas of eruption impact

(e.g., Procter et al., 2010). By probabilistically determining the specific sectors of a stratovolcano that may be affected by mass flows and the likelihood and severity of ashfalls, warning and community hazard preparations can be made more effective.

Summary

Stratovolcanoes are the typical snow-capped mountains of fairy tales. They are also the unpredictable agents of destruction that would not be out of place in nightmares. Many historical eruptions from such volcanoes have led to significant casualties and societal disruption from a large range of volcanic processes. Their danger lies not only in their unpredictable eruption processes, but also because they attract population growth nearby due to associated fertile soils and excellent water supplies. All the while, these volcanoes lull surrounding communities into a false sense of security with long periods of dormancy. Research into the volcanic histories, underlying magmatic processes, and statistics is helping to develop more effective hazard mapping and management strategies for these, the most common volcano type on Earth.

STRUCTURAL DAMAGE CAUSED BY EARTHQUAKES

Murat Saatcioglu
University of Ottawa, Ottawa, ON, Canada

Definitions

Drift (*Drift Ratio*). Horizontal displacement of a building, story level, or vertical element divided by respective height.
Inelastic deformability. Ability to deform in the inelastic range of deformations without significant strength decay (analogous to ductility).
Spalling. Crushing or separation of exterior segments of concrete in compression, usually in cover concrete of structural elements.
Yield. Deformation level beyond which the rate of deformations increase rapidly under very little increase in force.

Introduction

Earthquakes may cause structural and nonstructural damage during seismic excitations. Structural damage consists of distress induced in structural components of lateral and gravity-load-resisting systems, such as beams, columns, load-bearing walls, and shear walls, as well as horizontal diaphragms, such as slabs and roofs.

Seismic damage in structures is caused either by lack of sufficient strength or lack of inelastic deformability. Lack of strength is associated with insufficient member size, material strength, and/or reinforcement against seismic forces. It often results in damage to the critical regions of structures under different types of stresses. The lack of strength may also be attributed to the instability of members, which may be triggered by local or global buckling, or lack of adequate anchorage, connection, and continuity between the adjoining members. Seismic force demands in such structures are higher than the structural capacities provided in design and/or construction, imposing high inelastic deformation demands. Once the force capacity is exceeded, those structures that do not have the ability to deform in the inelastic range of deformations may suffer severe seismic damage. The ability to develop inelastic deformations without significant strength decay is referred to as "ductility" or "inelastic deformability," and it is often expressed in the form of a ductility ratio (maximum inelastic deformation divided by deformation at yield). Brittle construction materials, such as adobe, unreinforced masonry, or concrete without seismic detailing, do not have sufficient ductility against seismic forces. Well-designed and detailed reinforced concrete and steel

structures tend to perform in a ductile manner and dissipate seismic-induced energy, reducing vulnerability against earthquake damage. Lack of strength and/or deformability creates seismically deficient structures that often suffer significant damage during strong earthquakes.

Seismic demands on structures are associated with seismic hazards (magnitude, distance, and characteristics of earthquake), soil conditions, and structural layout (including structural mass and stiffness and associated dynamic characteristics of the structure). Irregularities in structures tend to increase seismic force and deformation demands. Vertical and horizontal discontinuities in buildings, asymmetry in floor plans, and especially the eccentricity between the centers of rigidity and mass generating torsional effects, increase seismic demands significantly, resulting in seismic damage. Seismic demands are also dictated by the intimate relationship that exists between the dynamic characteristics of earthquake excitation and those of the structure. High-frequency ground motions tend to excite low-rise buildings, which tend to have short natural periods (high frequencies), increasing structural demands. Inelasticity in a structure reduces stiffness and elongates structural period, which may reduce seismic demands, as the period of the structure moves away from the period of excitation. Therefore, ductility on a structural system also helps reduce seismic demands and associated damage.

Typical structural damage in buildings caused by earthquakes

Earthquake reconnaissance investigations after past earthquakes show a pattern of seismic damage in different types of structures (Saatcioglu and Bruneau, 1993; Mitchell et al., 1995a, b; Saatcioglu et al., 2001, 2006; Gillies et al., 2001). Seismic-force-resisting systems that form the majority of building inventory worldwide consists of; (1) adobe and masonry buildings, (2) reinforced concrete buildings, (3) structural steel systems, and (4) timber construction.

Adobe and masonry buildings

Structures built using brittle construction materials, such as unreinforced masonry and adobe units, experience essentially elastic behavior until they fail in a brittle manner. These types of structures do not possess the required ductility and energy dissipation capacity. Figures 1 and 2 illustrate typical failures of adobe and masonry buildings. A common use of unreinforced masonry in building construction includes infill panels as nonstructural elements in other lateral-force-resisting systems. Though used as nonstructural elements, during structural response, these walls may interact with the enclosing frame. In spite of their brittle characteristics, unreinforced masonry infill walls may provide lateral bracing to the enclosing frame, controlling lateral drift and reducing structural and nonstructural damage until their elastic limit is exceeded, depending on how well they are integrated with the

Structural Damage Caused by Earthquakes, Figure 1 Collapse of adobe buildings in Talca, Chile, after the 2010 Earthquake.

structure, their strength, and the duration of earthquake. For older buildings with sufficiently high wall-to-floor area ratios, especially in regions of the world where masonry walls are used as partition walls, these walls provide significant lateral bracing and damage control to otherwise seismically deficient structural systems. Figure 2b illustrates an apartment building located in an area that suffered significant damage during the 1999 Kocaeli Earthquake in Turkey. The building performed reasonably well due to the high wall-to-floor area ratio, whereas many other nearby buildings suffered partial or full collapses. Another building during the same earthquake, shown in Figure 2c, with a smaller amount of masonry infill wall only around the perimeter, suffered complete loss of masonry, though the nonductile framing system survived without structural damage. This could be explained by the duration of strong ground shakings that was not long enough to damage the frame beyond the failure of masonry and the elongation of building period which may have reduced seismic forces. In cases where the masonry walls are not able to sustain seismic forces during the full duration of earthquake and the structural system does not have sufficient inelastic deformability, structural collapse may occur as shown in Figure 2d. In-plane damage in masonry walls is typically caused by excessive diagonal tension, resulting in associated diagonal cracking. This is illustrated in Figure 2e, f. The same shear forces also produce diagonal compressive stresses, sometimes crushing masonry units along wall diagonals. When the ground shaking is significant in a direction perpendicular to the plane of the wall, out-of plane failures may develop. This type of failure occurs at different levels of severity, which ranges between the dislocations of a few masonry units and partial or complete collapse of the wall panel, posing significant threat to life safety. Figure 2c shows out-of plane failure of the entire exterior masonry enclosure of a frame building.

Reinforced concrete buildings

Damage to reinforced concrete frames occurs in critical regions that are often located at the ends of flexure-dominant members where plastic hinges may form, in beam-column connections, and shear deficient regions of elements. An important parameter that affects damage-control in potential plastic hinge regions of reinforced-concrete elements is the confinement of compression

concrete by closely placed and properly designed transverse reinforcement. The confinement reinforcement overcomes tendency of concrete to expand laterally when subjected to axial compression. This in turn prevents the crushing of concrete, while improving ductility. Compression elements such as columns and walls, which are often responsible for overall strength and stability of the entire structural system, benefit tremendously from concrete confinement. Confinement reinforcement has to be placed with due considerations given to the spacing and detailing requirements of current building codes. Figure 3 shows examples of column damage caused by lack of concrete confinement. Such column damage is especially common in soft stories where deformation demands become very high, as illustrated in Figure 3.

Lack of sufficient transverse reinforcement in reinforced concrete structural elements also reduces shear capacity substantially. In the absence of sufficient shear reinforcement, the degradation of shear transfer mechanism in concrete under reversed cyclic loading leads to

Structural Damage Caused by Earthquakes, Figure 3 Lack of sufficient confinement reinforcement in columns. a brittle shear failure that takes place along an inclined shear plane. This is illustrated in Figure 4. Sometimes, shear failures may be caused by diagonal compression, resulting in the crushing of concrete. Shear stresses may be critical in plastic hinge regions of flexure dominant members due to the deterioration of concrete in these heavily stressed regions. Furthermore, some elements, though designed as predominantly flexural members, may experience shear distress because of the amplification of shear stresses associated with reduced shear spans resulting from the presence of unintentional lateral supports. A nonstructural wall placed adjacent to a column around a window opening is a good example of an unintentional reduction in shear span, resulting in a "short" or "captive" column. Such interference of a nonstructural element is often not considered in

Structural Damage Caused by Earthquakes, Figure 4 (Continued)

structural design. These columns are notorious for suffering shear damage during seismic response. Examples of shear damage in captive columns are included in Figure 4c through Figure 4f.

Beam-column joints of reinforced concrete frames are another region where shear stress reversals take place during an earthquake. Joint shear is induced by the flexural action in attached beams, coupled with shear forces transferred from the columns. Joints without adequate shear reinforcement may be damaged, undermining the integrity of the entire framing system. Figure 5 depicts joint damage observed in previous earthquakes. Furthermore, a good seismic design practice calls for strong columns and weak beams at each joint. This promotes flexural hinging in beams for the dissipation of seismic energy while protecting the columns from damage. Strong beams and weak columns force the plastic hinges to occur in the columns, and may result in the collapse of the entire structural system in a manner that is often referred to as "pan caking." Figure 6 shows examples of structural damage and building collapse resulting from the use of strong beams and weak columns.

It is always a good practice to use a regular structural system, without vertical and plan irregularities. Any sudden change in strength and stiffness of a building along its height, as well as asymmetrical floor layout with potentials for torsional effects result in increased deformation demands on elements. Figure 7 shows damage induced in reinforced concrete buildings due to vertical and horizontal irregularities.

One of the best structural systems used in buildings against earthquakes is a shear wall system. Shear walls provide strength, stiffness, and ductility to the building, which are the qualities required during seismic response. Because shear walls tend to be very rigid as compared to the accompanying frames, they tend to attract a major portion of the total seismic force. Though shear walls generally perform well under seismic forces, they may develop diagonal tension and/or diagonal compression failures if not designed properly. Figure 8 illustrates seismic damage observed in reinforced concrete shear walls. These walls typically possess high flexural capacities because of the high internal lever arm associated with their geometry. However, most older shear walls lack boundary elements containing properly tied concentration of longitudinal reinforcement. These walls may suffer from the buckling of compression bars, as well as the crushing of unconfined concrete.

Structural steel systems

Steel structures generally perform well during earthquakes. This is attributed to the relatively low structural mass that exists in steel systems, compared with concrete and masonry structures, as well as the inherent ductility of steel as a material. Therefore, moment-resisting steel frames and braced frames are used successfully in

Structural Damage Caused by Earthquakes, Figure 5 Damage in beam-column joints. (**a**) Joint damage in a frame building in Banda Aceh, Indonesia during the 2004 South East Asian Earthquake. (**b**) Joint damage in a frame building in Banda Aceh, Indonesia during the 2004 South East Asian Earthquake. (**c**) Joint failure during the 1999 Kocaeli Earthquake in Turkey. (**d**) Collapse of a reinforced concrete frame building triggered by joint failures during the 1999 Kocaeli Earthquake in Turkey.

earthquake-prone areas. Structural damage in steel structures tend to be limited to the buckling of light steel braces and inadequate connections. The 1994 Northridge earthquake exposed one of the deficiencies in welded connections of steel structures. Over 200 buildings during this earthquake alone suffered weld ruptures, mostly at the beam-column connections where full penetration welds were used, resulting in a change in the practice.

Timber construction

Timber structures generally have superior performance during earthquakes. Low structural mass inherent to these structures limit seismic-induced inertia forces, while the nailed connections promote deformability. Single-family timber homes and multistory timber buildings have had a successful history of seismic performance, except for their brittle nonstructural components. A commonly observed seismic damage in such structures results from lack of proper anchorage to adjoining stiff and rigid elements, as in the case of single-family houses built on concrete foundations.

Seismic damage in bridges

Previous earthquakes indicate that bridges, as essential components of the transportation infrastructure, can be

Structural Damage Caused by Earthquakes, Figure 6 Strong beam-weak column joints resulting in damage during previous earthquakes. (**a**) Strong beam-weak column resulting in column hinging. (**b**) Total collapse of a frame building due to the use of strong beams and weak columns during the 1999 Kocaeli Earthquake. (**c**) Use of strong beams and weak columns, resulting in partial collapse of a shopping centre in Banda Aceh Indonesia during the 2004 Earthquake.

vulnerable to seismic damage. Bridges are simple structures that are comprised of a support system that consists of abutments and piers, and a bridge superstructure that consists of either simply supported single or multiple-span girders, or continuous girders supporting a bridge deck. Two types of seismic damage are common in bridges: (1) support failures, and (2) unseating and instability of bridge superstructure.

Bridge supports consist of bridge piers and abutments. Bridge piers with older concrete columns often do not have sufficient transverse reinforcement. This results in lack of shear capacity and flexural deformability. Figure 9 illustrates various bridge column failures observed during past earthquakes. Short and stubby shear dominant columns attract high shear force reversals and suffer from diagonal tension failures in the absence of adequate transverse reinforcement. Long and flexure-dominant columns develop plastic hinges at member ends, and fail through the crushing of concrete if the core concrete is not confined by sufficient confinement reinforcement.

Structural Damage Caused by Earthquakes, Figure 7 Effects of vertical and horizontal irregularities on seismic damage. (**a**) Vertical irregularity in a multi-storey building in Concepcion, Chile. (**b**) Front view of building in (**a**) that suffered damage at locations of sudden strength and stiffness change during the 2010 Earthquake. (**d**) Close-up view of column damage in building in (**c**) Photo by V. Bertero.

Bridge abutments are vulnerable against soil instability. Vertical, horizontal, and rotational movements and settlements of abutments during seismic excitations result in the separation of superstructure from the road surface, leading to the unseating of bridge girders. Similarly, excessive deformations and movements in bridge piers and columns may result in the unseating of bridge girders, causing the collapse of bridge superstructure. Figure 10 illustrates examples of seismic damage associated with support movements and unseating of bridge girders.

Building performance as affected by seismic damage

Post-earthquake use and occupancy of a structure is dependent on the level of damage sustained during the earthquake. Some buildings can be occupied immediately after the earthquake whereas others need to be repaired and strengthened before they can be used, and yet some others may have to be condemned for demolition. Different types of structures have different requirements for their functionality after a seismic event, that is, bridges must be passable with some minimum load, liquid containers must not leak and pose safety and environmental threats, transmission towers should maintain safe transmission capabilities, etc. While different structures have different performance requirements and may have to be assessed differently for post-earthquake use, building structures may be assessed on the basis of a commonly accepted performance criteria developed by the Federal Emergency Agency (FEMA) of the USA (FEMA 273, 1997; FEMA 356,

Structural Damage Caused by Earthquakes, Figure 8 Damage to shear walls. (**a**) Sliding shear damage in a structural wall in Santiago, Chile after the 2010 Earthquake. (**b**) Close-up view of structural wall in (**a**). (**c**) Shear wall damage during the 1999 Kocaeli Earthquake.

2000; ASCE 41-06, 2007) for seismic retrofit of buildings. These criteria may be adapted for post-earthquake assessment of buildings as presented below.

Structural damage associated with operational level of performance

This level of performance reflects very light overall damage. Structural elements essentially remain elastic with some minor hairline cracks. They retain their original strength and stiffness and do not experience permanent drift. Buildings demonstrating these characteristics can continue operation during and after an earthquake as expected from post-disaster buildings such as hospitals, and police and fire stations.

Structural damage associated with immediate occupancy performance level

This level of performance describes post-earthquake damage where the building remains safe to be reoccupied. The primary lateral-force- and gravity-load-resisting systems

Structural Damage Caused by Earthquakes, Figure 9 Bridge column damage observed during previous earthquakes. (**a**) Lack of confinement reinforcement and resulting column damage during the 1971 San Fernando Earthquake (Photo by V. Bertero). (**b**) Lack of confinement reinforcement in a bridge column that suffered damage during the 1999 Northridge Earthquake. (**c**) Bridge column shear failure during the 1995 Kobe Earthquake. retain almost their entire pre-earthquake design strength with light damage. Some minor structural repairs may be appropriate, though these can be done while the building is occupied.

Structural damage associated with life safety performance level

Life Safety level indicates a post-earthquake damage state in which significant damage to the structure has occurred, even though some margin of safety remains against partial or total structural collapse. Some structural elements and components may be severely damaged, resulting in injuries. However, the overall risk of life-threatening injury due to such damage is expected to be low. Some residual strength and stiffness is left in all stories. Gravity-load-carrying elements continue fulfilling their functions. Extensive damage is anticipated in beams, with hinge formation in ductile elements. Unreinforced masonry infill walls experience extensive cracking and some crushing of masonry units is expected. The structure requires a thorough structural evaluation before deciding whether it can be repaired and reused.

(**b**) Close-up view of the seat width for the bridge in (**a**). (**c**) Unseating of Xiao Yu Dong Bridge during the 2008 Wenchuan Earthquake in China. (**d**) Unseating of a bridge in Santiago, Chile during the 2010 Earthquake. (**e**) Unseating of bridge segments during the 1999 Northridge Earthquake. (**f**) Unseating of a bridge during the 2010 Chile Earthquake.

Structural damage associated with collapse prevention performance level

This level of performance indicates that the building is on the verge of partial or total collapse as a result of earthquake damage. Substantial damage to structural elements is expected, potentially accompanied by significant strength and stiffness degradation of the lateral-load-resisting system. Large permanent lateral deformations

of the structure and limited degradation of the vertical-load-carrying capacity are expected. However, the gravity-load-resisting system must continue carrying its gravity load demands. The structure is not repairable and not safe to reoccupy.

Definitions

Base isolation (device). A device used to isolate structures from earthquake motions.
Beam. Horizontal structural element that usually supports the floor or roof slab system.
Bracing element. Structural element that provides lateral support to increase stiffness and reduce deformations, while strengthening the structure.
Column. Vertical structural element that supports the attached beams while transferring loads to foundation.
Confinement. Containment of compression concrete in a properly designed steel cage of a structural element for improved strength and inelastic deformability.
Damping. Any effect that gradually reduces vibration amplitude or motion.
Damper. A device that introduces damping.
Drift. Horizontal displacement of a building, storey level, or vertical element divided by the respective height.
Ductility. Ability to deform in the inelastic range of deformations without a significant loss of strength.
Energy dissipation (device or mechanism). A device or mechanism that dissipates seismic-induced energy by transforming it to another form of energy, usually to inelastic strain energy.
FRP. Fiber reinforced polymer composite material that consists of carbon, glass, or aramid fibers in a polymer-based (usually epoxy) matrix used to strengthen/retrofit structural or nonstructural elements.
Inelastic deformability. Ability to deform in the inelastic range of deformations without significant strength decay (analogous to ductility).
Jacket. Enclosure around a member (usually column) that has sufficient strength and stiffness to enhance the performance of the member.
Retrofit. Improvement/rehabilitation introduced to enhance the performance of a structure, structural element, or nonstructural element.
Shear wall. Vertical element that is intended to resist lateral forces in the plane of the wall.
Slab. Horizontal structural element to serve as building floor or ceiling, or bridge deck.

Structure. An assembly of elements put together to carry or resist externally applied or internally generated loads and forces.
Structural element. A component of a structure that resists stresses induced by applied loads/forces.
Nonstructural element. An element designed to fulfill certain functional requirement, but not intended to carry or resist stresses induced by loads/forces.
Subassembly. A combination of structural components that are usually connected (e.g., beam-column subassembly).
Unseating of bridge girder. Sliding off of a bridge girder from its support due to seismic movement.
Wall. Vertical structural element that is designed primarily for vertical load (load-bearing wall), or primarily for lateral load (shear wall).
Yield. Deformation level beyond which the rate of deformations increase rapidly under very little increase in force.

Introduction

A large proportion of existing infrastructure worldwide consists of seismically deficient structural systems. These structures often perform poorly during strong earthquakes. The majority of buildings that were built prior to the enactment of modern seismic codes of 1970s, as well as those built more recently but located in areas where code enforcement is not ensured, fall in this category. Seismic design practices for bridges have a more recent history, leaving the majority of bridge infrastructure vulnerable to seismic damage. These structures constitute significant seismic risk, especially in large metropolitan centers. Because it is economically not feasible to replace seismically vulnerable infrastructure with those conforming to modern codes and standards, seismic retrofitting remains to be a viable structural mitigation strategy against earthquake hazards.

Seismic deficiency in a structural system occurs either due to lack of adequate strength or inelastic deformability (ductility). Individual elements, their connections, or assemblies may not have sufficient strength to resist seismic forces. These structures may exceed their elastic design capacities in critical regions, and may experience local or global structural damage, sometimes leading to partial or total structural collapse. Structures forced to experience inelastic deformations can withstand their inelastic deformation demands only if they are designed and detailed to have adequate seismic deformation capacity. Seismic-induced energy in such structures may be dissipated through the formation of plastic hinges. Most seismically deficient structures lack both strength and inelastic deformability. Non-ductile structures are especially prone to sudden and brittle failures during strong earthquakes. Lateral drift control protects brittle elements and reduces seismic damage. Structures with adequate lateral bracing perform well while ensuring structural stability and survivability of brittle elements.

Retrofitting of seismically deficient structures is implemented either at the system or component level, depending on the nature of seismic deficiency. If the entire structural system consists of brittle elements with strength deficiency, it may be more feasible to implement seismic retrofitting at the system level, and implement global structural strengthening and bracing strategy. This type of retrofit ensures sufficient strength against seismic forces, while ensuring elastic or near-elastic response, preventing damage associated with lack of inelastic deformability. If the structure suffers seismic deficiency in an element or group of elements, it may be possible to strengthen these elements locally while also potentially improving their inelastic deformability for ductile response.

Structural mitigation at the system level

Structures that have a large number of seismically deficient non-ductile elements are good candidates for retrofits at the system level. This retrofit strategy includes lateral bracing and strengthening, base isolation, passive and semi-active supplementary damping devices, and active energy dissipation devices and force control methods, all of which aim to reduce seismic demands on the entire structural system. Interventions at the system level can be categorized into three different groups: (a) passive retrofit techniques, (b) semi-active techniques, and (c) active control systems. Adding shear-walls, braces, or installing base-isolation systems or passive dampers form examples of passive retrofit methods. Semi-active control methods involve the installation of a central processing unit that can adjust the properties of the structure according to the nature of the earthquake excitation. Different types of controllable dampers fall under this category. Active control systems involve energy dissipation devices that are revised and repositioned in real time based on measured seismic response, or apply corrective control forces directly on the structure to oppose the seismic action, following a control algorithm. This method brings in an external source of energy into the system to derive the control mechanism (often in the form of hydraulic or electromechanical actuators). It is highly sensitive to time lags, but if utilized properly, offers a great potential, once fully developed.

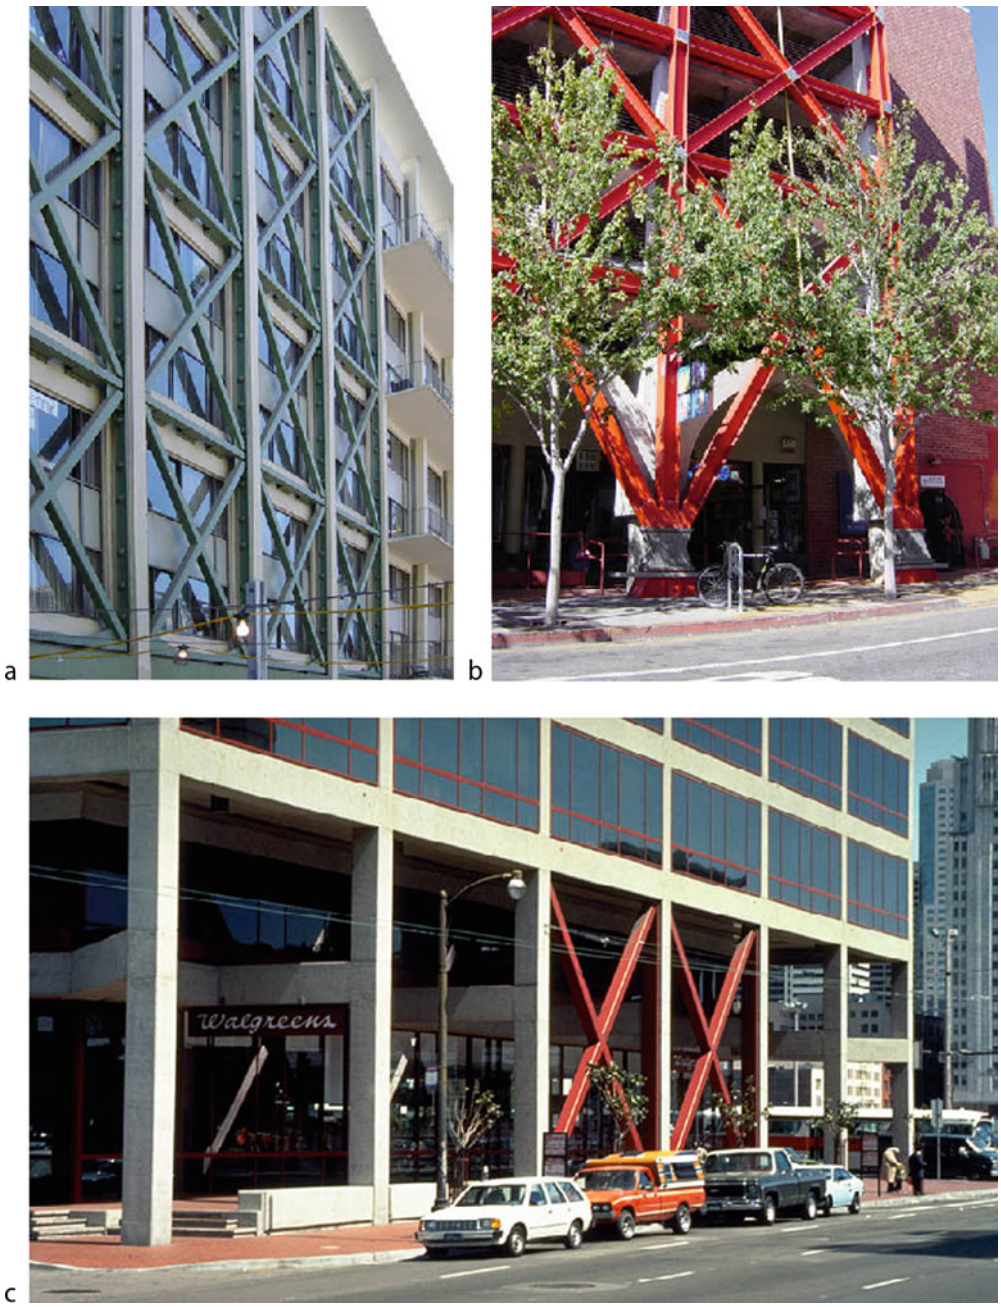
The system level seismic retrofit strategy can be explained by using the principles of the conservation of energy (Uang and Bertero, 1988). Accordingly,

$$E = E_k + E_s + E_h + E_d$$

where;

E : Total input energy by earthquake;
E_k: Absolute kinetic energy;
E_s: Recoverable elastic strain energy;
E_h: Irrecoverable energy dissipated by the structural system through inelastic deformation or other intrinsic forms of damping;
E_d: Energy dissipated by structural protective systems.

Seismic retrofit techniques discussed in the following sections are aimed at enhancing one or more of the energy terms on the right-hand side of the above equation.

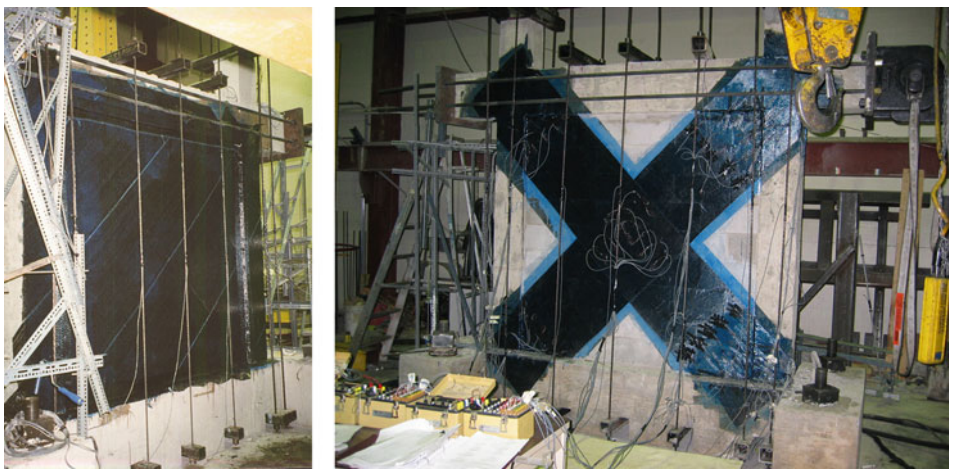


Structural Mitigation, Figure 1 Examples of adding reinforced concrete structural walls (Thermou and Elnashai, 2005).

Lateral bracing and strengthening: One of the conventional seismic retrofit strategies involves strengthening the structure through lateral bracing to promote elastic or near elastic response while controlling lateral drift and limiting associated seismic damage. Hence, this approach aims to increase the recoverable elastic strain energy in the system. A large number of existing buildings have non-ductile reinforced concrete frames with or without unreinforced masonry (URM) infill walls as their lateral load resisting systems. These buildings are primarily designed and detailed to resist gravity loads. A common approach to providing lateral strength and stiffness is to provide properly designed and detailed reinforced concrete shear walls that are well integrated with the existing structural system. This approach has been applied successfully over the years when it was possible to fill in existing bays (sometimes replacing existing masonry walls) with properly designed reinforced concrete structural walls. Three considerations become important for successful performance of these walls; (a) suitable locations within the plan of the building so that the required strength and stiffness (drift control) can be provided without creating significant torsional effects, (b) continuity in elevation without much strength and stiffness taper, and (c) integration with existing vertical and horizontal structural elements to ensure proper force transfer through existing floor diaphragms. Figure 1 illustrates examples of adding structural walls to existing buildings. The walls are designed as new structural walls following the seismic provisions of current building codes, with due consideration given to wall boundary elements, and the confinement of these elements in potential plastic hinge regions. A major challenge in this retrofit scheme is to ensure appropriate strength in the foundation. Often, the addition of a new structural wall may require strengthening of the existing foundation, which may be a significant undertaking.

Another effective approach to lateral bracing involves the use of steel braces. Diagonal bracing provided in one or more bays in critical direction(s) of buildings provide substantial increase in lateral force capacity and drift control. Steel braces provide diagonal tension ties, as well as diagonal compression struts, resisting seismic-induced inertia forces at floor levels. These members are often sufficiently strong to remain elastic during seismic response. However, if seismic force capacity is exceed, they may yield in tension and buckle in compression, while continuing to provide lateral force resistance under reversed deformation cycles. Figure 2 shows examples of multi-storey buildings retrofitted with structural steel bracing elements. Research is currently underway for developing buckling-restrained bracing elements (Berman and Bruneau, 2009; Xi, 2009; Di Sarno and Manfredi, 2010), as well as developing compression-only braces to avoid the implementation of expensive and difficult connection details for substandard old structural elements (Caron, 2010). Figure 3 shows recent research on steel braces as seismic retrofit elements.

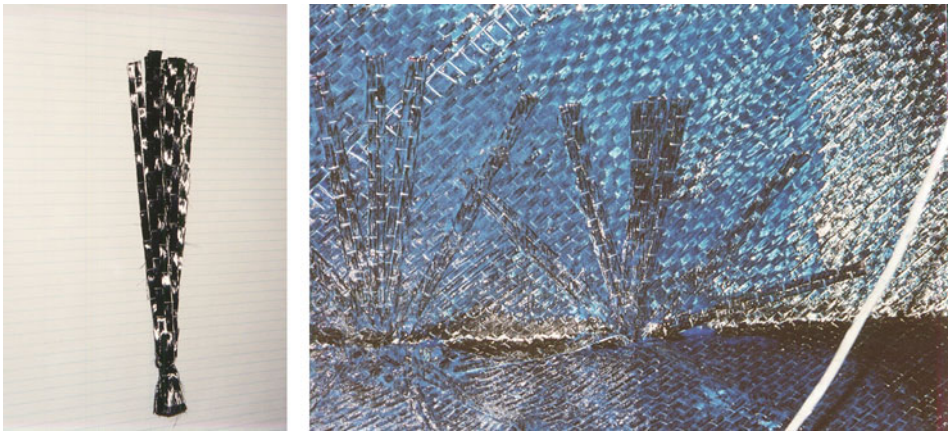
A significant proportion of non-ductile frame buildings have existing unreinforced masonry (URM) infill walls. These walls are often not intended to resist lateral forces, and therefore are not designed for seismic resistance. However, they are often not separated sufficiently from the structural framing system, and interact with the rest of the structure. When their elastic threshold is exceeded under in-plane seismic forces, or their stability is compromised under out-of-place excitations, they fail in a brittle manner, not only providing safety hazard, but also leaving the structural framing system without much lateral bracing. A convenient approach to enhance the lateral bracing capacity of these URM infill walls is the use of surface-bonded fiber-reinforced polymer (FRP) sheets. The use of FRP, either covering the entire wall surface area or by means of diagonally placed strips, well anchored to the enclosing frame, may provide sufficient diagonal tension and compression capacity to brace the entire frame (Saatcioglu et al., 2005). Figure 4 shows two test specimens, with carbon FRP sheets having carbon fibers aligned with wall diagonals, providing significant strength enhancement to the structure. This type of retrofitting can only provide strength and stiffness increase, without any ductility enhancement, as both the URM and the FRP are non-ductile materials. Hence, this retrofit scheme is most suited for structures that are expected to remain



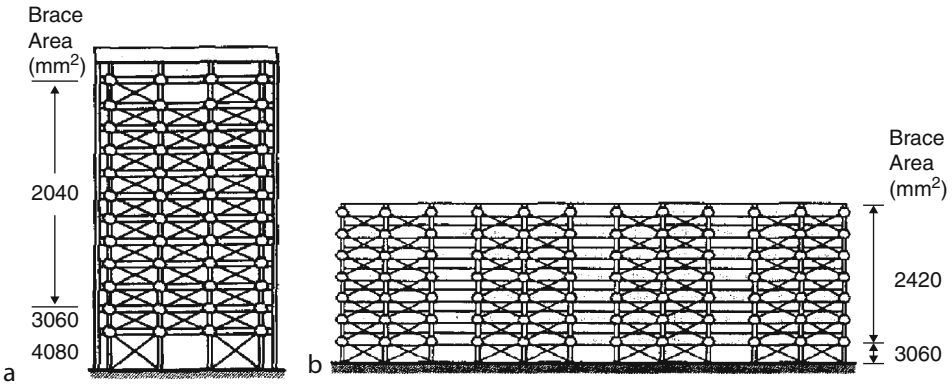
Structural Mitigation, Figure 2 Steel bracing as seismic retrofit strategy; (**a**) University of California dormitory, Berkeley, Ca., USA, (**b**) Parking garage in Berkeley, CA., USA, (**c**) Multi-storey building in San Francisco, Ca., U.S.A.

elastic during seismic response after the implementation of FRP strengthening. The major challenge in such application is the debonding of FRP during reversed cyclic loading. While epoxy-bonded FRP may have limited bond strength, the use of FRP anchors proves to be an effective means of providing additional physical anchorage (Saatcioglu et al., 2005; Ozbakkaloglu, 2009). Figure 5 shows the FRP anchors developed at the University of Ottawa, which ensure the development of full FRP strength when used to anchor surface-bonded FRP sheets on the enclosing concrete frame elements.

Another approach for lateral bracing involves the use of diagonal prestressing strands or cables, providing tension ties (Miranda and Bertero, 1989; Pincheira and Jirsa, 1992; Shalouf and Saatcioglu, 2006). High-strength steel cables secured at beam-column joints enable the development of diagonal tension ties in single or multiple bays, sometimes covering the entire height of the building



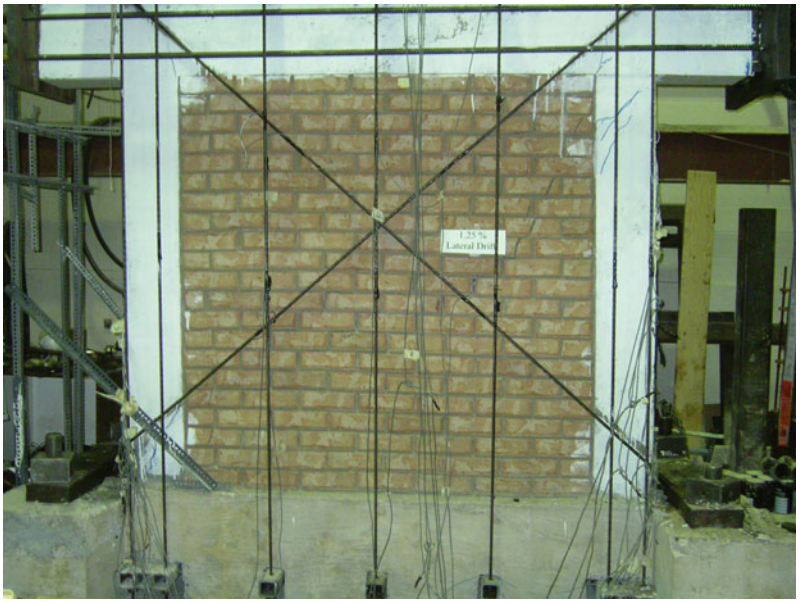
Structural Mitigation, Figure 3 Research on compression only steel bracing (Caron, 2010).



Structural Mitigation, Figure 4 Tests of R/C frames with URM infill walls, retrofitted with FRP (Saatcioglu et al., 2005).

as illustrated in Figure 6 (Pincheira and Jirsa, 1995). The cables are provided either snug-tight, allowing the development of passive resistance during seismic response, or prestressed to resist higher forces as one diagonal develops increased tensile forces and the opposite diagonal loses its prestressing force, allowing redistribution of forces among the cables, thereby increasing their effectiveness. Figure 7 shows a test frame with brick URM infill wall, retrofitted with prestressed diagonal cables, increasing the lateral force resistance of a non-ductile system significantly (Shalouf and Saatcioglu, 2006).

Perhaps one of the most vulnerable structural systems against earthquake effects is the URM load-bearing structures. URM buildings form a significant proportion of building inventory worldwide, especially in the developing world. They also form the majority of heritage building inventory in the form of stone masonry structures. The URM buildings do not have sufficient inelastic deformability, and fail in a brittle manner under in-plane and out-of plane seismic excitations. Though these buildings may benefit from their inherent lateral rigidity in controlling lateral drift, especially in buildings with high wall-to-floor area ratios, they exhibit extremely brittle behavior upon reaching their elastic strength threshold. These structural systems need to be retrofitted for increased strength and integrity, and if possible, for improved deformability, though replacement of the URM may be a strong possibility as a viable seismic risk mitigation strategy. Structural retrofit measures include

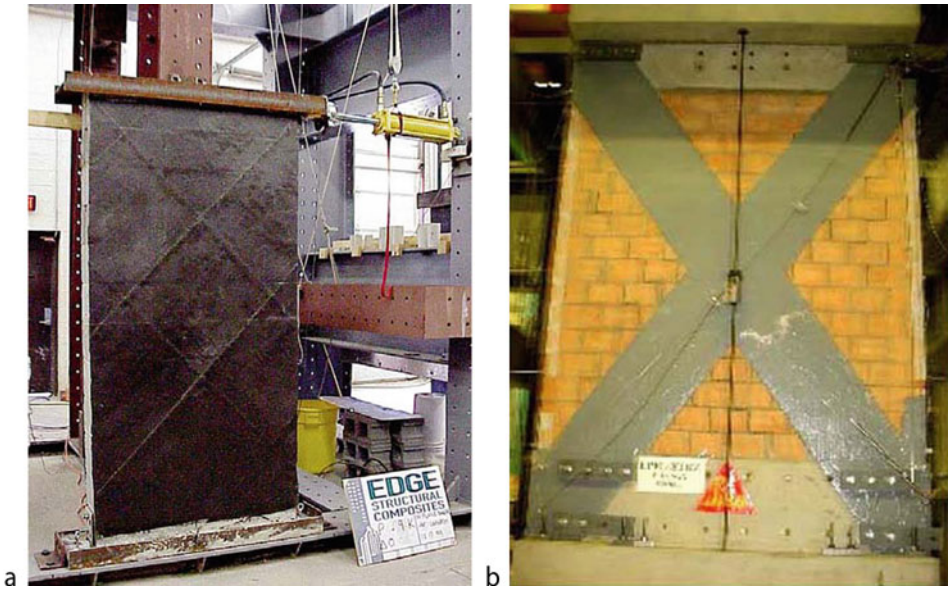


Structural Mitigation, Figure 5 FRP anchors developed at the University of Ottawa (Saatcioglu et al., 2005; Ozbakkaloglu et al., 2009).

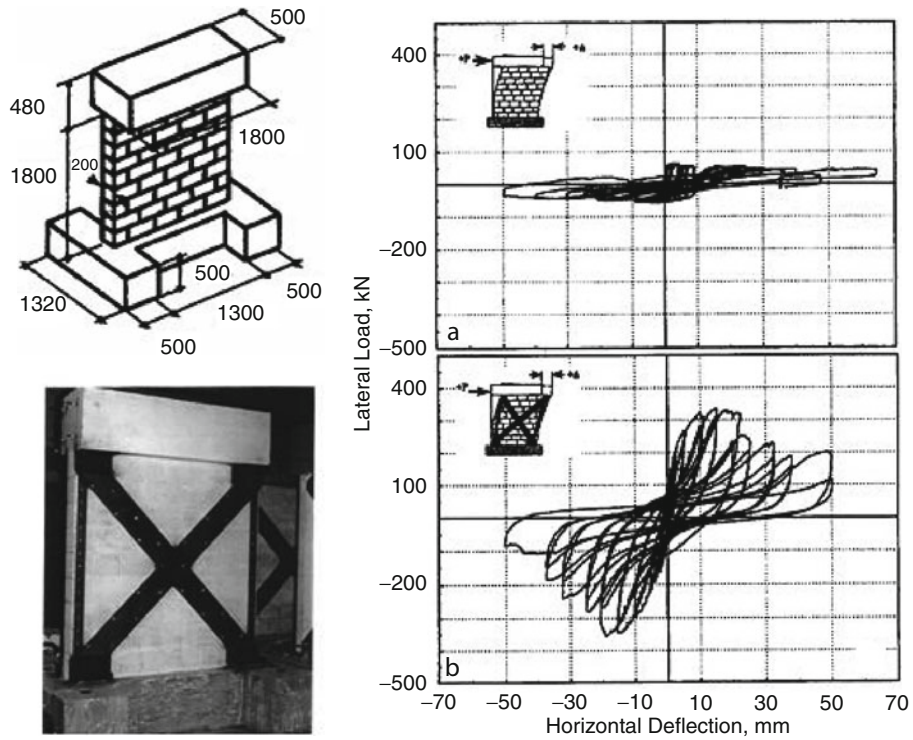
Structural Mitigation, Figure 6 Buildings with diagonal post-tensioning braces (Pincheira and Jirsa, 1995); (**a**) 12-storey building, (**b**) 7-storey building.

improving the integrity of the structure as a whole by attaching slabs and floor beams securely to the load-bearing walls. Buildings may have to be reinforced with additional vertical structural elements in the form of steel or reinforced concrete columns and walls to ensure vertical strength and stability of the entire lateral load resisting system. An increasingly accepted recent seismic retrofit technique involves the use of glass or carbon FRP systems. FRP sheets may be surface bonded on vertical URM elements for increased flexural and shear resistance. FRP sheets maintain out-of-plane stability while providing sufficient diagonal tension reinforcement against seismic forces, as the masonry continues providing diagonal compression struts. Figure 8 shows the application of FRP sheets on URM walls. Figure 9 shows URM test specimens retrofitted with carbon and glass FRP sheets/strips (Vandergrifit et al., 2010; ElGawady et al., 2006). The primary shortcoming of this system is the potential for premature debonding of FRP from the masonry substrate, as well as the invasive nature of the application creating challenges in preserving the heritage value of historical buildings. An effective alternative to using FRP sheets is the use of steel strips as vertical and diagonal elements, providing both flexural and shears strength enhancements (Taghdi et al., 2000a, b). Figure 10 illustrates the use of steel plates on both sides of a masonry wall, connected by drilled-through bolts to resist flexural tension and compression, as well as shear-induced diagonal tension and compression as the bolts prevent global buckling. The figure also illustrates the improvement attained in the hysteretic force-force deformation relationship.

Base isolation: The traditional approach to seismic retrofitting involves improving resistance to higher seismic forces and/or enhancing the energy dissipation capacity through ductile response. These improvements enhance both the recoverable elastic strain energy, and the dissipated inelastic energy. Seismic strengthening often involves lateral bracing, which inevitably results in reduced structural period and increased seismic forces. An alternative approach is to reduce seismic force and deformation demands through the use of a base isolation



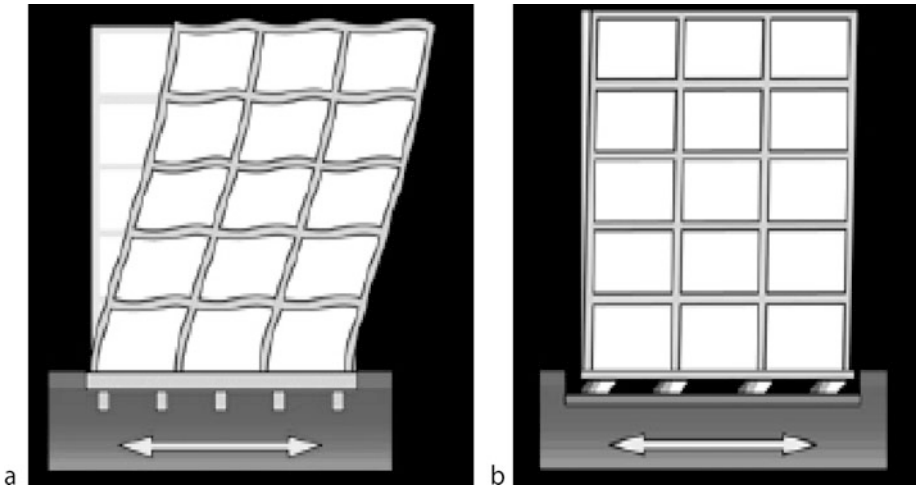
Structural Mitigation, Figure7 Reinforced concrete frame with infill masonry retrofitted with diagonal prestressing (Shalouf and Saatcioglu, 2006).



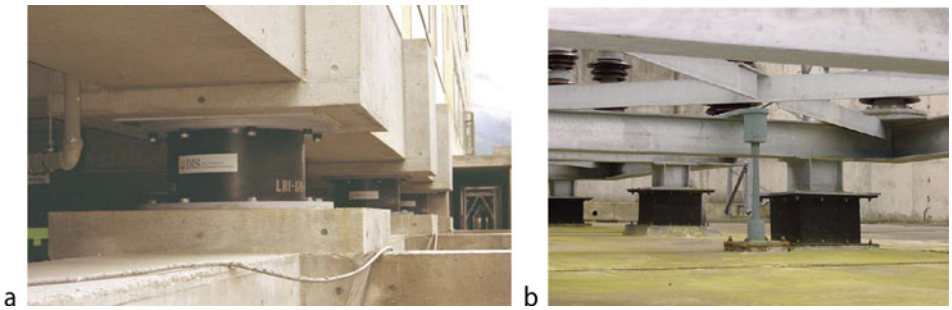
Structural Mitigation, Figure 8 Application of QuakeWrap FRP strips on URM walls in a school building in La Jolla, CA., USA (QuakeWrap, 2010).

system. In this approach the building is placed on a base isolation system, which is designed to prevent or control the transmission of ground motion from the building foundation to the superstructure. This essentially isolates the structure from the ground motion, reducing seismic demands imparted on the building superstructure significantly. The majority of seismic deformations occur in the isolator, while the building remains almost entirely elastic as a rigid body, experiencing only a limited motion, while ensuring the survival of often brittle nonstructural elements and building contents. This is why base isolation is most suited to rigid and non-ductile structures, including historical and heritage buildings, as well as buildings with motion-sensitive contents. Figure 11 illustrates schematically the function of a base isolation system. Figure 12 illustrates the application in the field.

Base isolation techniques have evolved quickly over the last decade, and many different types of isolators have become available for use in practice. Commonly used base isolators consist of laminated rubber bearings that provide sufficient strength against vertical loads while performing in a flexible manner under lateral seismic forces. Typical base-isolation systems in this category consist of elastometric bearings, lead rubber bearings, and high damping rubber bearings. These systems are often equipped with passive dampers or energy dissipation



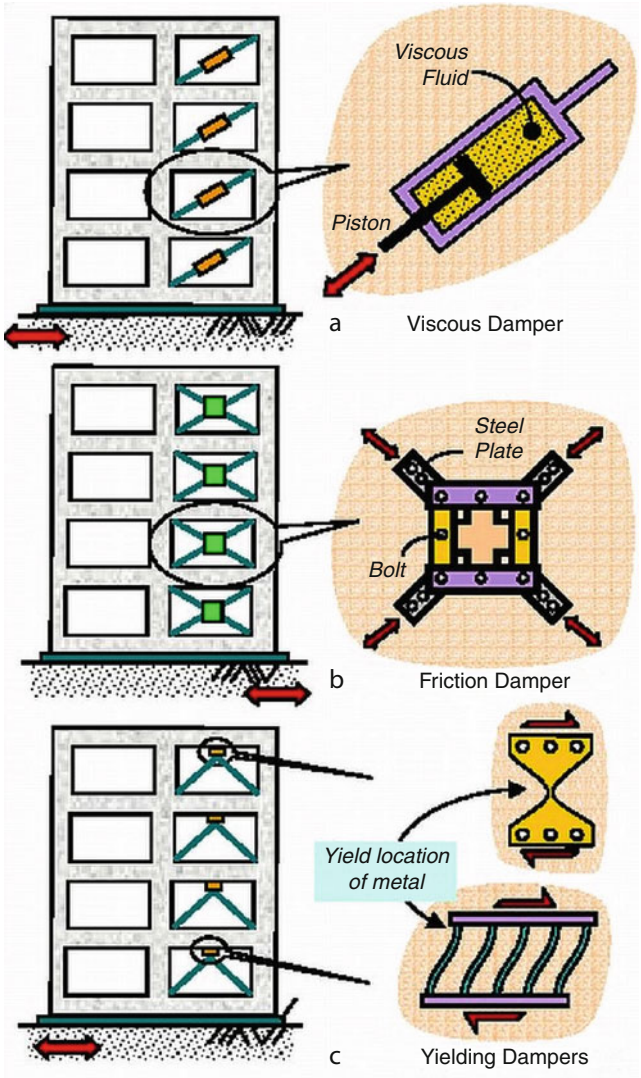
Structural Mitigation, Figure 9 Experimental research on FRP retrofitted URM walls; (**a**) Carbon FRP sheets on concrete block masory (Vandergrifit et al., 2010) (**b**) Glass FRP strips on brick masonry (ElGawady et al., 2006).



Structural Mitigation, Figure 10 Masonry wall retrofit using steel strips (Taghdi et al., 2000a).

capabilities to control excessive deformations. Other commonly used types of isolation systems involve roller, sliding, or rocking mechanisms. An example of the latter category is a sliding friction pendulum bearing. Some applications include high-tension springs; rubber bearings; or concave plates to control excessive lateral displacements and to re-center the isolators. During the past 2 decades, numerous structures have been equipped

Structural Mitigation, Figure 11 Schematic view of base isolation.



Structural Mitigation, Figure 12 Application of base isolation system in practice; (**a**) A hospital building (DIS, 2010) (**b**) An airport hangar (EMKE, 2010).

with base-isolation systems for seismic protection, especially in Japan and the USA (Bertero, 2010).

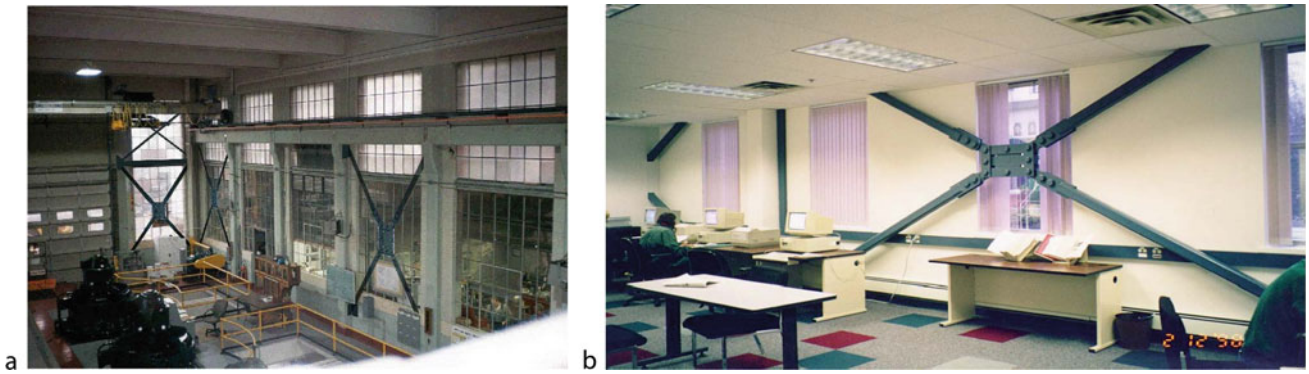
Supplementary damping devices: Seismic energy in structures can be dissipated either through inelastic action in structural members (hysteretic energy), or by enhancing structural damping through supplemental damping devices. Supplemental damping devices have been developed since the early 1980s for the purpose of retrofitting seismically deficient structures. These devices are often built into a bracing element, enhancing damping, while also contributing to the strength and stiffness of the structure, controlling deformations, and limiting structural and nonstructural damage during earthquakes. They are generally used as viscous dampers, friction dampers, yielding elements or viscoelastic dampers. Viscous dampers consist of a piston and a cylinder filled with viscous fluid. The energy is dissipated through the piston moving in the cylinder. Friction dampers consist of steel plates tightened against each other to generate sufficient friction to dissipate energy. Yielding dampers are equipped with metallic components that yield and dissipate hysteretic energy. Viscoelastic dampers consist of bonded layers of solids that dissipate energy through the shearing of elements. Figure 13 illustrates different types of supplementary damping devices schematically. Figure 14 shows the application of friction dampers in buildings.

Another form of a passive damping device is the use of sloshing fluid or a column of fluid to dissipate the motion. This method is used as a tuned sloshing damper to absorb energy through the sloshing of waves in a partially filled tank of liquid placed in a vibrating structure. The liquid tank in such a system is tuned to have approximately the same period as the fundamental period of the building. The period of the liquid is adjusted by the density, length, width, and depth of fluid.

Sometimes, dynamic vibration absorbers are employed to transfer energy from one mode of vibration to another, with a view of distributing them approximately equally among the modes of vibration. Examples include tuned mass dampers and tuned liquid dampers (Housner et al., 1997). Supplementary damping devices are more effective in flexible structures where deformations are large enough to activate the energy dissipation device.

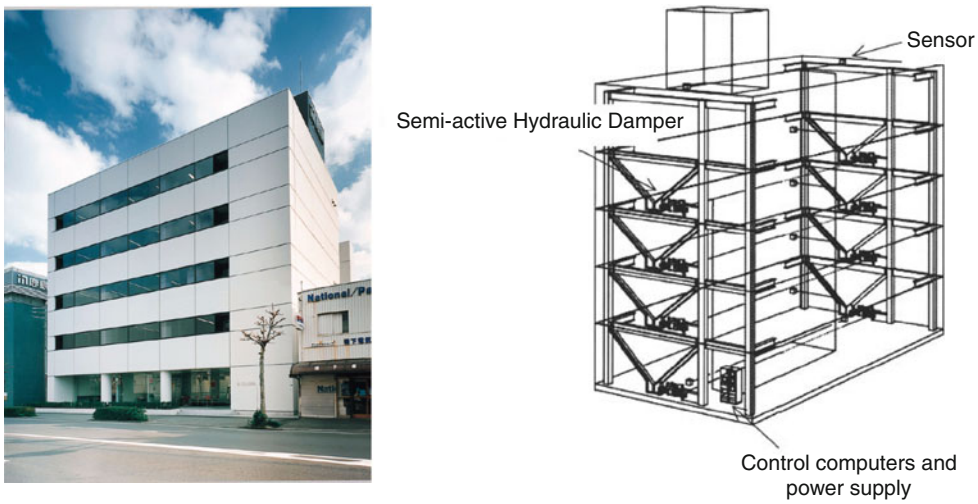
Structural Mitigation, Figure 13 Supplemental damping devices (Murthy, 2010).

Comprehensive reviews of passive dampers are presented by Soong and Dargush (1997), Housner et al. (1997), Symans and Constantinou (1999), and Soong and Spencer (2002). The theoretical concepts and behavior patterns of supplementary damping devices are well understood and their favorable performance in mitigating seismic damage is widely recognized.



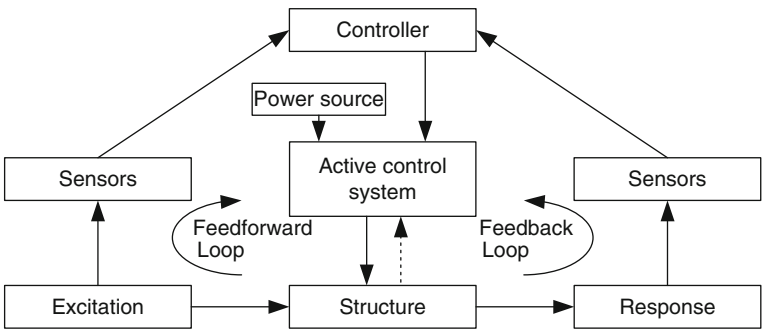
Semi-active control devices: A semi-active control device may be defined as a system that can optimally reduce the vibration amplitude by adjusting structural properties during seismic response without injecting any mechanical energy into the structure. Sensors are used to measure the excitation and/or the response of the structure. The readings from sensors are used to monitor building response and adjust the mechanical properties of the energy dissipation device to achieve the required building response. Such devices are often referred to as controllable passive devices (Housner et al., 1997; Symans and Constantinou, 1999; Spencer and Nagarajaiah, 2003). Examples of these devices include variable-orifice fluid dampers, variable friction dampers, smart tuned mass dampers, tuned liquid dampers, variable stiffness devices, and controllable fluid dampers.

In 1990, Feng and Shinozuka proposed a controllable, electromechanical, variable-orifice valve to adjust hydraulic fluid flow resistance in the damper. They suggested that the implementation of such a device on bridges could control the bridge movement during an earthquake. A modified version of the same semi-active damper was developed by Kobori et al. (1993) for buildings. Full-scale dampers of this type were installed in a five-storey steel structure in Shizuoka, Japan as illustrated in Figure 15 (Kurata et al., 1999, 2000). Each of the installed dampers in the building can produce up to a 1,000 kN damping force, and requires only about 70 W of power to operate. These systems usually require low power, and can be operated through the use of a battery.



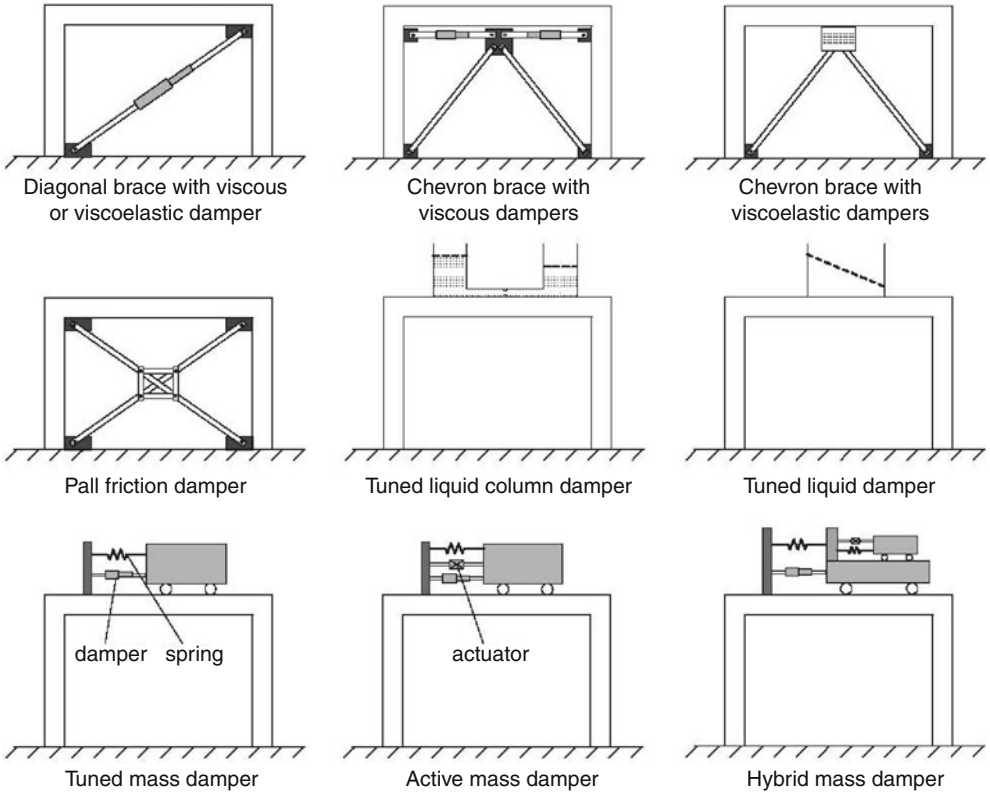
A semi-active control system was proposed by Akbay and Aktan (1991) and Kannan et al. (1995) based on surface friction to dissipate structural vibrations. A friction shaft is rigidly connected to a structural bracing system and the magnitude of the friction force is adjusted through changing the magnitude of the preload on the friction interface. A similar device was developed at the University of British Colombia (Cherry, 1994; Dowdell and Cherry, 1994). The researchers developed a control device that used an "OFF-ON" algorithm. In this algorithm, the device maintains a constant pressure over the friction interface (ON) until the inter-storey velocity comes close to zero; then, the device releases the pressure (OFF) to let the brace position itself, and after that it returns to its original condition again (ON).

Research during the past 2 decades has indicated that semi-active control systems, when appropriately installed, can show significantly better performance than passive control systems and have the potential to achieve the performance level of a fully active system (Dyke et al., 1996; Spencer and Sain, 1997; Spencer et al., 2000; Yi and Dyke, 2000; Jansen and Dyke, 2000).



Active control devices: An active control system may be defined as a system in which a control actuator applies control forces to the structure on the basis of real-time seismic response and/or earthquake motion to either improve the energy dissipation characteristics during response or to resist applied seismic forces. Control forces are computed in real time on the basis of measured structural responses and/or ground motion, depending on the algorithm employed. The control process is illustrated in Figure 16. Sensors that are mounted on the structure and/or ground record response and send the required data to the controller as feedback. The control forces are then computed on the basis of a prescribed control algorithm and are applied on the structure for the required corrective active. The actuator(s) are normally supported by an

Structural Mitigation, Figure 14 Application of friction dampers in buildings.



Structural Mitigation, Figure 15 Semi-active dampers installed in a five-storey building in Japan.

Structural Mitigation, Figure 16 Active structural control (Housner et al., 1997).

external power source due to the high operational power demand of electrohydraulic or electromechanical systems (Housner et al., 1997; Symans and Constantinou, 1999), and hence are susceptible to power failure during earthquakes. Different control algorithms are used to optimize the control action. A variety of active control systems were designed, developed, and modified during the past few decades. The most common active control systems

Structural Mitigation, Figure 17 Summary of commonly used supplemental energy dissipation devices (IST Group, 2010).

include, active mass dampers and active mass drivers, active tuned mass dampers, active variable stiffness or damping systems, active bracing systems, pulse generators, and active tendon controls. Problems associated with time lag, reliability of the computed response, and the possibility of power outage during earthquakes provide challenges for the widespread acceptance of active control techniques, though a number of buildings currently have active control systems installed for seismic risk mitigation, mostly in the form of active mass dampers.

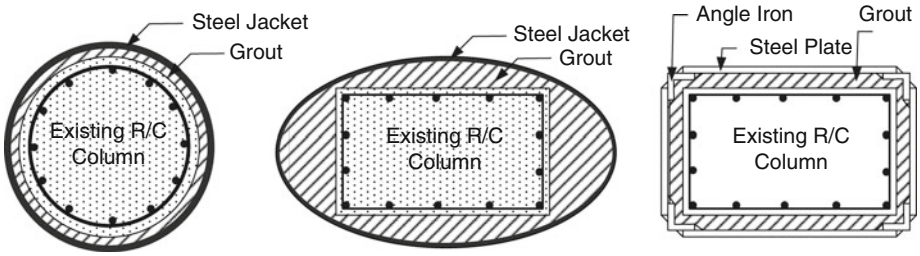


Figure 17 provides a schematic summary of supplemental energy dissipation systems.

Structural mitigation at the element or subassembly level

Structures with seismically deficient members can be retrofitted at the element or subassembly level to address local deficiencies that may otherwise trigger significant damage during seismic response, potentially leading to partial or total collapse. The most vulnerable members are vertical structural elements, which are responsible for overall strength and stability of the entire structure. The following section provides an overview of commonly employed seismic retrofit techniques for different types of building and bridge components.

Column retrofits

Reinforced concrete columns may suffer seismic damage primarily due to: (a) insufficient shear strength, (b) lack of concrete confinement, and (c) improper splicing of longitudinal reinforcement within the potential plastic hinge region. Jacketing is used to address these deficiencies as an effective seismic retrofit strategy for both bridge and building columns. Column jacketing is often implemented in the form of steel, reinforced concrete, or FRP jackets. Steel jacketing was advanced through a comprehensive research program (Priestley et al., 1994a, b; Chai et al., 1991; Chai, 1996; Daudey and Filiatrault, 2000). The technique was used in the bridge retrofit program of the California Transportation Department in the USA, especially after the 1994 Northridge Earthquake. The approach is fully effective in circular columns due to hoop tension. Preformed circular steel jackets are built in two half shells, rolled into a radius that is usually 20–30 mm larger than the column diameter. These two sections are then welded at the seams in the field. A gap of about 50 mm is left in the vertical direction between the jacket and the support to prevent bearing of the jacket on the supporting element. The most common steel casings are manufactured from 8 to 25 mm thick plates. The gap between the jacket and the column is filled with grout. The grout is pumped from the bottom in order to remove air gaps. Steel elliptical jackets are used to retrofit rectangular columns, and round

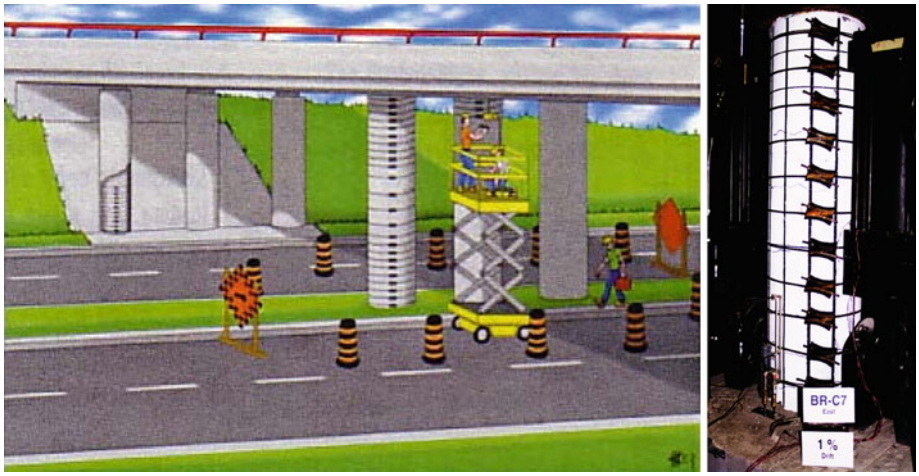
Structural Mitigation, Figure 18 Steel jacketing of columns.

Structural Mitigation, Figure 19 Steel jackets on bridge columns; (**a**) Steel jacket under construction in California, (**b**) Steel jacked bridge column survived the Kobe Earthquake.

jackets are used for square columns to achieve hoop tension. These applications are similar to that used for circular columns. However, the larger gaps that exist between the column and the steel jacket require more effort in the placement of the grout or in-filling concrete. Sometimes steel jackets of rectangular geometry are used, consisting of steel plates or angle irons that are field welded. The jackets can be partially prefabricated into two L sections with the final assembly completed in the field. They may be secured along the sides of columns by means of anchor bolts to improve the confining action. As in the previous application, a gap of about 25 mm is left between the steel jacket and the concrete column, which is filled with nonshrink grout. Figure 18 illustrates various steel jacketing configurations for circular and rectangular columns. Figure 19 illustrates steel jackets in the field.

Concrete jacketing involves the addition of a thick layer of reinforced concrete around the column (Rodriguez and Park, 1994; Priestley et al., 1996). New longitudinal bars must be dowelled into the footing or the storey below with sufficient anchorage depth to achieve full enhancement of flexural strength. In most cases, the footing must also be retrofitted to enhance the footing strength so that the plastic hinging develops in the column. The construction of a reinforced concrete jacket is similar to the construction of a new column. The longitudinal bars are installed first, followed by the placement of transverse reinforcement and the formwork prior to casting the concrete. Figure 20 illustrates the application of a reinforced concrete column jacket in the field.

The third type of column jacketing involves the use of FRP, and is a relatively new technology. The use of advanced composite materials for retrofitting reinforced concrete columns has been the focus of significant research during the last decade (Mirmiran and Shahawy, 1997; Saafi et al., 1999; Demers and Neale, 1999; Saatcioglu and Elnabelsy, 2001; Iacobucci et al., 2002; Elnabelsy and Saatcioglu, 2004; Saatcioglu et al., 2008). FRP systems can be assembled and constructed in a number of ways depending on



Structural Mitigation, Figure 20 Reinforced concrete jacket during construction (Thermou and Elnashai, 2006).

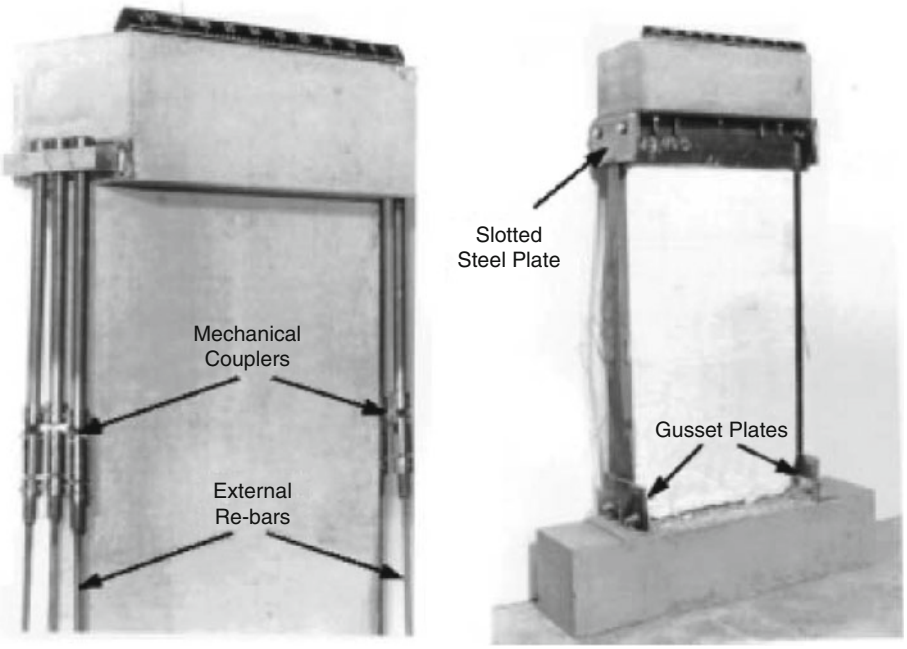
the materials used and the prevailing site conditions. They can be classified as "wet lay-up systems" and "pre-cured systems." The installation begins with repairing the substrate and preparing the surface prior to the application of the jacket. In the wet lay-up system, wet fibers are hand applied on the column while making sure that entrapped air is removed. Subsequent layers are placed before the previous layer is completely cured. In machine-applied systems, the wrapping machine is placed around the column, automatically wrapping the tow material around the perimeter of the column while moving up and down. Pre-cured jackets are placed around a column that has been covered with an adhesive and clamped until cured. Figure 21 shows the application of FRP jackets in practice.

The column jacketing applications discussed above result in shear strength enhancements. This is especially important for short and stubby columns, as well as the segments of columns that develop short column behavior due to unintentional lateral supports provided by adjacent nonstructural elements (captive columns). These columns are especially vulnerable to shear failure during earthquakes. The jackets also improve concrete confinement for increased inelastic deformability and energy dissipation. However, some of the jacketing techniques employed may not be suitable for strengthening reinforcement splice deficient regions, especially in rectangular columns. These jacketing techniques rely on passive lateral resistance during seismic response that develops due to the expansion of compression concrete. A method of column retrofitting has been developed recently based on transverse prestressing of columns,

Structural Mitigation, Figure 21 Application of FRP jackets in the field.

Structural Mitigation, Figure 22 Application of RetrfoBelt (transverse prestressing) on columns.

providing active lateral pressure (Saatcioglu et al., 2002; Saatcioglu and Yalcin, 2003; Yarandi et al., 2004). The technique is known as "Retro Belt System," and provides active and passive lateral confinement pressures, improving concrete confinement while also improving concrete shear capacity and reinforcement bond in splice deficient regions. Transverse prestressing is applied by placing 7-wire strands around columns in the form of individual hoops. The strand ends are tied using specially developed anchors. While circular columns can be prestressed directly on the concrete, producing uniform active lateral pressure, square and rectangular columns require the use of steel spreader elements to distribute the transverse prestressing force on concrete reasonably uniformly. Figure 22 illustrates the application of the RetroBelt retrofit system on concrete columns.



Structural Mitigation, Figure 23 Installation of FRP sheets on a reinforced concrete structural wall.

Wall retrofits

Shear walls are primary lateral load resisting elements. They often possess the required strength and ductility. However, older walls without adequate web reinforcement, or properly confined boundary elements may be critical during strong earthquakes. A number of retrofit techniques have been developed for such walls. These include surface-bonded FRP and externally applied steel plates or bars. Figure 23 shows a concrete wall specimen retrofitted with carbon FRP sheets for shear and flexural strengthening. In such applications, the anchorage of FRP sheets on concrete pose challenges. Steel brackets or FRP anchors like the one shown in Figure 5 may be used to anchor the FRP to the concrete substrate. Another retrofit technique for concrete flexural walls, developed by Elnashai and Salama (1992), involves the use of external unbonded re-bars. The researchers also used externally unbonded steel plates as tension elements. Figure 24 illustrates the technique on test specimens. Steel strips were used by Taghdi et al. (2000a, b) to retrofit seismically deficient reinforced concrete shear walls for strength and ductility enhancements. The strips were placed vertically on opposite sides of walls at the ends by means of closely spaced drilled-through bolts to create boundary elements. The researchers extended the same technique to retrofitting unreinforced and partially reinforced masonry load-bearing walls successfully. This is illustrated in Figure 10. In all cases, the wall strength increased substantially, with significant improvements in inelastic deformability.

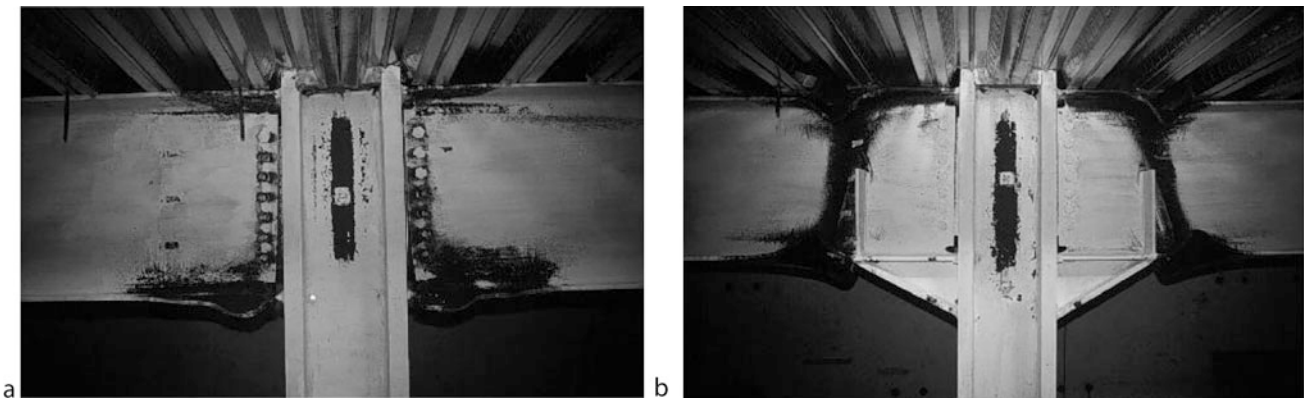
Beam retrofits

Though not as critical as vertical elements, seismically deficient beams may experience sudden and brittle shear failures when they lack adequate transverse reinforcement, resulting in local failures. Flexure dominant beams may also suffer from the crushing of compression concrete and buckling of compression bars near the face of the

Structural Mitigation, Figure 24 Reinforced concrete structural wall retrofit with external unbonded tension elements.

Structural Mitigation, Figure 25 Retrofitting beam end region with FRP sheets (Thermou and Elnashai 2006).

column where plastic hinges form, if not confined by properly designed transverse confinement reinforcement. Seismic retrofitting concrete beams can be performed by adding transverse reinforcement externally in the form of steel brackets clamped on the beams, surface-bonded FRP strips or as surface mounted steel plates. When appropriate, adding a reinforced concrete jacket improves beam capacity to desired levels. However, care must be exercised to ensure that the beams do not become stronger than the framing columns so that the strong-column weak-beam design principle is not violated. Figure 25 illustrates the application of FRP sheets on a concrete beam.



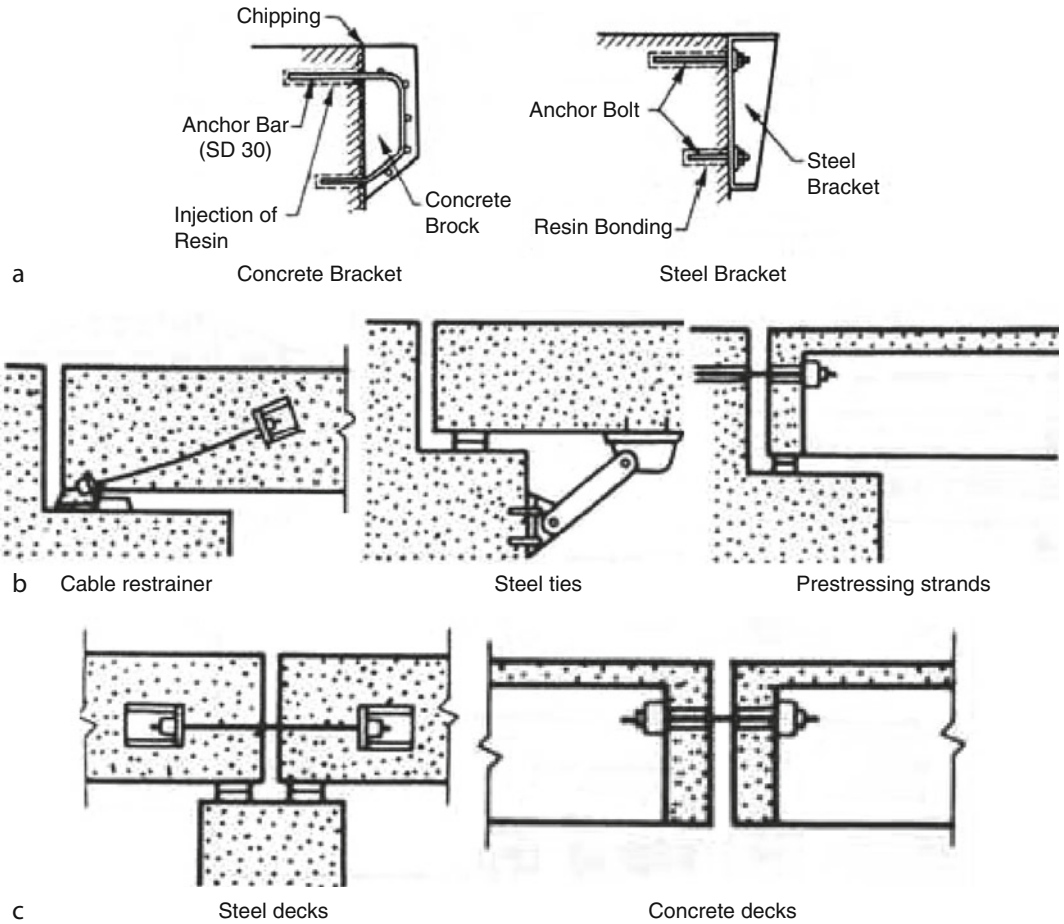
Beam-column joint retrofits

One of the critical areas of reinforced concrete frame buildings is the beam-column joint region. Under lateral seismic forces, these connection regions are subjected to shear stress reversals, resulting in excessive diagonal cracking and concrete deterioration, compromising the overall rigidity of the structure. Joint retrofits often involves steel or reinforced concrete jackets built around existing joints, including passing longitudinal reinforcement through the slabs (Alcocer and Jirsa, 1993; Beres et al., 1992; Corazao, 1989). Because of the difficulties associated with working around a connection area where the columns, the beams, and the slabs join, the use of surface-bonded FRP has gained popularity in recent years as a seismic retrofit technique (Pantelides and Gergely, 2008; Ghobarah, et al., 1996; Ghobarah and Said, 2001; Mosalam, 2008). Figure 26 shows the application of FRP strips on a bridge joint.

The 1994 Northridge Earthquake exposed one of the deficiencies of welded connections in steel frame buildings. After the earthquake, widespread weld failures were observed in steel buildings. A number of solutions were developed for retrofitting such buildings, including weld strengthening, the addition of a welded haunch at the bottom flange of beams, and reducing beam sections near the connection by cutting the flange (dog-bone shaped flange) to promote beam yielding prior to joint weld failure (Engelhardt and Husain, 1993; Engelhardt

Structural Mitigation, Figure 26 Retrofitting beam-column joint with FRP in a bridge structure (Pandelides and Gergely, 2008).

Structural Mitigation, Figure 27 Retrofitting steel beam-column connections with weld deficiencies (Civjan et al., 2000); (**a**) Specimen with bottom flange weakened by cutting to form a dog bone shape, (**b**) Specimen with hunched bottom.



et al., 1996; Tremblay et al., 1997; Civjan et al., 2000). Sample test specimens involved in such development are shown in Figure 27.

Slab retrofits

Reinforced concrete slabs may be vulnerable against punching shear failures when subjected to shear reversals caused by moment transfer from the columns. They may also be subjected to direct shear due to vertical earthquake excitations. Therefore, column-slab connections may require seismic retrofitting. A number of techniques have been developed to increase punching shear perimeter by adding concrete or steel drop panels (Masri, 1996; Lou, 1994; Martines, 1994). Adding shear reinforcement to concrete slabs by means of through-bolts placed between steel plates was also suggested (Martines, 1994). The use of surface-bonded FRP on concrete slabs has gained popularity in recent years due to ease in application (Mosalam, 2002; Binici and Bayrak, 2008; Stark et al., 2005).

Bridge superstructure retrofits

Two types of seismic damage dominate bridge performance: (a) column damage due to lack of adequate transverse reinforcement and longitudinal reinforcement splice length, and (b) unseating of bridge superstructure. The column retrofit methodologies discussed earlier provide effective solutions for bridge columns. In fact, some of these techniques were originally developed for bridge columns. The separation and unseating of bridge superstructure from its supports (columns and abutments) are frequently observed after major earthquakes. The retrofit techniques for this type of deficiency involve increasing

Structural Mitigation, Figure 28 Prevention of unseating of bridge superstructure; (**a**) Extension of seat width, (**b**) Connection of superstructure to substructure, (**c**) Connection between decks.

the support seat width, retrofitting the abutments, including stabilizing the soil around the abutments, and use of restrainers to ensure the integrity of superstructure with its support. Figure 28 illustrates the retrofit methods available for bridge superstructure.

Single and multifamily residential house retrofits

Single family and multifamily residential houses are often built using timber construction. Timber buildings offer superior performance during earthquakes because of their relatively light mass and flexible nailed connections. However, this does not guarantee damage-free performance. Primary seismic deficiency in such buildings is the lack of continuity between the timber framing system and the concrete foundation. Racking action caused by seismic motion can free up the building frame from its foundation (basement or crawl space) wall, or its footings, causing horizontal sliding, and, under extreme cases, overturning of the building. Seismic retrofit against these actions involves securing the floor beams to load-bearing walls and the walls to foundations. Sometimes, the addition of timber shear walls or timber bracings may be appropriate for areas where parking garages may create soft stories.

A large proportion of residential buildings, including houses, is enclosed with stone or brick masonry veneers. These masonry veneers do not have a structural function and provide additional mass to the building, increasing seismic force demands. While they need to be tied back and secured to vertical structural elements by means of metal straps, the connections may not be sufficiently strong during seismic action. The metal straps may be completely missing in older buildings. This may cause safety hazard for the occupants and they need to be secured along the height. Another nonstructural element that may be a seismic safety hazard is the brittle masonry chimneys, which may have to be retrofitted by means of steel straps and additional supports.

Conclusions

Earthquake risk reduction policy in any municipality should include retrofitting seismically deficient structures.

Structural retrofits prevent or minimize damage in buildings, bridges, and other infrastructure, mitigating seismic risk on society. Research over the last four decades has produced seismic retrofit methodologies that can be applied either at the system level, or at the element or subassembly level, enhancing structural performance during earthquakes. Conventional retrofit techniques involve modifications to the structural system or individual elements for improved strength and ductility. While these techniques have improved over the years, new approaches have also evolved in the form of base isolation, supplementary energy dissipation devices, and active control. The suitability of a retrofit approach depends on the characteristics of the structure and the prevailing conditions. The decision for seismic retrofitting, including the selection of the technology, requires the consideration of multiple factors; including structural safety, sustainability, and economic feasibility. The infrastructure owner, engineer, and decision maker should weigh the costs and benefits of seismic safety and decide what measures to take.

Synonyms

Descending of the lithosphere; Lithosphere subduction

Definition

The word "subduction" came from the Latin *subductus*, which means "carry off" or "transfer." In plate tectonics, the process in which an oceanic lithosphere (plate) descends into the Earth's interior is referred to as *subduction*. The descending plate generates seismicity and volcanism.

Discussion

Observations of large gravity anomalies and high seismic activity, associated with oceanic trenches, resulted in the hypothesis that trenches are the sites of crustal convergence and consumption (e.g., Hess, 1962). The loss of the surface area at trenches (compared to surface augmentation at seafloor spreading zones) became later known as *subduction*, one of the basic elements of plate tectonics. As the lithosphere moves away from an oceanic ridge, it cools, densifies, and thickens. Once the lithosphere becomes sufficiently dense compared to the underlying mantle rocks, it bends, founders, and begins sinking into the hot mantle due to gravitational instability. As results of subduction, an oceanic trench forms in the front of the overriding lithosphere, and an accretionary prism evolves from the sediments that scraped off from the descending oceanic crust.

Because the lithosphere behaves elastically at short time scales, it can transmit stresses. The downward buoyancy forces (generated due to the excess density of the rocks of the descending lithosphere) promote the sinking of the lithosphere, but elastic, viscous, and frictional forces resist the descent. The combination of these forces produces shear stresses high enough to cause earthquakes. Other processes contributing to stress generation in the descending lithosphere and its release in earthquakes can be plastic instability at high temperature, faulting due to metamorphic phase transitions, and dehydration-induced embrittlement. Oceanic trenches are the sites of the world largest earthquakes. The earthquakes at oceanic trench zones can occur along the descending lithosphere to depths of about 660 km depending on the thermal state in the mantle. This seismogenic region called the Wadati–Benioff zone (Wadati, 1928; Benioff, 1949) delineates the shape of the descending lithosphere.

Volcanoes in the overriding lithosphere associated with subduction lie normally parallel to the oceanic trench. These volcanoes may form an island arc or may generate a volcanic chain on a continent. The volcanoes exist due to melting of the subducting lithosphere and/or of mantle rocks above the descending lithosphere and subsequent upward magmatic migration.

SUBSIDENCE INDUCED BY UNDERGROUND EXTRACTION

Devin L. Galloway
US Geological Survey, Sacramento, CA, USA

Synonyms

Anthropogenic subsidence; Land subsidence; Mining subsidence; Subsidence

Definition

Subsidence. Sinking or settlement of the land surface caused by natural or human-induced processes. As commonly used, the term principally relates to the vertical downward movement of natural surfaces although some generally small-scale horizontal movement may be present.

Underground extraction. Purposeful withdrawal of mass (solids, liquids, or gases) and (or) heat from the subsurface.

Introduction

Subsidence induced by underground extraction is a class of human-induced (anthropogenic) land subsidence that principally is caused by the withdrawal of subsurface fluids (groundwater, oil, and gas) or by the underground mining of coal and other minerals. Subsidence in general (see *Land Subsidence*) is a surface manifestation of the mass-wasting or rearrangement of subsurface materials that reduces their bulk volume, and is caused by a variety of anthropogenic and natural processes (National Research Council, 1991) including:

1. Subsurface fluid and heat withdrawal
2. Underground mining
3. Drainage of organic soils
4. Sinkholes (see Sinkhole)
5. Hydrocompaction (see Hydrocompaction Subsidence)
6. Thawing permafrost (see Permafrost)
7. Natural consolidation
8. Underground erosion (see Piping Hazard)
9. Volcanism and tectonism

In many developed areas, most anthropogenic subsidence, as measured by the area affected, is caused by the extraction of subsurface fluids (principally groundwater from porous granular media) and by the underground mining of coal. Subsidence accompanies a variety of natural processes (e.g., items 3–9 above) that constitute the geologic and climatic history of many areas. These natural processes often are accelerated or amplified by anthropogenic factors such as excavation (mining), surface mechanical loading, drainage of wetlands, redirected or focused surface-water drainage and groundwater infiltration, and the extraction of subsurface fluids.

Globally, many subsidence areas have been identified, mapped, and documented (see, e.g., Poland (1984) and Galloway et al. (1999, 2008)). Though regional subsidence, such as that caused by the extraction of groundwater in susceptible aquifer systems, may be subtle and difficult to identify, various factors aid identifying unrecognized subsiding regions, such as increased incidences of damaged or protruding wells, a history of adjustments to local geodetic controls, increasing incidences of coastal or riverine flooding, local conveyance and drainage problems, and ground failures – surface faulting and earth fissuring. Measuring, mapping, and monitoring subsidence are necessary to assess subsidence hazards. Analysis and simulation of subsidence processes, constrained by the available data, often are used to assess present and potential future hazards.

Subsidence contributes to permanent inundation of coastal lands as they settle with respect to sea level (see "*Sea Level Change*," "*Coastal Zone Risk Management*," and "*Coastal Erosion*"), aggravates riverine flooding, alters topographic gradients, ruptures the land surface, disrupts cultural infrastructure (see "*Damage and the Built Environment*"), and causes other hazards related to deterioration of land and water resources. The assessment of costs related to subsidence is complicated by difficulties in identifying and mapping the affected areas, establishing cause-and-effect relations, assigning economic value to environmental resources, and by inherent conflicts in the legal system regarding the recovery of damages under established land and water rights.

Subsidence related to subsurface fluid withdrawal and underground mining

Subsurface fluid withdrawal

Extraction of fluids from subsurface formations perhaps is the best understood of all causes of subsidence. Many areas of subsidence caused by withdrawal of groundwater, hydrocarbons, and geothermal fluids have been identified, surface and subsurface changes have been monitored, and corrective measures have been devised. Decades ago, the topic of "Land Subsidence Due to Fluid Withdrawal" was reviewed by Poland and Davis (1969). A brief overview of groundwater pumping–induced subsidence is given by Phillips and Galloway (2008).

Experience in identifying and coping with subsidence caused by withdrawing groundwater in many parts of the world is reported in Poland (1984). Countries where documented subsidence is attributed to groundwater withdrawal include Australia, Great Britain, Hungary, India, Indonesia, Iran, Italy, Japan, Mexico, Philippines, the Peoples Republic of China (PRC), Spain, Taiwan (Republic of China), Thailand, the USA, and Vietnam. Subsidence exceeding 9 m attributed to groundwater withdrawal has occurred in Mexico City and in the San Joaquin Valley in California (Figure 1). By areas affected, the USA and PRC are most impacted by subsidence attributed to groundwater withdrawal. Extraction of subsurface fluids, principally groundwater, from clastic sediments has permanently lowered the elevation of about 26,000 km^2 of land in the conterminous USA – an area of similar extent to the State of Massachusetts (Holzer and Galloway, 2005). In recent decades, the occurrence, recognition, and assessment of subsidence in the PRC have increased dramatically. In 2003, the total subsiding area was more than 90,000 km^2 affecting more than 50 cities and other areas primarily in the Yangtze River Delta, the North China plain, and Fen-Wei Faulted Basin (He et al., 2005; Yang et al., 2005b). The maximum subsidence reported was more than 3 m in Tianjin.

Subsidence Induced by Underground Extraction, Figure 1 Approximate location of maximum measured subsidence in the San Joaquin Valley, California, USA. Land surface subsided approximately 9 m from 1925 to 1977 due to aquifer-system compaction from groundwater withdrawal. Signs on the pole are positioned at the approximate former elevations of the land surface in 1925 and 1955 (Photograph by R.L. Ireland, USGS, ca 1977).

Subsidence attributed to the extraction of oil, gas, and associated water and brines from petroleum reservoirs has been documented in many basins of the world (Yerkes and Castle, 1969; Martin and Serdengecti, 1984; Chilingarian et al., 1995; Nagel, 2001). Subsidence at the Wilmington (California) and Ekofisk (North Sea, Norwegian sector) oil fields are well-known examples due both to the magnitude of subsidence as well as the cost of remediation. Parts of the city and port of Long Beach suffered major problems owing to rapid (as much as 750 mm/year) subsidence during 1937–1962 related to extraction of oil, gas, and associated water from the underlying Wilmington oil field (Gilluly and Grant, 1949; Mayuga and Allen, 1969). Total subsidence in Long Beach reached as much as 9 m before the land surface was stabilized by an integrated program of fluid injection to balance the extraction. Elsewhere in California, the Lost Hills and Belridge oil fields in the San Joaquin Valley subsided at a rate of about 400 mm/year during 1995–1996 (Fielding et al., 1998). In the area of Daqing, the largest oil-producing region in the PRC, as much as 1.5 m of subsidence has occurred since 1959 owing to oil and natural gas production. The subsidence in Daqing is further complicated by groundwater withdrawal associated with waterflooding applied to maintain peak rates of oil production (Zhou et al., 2005). In the Netherlands, the large Groningen gas field began production in the 1960s. The maximum measured subsidence by 2003 was about 0.25 m and it was subsiding at an average rate of about 7.5 mm/year (Ketelaar et al., 2005). Even small amounts of subsidence pose significant challenges in the Netherlands because large portions of the country are below sea level and protected by dikes.

Subsidence due to subsurface fluid extraction in coastal regions such as those near Bangkok, Houston, Jakarta, Long Beach, Manila, New Orleans, Santa Clara Valley in California, Shanghai, and Venice plays a role in the rise of Local Mean Seal Level (LMSL). LMSL is affected by land movements attributed to isostasy, and sea level changes attributed to eustasy (see "*Sea Level Change*"). The observed rate of eustatic rise is 1–2 mm/year (IPCC, 2001), of which global climate change likely is a significant contributor (see "*Climate Change*"). Estimated average subsidence rates vary widely and are confounded by estimates of the relative (subsidence and uplift) contributions from isostasy (González and Törnqvist, 2006): natural consolidation, tectonic uplift and downwarping, and continental rebound from glacial retreats and from local and regional land subsidence caused by anthropogenic factors. Locally, during the latter part of the twentieth century, much of the isostatic decline can be attributed to subsidence caused by the compaction of sediments owing to the withdrawal of subsurface fluids; sediment compaction rates greater than 100 mm/year have been measured in coastal basins while compaction rates attributed to other processes contributing to relative sea level rise were nearly one to two orders of magnitude less. Some of the hazards and environmental consequences associated with coastal subsidence include damage to engineered structures, enhanced coastal and riverine flooding, loss of saltwater and freshwater marsh ecosystems, formation of earth fissures, and reactivation of surface faults.

Several areas have experienced subsidence caused by the extractions of fluids and heat from geothermal fields, including Wairakei, New Zealand, Cerro Prieto, Mexico, and the East Mesa, Casa Diablo and the Geysers in California (Massonnet et al., 1997; Carnec and Fabriol, 1999; Singhal and Gupta, 1999; Howle et al., 2003). In Wairakei, ground surface has subsided by as much as 5–10 m (Elder, 1981). In geothermal fields, the cooler reinjected fluids can exacerbate thermally induced subsidence.

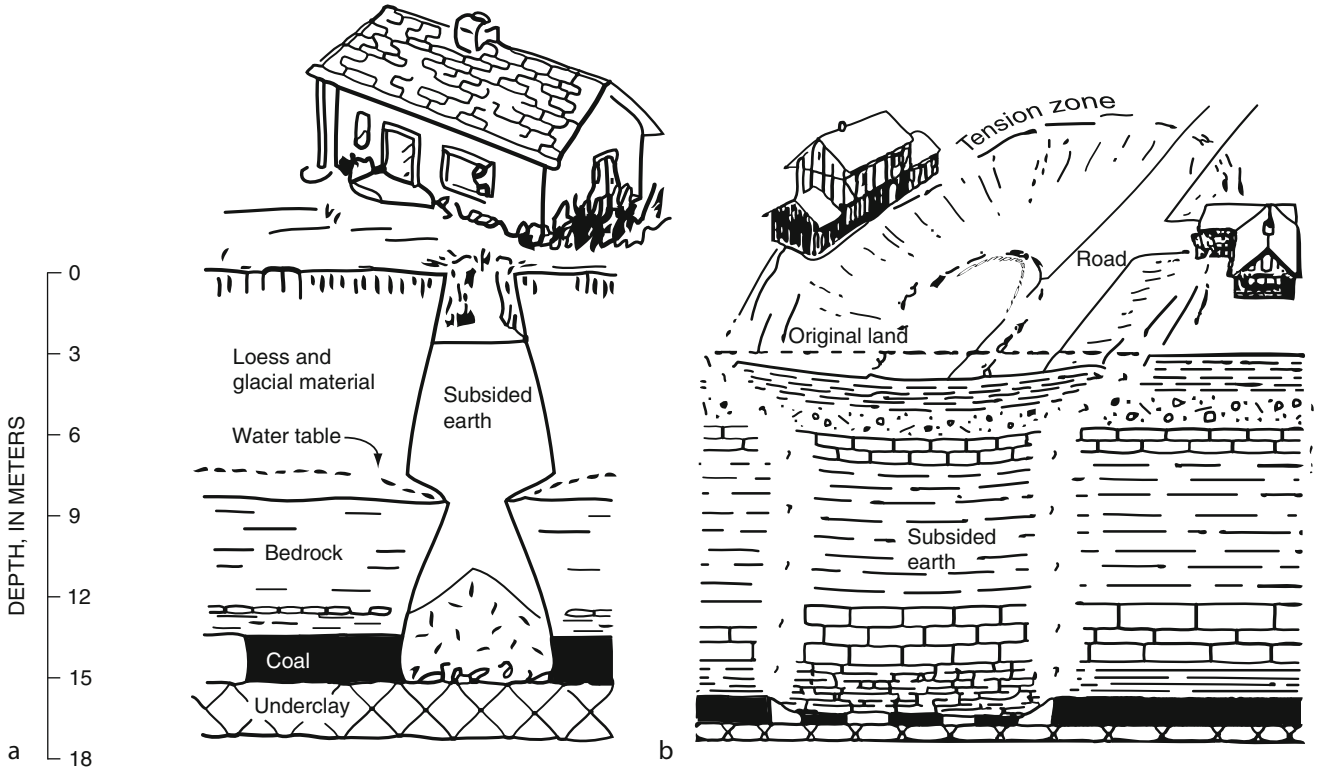
Underground mining

Underground mining of coal and other minerals has caused subsidence of an estimated 8,000 km^2 of land in the USA; most of this fraction is associated with underground

mining for coal (National Research Council, 1991). Coal mining in the PRC, India, Germany, Great Britain, and the Netherlands has resulted in widespread subsidence (Saxena, 1978; Yang et al., 2005a). In the PRC, the largest coal producer in the world, subsidence occurs in many coal mining fields. Subsidence caused by coal extraction at Fushun in the northeastern PRC is as much as 16.4 m with a subsiding area of 18.4 km^2 (Yang et al., 2005a). The chief cause of documented subsidence in India is due to the underground mining of coal deposits from Lower Gondwana coalfields in the Jharia and Raniganj coalfields (Saxena and Singh, 1991; Anon, 1997). In these two coalfields, an area of about 100 km^2 has subsided 1–5 m. Such subsidence has led to severe alteration of surface topography, development of mine fires [see "*Coal Fire (Underground)*"], damage to buildings, roads, and other structures, and serious damage to surface water and groundwater systems.

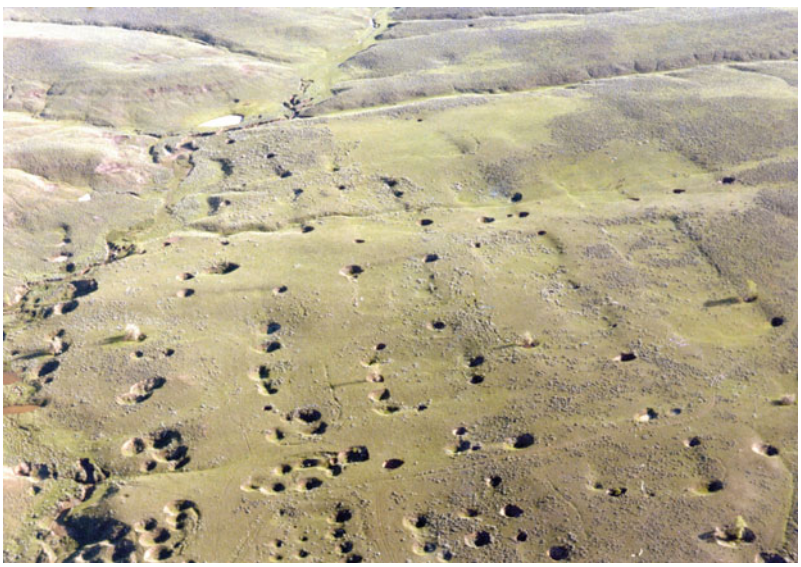
Subsidence related to subsurface fluid withdrawal and underground mining: mechanisms

Subsurface fluid withdrawal



Permanent subsidence can occur when fluids stored beneath the Earth's surface are removed by wells or drains. Because most of the identified subsidence attributed to subsurface fluid withdrawal has been caused by groundwater extraction, the following discussions focus on the development of groundwater resources in aquifer systems. Withdrawing groundwater from the aquifer system decreases pore-fluid pressures which reduce pore volume and the volume of the aquifer system causing subsidence. Support for the overlying material – the overburden or equivalent geostatic stress – is provided by pore-fluid pressure and the compliant granular structure, the so-called skeleton of the aquifer system. A shift in the balance of support provided by fluid pressure to support provided by the skeleton – the intergranular or "effective stress" – causes the skeleton to deform slightly. Both the aquifers (coarse-grained sediments) and aquitards (fine-grained sediments) that constitute the aquifer systems undergo deformation, but aquitards deform much more than aquifers. This phenomenon, known to hydrogeologists as compaction and to soil engineers as consolidation, is based on the theory of primary one-dimensional consolidation of clays (Terzaghi, 1925; Terzaghi and Peck, 1967). This theory commonly is used to estimate the magnitude and rate of settlement or compaction that will occur in fine-grained clay deposits under a given change in stress. According to the theory, compaction in low-permeability, fine-grained deposits results from the transfer of stress from the pore water to the skeleton as pore water gradually is released from the stressed deposits. When the effective stress exceeds the previous maximum stress (preconsolidation stress) on the skeleton, the compaction is essentially permanent and irreversible. Almost all the permanent subsidence in aquifer systems is attributable to the compaction of aquitards during the typically slow process of aquitard drainage (Tolman and Poland, 1940). This concept, known as the *aquitard drainage model*, has formed the theoretical basis of many successful subsidence investigations (Holzer, 1998), and is the approach used to simulate subsidence (Hoffman et al., 2003; Leake and Galloway, 2007) using the MODFLOW groundwater flow model (Harbaugh, 2005).

In compacting aquifer systems, the deformation is generally spread over a large area so that regional-scale lateral (sub-horizontal) strains are small. Locally, however, lateral strains may be large, such as near pumping wells where hydraulic gradients are large, where the aquifer system thins abruptly above inflections in the basement topography of the aquifer system, and near the boundaries of hydrogeologic units with contrasting material properties. The conventional groundwater theory approach to evaluating aquifer-system compaction and subsidence may be suitable for evaluating regional groundwater resources, but it has limitations in evaluating the hazards associated with ground displacements on local scales (Burbey, 2001, 2002). With respect to evaluating hazards, local factors should guide the evaluation and where relevant, the application of multidimensional poroelastic models based on Biot (1941) consolidation theory should be considered.



Underground mining

Subsidence attributed to underground coal mining, generally classified as pit subsidence or sag/trough subsidence (Figure 2), is time dependent with vertical (generally largest) and horizontal components of movement, depending on the type and extent of mining. Pit subsidence is a circular hole in the ground with essentially vertical to belled-outward sidewalls. The diameter of subsidence pits ranges from about 1 to 12 m and generally occurs over shallow mines (depths less than about 50 m) with incompetent bedrock overburden. Sag subsidence is a rectangular depression with gently sloping sides and is typically developed over room-and-pillar mines at greater depths (20–100 m or more) and with more competent overburden. Trough subsidence is similar in surface geometry to sag subsidence.

Pit and sag subsidence occurs more or less randomly and unexpectedly when pillars of coal collapse under overburden loading, typically long after an underground mine has been abandoned (Figure 3). Pit subsidence may involve collapse of only a few pillars, while sag subsidence may involve progressive failure of many pillars. Trough subsidence typically occurs in conjunction with longwall mining, which involves use of moveable hydraulic roof supports that are advanced behind the excavation so the mine roof and overlying rock fracture

Subsidence Induced by Underground Extraction, Figure 2 Typical types of subsidence associated with underground coal mining: (**a**) Pit subsidence, and (**b**) Sag subsidence (Modified from Bauer and Hunt, 1982).

Subsidence Induced by Underground Extraction, Figure 3 Subsidence depressions and pits above the abandoned Old Monarch Mine (coal) in operation from 1904 to 1921 near Sheridan, Wyoming, USA. Rectangular depressions, some of which are bounded by pits, are evident on the *right* (Photograph by C.R. Dunrud, USGS, May 1978).

and collapse into the void behind the supports. Caving and fracturing propagate up through the overlying rock mass and bulking occurs until the collapsed rock supports the overlying strata. The overlying rock mass subsides and the ground surface ultimately deforms into a trough.

Prediction of mining subsidence involves the use of mathematical models to compute the subsidence profile. Models based on the influence function approach assume that extracting a tiny element of an underground seam, for example, a coal seam, will cause the ground surface to subside into a predefined shape such as a normal probability distribution. The ground surface directly above the extracted element receives the greatest amount of influence. Coal seam elements offset from this location have less influence on that surface point. The final subsidence at this point is the summation of the influence of each mined-out element. Explicit techniques that employ finite-element or distinct-element models are capable of accounting for the engineering characteristics of various rock strata and the orientation of bedding planes and preexisting faults. The more explicit modeling techniques require much more information than the influence models, and the numerous input parameters can make it much more difficult to calibrate to case histories.

Early underground mining was less efficient than more recent underground mining. Subsidence over early mines can occur tens to hundreds of years after mining has ceased, whereas subsidence over more recent mines where virtually total extraction is practiced tends to occur contemporaneously with mining. Subsidence over underground coal workings develops as a gradual downwarping of the overburden into mine voids and is generally unrelated to subsurface water conditions.

Abandoned tunnels and underground mining for metallic ores, limestone, gypsum, and salt contribute a small percentage of the subsidence attributed to underground mining. These mined areas are subject to downwarping of the overburden, but limestone, salt, and gypsum whether undermined or not are susceptible to extensive dissolution by water, frequently leading to sinkholes (see "*Sinkhole*") and in some cases catastrophic collapses (Galloway et al., 1999).

Summary

Subsidence induced by underground extraction is a class of anthropogenic land subsidence that principally is caused by the withdrawal of subsurface fluids (groundwater, oil, and gas) and the underground mining of coal and other minerals. Permanent subsidence can occur when fluids stored beneath the Earth's surface are removed by wells or drains. Most of the identified subsidence attributed to subsurface fluid withdrawal has been caused by groundwater extraction. Underground mining of coal and other minerals has caused widespread subsidence; most of this fraction is associated with underground mining for coal.

Globally, many subsidence areas have been identified, mapped, and documented. Measuring, mapping, and monitoring subsidence are necessary to assess subsidence hazards. Analysis and simulation of subsidence processes, constrained by the available data, often are used to assess present and potential future hazards.

SUNSPOTS

David H. Boteler
Earth Science Sector Natural Resources Canada, Ottawa, ON, Canada

Definition

Sunspots are dark regions on the Sun's surface. The number of sunspots varies with an approximately 11-year cycle and is a used as an indicator of the level of solar activity that drives space weather.

Discussion

When Galileo pointed his telescope at the Sun and observed dark regions instead of a uniform disk, it triggered an upheaval in thinking about the Sun. We now know that sunspots are regions of strong magnetic fields that inhibit the heat convection from the Sun's interior resulting in regions (4,500 K) that are cooler than the surrounding areas (6,000 K) and so appear darker. The strong magnetic fields within sunspot groups lead to solar flares and eruptions on the Sun producing "space weather," which is a hazard to modern technology. The number of sunspots provides a good indicator of the level of solar activity and the space weather hazard to a variety of systems. Regular drawings of sunspots have been made for many years and used to produce a daily sunspot number calculated from the number of sunspot groups multiplied by ten added to the number of individual spots. The International Sunspot Number is now produced by the Solar Influences Data Centre in Belgium (www.sidc.be). A plot of the sunspot number shows the cycles of solar activity which last between 10 and 14 years with an average length of 11 years. During peak years of the solar cycle, there are increased hazards from magnetic storms to power systems and ionospheric disturbances affecting radio communication and positioning systems.

SUPERNOVA

Lev I. Dorman
Tel Aviv University, Qazrin, Israel
Russian Academy of Sciences, Troitsk, Moscow, Russia

Synonyms

Stellar explosion

Definition

A supernova is a stellar explosion that is extremely luminous and may cause a burst of radiation that often briefly outshines as a whole galaxy, before fading from view over several weeks or months. The explosion ejects the main part of star's material at a velocity of up to 30,000 km/s driving a shock wave into the surrounding interstellar medium. This shock wave sweeps up an expanding shell of gas and dust called a supernova remnant and generates huge fluxes of cosmic rays (CR) with energy up to about several millions GeV (1 GeV = 10^9 eV).

Supernovae as main source of cosmic rays in galaxy and estimation of their average frequency

From the energetic balance of CR in the Galaxy (taking into account the energy density of CR at about 1 eV/cm^3, and an average life of CR in the Galaxy about 30 million years), it follows that the full power for CR production is about 3×10^{27} MW. Now, it is commonly accepted that only supernovae explosions may supply such significant power to be the main source of galactic CR. At each explosion, the average energy transferred to CR is about 10^{43}–10^{44} J. From this, it follows that the average frequency of supernovae explosions must be about 10^{-1}–10^{-2} per year.

Types of supernovae

Most supernovae are of types Ia, Ib, Ic (e.g., type Ia is formatted from double stars with a white dwarf as an accreting star and different masses slightly more than mass of the Sun). Supernovae of type II are formatted from an evolving star of a mass more than about nine times the Sun's mass. In a typical type II supernova, the newly formed neutron core has an initial temperature of about 100 GK, that is, 6,000 times the temperature of the Sun's core. The core temperature of a star of over about 140 solar masses can become so high that photons convert spontaneously to electron–positron pairs, reducing the photon pressure supporting the star's outer layers and triggering a collapse that vaporizes the star. In this case, about 10^{46} J of energy is converted into a ten-second burst of neutrinos, which is the main output of this type of event.

Interstellar impact of supernovae and role in formation of the sun and solar system

Supernovae are a key source of elements heavier than oxygen in the Universe and, particularly, during formation of the Sun and solar system about 4.6 billion years ago. These elements are produced by nuclear fusion (for iron-56 and lighter elements), and by nucleo-synthesis during the supernova explosion for elements heavier than iron.

Nearby supernovae and their possible effects

Supernova between 30 and 1,000 pc, depending upon type and energy output, can be dangerous for the Earth's biosphere, human life, and high-level technology. Gamma rays from a supernova could induce chemical reactions in the upper atmosphere converting molecular nitrogen into nitrogen oxides, depleting the ozone layer enough to expose the surface to harmful solar and cosmic radiation. It was proposed that a nearby Supernova was the cause of the terminal Ordovician extinction, which resulted in the death of nearly 60% of the oceanic life on Earth. It has also been suggested that traces of past supernovae might be detectable on Earth in the form of metal isotope signatures in rock strata. Indeed, iron-60 enrichment was recently found in deep-sea rock of the Pacific Ocean. Type Ia supernovae are thought to be potentially the most dangerous if they occur close enough to the Earth. Because these supernovae arise from dim, common white dwarf stars, it is likely that a supernova that can affect the Earth will occur unpredictably and in a star system that is not well studied. One theory suggests that a Type Ia supernova would have to be closer than a 1,000 pc to affect the Earth. Several large stars within the Galaxy have been suggested as possible supernovae within the next 100 million years (Rho Cassiopeiae, Eta Carinae, RS Ophiuchi, U Scorpii, VY Canis Majoris, Betelgeuse, Antares, Spica, and many Wolf-Rayet stars). The nearest known supernova candidate is IK Pegasi (HR 8210), located at a distance of 150 light-years. In case a nearby supernova should occur, the information obtained from optical, x-ray, γ-ray, and cosmic ray observations will help to produce ALERT on expected different types of natural hazards (including radiation hazard) for people, biosphere, technology (especially for satellites and space-ships with astronauts), so that experts could decide what to do next (see also *Automated Local Evaluation in Real Time (ALERT)* and *Radiation Hazards*).

SURGE

Giovanni Cuomo
Hydraulics Applied Research & Engineering Consulting (HAREC) s.r.l., Rome, Italy

Synonyms

Sea level rise; Wave setup

Definition

A surge is a relatively long lasting increase in water level. Surges result from the combination of a series of factors including: sea level rise, astronomical tide, wind setup, atmospheric pressure gradient, wave setup, tsunami, and seiches. These phenomena become more evident in shallow water and coastal regions where their effects are enhanced by local bathymetric and topographic features.

Discussion

The (eustatic) sea level rise results from melting of the polar ice caps and thermal expansion of the water mass with temperature change. Observation suggests that it has occurred at a mean rate of 1.8 mm/year for the past century with more recent estimates (1993–2003) indicating an actual rise of 3 mm/year.

Astronomical tides are periodic oscillations of the sea level caused by the gravitational attraction of the Moon, the Sun, and the other astronomical bodies acting on the rotating Earth. Tides are the largest sources of short-term sea-level fluctuations and generate level variations that can exceed 10 m; their prediction is therefore essential to ensure safety of coastal navigation and the correct design of coastal structures. The world's largest tides have been recorded in Minas Basin, Nova Scotia, with a maximum tidal range recorded at 16.8 m (54.6 ft).

Wind setup is an increase of the water level due to the action (shear stress) exerted by inshore wind over the water surface and can build up the water level by up to 3 m in height. An initial estimate of the setup Δh of the water level induced by the wind over a distance Δx is given by:

$$\Delta h = K \frac{U^2}{gD} \Delta x$$

where $K = 3.2 \times 10^{-6}$ is a constant, U is the wind speed, g is the gravitational acceleration, and D is the water depth.

Similarly, wave setup is the increase in water level forced by the onshore mass transport of water by wave action. In the surf zone, wave setup can reach up to 30% of the incident (deepwater) wave height.

A barometric surge (Δh) is induced by the passage of a low atmospheric pressure front to balance the reduction

of hydrostatic pressure (Δp) exerted by the air column on the water surface:

$$\Delta h = \frac{\Delta p}{\rho g}$$

where ρg is the specific weight of the water body.

Wind-induced setups are usually accompanied by a fast movements of a pressure front (for example during tropical cyclones) and major wave storms, and have caused some of the most disastrous flooding and coastal catastrophes in the world's history including: the 1990 flood in Bangladesh, the 1953 flood in UK and the Netherlands, and the 2005 flood of New Orleans during passage of Hurricane Katrina. The highest storm surge noted in historical accounts was 13 m (43 ft) during the passage of the 1899 Cyclone Mahina over Bathurst Bay, Australia.

Tsunami, seiches, and other long period waves can also cause a sudden rise of the water surface. The largest ever observed tsunami was triggered on July 9, 1958 by an earthquake generated landslide in Lituya Bay, originating a giant wave measuring 524 m (1,719 ft) in height.

SUSCEPTIBILITY

María José Domínguez-Cuesta
Universidad de Oviedo, Oviedo, Spain

Synonyms

Lack of resistance; Hazardousness of place; Spatial hazard

Definition

Susceptibility means "the state of being susceptible" or "easily affected." In natural hazards terms, susceptibility is related to spatial aspects of the hazard. It refers to the tendency of an area to undergo the effects of a certain hazardous process (e.g., floods, earthquakes, tsunamis, subsidence, etc.) without taking into account either the moment of occurrence or potential victims and economic losses.

Discussion

Susceptibility linked to slope instabilities, for instance, indicates the tendency of an area to breakdown. According to Brabb (1984), susceptibility is the probability of an event happening in a specific zone, depending on the correlation of the instability-determining factors with the distribution of the past movements.

By applying different methods, including heuristic, probabilistic, nearest neighbor distance, matrix, or density methods among others, it is possible to draw up susceptibility maps that classify a territory into classes depending on the probability of undergoing future hazardous events. Good examples of sinkhole susceptibility maps can be seen in Galve et al. (2009).

CASE STUDY

TANGSHAN, CHINA (1976 EARTHQUAKE)

Zhengwen Zeng[1], Chenghu Wang[1,2]
[1]University of North Dakota, Grand Forks, ND, USA
[2]China Earthquake Administration, Beijing, China

Introduction

Seismic characteristics

The 1976 Tangshan Earthquake occurred at 03:42:56 a.m. on July 28, 1976 (local time). The epicenter was on Jixiang Road, Lunan District, Tangshan City, Hebei Province, China (Figure 1); geographic coordinates is 39.63°N 118.18°E. The focal depth was about 11 km. The sequence of the 1976 Tangshan Earthquake included five major events: two of magnitude >Ms 7, and three between Ms 6 and Ms 7. The Main seismic parameters of Tangshan Earthquake are as shown in Table 1, and the statistics of the earthquake sequence is in Table 2.

Tectonically, the Tangshan Earthquake occurred at the intersection of the east–west active faulting belt of Yinshan-Yanshan Mt. and the NNE active tectonic belt of North China Plain. Tangshan Earthquake ruptured 100 km (62 mile) along the Tangshan Fault, a right-lateral strike-slip fault in the north-northeastern direction. The epicenter area experienced 10 km (6 miles) extensive faulting. The fault ran through the city centre of Tangshan with a horizontal displacement up to 1.5 m (5 ft). During the main shock, much of northern China felt the tremors. The disaster-affected areas including Tangshan City and Tangshan Prefecture of Hebei Province, Tianjin Municipality, Beijing (Peking) Municipality, and adjacent areas. The most severely affected areas were Tangshan City, Tangshan Prefecture, and Tianjin Municipality. These three areas account for 99% of all casualties and property losses. Figure 2 is the intensity contour map of the Tangshan Earthquake (Guo, 2008).

Overview of the affected areas before the earthquake

Tangshan

Tangshan included two independent administrative units: Tangshan City and Tangshan Prefecture; both were under the direct administration of Hebei Province.

Tangshan City is located in the northeast of the province. In 1976, it was composed of two downtown districts (Lunan and Lubei), one industrial district (Kailuan Mine), and one suburban district (Kaiping). It was an important industrial city in the province; its industrial production output value was the second largest in the province. By 1976, Tangshan City had also become a very important part of Beijing-Tianjin-Tangshan economic zone. As of 1975, the gross industrial production of Tangshan City reached 2.2 billion RMB (1.2 billion USD), which accounted for nearly 1% of the national gross industrial production of China at that time.

Tangshan Prefecture included one city (Qinghuangdao) and 12 counties (Changli, Fengnan, Fengrun, Funing, Leting, Luanxian, Luan'nan, Lulong, Qian'an, Qianxi, Yutian, and Zunhua).

Tianjin

In 1976, Tianjin was one of the three municipalities directly under the jurisdiction of the central government in China. It is located in the northeastern part of North China Plain, close to Yanshan Mt. in the north, and adjacent to the Bohai Bay in the east. The entire city was composed of six downtown districts (Hebei, Hedong, Heping, Hexi, Hong Qiao, and Nakai), two industrial districts (Hangu and Tanggu), four suburban districts (Beijiao, Dongjiao, Nanjiao, and Xijiao), and five rural counties (Baodi, Jinghai, Jixian, Ninghe, and Wuqing). By population, Tianjin was the third

largest city in China, following Shanghai and Beijing. The gross industrial output value in 1975 was up to 14.4 billion RMB (7.7 billion USD). At that time, Tianjin had become one of the largest industrial, trading, finance, and communication centers in North China.

Casualties

The accuracy of casualties have been investigated and discussed by many specialists all over the world since the earthquake, the most recent research findings show

Tangshan, China (1976 Earthquake), Figure 2 Intensity contour map of Ms 7.8 Tangshan Earthquake.

Tangshan, China (1976 Earthquake), Table 3 Casualties of Tangshan Earthquake

Area	Dead	Severe injury	Light injury	Subtotal
Downtown Tangshan City	135,919	81,630	257,384	474,933

Total	242,469	167,124	541,463	951,056

that the Tangshan Earthquake had caused the death of 242,469 and 730,876 injuries across China, as detailed in Table 3 (Guo, 2008; Zou et al., 1990).

Statistics of casualties in Tangshan city

Pre-earthquake population of Tangshan City was 1,062 million. Due to the earthquake, 135,919 died, accounting for 12.8% of the total population; 81,630 people were severely injured, accounting for 7.7% of the total population; and the ratio of death to injury was 1.7. Lunan District of Tangshan City was the meizoseismal area; 34,089 people died, at a death rate of 26.7%. In Lubei District, the death rate was 16.4%; in suburban area, the death rate dropped to 10.2% elsewhere. Tables 4–7 show more detailed statistics on earthquake casualties. Table 5 shows that the death ratio between male and female was 1:1.21; the number of dead females was much greater than that of males. One of the reasons for that was there were more

male than female workers in the night shift when the earthquake occurred.

Statistics of casualties in Tianjin

In total 24,398 people died from the main earthquake of Ms 7.8 on July 28, 1976, and the strongest aftershock of Ms 7.2 in the afternoon on the same day, accounting for 0.49% of the entire population in Tianjin at that time (Guo, 2008; Zou et al., 1990). In addition, 21,874 people were severely injured, accounting for 0.31% of the population in the municipality. The ratio between death and severe injury was 1.12. There were 1,589,626 households in Tianjin; 31,545 households experienced dead or injured family members, accounting for 1.98% of the entire households (Table 8).

Economic loss

The high-intensity area of Tangshan Earthquake included Tangshan City and suburban, and Tianjin and suburban. The economic loss was concentrated in these areas.

Economic loss in Tangshan City

According to detailed investigation into Tangshan City downtown districts (Lubei and Lunan), industrial district (Kailuan Coal Mine), suburban district (Kaiping), and the City's orchards, the total economic loss caused by the earthquake was about 2.8 billion RMB (1.4 billion USD), as shown in Table 9 (Guo, 2008; Zou et al., 1990).

Before the earthquake, buildings and infrastructures in Tangshan City were built according to totally different codes and standards to meet diversified needs. Most were below poor construction standards. The entire city was virtually non-earthquake-resistant. The downtown districts were severely damaged. The damage rates of urban and rural buildings were 96% and 91%, respectively, as shown in Table 10 (Guo, 2008; Zou et al., 1990).

Economic loss in Tianjin

Based on investigation of the six urban districts (Hebei, Hedong, Heping, Hexi, Hongqiao, and Nankai) and the two industrial districts (Hangu and Tanggu), the total direct economic loss of Tianjin was 6.2 billion RMB

Value (billion RMB)	6.2	2.3	0.2	0.6	0.2	2.9

(3.2 billion USD), as shown in Table 11 (Guo, 2008; Zou et al., 1990).

According to statistical data, more houses in rural areas were destroyed or severely damaged than that in urban areas. In rural areas of Tianjin City, over 50% of the houses collapsed, and more than 30% of the houses were severely damaged.

Earthquake prediction and preparation

Seismic zoning and earthquake-resistant design

Before the 1976 earthquake, Tangshan was a city with considerable low-earthquake-resistance capabilities. According to the 1957 version of "China Earthquake Intensity Table" and "China Seismic Zoning Map," Tangshan was classified as seismic intensity VI area, because no big earthquakes had occurred in that region in documented history. By China's building code at that time, earthquake-resistant design was not compulsory in areas of seismic intensity VI and below. Therefore, before 1976 most buildings, old and new, in Tangshan did not have earthquake-resistant capacity.

By 1976, Tangshan was a middle-sized city growing from the integration and expansion of small towns and rural villages. Before the 1976 earthquake, buildings and infrastructures were built following different construction standards in different periods of time. Until 1949, when the People's Republic of China was founded, most downtown buildings were single-story houses owned by individual inhabitants; and coal miners were living in extremely simple work sheds. During the 1950s, Kailuan Coal Mine and other major state-owned enterprises built many single-story brick-and-stone residential houses for to be rented by their employees. Since the end of 1950s, local government and enterprises started building multi-level brick-and-concrete office buildings, most were 3 to 4 stories, some up to 7 to 8 stories; industrial buildings erected in that period of time were mainly single-story factory workshops, a few were frame structured. Except for some of the multi-story buildings constructed after 1960s which had been designed to resist seismic intensity of VI, the rest of Tangshan buildings were not designed for earthquake resistance. Therefore, Tangshan was virtually a city without any earthquake-resistance measures designed for such a strong earthquake.

Earthquake prediction

Scientific study of earthquake prediction in Tangshan started in 1968, 2 years after the destructive Xintai earthquake(s). In 1975, China predicted the Ms 7.3 Haicheng earthquake in which evacuation was ordered 1 day in advance. After this successful earthquake prediction, the first in human history, monitoring and prediction work for possible earthquakes in Tangshan and the nearby area was greatly intensified due to its closeness to Haicheng. At the beginning of 1976, the Tangshan Earthquake Administration Office issued its annual prediction stating that "between July and August or later in the year, strong earthquakes of Ms 5–7 may occur within 50 km around Tangshan City." Due to this prediction, many local governments and organizations established earthquake

preparation groups to lead and promote in earthquake prediction and disaster-reduction preparedness. Thereafter from April to July, many earthquake precursors had been observed. Many meetings at different scales and levels had been organized by the State Seismological Bureau (SSB, a.k.a. China Earthquake Administration) and the local earthquake administration office to discuss future earthquakes. Just 2 weeks before the earthquake, a national earthquake prediction meeting was held in Tangshan. Unfortunately, a unanimous opinion was not reached, and no official prediction was issued by SSB, on the imminent Tangshan Earthquake. However, knowing the situation from their representative, officials of Qinglong County (Figure 2) issued their order of evacuation 2 days before the earthquake. Though 7,300 houses collapsed and many more houses were damaged, there was only one direct death from the earthquake in the whole county. This evacuation order was one of the biggest miracles attributed to this disaster.

Earthquake emergency response

After the occurrence of the Tangshan Earthquake, the Chinese government started the earthquake emergency response system right away on the morning of July 28, 1976, established the earthquake response headquarters, and sent out the rescue troops in a very short time. Thousands of organizations and tens of thousands of people participated in the campaign of disaster relief. According to one brief statistical data issued on September 24, 1978, more than 110,000 army personnel (including 12,000 civil engineering soldiers) were involved in the rescue campaigns in the Tangshan Earthquake area.

On knowing the earthquake news, all the Chinese people were very active to donate money and materials. According to the statistical data of late October 1976, over 700,000 t of goods and materials for disaster relief from all over China were transported to the Tangshan Earthquake area, including 9,740 t of preserved foods and 150,000 t of finished grains. In order to transport these goods and materials to the disaster area, the government allocated large quantities of transport vehicles: over 1,000 sorties of flights, 18,000 train vehicles, and 8,000 military trucks were mobilized.

The Tangshan Earthquake astonished the world, and received close attention from foreign countries and citizens. Leaders of many countries sent telegrams to express their sympathies to the people of the disaster area and support to the disaster relief campaign. However, substance support from other countries was very limited, mainly due to the cold war at that time and China's practice to be self-reliant.

Recovery and reconstruction

As early as August 8, 1976 the Chinese government began to draft the recovery and reconstruction plan of Tangshan City. In September 1976, it was decided that Tangshan would be rebuilt on its original site. Three districts would form the new Tangshan: the residential city with its parks and public buildings, the Fengrun industrial district in the north, and the mining district in the east. The total planned population would be 760,000 and would occupy an area of 73.22 km^2. The reconstruction fund from the central government for housing, infrastructures, public buildings, etc., would be 2.44 billion RMB. But the fund to restore large, state-owned enterprises, such as Kailuan Coal Mine, Tangshan Steel Corp., Railway Systems, Mailing Systems, etc., would be collected from other channels.

In March of 1978, the reconstruction headquarter of Tangshan City was established to take charge of planning, design, construction, land use claim, relocation, building material preparation, and all other related things. This was also a milestone to the recovery and reconstruction of Tangshan City. The reconstruction process lasted for 8 years, from March 1978 to the end of 1985. A new city finally was erected from ruins. By the end of 1985, about 17,700,000 m^2 buildings had been finished, including 11,000,000 m^2 residential buildings and 6,700,000 m^2 industrial and office buildings. By early 1986, all temporary, simple buildings disappeared. This marked the successful completion of recovery and reconstruction of Tangshan City.

TECTONIC AND TECTONO-SEISMIC HAZARDS

James P. McCalpin
GEO-HAZ Consulting Inc., Crestone, CO, USA

Definition

Tectonic Hazard: Threats to humans and infrastructure posed by tectonic processes.
Tectono-Seismic Hazards: The subset of tectonic hazards that occurs during and immediately after an earthquake.

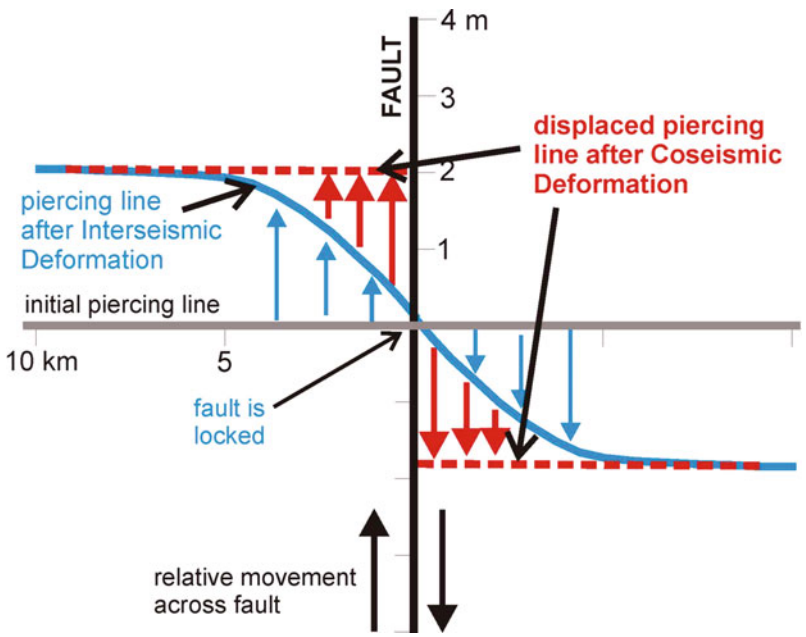
Tectonic versus tectono-seismic hazards

Tectonics is the field of study within geology concerned with structures within the lithosphere (faults, folds), and particularly with the forces and movements that have created such structures. Tectonic processes include the various movements of the Earth's crust, such as slip along active geologic structures, the vertical warping of the crust due to loading or unloading, or the movement of molten rock (magma). Such processes can be slow or rapid, although slow processes rarely result in life-threatening disasters (see *Geological/Geophysical Disasters*).

Tectonic hazards result from three general types of physical processes:

1. Rapid fault rupture and its associated earthquake (see *Fault*; *Earthquake*). These hazards are often referred to as "tectono-seismic hazards," or simply "seismic hazards."
2. Physical displacement or warping of the Earth's crust (uplift, depression, folding, tilting and horizontal motion) that occurs either rapidly or slowly. These are "tectonic hazards."
3. Movement of molten rock material (magma) within the Earth's crust (intrusive igneous activity) and at the Earth's surface (extrusive volcanic activity). These are "volcanic hazards" (see *Volcanoes and Volcanic Eruptions*).

Because most injuries and damages are the result of tectono-seismic hazards (related to earthquakes), these are addressed first, even though they form a subset of all tectonic hazards.



Seismic hazards, the physical processes

Seismic hazards arise from earthquakes (see *Earthquake*; *Seismology*). Typical earthquakes are caused by sudden slippage on faults that were previously locked and had been accumulating *crustal strain* over considerable time. The earthquake trigger can be natural strain accumulation or an anthropogenic increase in strain or a decrease in frictional resistance (see *Induced Seismicity*). During the earthquake, the stored energy in the strained crust on either side of the seismogenic fault is released as vibratory seismic waves when the fault suddenly slips (see *Elastic Rebound Theory*).

Seismic Hazards are typically divided into three categories:

1. Hazards due to vibratory ground shaking (strong ground motion)
2. Hazards due to surface rupture of the causative fault
3. Hazards due to secondary effects of ground shaking, such as landsliding and liquefaction.

All of these processes may occur at the time of the earthquake, so they comprise the "coseismic" part of the

Tectonic and Tectono-Seismic Hazards, Figure 1 Schematic diagram of movement across a fault (*center*) during the earthquake deformation cycle. The drawing can be viewed either as a plan view (map) or as a vertical cross-section. Any initial piercing line (*gray*) extending across the fault (*black*) will be slowly bent by interseismic deformation (*blue arrows*), but there is no offset at the fault plane because it is locked. During an earthquake, the fault "unlocks" and slips, and the two sides slide past each other and rapidly unbend, resuming their initial shape. It is this unbending ("rebound") that releases the earthquake elastic waves. After coseismic deformation (*red arrows*), the initial piercing line is once again straight, but is displaced at the fault. Dimensions labeled on the axes represent a fault with 4 m of coseismic displacement, preceded by interseismic strain that extended 5 km away from the fault.

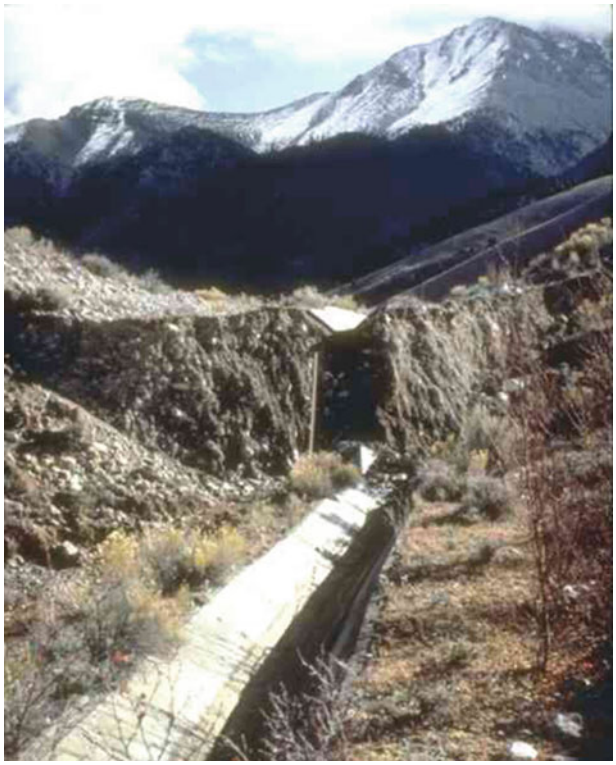
earthquake deformation cycle (Figure 1). After the earthquake, crustal deformation continues at a slow rate during the interseismic part of the earthquake deformation cycle, until finally stress again exceeds fault strength and another earthquake occurs. Interseismic deformation is described later under Tectonic Hazards.

Vibratory ground shaking (strong ground motion)

When earthquake elastic waves reach the Earth's surface they produce vertical and horizontal accelerations of the surface and of all objects that lie on or beneath the surface (buildings, roads, bridges, pipelines, etc.). These waves are strongest nearest the earthquake epicenter and weaken with distance. Motions can be further amplified by certain geological site conditions (e.g., soft sediments overlying bedrock) or topographic site conditions ("whipping" of hilltops and ridge crests).

Fault surface rupture

In large earthquakes (Moment Magnitude [Mw] greater than 6.5–7; see *Magnitude Measures*), displacement on the fault plane is so great that it propagates upward to the ground surface and displaces the ground surface along the mapped fault trace (Figure 2). Fault surface rupture increases in height and length with increasing earthquake magnitude. Vertical displacement along a normal or reverse fault can create a surface fault scarp as high as 10 m along the fault trace (e.g., 1897 Assam, India earthquake). On strike-slip faults, the largest historic coseismic displacement was 18.7 m during the 1855 Wairarapa earthquake, New Zealand (pure horizontal, right-lateral movement).



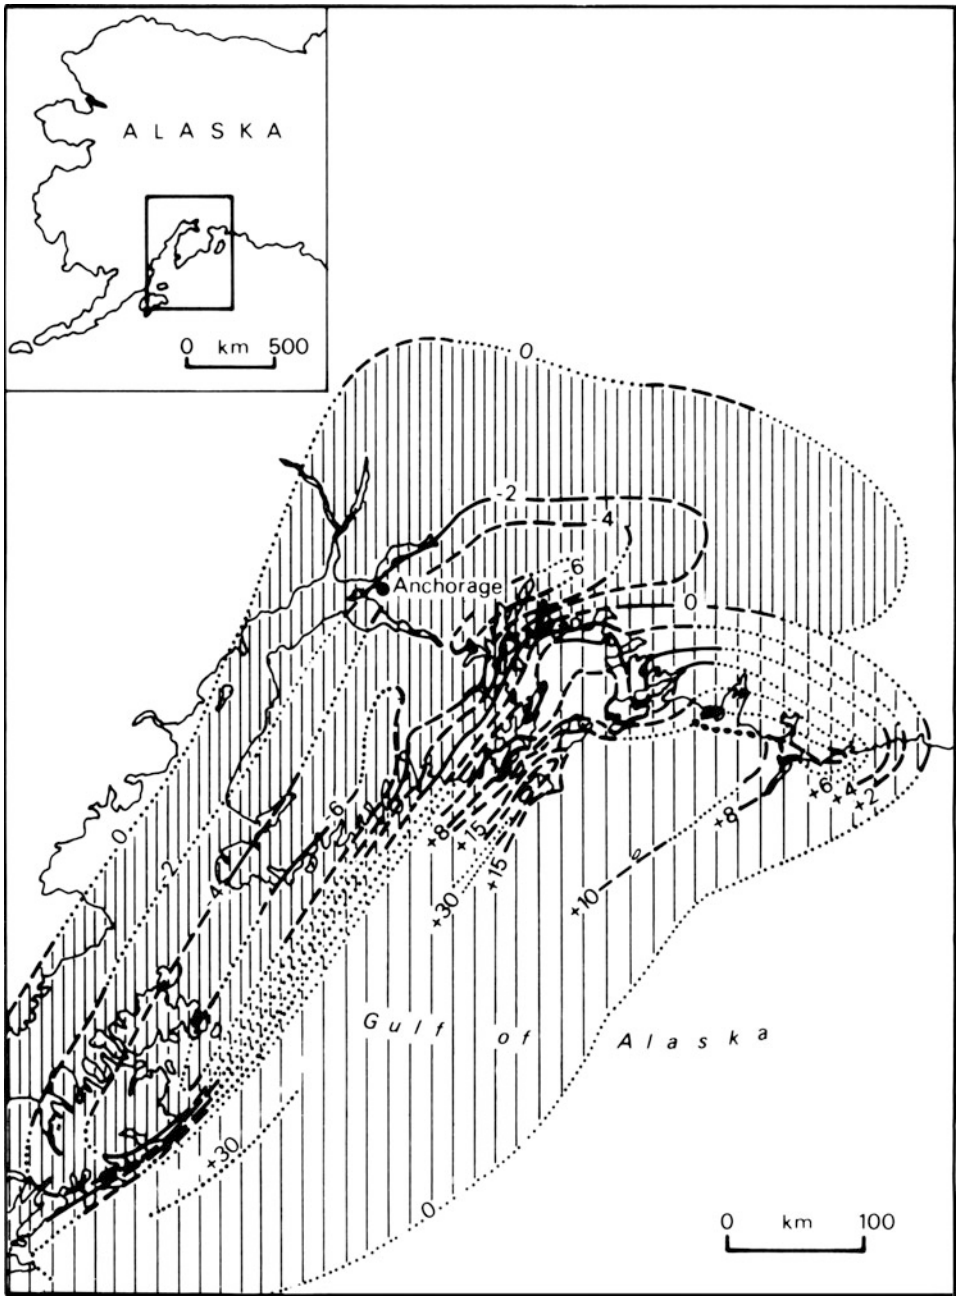
Coseismic geodetic changes (uplift, subsidence)

During an earthquake the large crustal blocks on either side of the coseismic fault slip rapidly past each other, and also bend (rebound) to try to regain their original, pre-strain shape (see *Elastic Rebound Theory*). This rapid coseismic rebound causes vertical movements of the crust far away from the fault during very large earthquakes. For example, in the 1964 Mw 9.2 Alaska earthquake, an area of 150,000 km^2 landward of the coast subsided up to 6 m (Figure 3) and a corresponding area of 150,000 km^2 offshore rose up to 30 m (see *Subduction*).

Seismic hazards, how processes create hazards

Vibratory ground shaking (strong ground motion)

Every earthquake produces some ground motion, but for the vast majority of earthquakes on the planet, this motion is so small that it can only be measured by sensitive seismographs. Humans seldom report earthquakes as "felt" if the magnitude is less than 2.0, and the ground acceleration less than about 0.02 g. In general, earthquakes smaller than about M5.0 rarely generate strong enough ground motions to cause damage, even near the epicenter. Lee et al. (2003) suggest that an acceleration of 0.1 g is the approximate threshold for damage to old structures and non-earthquake-resistant structures.



Tectonic and Tectono-Seismic Hazards, Figure 2 The magnitude 6.9 earthquake of October 28, 1983, near Borah Peak, Idaho, produced this normal-oblique fault scarp. The scarp and fracture zone are located on Rock Creek, near Dickey, Idaho, and Double Springs Pass Road. The wooden pole is 1.9 m high. This normal fault shows characteristics of oblique slip, where there is both vertical and horizontal displacement. The horizontal movement is left-lateral. The fault scarp extended for more than 35 km, with vertical displacements up to 2.5 m observed between MacKay and Challis, Idaho (Photo credit: G. Reagor, U.S. Geological Survey. Source: NGDC, 1997).

Strong earthquake ground motion can exceed the design tolerances of the structures and can cause damage of various sorts (see *Earthquake Damage*). This exceedance often occurs because the dominant period of the seismic waves matches either the resonant period of the structure, causing amplified resonant motion in the structure, or the resonant frequency of the structure's geological foundation. Most of the deaths, injuries, and damage in historic earthquakes have been caused by collapse of buildings due to strong ground acceleration (Figure 4). This is particularly common for unreinforced masonry buildings (see *Unreinforced Masonry Building*). Vibratory ground motion also creates a suite of "secondary hazards" (described later).

Fault surface rupture

Fault surface displacement will rupture any structure located on or across the fault trace, such as a building, road, bridge, dam, buried utility lines, etc. For buildings,

Tectonic and Tectono-Seismic Hazards, Figure 3 Regional coseismic deformation produced by the Mw 9.2 1964 Alaskan earthquake. Regional subsidence (*closely spaced lines*) and uplift (widely *spaced lines*) encompassed most of the forearc along the length of the rupture. The axis of maximum regional subsidence and maximum regional uplift were located near the zero isobase (no land-level change). Measurements are in feet (From Vita-Finzi (1986), after data in Plafker (1969)).

vertical displacement of more than 30 cm typically causes collapse; smaller displacements can often be repaired (Youd, 1980). Buried utility lines can break by decimeter to meter-scale displacements, either vertical or horizontal. Roads have the greatest resilience to fault surface rupture, because unpaved roads can simply be rebuilt.

Coseismic geodetic changes (uplift, subsidence)

Coseismic geodetic changes cause the most damage along shorelines of oceans or lakes because they cause a shift in the area of inundation. Coastal regions that permanently subside are invaded by water, which can submerge coastal buildings, roads, and docks. In coastal regions that

Tectonic and Tectono-Seismic Hazards, Figure 4 Collapse of diaphragms (floors) leaving walls standing in building in Leninakan, Armenia, during the 1988 Spitak earthquake (M 6.9). This three story building is one of the older buildings. Most of the newer ones and two story dwellings and two and three story commercial buildings in Leninakan received little damage. The debris of a nine story building is to the right. Such collapses left no spaces for occupant survival. One hundred and thirty-two nine story precast-concrete-frame buildings collapsed or were heavily damaged in this city (Photograph Credit: U.S. Geological Survey (C.J. Langer). Source: NGDC, 1997).

permanently rise (uplift), docks and harbor facilities become stranded above the water line and become unusable (Figure 5).

Secondary hazards

Vibratory ground motion during the earthquake can cause ground failures such as landslides (see *Landslide*; *Mass Movement*); lateral spreads (a type of low-gradient landslide caused by liquefaction) (see *Lateral Spreading*); snow avalanches (see *Avalanches*); and liquefaction (see *Liquefaction*). Because these ground failures require high ground accelerations, they occur mainly in the epicentral region, but in very large earthquakes the epicentral region can be significant in size. For example, in the Alaska earthquake of 1964, landslides (Figure 6) were triggered in an area of 300,000 km^2. Likewise, liquefaction can cause sudden loss of foundation strength and foundation bearing failures in the epicentral area (Figure 7). In such cases, even though the building withstands the strong ground shaking during the earthquake and does not collapse, it subsides or tilts to such a degree it becomes unusable.

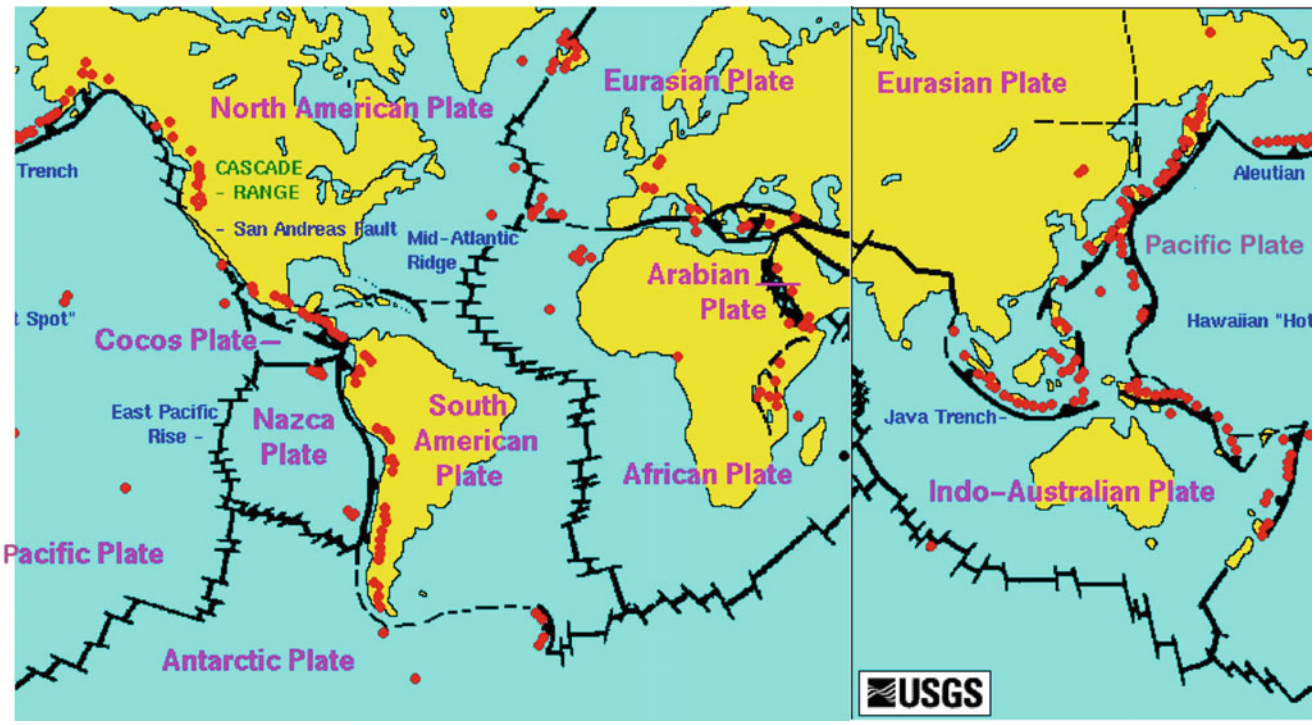
In many earthquakes, relief efforts are obstructed by secondary ground failures (landslides, rockfalls, lateral spreading), which block roads and railroads into the epicentral area. Added to this is the breakage of critical utility lines (water and gas pipelines, electrical lines), also due to secondary ground failures. The lack of water supply, electricity, and heat further exacerbates the so-called "follow-on" hazards such as fire and disease.

Coseismic geodetic changes can cause tsunamis (see *Tsunami*; *Indian Ocean Tsunami, 2004*) and seiches (see *Seiche*). A estimated 228,000 persons were killed or missing (and presumed dead) after the 2004 Sumatra earthquake (Mw 9.1), mostly due to a tsunami that reached a height near 35 m along the Sumatran coast, and more than 5 m on the east coast of India, 2,000 km from the epicentral region.

Numerous "Follow-on" Secondary Hazards typically occur during the aftermath of a large earthquake. These include fire (see *Fire and Firestorms*); disease (see *Epidemiology of Disease in Natural Disasters*); looting, etc. Although these hazards are not strictly tectonic hazards, they are ultimately caused by a tectonic hazard.

Seismic hazards, the spatial distribution

The worldwide distribution of earthquakes and volcanoes shows a strong spatial association with plate boundaries (Figure 8; see Plate Tectonics). Specifically, divergent plate boundaries (mid-ocean spreading centers and their on-land extensions) are characterized by extensional tectonic faulting, shallow earthquakes, and basaltic volcanism (e.g., Iceland on the Mid-Atlantic Ridge). In contrast, convergent plate boundaries are typified by reverse and thrust faulting, subduction, folding, and



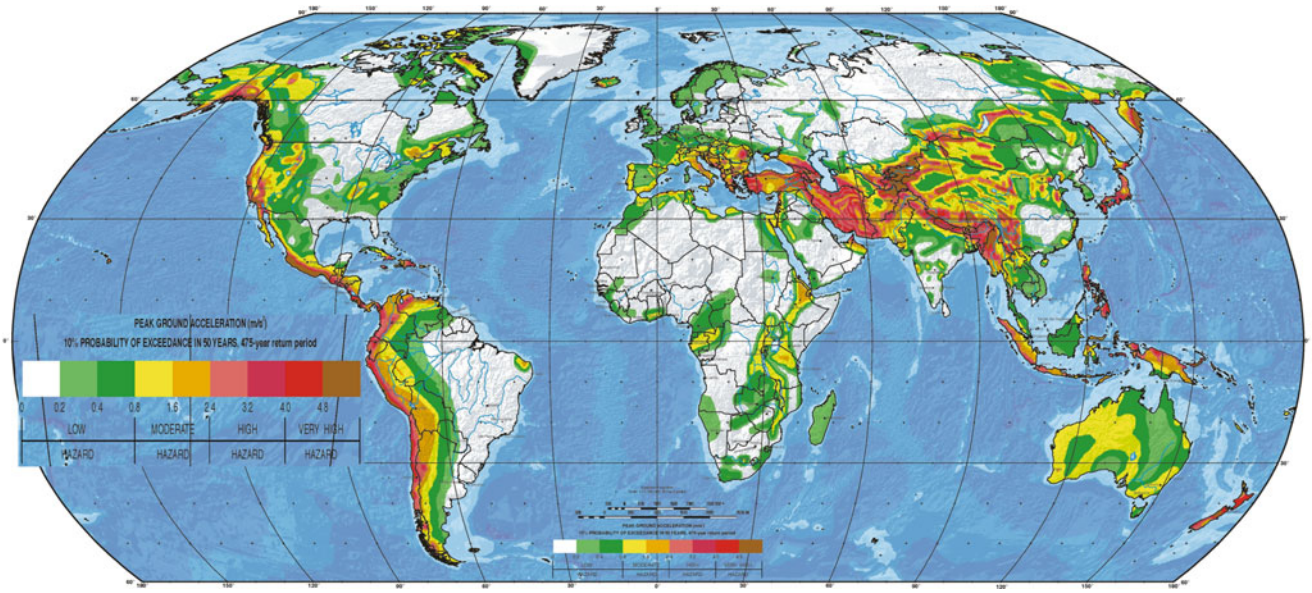
Tectonic and Tectono-Seismic Hazards, Figure 5 Uplifted dock, Prince William Sound, Alaska. The dock on Hinchinbrook Island, Prince William Sound, shows uplift. Land in this area rose about 8 ft (2.4 m) during the earthquake, and the dock could then be used only at extremely high tides. Tsunami damage also occurred in this area (Photo credit: U.S. Geological Survey, Menlo Park, CA. Source: NGDC, 1997).

Tectonic and Tectono-Seismic Hazards, Figure 6 The Government Hill Elementary School in Anchorage, Alaska was torn apart by subsidence of the graben at the head of the Government Hill landslide, during the 1964 M 9.2 earthquake. The south wing of the school dropped about 30 ft (9 m); the east wing split lengthwise and collapsed. The playground became a chaotic mass of blocks and fissures. Part of this slide became an earth flow that spread 150 ft (45.5 m) across the flats into the Alaska Railroad yards. During the earthquake, the shaking loosened clay beneath Government Hill and the clay began to move toward the flats. On the hill, 400 ft (121.2 m) back from the rim of the bluff, the earth cracked on a front 1,180 ft (357.6 m) wide (Photo credit: U.S. Geological Survey, Menlo Park, CA. Source: NGDC, 1997).

Tectonic and Tectono-Seismic Hazards, Figure 7 Aerial view of leaning apartment houses in Niigata, Japan, produced by soil liquefaction during the June 14, 1964 Niigata earthquake (M 7.4). Most of the damage was caused by cracking and unequal settlement of the ground such as is shown here. About one third of the city subsided by as much as 2 m as a result of sand compaction. The magnitude 7.4 earthquake killed 26 people and destroyed 3,018 houses and moderately or severely damaged 9,750 in Niigata prefecture (Source: NGDC, 1997).

Tectonic and Tectono-Seismic Hazards, Figure 8 World map of major tectonic plates (names in *purple*), divergent plate boundaries (*black lines* segmented by numerous cross-faults), convergent plate boundaries (*black lines* with *triangles*), and active volcanoes (*red circles*) (Source: U.S. Geological Survey, Cascades Volcano Observatory).

explosive island-arc volcanism (e.g., west coast of South America and the Andes volcanic chain).



Within the interiors of the major tectonic plates, both earthquakes and volcanoes are less abundant. This is particularly true of the so-called "stable continental regions," the core areas of continents composed of Precambrian basement rocks, such as the Canadian and Fennoscandian Shields. However, many major tectonic plates also contain sub-plates (microplates) in which contemporary deformation is concentrated. An example is the Basin and Range extensional province of the North American plate.

Figure 9 shows the uneven spatial distribution of worldwide seismic hazards. Large parts of the continental interiors of North America, South America, Africa, and northern Asia have very low seismic hazard (white areas in Figure 9). Surrounding these areas are bands of low seismic hazard (green). The high hazard areas (pink, red, brown) comprise narrow bands parallel to major active faults at plate boundaries. Thus, high hazard zones on the western margins of North and South America coincide with the ocean-continent subduction and transform faults of the eastern margin of the Pacific plate. The high hazard zones extending from southern Europe to southeast Asia coincide with the great zone of ongoing continent-continent collision between African and Indo-Australian plates to the south, and the Eurasian plate to the north. High hazard zones of the western Pacific rim (from Kamchatka, south to New Zealand) coincide with ocean-ocean subduction and transform faults. The moderate seismic hazard in eastern Africa coincides with the East African rift zone, a zone of intra-continental spreading (incipient divergent plate boundary). Other anomalous areas include Australia, which displays moderate seismic hazard despite being composed of older plate interior rocks.

Seismic hazards, the temporal distribution

In those regions where most of the seismic hazard emanates from a single fault, the true seismic hazard in the near future may depart significantly from the hazard shown in Figure 9. This arises due to the temporal character of the earthquake deformation cycle, in which stress on a fault builds up over time, eventually culminating in a large earthquake, after which stress falls to low levels and must rebuild until the next earthquake. From this periodic model of large earthquake occurrence, it follows that each fault has a "memory" of when it last ruptured. The seismic hazard on such a fault varies through time, being the lowest just after a major earthquake (near-total stress release), and progressively higher until the next earthquake.

The seismic hazard values shown in Figure 9 do not reflect the fact that faults have a "memory." Thus, the accelerations shown are derived from long-term average slip rates on the faults, with no knowledge of when the latest earthquake occurred on them. Such a seismic hazard model is "memoryless," and assumes that the probability of a large earthquake occurring on a fault is the same in every year within the earthquake deformation cycle, from the year after a large earthquake, to hundreds or thousands of years later. The latest generation of seismic hazard models do incorporate memory for selected faults, and

Tectonic and Tectono-Seismic Hazards, Figure 9 Seismic hazard map of the world. Color shading represents classes of predicted peak ground acceleration (m/s^2), which have only a 10% probability of being exceeded in any 50-year time span. This is equivalent to the largest ground motion expected in a 475-year return period. (Note: to convert these accelerations to *g*, divide by 9.8. Source: Global Seismic Hazard Assessment Program (www.seismo.ethz.ch/GSHAP)).

the resulting probabilities of accelerations are termed "conditional probabilities." They are conditioned from the fact that the latest large earthquake occurred at a given time in the past, implying that we are now within a certain part of the (current) earthquake deformation cycle.

Seismic hazards, mitigation

All geohazards can be mitigated by one of four basic approaches: (1) Avoid the hazard, (2) Mitigate the process causing the hazard, (3) Mitigate what is at risk from the hazard, or (4) Accept the hazard and insure against it. To avoid a hazardous seismic process, one must know only *where* it will operate in the future, not necessarily *when* it will occur. For example, mapping active fault traces will show where future hazards exist from surface fault rupture, and thus which areas to avoid for development. Government agencies may require builders to certify that their proposed buildings do not overlie an active fault trace (e.g., California's "Alquist-Priolo" Special Study Zones; www.consrv.ca.gov/CGS/rghm/ap/Pages/index.html).

Due to the distributed nature of earthquake ground shaking, it is not possible to avoid it in seismically active areas, nor to "mitigate the process" (i.e., to stop the occurrence of earthquakes at their sources). Instead, most seismic mitigation involves mitigating the facilities that are at risk from seismic ground motions. The first step is to predict the levels of seismic shaking, either at a single site (site study) or over a larger area (seismic hazard map, such as Figure 9). Both approaches require not only characterizing all relevant seismic source zones, but also the attenuation of seismic waves with travel distance from each source, and the response (often complex) of local geologic deposits to shaking. The latter factor is mainly considered in local, rather than regional, seismic hazard analyses and is a component of seismic microzonation. Macrozonation results in global-scale or regional-scale seismic hazard maps based on historic and prehistoric seismicity (for the latter, see *Paleoseismology*) and attenuation relationships only.

Once the strength and probability of future ground motions is predicted, builders must choose a design acceleration (or velocity) for the building; that is, an acceleration below which the building will not fail. The choice of design acceleration is typically determined by the consequences of failure and the cost-benefit ratio. If the consequence of failure is catastrophic (a nuclear power plant, a large dam), the design acceleration will be high, perhaps 0.5 g or higher. Conversely, if the consequences of failure are small (a retaining wall along a minor highway), the design acceleration may be quite low (say, 0.2 g or lower). Once the design acceleration is chosen, the builder will follow established principles of structural engineering to ensure that the structure will not fail at levels below the design acceleration (see *Structural Mitigation*).

Tectonic hazards

Tectonic hazards arise from slow to rapid movements of the Earth's crust that are not coseismic, that is, do not occur during an earthquake or the coseismic part of the earthquake deformation cycle. These processes include slow displacement along faults (creep), slow folding or tilting, crustal uplift, and crustal subsidence (depression). Ultimately, these processes are caused by either plate tectonic motions or by vertical loading/unloading of the crust. The tectonic processes occur mainly in the vicinity of active faults during the *interseismic* part of the earthquake deformation cycle.

Tectonic hazards, the physical processes

Slow displacement along faults

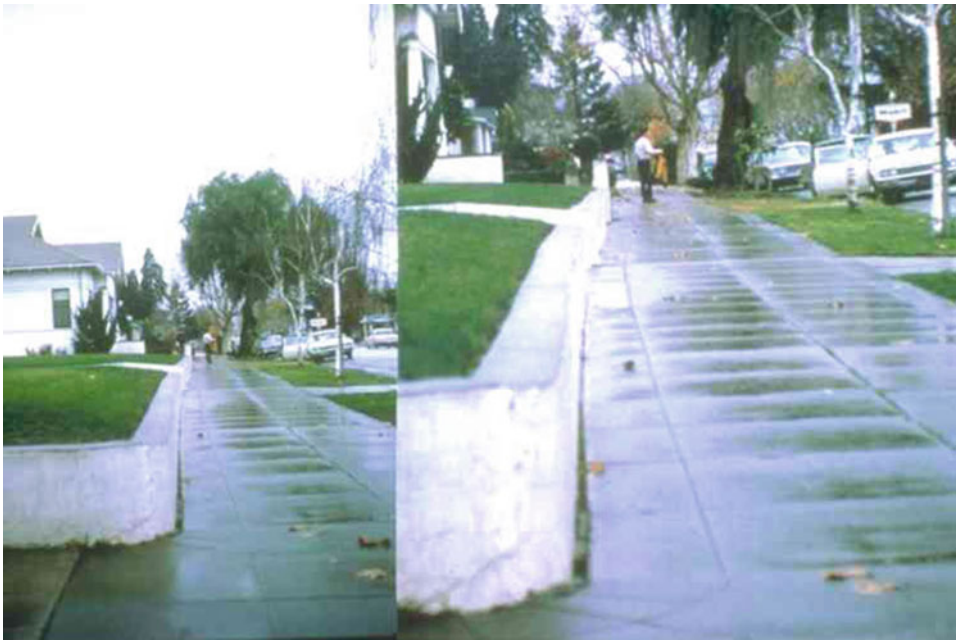


Figure 1 shows how the crustal blocks on either side of a fault bend during the interseismic part of the earthquake deformation cycle, while the fault remains locked. This is the normal behavior of faults, but in extremely weak rocks the friction on the fault plane is so small that the fault never locks, but instead continuously slips. This slow, continuous slip is termed fault creep. A well-known example of fault creep occurs in the Hollister section of the San Andreas fault, USA, where the fault passes through a region of weak serpentinites. Right-lateral slip occurs more or less continuously but slowly across the fault in a narrow zone (Figure 10).

Slow earthquakes

During most earthquakes, the fault ruptures at approximately the P-wave velocity in rock, roughly 3–5 km/s. Thus, a 20 km-long rupture would occur in 4–6 s. However, in the past decade, a new class of "slow earthquakes" has been detected by precise geodetic measurements. These slip events have so far only been detected on subduction zone megathrusts, and are not "earthquakes" per se, since they do not release seismic waves. Instead, the fault plane undergoes periods of anomalously rapid slip, amounting to several meters in a week or a month.

Crustal uplift and subsidence

The Earth's thin rigid crust overlies a more ductile mantle layer, and placing loads on the crust will cause sagging (subsidence) of the crust as the ductile mantle material extrudes laterally away from the load. Conversely, removal of a load on the crust permits the mantle material to return, which pushes the crust upward (crustal uplift, or rebound). Most measured crustal uplift and subsidence has been caused by the adding or removal of thick glacial ice, for example, the melting of the continental ice sheets since the Latest Glacial Maximum (LGM) at ca. 18,000 years before present. Such uplift has amounted to several tens of meters in the past 18 ka, at rates up to a few tens of mm/year. In the most extreme case, Morner (2003) cites reconstructed glacial rebound rates of 50 cm/year occurring around 10 ka from the center of the former Fennoscandian ice sheet, which he associates

Tectonic and Tectono-Seismic Hazards, Figure 10 Examples of fault creep in California, USA. In the town of Hollister, the Calaveras fault (a subsidiary of the famous San Andreas fault) is slowly slipping right-laterally, producing noticeable offsets and damage to curbs, sidewalks, fences, and even houses. *The left photo* shows a slightly bent curb northeast of the corner of 4th and Locust Streets, looking down 4th Street, in December, 1966. The movement along the fault is causing the standing wall to be slightly bent. *The right photo* was taken in 1995 and shows the additional creep-related deformation over 29 years (Source: NGDC, 1997).

with a brief but intense period of rebound-caused earthquakes.

However, other geologic processes can create and remove loads. An example of rapid unloading is the desiccation of late Quaternary lakes such as Lake Bonneville in the western USA, which removed a significant water load in only a few thousand years (the LGM lake had a maximum depth of 300 m and covered 50,000 km^2; Gilbert, 1890). The rebound was measured from uplifted shorelines and amounts to +51 m near the center of the former lake.

Normally, geologic loading/unloading proceeds more slowly than the rates cited above, associated with the accumulation of thick volcanic deposits or the erosion of mountain ranges (measured in mm/year). The latter phenomenon gave rise to the concept of isostasy, which predicts that as erosion removes weight from a continental landmass, the continental crust will slowly rise due to buoyant forces from the mantle, thus "replacing" some of the elevation lost to erosion.

Tectonic hazards, how processes create hazards

Slow displacement along faults (creep)

Creep movement on active faults will slowly displace any structures or lifelines (roads, utilities, pipelines) built across them. Whether the creep poses a hazard depends on how fast the creep rate is, how sensitive the structure is to displacement, and whether the creep is occurring undetected or not. In most cases detected fault creep simply causes maintenance problems in structures or utilities (Figure 10). However, undetected creep proceeding at a high rate over a long time period could conceivably strain underground utilities, such as high-pressure gas lines, so they would eventually break.

Crustal subsidence

Crustal subsidence can be caused by a variety of mechanisms, from interseismic deformation near an active fault, to slow movement on a downwarping fold (syncline), to depression from crustal loading. (Non-tectonic mechanisms can also cause subsidence of the surface; see *Land Subsidence*).

Slow crustal subsidence does not generally pose a hazard except for:

1. Along the margins of water bodies such as lakes or oceans. Coastal subsidence causes submergence of land along the coastline, and infrastructure becomes invaded by water. The effect of shoreline erosion is brought farther inland. Engineered systems such as sewer lines and their outfall ends are put under deeper water, and may no longer perform as designed.
2. Where the lateral gradient of uplift/subsidence is high, such that the ground surface tilts. Many engineered structures are sensitive to small tilts, such as elevated water tanks, high-rise buildings, etc.

Crustal uplift

Crustal uplift can be caused by a variety of mechanisms, from interseismic deformation near an active fault, to slow movement on an upwarping fold (anticline), to rebound from crustal unloading.

Slow crustal uplift does not generally pose a hazard except:

1. Along the margins of water bodies such as lakes or oceans. Coastal uplift will eventually cause the shoreline to retreat seaward, leaving shore facilities separated from the shoreline, and decreasing the water depth at docks and slips. For example, docks and other loading facilities may no longer have sufficient water depth to be used, requiring dredging.
2. Where the lateral gradient of uplift is high, such that the ground surface tilts. Many engineered structures are sensitive to small tilts, such as water tanks, high-rise buildings, etc.

Tectonic hazards, the spatial distribution

Those tectonic hazards associated with active faults and folds have a similar geographic distribution to tectono-seismic hazards, which were described previously. However, due to their slow movement rate, tectonic processes create their most significant hazards in coastal regions, where land elevation changes cause shifts in shorelines. Crustal loading and unloading is greatest in areas where glacial ice thickness is rapidly changing today, or has changed in the past. The latter includes the large continental ice sheets such as the Laurentide in North America and the Fennoscandian in Europe.

Tectonic hazards, mitigation

Slow tectonic hazards are seldom mitigated, because they pose little threat to life safety or to the structural soundness of buildings. Accordingly, they are dealt with more as nuisance problems by routine maintenance.

Summary

Tectonic processes result in movements of the Earth's crust, and these movements can cause hazards to life via earthquakes when the movement is very rapid (tectono-seismic hazards), and to certain structures when movement is slower. Tectonic hazards in general result from three types of physical processes:

1. Rapid fault rupture and its associated earthquake (see *Fault*; *Earthquake*).
2. Physical displacement or warping of the Earth's crust (uplift, depression, folding, tilting, and horizontal motion) that occurs either rapidly or slowly.
3. Movement of molten rock material (magma) within the Earth's crust (intrusive igneous activity) and at the Earth's surface (extrusive volcanic activity). These are "volcanic hazards." (see *Volcanoes and Volcanic Eruptions*).

Most injuries and damages in historic time have been caused by tectono-seismic hazards (related to earthquakes), rather than to the slower tectonic processes such as fault creep, warping, tilting, uplift, and subsidence.

TECTONIC TREMOR

David Shelly
U.S. Geological Survey, Menlo Park, California, CA, USA

Synonyms

Deep low-frequency tremor; Non-volcanic tremor

Definition

Tectonic, non-volcanic tremor is a weak vibration of ground, which cannot be felt by humans but can be detected by sensitive seismometers. It is defined empirically as a low-amplitude, extended duration seismic signal associated with the deep portion (~20–40 km depth) of some major faults. It is typically observed most clearly in the frequency range of 2–8 Hz and is depleted in energy at higher frequencies relative to regular earthquakes.

Discussion

Origin

Tectonic "non-volcanic" tremor was first reported in 2002, when it was identified in the Nankai Trough subduction zone of southwest Japan (Obara, 2002). Since then, tremor has been identified in other subduction zones (Rogers and Dragert, 2003) and the strike-slip San Andreas fault (Nadeau and Dolenc, 2005), yet it remains incompletely understood (Schwartz and Rokosky, 2007; Rubinstein et al., 2010). Tremor appears to be composed of numerous small overlapping earthquakes, sometimes called low-frequency earthquakes (LFEs) (Katsumata and Kamaya, 2003). Growing evidence suggests that tremor is generated by shear slip on these deep faults (Ide et al., 2007; Shelly et al., 2007a; Wech and Creager, 2007), often as part of larger slow slip events (Rogers and Dragert, 2003; Obara et al., 2004). Slip from larger multi-day events can often be observed geodetically with Global Positioning System (GPS) (Rogers and Dragert, 2003) or borehole tilt instruments (Obara et al., 2004). In Cascadia and southwest Japan, tremor and slip events occur semi-regularly with periods ranging from 3 to 20 months, depending on the location (Rogers and Dragert, 2003; Obara et al., 2004; Brudzinski and Allen, 2007). The coupled phenomenon is sometimes called "Episodic tremor and slip" (ETS) (Rogers and Dragert, 2003).

Triggering

Unlike regular earthquakes, tremor is commonly triggered by minute stresses imparted by teleseismic waves (especially surface waves) (e.g., [Miyazawa and Mori, 2005; Rubinstein et al., 2007; Peng et al., 2009]) and tidal stresses (e.g., [Nakata et al., 2008; Thomas et al., 2009]). These observations suggest that the affected faults are critically stressed and they support the notion that high pore fluid pressures exist within the fault zone, as suggested by some seismic imaging studies (Shelly et al., 2006).

Unanswered questions

Despite recent study, many aspects of the underlying physics of tremor remain unexplained. In particular, why are such events slow? Observations of tremor migration in subduction zones at ~10 km/day along strike (Obara, 2002; Kao et al., 2007) and 30–150 km/h (Shelly et al., 2007b) in the slip direction suggest that fault geometry may play a role, but the physics behind these migration velocities is still poorly understood.

The relationship between tremor (and slow slip) and shallower earthquakes is of particular interest to earth scientists, yet also remains poorly constrained. Future observations will help understand whether tremor behavior might evolve during a seismic cycle and indicate time of increase hazard or whether tremor can be used to delineate the downward extent of rupture in a major earthquake.

Future potential

Tremor provides exciting information regarding the behavior of deep faults and represents a new tool for measuring subtle deformations that have previously remained hidden. In addition, because tremor occurs on portions of the fault without regular earthquakes, it gives new constraints on physical properties in its source region and could eventually be used to improve knowledge of neighboring earth structure.

THUNDERSTORMS

Colin Price
Tel Aviv University, Ramat Aviv, Israel

Synonyms

Definition

Thunderstorms are defined as weather storms that are associated with lightning discharges, which result in the production of acoustic waves called thunder.

Discussion

There are approximately 2,000 thunderstorms active at any time around the globe, with all these thunderstorms producing between 50 and 100 lightning discharges per second. Thunderstorms are the result of strong vertical air currents in the lower atmosphere, produced when the atmosphere becomes unstable. More than 90% of all thunderstorms occur within the tropical regions, where the air becomes unstable due to the daily solar heating of the surface, and the resulting rising thermals. The air condenses as it rises and cools, with additional heating of the air occuring due to the release of latent heat within the clouds, enhancing the development of the thunderstorms. The larger the instability, the larger the vertical winds (updrafts) and the greater the hazards associated with the thunderstorm. These hazards include heavy rain, lightning, hail, strong winds, and even tornados.

Lightning is responsible for thousands of deaths every year, and many more injuries. Lightning is also a major cause of wildfires in temperate and high latitudes during summer months, while being a major hazard to commercial aviation. Hailstorms produce significant agricultural damage every year across the globe, with additional damage to property, cars, aircraft, etc. Tornados can result in severe damage to property and loss of life, and are always associated with thunderstorms. Whereas lightning is most prominent in tropical regions, tornados are more prominent in mid-latitude regions. Heavy rainfall from thunderstorms can often result in flash floods that appear with very short warnings. Finally, downbursts and straight-line winds can be extremely hazardous around airports, causing extensive property damage as a result of the intense winds.

Whereas most thunderstorms occur in the tropics, the majority of these storms occur over the continental landmasses, and not over the oceans. Furthermore, thunderstorms occur primarily in the summer months, although some regions experience winter thunderstorms over warm ocean waters (e.g., Gulf Stream, Mediterranean Sea, Koroshiu Current). By definition, thunderstorms are associated with lightning, and lightning activity can be detected and tracked by monitoring the electromagnetic pulses emitted by lightning channels. These radio waves can travel thousands of kilometers before decaying into the background noise, and hence we can use ground-based lightning networks to track in real time the lightning activity over large regions of the globe, allowing us to monitor such hazardous storms in close to real time.

TIDAL BORES

Hubert Chanson
The University of Queensland, Brisbane, QLD, Australia

Synonyms

Benak (Malaysia); Bono (Indonesia); Burro (Mexico); Mascaret (France); Pororoca (Brazil)

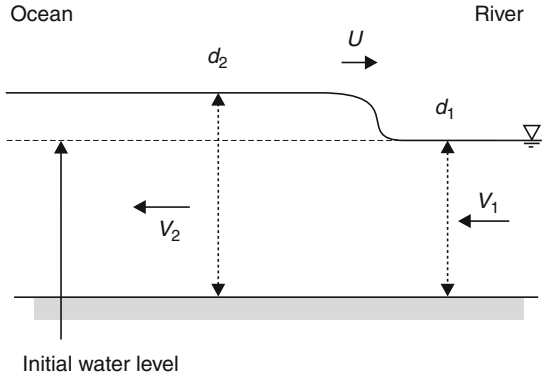
Definition

A tidal bore is a positive surge of tidal origin that may occur in an estuary when the tidal flow turns to rising; the existence of a tidal bore is linked with a large tidal range, an estuarine bathymetry that amplifies the tidal wave and a low freshwater level.

Discussion

A tidal bore is an unsteady flow motion generated by the rapid water level rise at a river mouth during the early flood tide when the flood tide waters rush into a funnel-shaped river mouth that amplifies the tidal range. A bore is a sudden increase of the water depth as illustrated in Figures 1 and 2. Figure 1 shows a tidal bore in the Bay of Mont Saint Michel (France). The tidal bore advances in the river channel and on the surrounding sand flats. Figure 2 presents the tidal bore of the Dordogne River (France). The surfers give the scale of the bore front. Worldwide, it is estimated that over 400 estuaries are affected by a tidal bore process, on all continents but Antarctica. Some famous tidal bores include the "pororoca" of the Amazon River in Brazil, the bore of the Qiantang River in China, and the 'mascaret' of the Seine River in France (Malandain, 1988).

A tidal bore is almost a mythical phenomenon because it is rare to observe. It occurs only during the flood tide under spring tidal conditions and low freshwater levels. Its passage is very rapid, that is, a few minutes at most and it is easily missed. The bore is a sharp front that propagates upstream into the river mouth and may travel several dozens of kilometers inland before vanishing. The presence of a tidal bore indicates some macro-tidal conditions (tidal range $>$ 4.5–6 m) associated with an asymmetrical tide. The flood tide is typically shorter than the ebb tide period and the flood flow is much faster. A feature of the tidal bore is its rumble noise that can be heard from far away. Some field measurements show that the generated sounds have a low-pitch comparable to the sounds generated by bass drums and locomotive trains (Chanson, 2009).



Tidal Bores, Figure 1 Tidal bore in the Mont Saint Michel Bay in France on October 19, 2008 morning – Bore propagation from right to left.

Tidal Bores, Figure 2 Tidal bore of the Dordogne River (France) at Port de Saint Pardon on September 2, 2008 evening – Looking downstream at the incoming tidal bore.

Theoretical considerations

A tidal bore may occur when the tidal range exceeds 4.5–6 m and the bathymetry of the river mouth amplifies the tidal wave. The driving process is the large tidal amplitude. The tides are forced oscillations generated by the attractions of the Moon and Sun, and have the same periods as the motion of the Sun and Moon relative to the Earth. At full moon or new moon, the attraction forces of the Sun and Moon reinforce one another, and these conditions give the spring tide conditions. The tidal range may be locally amplified further by a number of factors, such as when the natural resonance of the bay and estuary is close

Tidal Bores, Figure 3 Definition sketch of a tidal bore propagating upstream.

to the tidal period. This coincidence implies that the general sloshing of the waters around the inlet or bay becomes synchronized with the lunar tides and amplifies their effect, yielding often the best tidal bores a couple of days after the date of the maximum tidal range.

When the sea level rises with time during the flood tide, the tidal wave becomes steeper and steeper, until it forms an abrupt front: the tidal bore. The inception and development of a tidal bore may be predicted using the Saint-Venant equations and the method of characteristics (Peregrine, 1966; Chanson, 2004). After the formation of the bore, the flow properties directly upstream and downstream of the tidal bore front must satisfy the equations of conservation of mass and momentum. The integral form of the continuity and momentum principles gives a well-known relationship between the flow depth in front of and behind the tidal bore front:

$$\frac{d_2}{d_1} = \frac{1}{2}\left(\sqrt{1 + 8 \times \mathrm{Fr}_1^2} - 1\right) \quad (1)$$

where Fr_1 is the tidal bore Froude number defined as: $Fr_1 = (V_1 + U)/\sqrt{g \times d_1}$ with g the gravity acceleration, V the flow velocity positive downstream towards the river mouth, U the bore speed for an observer standing on the bank, d the water depth, and the subscript 1 refers to the initial flow conditions whereas the subscript 2 refers to the new flow conditions (Figure 3).

The Froude number of the tidal bore is always greater than unity and the quantity (Fr_1-1) is a measure of the strength of the bore. If the Froude number is less than unity, then the tidal wave cannot become a tidal bore. For a tidal bore Froude number between unity and 1.5–1.8, the bore front is followed by a train of well-formed, quasi-periodic free-surface undulations, also called whelps. For larger Froude numbers, the tidal bore is characterized by a breaking front as seen in Figure 1 (Koch and Chanson, 2009). Some simple energy considerations show that a tidal bore can occur only with a net flux of mass from downstream to upstream. This characteristic sets apart the tidal bore from a wave or soliton.

Impacts of tidal bores

The tidal bores can be dangerous and some have had a sinister reputation. For example, in the Seine River estuary (France), more than 220 ships were lost between 1789 and 1840 in the Quilleboeuf–Villequier section. Similarly, the bores of the Petitcodiac River (Bay of Fundy, Canada) and Colorado River (Mexico) are feared by some of the populace. In China, some tidal bore warning signs are erected along the Qiantang River banks and yet a number of tragic accidents happen every year. The tidal bores affect the shipping and navigation in the estuarine zone as in Papua New Guinea (Fly and Bamu Rivers), Malaysia (Benak at Batang Lupar), and India (Hoogly bore).

However, the tidal-bore affected estuaries are the feeding zone and breeding grounds of several forms of wildlife. For example, some large predators feed behind the bore: sharks in Australia, whales in Alaska, seals in France, crocodiles in Australia and Malaysia. The estuarine zones are the spawning and breeding grounds of several fish species, while the turbulent mixing and aeration induced by the tidal bore contribute to the abundant growth of many species of fish and shrimps.

Related processes

A number of geophysical, as well as man-made, processes are related to the tidal bore. In the Bay of Bengal, the development of a *storm surge* during the early flood tide with spring tidal conditions may yield a rapid rise in water levels generating a bore front. The wind shear amplifies the tidal range and the phenomenon has been observed in Bangladesh where the storm events are called locally "tidal bores." Another related process is the *tsunami*-induced bore. After breaking, a tsunami wave propagating in shallow-water regions is led by a positive surge. In shallow rivers, the process is somehow similar to a tidal bore and the tsunami-induced bore may propagate far upstream in a river mouth as observed in Hawaii, in Japan, and more recently during the December 26, 2004 Indian Ocean tsunami catastrophe in Malaysia, Thailand, and Sri Lanka. At a smaller scale, some *swash*-induced bores may be observed on beaches when the wave run-up enters into a small creek or channel.

Positive surges and bores may be observed in irrigation channels and water power canals during gate operation. Some bores are also observed at the leading edge of violent *flash floods* propagating downstream narrow canyons. Lastly, some water theme parks include large *artificial beaches* in which man-made waves somehow similar to a bore are generated for the agreement of the visitors.

Summary

A tidal bore is a series of waves propagating upstream in the river mouth as the tide turns to rising. It forms during the spring tide conditions with a tidal range in excess of 4.5–6 m in a narrow funneled estuary with low freshwater

levels. The presence of a tidal bore indicates some macrotidal conditions associated with an asymmetrical tide. Two key features of a tidal bore are (a) its rumble noise that can be heard from far away, and (b) the turbulent mixing induced by the bore propagation that stirs the sediments and matters.

TILTMETERS

Erik Eberhardt
University of British Columbia, Vancouver, BC, Canada

Synonyms

Clinometers; Tilt sensors

Definition

Tiltmeters are devices used to monitor the change in inclination of a ground surface point; see Dunnicliff (1993) for a detailed description. The device consists of a gravity sensing transducer (e.g., servo-accelerometer, electrolytic tilt sensor, pendulum-actuated vibrating wire, etc.) capable of measuring changes in inclination as small as one arc second (0.00028 degrees). They are used to monitor slope movements where the landslide failure mode is expected to contain a rotational component. Advantages of using tiltmeters are their light weight, simple operation, and relatively low cost; tiltmeters can be read manually or automated by connecting to a data logger.

TIME AND SPACE IN DISASTER

Thomas Glade[1], Michael James Crozier[2], Nick Preston[2]
[1]University of Vienna, Vienna, Austria
[2]Victoria University of Wellington, Wellington, New Zealand

Disasters in time and space

Early attempts to define disasters were based on the exceedence of certain loss thresholds. For instance, Sheehan and Hewitt (1996) classified as disasters all those events that killed or injured at least 100 people or caused at least US $1 million damage. This definition was further developed in more qualitative terms, e.g., by UNDRO (1984) "... an event, concentrated in time and space, in which a community undergoes severe danger and incurs such losses to its members and physical appurtenances that the social structure is disrupted and the fulfillment of all or some of the essential functions of the society is prevented." Other definitions reduce the term disaster to those events where ".. large numbers of people exposed to hazard are killed, injured or damaged in some way ..." (Smith, 2004, p. 5). In this context, Smith also states, that "there is no universally agreed definition of the scale on which loss has to occur in order to qualify as a disaster." Further, Smith (2004, p. 22) writes that "... a disaster generally results from the interaction, in time and space, between the physical exposure to a hazardous process and a vulnerable human population." For statistical purposes some authorities require the impact of a natural event to exceed certain thresholds of areal extent, as well as lives lost, or economic costs before they are classified as disasters. In this contribution, disasters are defined as those damaging events that exceed the coping capacity of affected individuals, groups, or institutions and, in some cases, even nations. This definition avoids the use of absolute quantitative measures, which can vary dramatically between different countries, or in more general terms, between different social groups.

Thus, irrespective of the magnitude of the natural event, disasters are defined in terms of human impact and related consequences. In the contextual framework of natural hazards, disasters can be localized. They occur at a specific location or in a region as a sudden onset or as slow creeping, often unstoppable processes. Sources and affected areas can be very distinct with easy to delineate boundaries (e.g., a debris flow with source area, travel path, and deposition) or difficult to assess (e.g., pollution of ground water). Whereas the boundaries of source and impact areas may be identifiable after an event, it is not

always possible to predict where a disaster may occur. Some hazards that give rise to disasters tend to recur in the same locality; these are described as *location-specific*, e.g., lahars, debris flows, snow avalanches, and in some cases earthquakes and volcanic eruptions. *Non–location-specific* hazards which are more or less random in terms of place of occurrence include events such as drought, epidemic, and many weather related phenomena. However, because vulnerability and resilience of human communities have a large influence on the magnitude of consequences resulting from a hazard event, most disasters occur in the poorer less-developed countries of the world (Table 1). Nevertheless industrialized regions can also suffer from major disasters, for example, when design thresholds of mitigation structures are exceeded (refer to Hurricane Katrina in USA). Although economic losses can be large in industrialized regions, in contrast, in the transient states, loss of life and other direct effects on the population are generally much higher (Table 1). These differences do not simply represent a decadal trend, but can be observed over much longer periods (e.g., OFDA/CRED International Disaster Database).

Because of the human element implicit in the notion of disasters an understanding of their causes and behavior requires information not only on the properties and patterns of the natural event, but also on the socioeconomic conditions of the affected area. In numerous regions of the world, people are unable to divert resources toward counter measures against natural hazards. They have to face much more dramatic problems such as unemployment, famine, crime, and so on. These problems become much more severe with constantly growing cities and urban agglomerations and thus, these social groups become increasingly vulnerable toward natural events. Some socioeconomic factors that turn an event into a disaster relate to:

- Demographic characteristics
- GDP
- Urbanization
- Emergency preparedness
- Insurance coverage
- Community perception and awareness

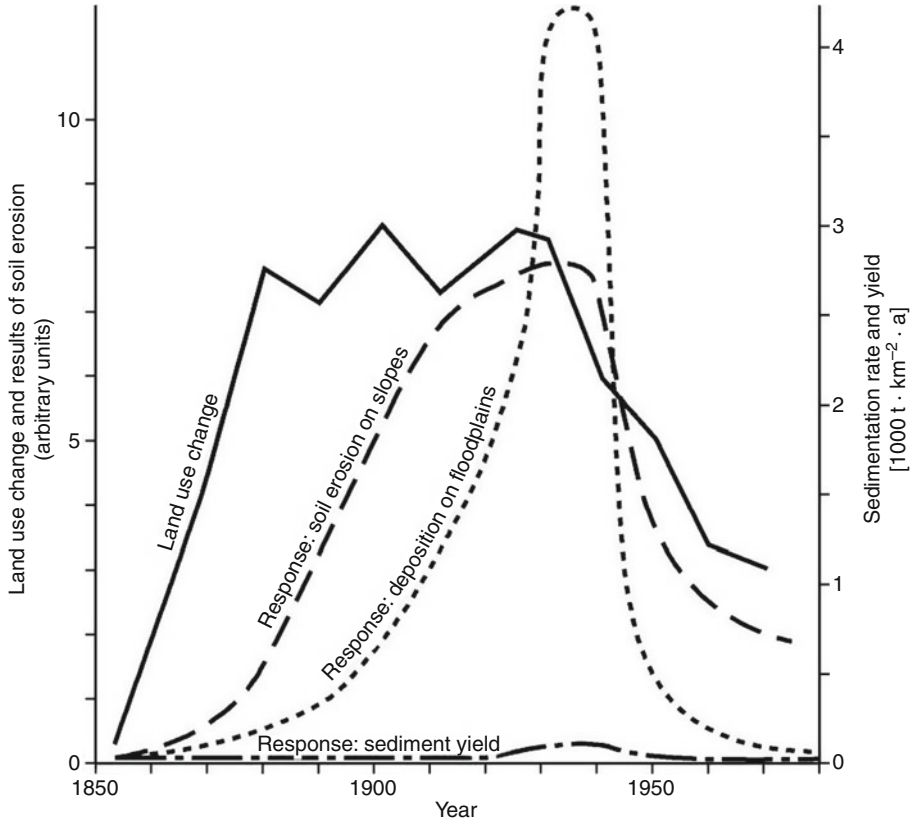
These factors alone are all subject to constant, often rapid change, producing dramatic transformations of the human condition within time and space. Consequently, risk is changing as well – and as a result the magnitude and areal extent of disasters have tended to increase with time. Thus, not only do the characteristics of the physical process change (e.g., more intense rainstorms, stronger winds, higher waves), but also the elements at risk undergo a continuous change (Hufschmidt et al., 2005; Keiler, 2004).

Another important issue is the time lag between the triggering input, the occurrence of the process and the resulting disaster. In the case of a debris flow, it is straightforward. Heavy rain accumulates in the flow lines and starts to move erodible material until there is sufficient sediment that the debris flow is formed, travels down a channel and affects the downstream people or infrastructure. Other processes such as soil erosion caused by human activity are much more difficult to assess. The time lag between deforestation, start of soil erosion and erosion cycles that are based on the timing of the precipitation event and the agricultural usage is often very large. Also, the onset of the associated disaster is gradual rather than sudden. In such cases agricultural productivity slowly decreases and although the affected social groups might be able to cope with these changes in the beginning, the continuous increase of pressure and then the sudden drop of productivity can lead also to a disaster. Therefore, it is important to consider the chain of cause – consequence for disasters (Figure 1).

As indicated earlier, both slow and fast-onset natural hazards can cause disasters. The consequences of the fast-onset processes are mostly clearly visible and these disasters are often quantifiable in terms of their impact. In contrast, slow onset disasters continue over long periods. Besides desertification and soil erosion, other examples include water pollution or subsidence through extensive ground water removal. These "creeping" or gradual processes still cause disasters in the above defined sense – at some stage, there may be no soil left for agricultural use and the farmers have to move, or the ground water has been extensively extracted to an extent, where there is no readily available water. The now nearly dry Aral lake (Waltham and Sholji, 2001) is a dramatic example of excessive water usage in the upper catchment for irrigation purposes to the extent, that in certain years virtually no water reaches the lake (Cai et al., 2003). The lake now has more or less disappeared causing a dramatic disaster for the affected population – not only in terms of water shortage and depressed economy, but also in terms of an increase in the impact of pesticide polluted dust storms (O'Hara et al., 2000). Therefore, the time lag between input and consequences can be several years, and in some cases, even decades.

Another issue in this context is difference between the source area and the potential effects. Although snow avalanches, rock falls, and hurricanes have distinct and localized occurrences and consequential damage potential, a debris flow or a flash flood might be initiated high up in the catchment area but will cause destructive damages far away from the source. Similarly tsunami with travel distances of thousands of kilometers or ash clouds from volcanic eruptions with consequent and long-lasting flight interruptions are other examples (e.g., eruption of Icelandic volcano Eyjafjallajokull in March and April 2010).

Different perspectives



Assessing the temporal and spatial distribution of disasters is often very difficult particularly for events that have taken place in the past when instrumental and other records are limited. The human memory and associated observations can be useful sources of information. However, the larger the time lags between event occurrence and the recording of the event, the vaguer the information. In addition, smaller events are more often forgotten in

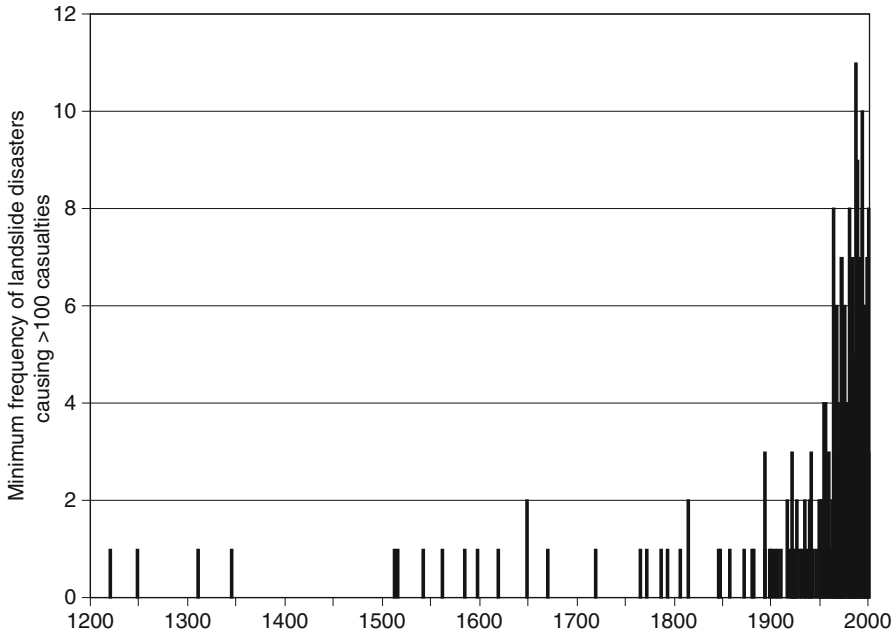
Time and Space in Disaster, Figure 1 Potential time lag between cause and different responses (Dearing et al., 2006), for the example, of soil erosion. Please note that such time lags operate as well in the social system.

time. Within historical research on former disastrous events, this is often a major problem (refer to entry "*Disaster Research and Policy, History*"). Therefore, graphs showing the development of disasters over time have to be treated with care (e.g., Figure 2). Such trends might reflect a number of factors unrelated to actual occurrence, such as increased awareness and thus enhanced reporting, better data availability, higher exposure of elements at risk, and so on. It is therefore important to carefully analyze temporal records to ensure any apparent trends are indeed real.



In recent years, media coverage has changed the public perception of disasters. For example, in some parts of the world, very small and localized events receive prominent media attention and provide a false impression of the magnitude of the event (e.g., snow avalanches in Galtür, Austria on the 22.02.1999). On the other hand, significant disasters such as desertification in certain regions often do not receive equivalent reporting representation and are thus not perceived by the public as large disasters.

Media, of course, play an important role in emergency management and disaster communication as well as being an important educational source about the causes and consequences of disasters. For instance, in Germany two large floods occurred in the Rhine valley within the 2 years (1995 and 1996). The result of comprehensive media coverage on the first flood meant that the public were well informed and were better prepared for the second flood and as a result the damages of the second flood were much lower (Engel, 1997). This again demonstrates the need to examine media reports carefully before using these in any form of magnitude frequency record, particularly noting the effect of reporting on events closely associated in time.

Future trends

There is a need for a better understanding of the causative factors of disasters, not only in terms of increased knowledge within natural sciences issues, but also within the social sciences. In this respect, of critical importance is the need to investigate the relationships between these two systems, the interconnections, the dependencies, the different reaction and response times, and the spatial implications associated with each system.

Therefore, studies of disasters should not confine themselves solely to post-event analysis and single-case studies. In order to understand better the root-cause-consequence principle in all its dimensions long-term investigations are necessary. Monitoring is a crucial part

Time and Space in Disaster, Figure 2 Historical data of landslide disasters causing >100 causalities (Glade and Dikau, 2001). Note: This graph does not necessarily express a real increase of landslide disasters, but is purely reflecting the available reports and the better reporting within the last decades.

of this process, in particular, monitoring the natural system, the social system and – most importantly – the linkages between these elements. The resultant understanding of the basic underlying causes, the factors enforcing or reducing adverse affects, and – in principle – how disasters happen can support decision and policy makers in evaluating potential developments and promoting sustainable development for potentially disaster prone regions.

Summary

It has been stressed, that for a detailed and useful understanding of time and space in disasters, all factors have to be taken into consideration, the natural science, the social science, and the inherent interrelationships. It is evident, that disasters do not stop at any pre-subscribed boundaries, whether ethical, governmental, or topographic. Physical hazards can change their behavior, onset time, processes, and intensity in time and space. The human condition and state of development is also changing with implications for vulnerability and resilience. Associated risks and disaster occurrence can consequently change dramatically in time and space. The changing dynamic of disaster occurrence represents one of the most important and concerning elements of global change facing mankind.

CASE STUDY

TOHOKU, JAPAN (2011 EARTHQUAKE AND TSUNAMI)

Kenji Satake
Earthquake Research Institute, University of Tokyo, Bunkyo-ku, Tokyo, Japan

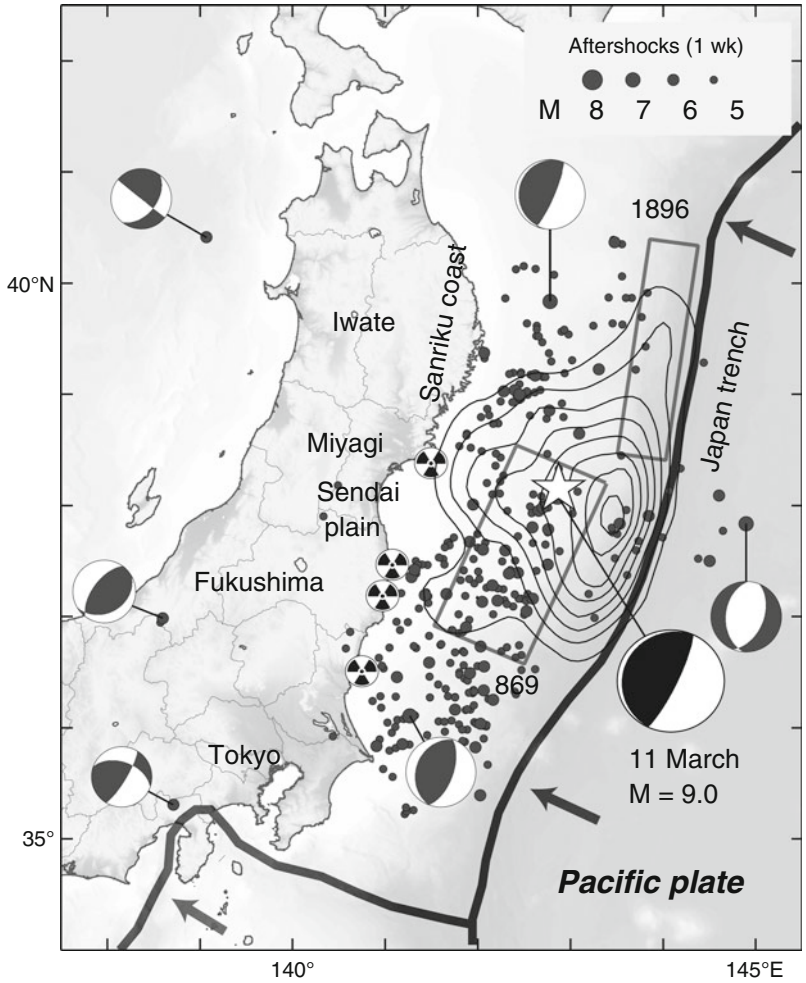
Definition

- The giant earthquake (Magnitude 9.0) off Tohoku, Japan, was the largest earthquake in Japan's history.
- It caused nearly 20,000 casualties, mostly from devastating tsunamis.
- The earthquake and tsunami also caused serious damage to the Fukushima nuclear power station, causing meltdown of the reactor, hydrogen explosion, and release of radioactive materials.
- Similar tsunami hazards occurred in the past, but the experience was not utilized to reduce the disaster.
- The lessons learned include the reexamination for preparedness for such infrequent hazards.

Introduction

A giant earthquake (official name: off the Pacific coast of Tohoku earthquake, abbreviated as the Tohoku earthquake) occurred near northern Honshu, Japan, on March 11, 2011. This earthquake, with magnitude M 9.0, was the largest in Japan's history, and produced a devastating tsunami disaster, as well as serious damage to the nearby Fukushima Dai-ichi nuclear power station.

The earthquake source parameters provided by the Japan Meteorological Agency (JMA) are: the epicenter was at 38° 06.2′ N, 142° 51.6′ E, depth 24 km, the origin time 14:46:18.1 JST. The earthquake was felt in more than a half of the Japanese islands, with the largest seismic intensity of 7 (the highest) on JMA's scale, with nearly 3,000 gals of peak ground acceleration.



The earthquake and tsunami caused about 15,900 deaths, 3,100 missing, and 6,000 injured. The damaged houses consisted of 129,000 totally collapsed, 255,000 partially collapsed, and about 697,000 partially damaged. Among them, some 7,600 houses were destroyed by ground shaking, 19,000 were damaged by liquefaction, and the rest affected by the tsunami. The total economic loss is estimated as 16,900 billion yen (about 200 billion U.S. dollars) according to the Central Disaster Management Council.

The 2011 Tohoku earthquake occurred on the boundary between the Pacific plate and overlying plate (Figure 1). The earthquake focal mechanism solution shows a thrust-type fault movement on a shallowly dipping plane. The Pacific plate subducts beneath northern Honshu at the Japan trench at a rate of about 8 cm per year. This movement usually causes westward movement of northern Honshu, as observed before 2011 by the land-based GPS network (Ozawa et al., 2011). At the time of the 2011 Tohoku earthquake, the GPS network recorded large movements in the direction opposite to the previous observations, with a maximum of 5.3 m eastward and 1.2 m downward motions (Ozawa et al., 2011). The marine geodetic measurements showed that the seafloor near the epicenter moved as much as 24 m in a horizontal direction and 3 m in a vertical direction (Sato et al., 2011). Repeated multi-beam sonar soundings also indicated that seafloor horizontally moved nearly 50 m near the trench axis (Fujiwara et al., 2011).

Unforeseen earthquake

After the 1995 Kobe earthquake, the Japanese government made long-term forecasts of large earthquakes in and around Japan based on past earthquake records. On the basis of the long-term forecast, national seismic hazard maps were published. Off Miyagi prefecture, near the epicenter of the 2011 Tohoku earthquake, large (M∼7.5) earthquakes have repeatedly occurred since 1793 with an average interval of 37 years. On the basis of this recurrence, the probability of a great (M∼8) earthquake in the next 30 years was estimated as 99 % (Earthquake Research Committee, 2009). Similar forecasts were also made in the neighboring regions, assuming that characteristic earthquakes repeat at each region. The forecast also estimated that a tsunami earthquake, an unusual earthquake that produces much larger tsunamis than expected from seismic waves, may occur anywhere along the Japan trench with 20% probability in the next 30 years.

The 2011 Tohoku earthquake, however, was much larger than the forecast, both in magnitude and the source area. The rupture started off Miyagi but propagated into neighboring regions. The source area was about 500-km long and 200-km wide, including the region along the Japan trench. The long-term forecast thus failed to predict the occurrence of the 2011 Tohoku earthquake, because it was based on past earthquake records and the occurrence of giant (M∼9) earthquakes was not evident in Japan.

Tohoku, Japan (2011 Earthquake and Tsunami), Figure 1 The source region of the 2011 Tohoku earthquake. The mainshock (*white star*) and earthquakes with $M \geq 5.0$ occurred within a week (*black circles*) are shown with focal mechanism solutions for large ($M \geq 6.0$) earthquakes, according to Japan Meteorological Agency. Thick curves are plate boundaries and the arrows are the relative motions. The contours show the slip distribution with 4-m interval estimated from the tsunami waveforms (Satake et al., 2012). *Gray rectangles* are the fault models of the 1896 Sanriku and 869 Jogan earthquakes. Locations of four nuclear power stations are also shown.

Forgotten past tsunamis

The Sanriku coast of Tohoku had been devastated by previous tsunamis. The 1896 Sanriku earthquake caused a large tsunami, with a maximum height of 38 m, despite its weak ground shaking. It was a typical tsunami earthquake. The 2011 tsunami heights along the Sanriku coast were as high as nearly 40 m, roughly similar to the 1896 tsunami heights. The 1896 tsunami caused about 22,000 casualties, somewhat more than the 2011 tsunami. Study of tsunami waveforms indicates that the 1896 earthquake was generated from a fault motion near the trench axis (Tanioka and Satake, 1996). The 1933 Sanriku earthquake also caused tsunami, up to 24 m, and caused about 3,000 casualties.

To the south, in Sendai plain in Miyagi prefecture, the 2011 tsunami inundated about 5 km from the coast, whereas the past Sanriku tsunamis produced a few meters of coastal heights and did not flood the plain. A similarly large earthquake and tsunami occurred there in the past. A national history book depicts strong shakings, collapse of houses, kilometers of tsunami flooding with 1,000 drowned people in Sendai plain in AD 869 in Jogan era. Tsunami deposits from the Jogan earthquake had been found as far as 3 km from the coast lines in Sendai plain (Minoura and Nakaya, 1991; Sawai et al., 2008). Older tsunami deposits were also found, indicating the recurrence interval of 500–800 years if they are from the same type of earthquakes. Based on the distribution of tsunami deposits, the 869 Jogan earthquake was modeled as an interplate earthquake with $M = 8.4$ (Satake et al., 2008).

Tsunami warning: success and failure

The JMA issued a tsunami warning at 14:49, 3 min after the earthquake. They estimated the tsunami heights as 6 m on Miyagi coast, and 3 m on Fukushima and Iwate coasts, based on the initial estimate of magnitude (M = 7.9) and tsunami numerical simulation results stored in a database (Ozaki, 2011). Very strong ground shaking and the tsunami warning urged many coastal residents to evacuate to high ground and thus saved their lives.

The 2011 tsunami was first recorded on ocean bottom pressure and GPS wave gauges. The bottom pressure gauge about 76 km off Sanriku coast at a 1,600-m water depth recorded ~2 m water rise in about 6 min starting immediately after the earthquake, followed by an impulsive wave with additional 3 m rise within 2 min (Fujii et al., 2011). Similar two-step tsunami waveforms were also recorded on a GPS wave gauge near the coast 12 min later, just before tsunami arrival on the coast.

The JMA upgraded the tsunami warning messages at 15:14 (28 min after the earthquake), after detecting the large offshore tsunami data. However, this updated information did not reach all the coastal communities, because a power failure occurred and the residents had already started evacuation.

The tsunami arrived at the Sanriku coast about 30 min after the earthquake, with the maximum heights of nearly 40 m. The tsunami reached the Sendai plain about 1 h after the earthquake. Despite the considerable time delay between the earthquake and tsunami arrival, nearly 20,000 people lost their lives. More than two thirds of the casualties were elderly (60 years or older), who experienced difficulties in prompt evacuation. The total area of the 2011 tsunami inundation was estimated as 561 km^2 by Geospatial Information Authority of Japan, and the population in the inundation area was about 600,000.

The JMA, based on lessons from the 2011 Tohoku earthquake, attempts to improve the tsunami warning system, including technical developments to estimate the earthquake size in a few minutes by using various and redundant information, to deploy and utilize the offshore tsunami observations, to issue a warning based on the worst case scenario if a possibility of giant earthquake exists, and to announce the expected tsunami heights in simpler expressions considering the uncertainties.

Tsunami hazard maps were made and distributed to the coastal residents. On the Sanriku coast, the 2011 tsunami inundation areas were roughly similar to the estimated flood areas. In the Sendai plain, the tsunami hazard maps assumed the M~8 earthquake with 99% probability, and estimated much smaller inundation areas than the 2011 tsunami.

The 2011 earthquake model: deep and shallow slips

The 2011 Tohoku earthquake source has been modeled by various geophysical data, including seismic waves (e.g., Ide et al., 2011), land-based GPS data (Ozawa et al., 2011), tsunami data (Fujii et al., 2011), or combination of these (e.g., Simons et al., 2011). A common feature of the source models is that huge (30–50 m) slip occurred on a shallow plate interface near the trench axis. This was a surprise to many geophysicists, because the shallow plate interface has been considered to be weakly coupled and unable to accumulate strain.

The tsunami modeling indicates that the 2011 earthquake was a combination of a tsunami earthquake and a deeper interplate earthquake (Fujii et al., 2011). A huge slip near the trench axis, similar to the 1896 Sanriku tsunami earthquake, caused the impulsive tsunami waves to be recorded on the pressure and GPS gauges, and was responsible for the high tsunamis along the Sanriku coast. The fault motion along the deeper plate interface, similar to the previous model of the 869 Jogan earthquake, produced long-wavelength seafloor deformation and caused the first gradual rise at the gauges, as well as the large tsunami inundation in Sendai plain. The modeling also confirmed that the deeper interplate slip was essential for the 869 Jogan earthquake, but it is currently unknown whether or not the shallow huge slip also occurred in 869.

Activated seismicity in Japan

Many aftershocks followed the mainshock of March 11. Within 2 months (until May 10), five $M \geq 7$ earthquakes, 76 $M \geq 6$ earthquakes, and 449 $M \geq 5.0$ earthquakes occurred in the source region, about 500-km long and 200-km wide.

Although many aftershocks had similar mechanism to the mainshock, or a thrust faulting, some had different mechanisms. Among three $M > 7$ aftershocks within 1 h of the mainshock, two in the northern and southern ends of aftershock area had similar mechanisms to the mainshock, but one occurred in the east that had a normal fault mechanism, indicating an opposite causative stress.

The 2011 Tohoku earthquake also triggered seismicity outside the source region. Three inland earthquakes with $M > 6$ at large distances (more than a few hundred kilometers away) occurred within 7 days of the mainshock. In Fukushima prefecture, a normal fault type earthquake with M 7.0 occurred on April 11 and was followed by many aftershocks, due to east-west extensive stress, opposite to the stress condition before March 11. The number of large $M \geq 6$ earthquakes in Japan within 1 year since March 2011 was 116, including the Tohoku aftershocks, which is much larger than the annual average of 14.

Fukushima nuclear plant crisis

The 2011 tsunami also impacted four nuclear power stations (NPS) located near the source area. At these stations, the strong ground shaking automatically shut down the reactors, and the diesel generators started to cool

down the reactors. The strong ground shaking also damaged the external power supply system at the Fukushima Dai-ichi station, making the station blacked out. The 15-m high tsunamis flooded and damaged the diesel generators at Fukushima Dai-ichi and Dai-ni stations. Without external power and diesel generator, the Fukushima Dai-ichi station failed to cool down and caused a meltdown of the reactors, then hydrogen explosions of three reactors, and release of radioactive materials. Areas about 20 km from the station became off limit, due to high radioactivity, and the residents were forced to evacuate. At the Fukushima Dai-ni station, the external power was used to cool down the system. At the Onagawa station, the tsunami was about 14-m high, but did not reach the level of major facilities. At the Tokai station, the tsunami height was about 6 m, but the construction of a breakwater was almost completed, which prevented major flooding.

Earthquake and tsunami hazard assessment

After the Tohoku earthquake and tsunami, the Japanese government established a general policy for future tsunami hazards. The possible future tsunamis are classified into two levels: L1 and L2. The L2 tsunamis are the largest possible tsunamis with low frequency of occurrence, but cause devastating disaster once they occur. For such events, saving people's lives is the first priority and soft measures such as tsunami hazard maps, evacuation facilities, or disaster education need to be prepared. The L1 tsunamis are expected to occur more frequently, typically once in a few decades, for which hard countermeasures such as breakwater must be prepared to protect lives and properties of residents as well as economic and industrial activities.

Conclusions

The 2011 Tohoku earthquake was the largest earthquake in Japan's history, and such a giant ($M = 9.0$) earthquake was not foreseen. However, similar tsunamis occurred in the past on the Sanriku coast from the 1896 Sanriku tsunami earthquake and in Sendai plain from the 869 Jogan earthquake. The tsunami analysis indicated that the 2011 earthquake was a combination of a tsunami earthquake with a huge shallow slip near the trench axis and a deeper interplate earthquake similar to the previously proposed model of the Jogan earthquake. The Tohoku earthquake not only caused many aftershocks but also activated the seismic activity in Japan.

Most of nearly 20,000 casualties were due to the tsunami. Although the tsunami warning saved many lives, the tsunami warning system will be further improved to help residents take more immediate actions. Education to coastal residents is important: instructing each individual to run to higher ground when they feel strong ground motion. The experience from the past tsunamis was not adequately utilized to reduce the tsunami damage.

The long-term forecast of large earthquake should incorporate paleoseismological studies such as tsunami deposits for infrequent giant earthquakes. Preparations for such infrequent hazard include hazard maps and education to save lives, but hard countermeasures are also needed for critical facilities including nuclear power stations.

TORINO SCALE

Norm Catto
Memorial University of Newfoundland, St. John's, NL, Canada

Torino Scale

A numerical scale measuring the statistical chance that a specific Near-Earth Object will impact Earth.

The Torino Scale (http://neo.jpl.nasa.gov/risk) was developed by researchers with NASA (USA) following a conference in Torino, Italy. It assesses the likelihood that any particular Near-Earth Object (NEO), including asteroids in Earth orbit or near the Earth, and meteorites, and comets, will impact Earth. The scale includes both the statistical chance of an impact and the consequences, based on the size of the NEO.

The trajectory for each known, individual NEO can be plotted, and the statistical probability of an impact with Earth assessed. Identification of the trajectories of NEO is one component of a response strategy to the impact hazard of NEO. Groups and agencies working to identify NEO and calculate their orbits include the Jet Propulsion Laboratory (JPL), part of NASA; the United States Air Force; the Meteorite and Impact Advisory Committee of the Canadian Space Agency; the Anglo–Australian Near-Earth Asteroid Survey; the European Asteroid Research Agency (EARA); and the Spaceguard Foundation (based in Europe).

Although the Torino Scale includes all levels of potential impacts, no rating higher than 0 has yet been determined for any NEO.

Definition

Tornado: A violently rotating column of air, in contact with the ground, either pendant from a cumuliform cloud or underneath a cumuliform cloud, and often (but not always) visible as a funnel cloud.

Severe thunderstorm: A thunderstorm producing one or more of the following; hail of diameter 25.4 mm (1 in.) or greater; wind gusts of 25 ms^{-1} or greater; one or more tornadoes.

Buoyant instability: A state of the atmosphere such that an air parcel, when displaced vertically, would be accelerated in the direction of the displacement.

Temperature lapse rate: The rate of decrease of temperature with height in the atmosphere.

Vorticity: A measure of the local rotation in a fluid.

Wind shear: The local variation of the wind vector or any of its components in a given direction.

Introduction

Tornadoes are arguably the most violent of all meteorological phenomena on Earth. Indeed, wind speeds estimated from observed damage, or as measured by radar, may be higher than those generated by any other type of weather system, reaching 110–135 ms^{-1} (250–300 mph) in extreme cases (Bluestein et al., 1993; Wurman et al., 2007). Such violent tornadoes result in the wholesale destruction of natural and man-made obstacles along their narrow but well-defined damage tracks, and on occasion, very considerable loss of life. Fortunately, most tornadoes do not attain such violent intensity, though, even in the case of relatively weak tornadoes, the threat to life and property is not negligible. Owing to their small scale, however, the destruction resulting from tornadoes is extremely localized and only affects small areas. Even the widest tornadoes rarely exceed a kilometer in diameter. This may be compared, for example, with the typical diameter of a hurricane, which is on the order of hundreds of kilometers. Commensurate with their small scale, tornadoes are also generally short-lived phenomena. The longest-lived tornadoes may have lifetimes on the order of an hour or two and path lengths exceeding 100 km; for example, the infamous "Tri-State" tornado of March 18, 1925, affecting the US states of Missouri, Illinois, and Indiana, traveled over 320 km during its three and a half hour lifetime (though there is still debate as to whether this was a single tornado or in fact a series of several tornadoes along an extended track). During the so-called "Super-outbreak" of April 3–4, 1974, also in the USA, tornadoes with path lengths of up to 145 km were recorded (Corfidi et al., 2010). Such examples are exceptions to the rule however. More typically, damage may occur for periods of a few minutes, along tracks ranging from several hundred meters to several kilometers long, and lifetimes of individual tornadoes very seldom exceed an hour. Due to their generally short lifetimes and small scale, the chances of any one location being hit by a tornado are remote, even in the most tornado-prone areas on Earth. Despite this, on regional and national scales, the tornado hazard may be considerable. For example, in the USA, tornadoes are responsible for an average of around 60 deaths per annum, with most deaths attributable to injury from flying or

falling debris (SPC, 2009). Annual death tolls and even insurance losses may be heavily dominated by a few, large events. So whilst the mean frequency, per unit area, of events may be low, the effect of occasional, large events can be devastating.

Tornado intensity scales

Tornadoes are most commonly classified according to their strength. In the 1970s two tornado damage scales were devised; the Fujita (F) scale (Fujita, 1971) (see *Fujita Tornado Scale*), and the International Tornado Intensity Scale (subsequently referred to as the "T scale") (Meaden, 1983; http://www.torro.org.uk/site/tscale.php). Both scales assign a rating based on the maximum intensity of observed damage, which equates, theoretically, to a given wind speed range. Since wind speed is estimated from a subjective judgment of damage intensity as opposed to being directly measured, the wind speed estimates contain much uncertainty. The nature of the object subject to damage must be considered. For example, factors such as building type, size, material, construction methods, and condition may have a significant effect on the level of damage sustained at any given wind speed. This makes standardization of the relationship between damage and wind speed essentially impossible. Other factors such as the availability or absence of objects to damage, and the translational speed of the tornado may also impact substantially on the apparent level of damage. To help address some of these problems, the Enhanced Fujita (EF) Scale was adopted as the official tornado intensity scale in the USA from 2007 (Doswell et al., 2009). The reader is referred to Doswell and Burgess (1988) for a more detailed discussion of issues related to tornado intensity rating.

The Fujita scale, comprising six categories ranging from F0 (weakest) to F5 (strongest), has gained the most widespread acceptance globally. The T scale, which comprises 11 categories ranging from T0 (weakest) to T10 (strongest), is the official tornado intensity scale in the UK and is also frequently used, for example, in parts of Europe. Tornadoes rated as F0–F1 (T0–T3) are classified as "weak" and are associated with winds of up to approximately 51 ms^{-1} (115 mph). Tornadoes rated at F2–F3 (T4–T7) are considered "strong," whereas those rated at F4–F5 (T8–T10), equivalent to estimated wind speeds higher than approximately 93 ms^{-1} (200 mph), are described as "violent." On the evidence of engineering studies of building damage, estimates of wind speed in the more intense tornadoes were revised down on introduction of the EF scale; for example, the EF3-4 threshold was revised down to 74 ms^{-1} (166 mph). The vast majority of tornadoes globally are rated as weak. Violent tornadoes are very rare. For example, even in the USA, which has the highest known frequency of violent tornadoes of any country in the world, only about ten such tornadoes occur across the whole country each year on average, equating to only 1% of all recorded tornadoes. F5-rated tornadoes are even rarer, accounting for around 0.1% of the total.

In addition to the damage intensity rating, tornado statistics typically recorded by research bodies and organizations such as the Tornado and Storm Research Organization (TORRO), the European Severe Weather Database (ESWD), and the US National Climatic Data Center (NCDC), include location, damage track length, maximum track width, and path direction. In some cases, more detailed surveys may be conducted which allow intensity ratings to be assigned at various points along the tornado's damage track. The overall rating given to a tornado is always that corresponding to the maximum observed damage along the track. The documentation of such information is an essential requirement for severe weather research, and for construction of accurate tornado climatologies, which permit quantitative assessments of the tornado hazard and its variation in time and space.

Meteorological conditions supportive of tornadoes

In order to understand the observed distribution of tornadoes across the globe, it is useful to consider the basic meteorological environments supportive of tornado development. A key concept is that tornadoes can occur anywhere that meteorological conditions become suitable; it naturally follows that higher tornado frequencies will tend to be found at locations experiencing those suitable conditions more frequently.

For convenience, tornadoes may be split into two main types; those associated with supercell thunderstorms, and those not associated with supercell thunderstorms (hereafter "supercell" and "non-supercell" tornadoes, respectively). The defining characteristic of a supercell thunderstorm is a deep, persistent, rotating updraft. This rotation is associated with a dynamically-induced area of low pressure, known as a mesocyclone. Rotation typically develops initially at mid-levels within the storm (i.e., 3–7 km above ground level) and the comparatively low pressure at these levels enhances the updraft at lower levels within the storm. This enhanced updraft helps to explain why supercell thunderstorms produce a disproportionate amount of other severe convective weather, including very large hail and damaging non-tornadic ("straight line") wind gusts (Moller et al., 1994; Thompson et al., 2003). In some supercells, rotation remains at mid-levels and fails to develop closer to the ground. However, in other cases, rotation does subsequently develop at ground level (a low-level mesocyclone). The development of a low-level mesocyclone involves processes related to the downdraft within the supercell, unless significant preexisting rotation about a vertical axis (vertical vorticity) is present in the storm environment. This low-level rotation can sometimes lead to tornadogenesis, via mechanisms that are still not fully understood. For a detailed review of current understanding concerning tornadogenesis within supercells, the reader is referred to Markowski and Richardson (2009).

Supercells require a rather specific combination of meteorological conditions in order to form. As is the case for all thunderstorms, three basic ingredients are required (Doswell et al., 1996): moisture, instability, and a source of lift (ascent). In addition, supercells also require strong vertical wind shear in the lowest few kilometers above ground level, that is, gradients in wind speed and direction with height above the ground. Rotation about a vertical axis develops via tilting, by the storm updraft, of initially horizontal vorticity, which is present in these strong shear environments. Observational and modeling studies in the USA have shown that supercell storms generally occur only when the "deep-layer" wind shear (0–6 km above ground level) exceeds around 15–20 ms^{-1} (30–40 knots).

Although there is an association between violent tornadoes and supercells, it should be noted that most supercells do not in fact produce tornadoes. This is because the required combination of conditions for *tornadic* supercells is even more specific than that required for the development of supercells per se; studies suggest tornadoes are more likely in environments which additionally exhibit very strong wind shear in the lowest layers of the atmosphere (in particular, combinations of strong directional and speed shear), significant instability at low levels, and low cloud base heights (indicative of high relative humidity at ground level) (e.g., Markowski et al., 2002). Hence, many conditions must be satisfied in order for supercell tornadoes to occur, which perhaps helps explain their relative rarity.

While weak to strong tornadoes occur in many different meteorological environments, it is generally accepted that the vast majority of violent, long-lived tornadoes are associated with supercells. Indeed, the relatively high frequency of violent tornadoes over the Great Plains of the USA can be linked to the relatively high frequency of occurrence of supercell thunderstorms in this region. Accordingly, the vast majority of what is currently known about supercell storms comes from research conducted in the USA. However, tornadic supercell thunderstorms have also been observed in many other parts of the World, including Canada, China, Australia, and most European countries, although in some of these places such storms are rare and supercell tornadoes may account for only a very small fraction of all reported occurrences. In northeast India and more especially Bangladesh, although scientific accounts of tornado producing storms have historically been lacking, the occurrence of strong and even violent tornadoes in environments characterized by strong instability and substantial wind shear (Yamane and Hayashi, 2006), suggests that tornadic supercells almost certainly occur from time to time. Further study is required in order to reveal how frequently such storms occur in this region.

Although supercell storms have been the focus of much research owing to their association with strong and violent tornadoes, and indeed with other types of significant severe weather, many tornadoes are not associated with supercell thunderstorms. Unfortunately, the ratio of supercell to non-supercell tornadoes, globally, is not currently known. Although non-supercell tornadoes are typically weak, they may occasionally be strong. The ingredients required for non-supercell tornadoes may arise in a number of different meteorological environments. Given that all tornadoes occur in association with moist convection, the basic ingredients of moisture, instability, and a source of lift are of course required, as is the case for supercell tornadoes. A further requirement for non-supercell tornadoes is strong preexisting vertical vorticity around and below cloud base height, and some mechanism by which this vorticity can be stretched. Stretching is required in order to amplify the preexisting vertical vorticity, which is usually rather weak, to tornadic speeds and strengths. This is generally achieved by strong updrafts, and so non-supercell tornadoes also tend to be associated with vigorous convection. Steep temperature lapse rates in the sub-cloud layer are particularly favorable, since this promotes strong stretching at low levels, where the preexisting vertical vorticity resides. Therefore, non-supercell tornadoes are possible when preexisting vertical vorticity and a convective updraft become collocated. Strong vertical wind shear is not essential. In fact, weak shear (which usually occurs in a situation of light winds throughout the depth of the troposphere) may increase the chances of non-supercell tornadoes in some circumstances, by increasing the length of time that a given updraft can reside over the area of preexisting vertical vorticity (owing to small storm motions associated with the generally weak winds).

Substantial vertical vorticity is often found along mesoscale or synoptic-scale boundaries that exhibit substantial and abrupt changes in wind speed and/or direction within a short distance. Examples occurring frequently include synoptic-scale fronts (air-mass boundaries), sea breeze fronts, outflow boundaries from preexisting convection, and terrain-induced convergence lines. Of course, boundaries of one type or another occur at almost all locations over the globe. The relative frequency with which each type occurs varies substantially from region to region however, depending on such factors as topography, homogeneity of the land surface, frequency of deep convection, and proximity to coastlines.

A further important tornado environment is the land-falling hurricane or tropical storm. Tornadoes occurring in such situations comprise a reasonable portion of the total number of observed tornadoes in Japan, eastern China, and parts of the USA adjacent to the Gulf Coast, and to a lesser extent along the Eastern Seaboard. Tornadoes are most likely in the right, front quadrant of the land-falling storm, owing to favorable configurations of vertical wind shear (McCaul, 1991). Instability in such situations is typically weak, but tornadoes tend to be associated with environments exhibiting some instability at low levels, coincident with the layer of strongest wind shear (e.g., McCaul and Weisman, 1996). Tornadoes in such environments generally occur in association with small supercell storms. Although hurricane-associated tornadoes are generally weaker than those associated with supercell storms in continental, midlatitude regions, reasonably large outbreaks of tornadoes may occur on occasion (e.g., McCaul, 1987).

Global distribution of tornado frequency

Existing databases and their limitations

One way to assess the magnitude of the tornado hazard across the globe is to consider the distribution of tornado frequency by country. Before discussing this, the limitations of the available data should be considered. A primary limitation is the absence, in many countries, of a systematic method of reporting and recording of events, which prevents reliable tornado climatologies from being constructed. Encouragingly, this situation has recently improved in many countries, with the formation of national and international bodies responsible for the collection of tornado event data. Examples include the recently established European Severe Weather Database (Dotzek et al., 2009) and TORRO (Rowe, 1985). The increased ownership of mobile phones and digital cameras and the advent of the internet has allowed for more detailed documentation and greater ease of reporting of tornadoes in recent years. Whereas in the long term this should lead to more accurate estimates of true tornado frequency, in the short term it introduces temporal trends in the apparent tornado frequency, making the construction of reliable climatologies challenging.

Since the frequency of tornadoes varies substantially on annual and even decadal timescales, climatologies must be constructed from datasets spanning at least several decades in order to be considered representative. At present, such long-period data series are only available in a few countries around the world. Even in these countries, many issues surround the quality of the data. One important consideration is underreporting. Reported frequency is always lower than the true frequency, because a certain proportion of events inevitably go unreported. This is more likely in the case of weak or short-lived tornadoes. The extent of underreporting may vary substantially from region to region, which makes meaningful comparison difficult. In sparsely populated regions, a higher proportion of events are likely to go unreported, since events are less likely to directly affect people or infrastructure. Conversely, in densely populated areas where established reporting mechanisms exist, it is likely that the large majority of events will be recorded. This bias can explain the clusters of apparently high tornado frequency occurring in and around major cities, as has been documented in the tornado climatologies of many countries around the world (e.g., Niino et al., 1997; Hanstrum et al., 2002; Meaden and Chatfield, 2009). Other issues include, but are not limited to, the misclassification of non-tornadic wind damage as tornadic and vice versa, issues relating to public education and awareness, the availability and coverage of meteorological observations such as Doppler radar, trends in population density, and changes in warning and reporting procedures. The reader is referred to Verbout et al. (2006) and Dotzek (2003) for more detailed discussions of these and other related issues.

Table 1 shows the reported tornado frequency, expressed as the number of tornadoes per 10,000 km^2 per year, for a selection of countries which possess climatologies sufficiently well developed to allow reasonably meaningful quantitative estimates to be made. When considering strong and violent tornadoes only, by far the highest reported frequencies are found in the USA, east of the Rocky Mountains (e.g., note the high frequency of F2 and stronger tornadoes in Oklahoma). When considering tornadoes of all intensities, there are some interesting differences. Some of the highest frequencies are found over parts of northwestern Europe. Indeed, reported frequencies per unit area

Tornadoes, Table 1 Reported mean annual tornado totals and frequencies (per 10^5 km^2) for a selection of countries and regions worldwide.

Location	Mean annual total (all)	Mean annual total (F2+)	Per 10,000 km^2 per year	F2+ per 10,000 km^2 per year	Period	Source

Tornadoes, Figure 1 World map showing known areas of relatively high tornado frequency (*shaded*). *Darker shaded* areas denote regions of highest tornado frequency, according to currently available climatologies.

in the UK and the Netherlands are comparable to those in the most tornado-prone parts of the USA, including Oklahoma. Fortunately, strong and violent tornadoes are comparatively rare in these countries, as shown by the relatively low frequencies of F2 and stronger tornadoes. A further issue with derivation of quantitative estimates of tornado frequency over specified areas is illustrated by the tornado frequency for Argentina, as quoted in Table 1. Although the figure is very low for the country as a whole, there exists a much smaller area in which tornado frequency is far higher than the national average (Schwarzkopf and Rosso, 1982), outside of which tornadoes apparently seldom occur. Such regional variations occur within all countries. Further examples can be seen in Table 1 by comparison of figures for Oklahoma with those for the whole conterminous USA, and those of England with those of the whole UK. This illustrates that the obtained frequency can be highly dependant on the exact location and size of the area which is chosen for inclusion in the analysis, a further limitation of quantification and comparison of tornado frequencies by country, and indeed, regions of any arbitrary size.

Although these limitations preclude the possibility of obtaining quantitative estimates of tornado frequency in most countries, it is possible to qualitatively identify regions of enhanced tornado frequency across the globe. Fujita (1973) was the first to produce a global map showing areas of enhanced tornado frequency. Figure 1 shows a modified version of this map, as can best be constructed from current climatologies. No attempt has been made to quantify tornado frequencies within the "high frequency" areas highlighted here, owing to the uncertainties previously discussed. It can be seen that tornadoes occur in many regions of the world. In fact, tornadoes of strong and violent intensity (i.e., F2 (T4) and greater) have been documented on every continent, with the exception of Antarctica. At the broadest level, tornadoes occur most frequently in the midlatitudes, that is, between approximately 25° and 55° north and south of the equator. Regions of enhanced tornado frequency within these midlatitude belts include large parts of North America, northern and central parts of Europe, Japan, South Africa, parts of the Indian subcontinent, parts of Southern and Western Australia, New Zealand and parts of Argentina. Some explanations for the observed distribution of the more tornado-prone areas are offered in the following sections.

Areas of low tornado frequency

Bearing in mind the range of tornado-producing environments described previously, and the principal conditions required for tornado formation, it is possible to explain some of the broader aspects of the observed global distribution of tornado frequency. First consider areas with lowest observed frequencies. Many of the areas of apparently low tornado frequency are also areas of very low

population density. This is no coincidence. In fact, it is almost certain that population bias has a strong impact on the apparent global extent and distribution of areas of low tornado frequency, as shown in Figure 1. However, the population density itself is influenced strongly by climate, and there are good meteorological reasons to expect low tornado frequencies in some of the sparsely populated parts of the world. Figure 1 shows that tornadoes tend to be absent from areas with desert or semiarid climates. Low tornado frequencies would be expected in these areas simply because deep, moist convection occurs rarely, if at all, owing to the lack of moisture. Occasional storms which do form are usually high based owing to low relative humidity, and such storms are not conducive to tornado development. This helps to explain the minima in tornado activity over large parts of North Africa, the west coast of South America, much of inland western North America, and parts of the interiors of Russia and Australia.

Figure 1 also shows that tornadoes are rare or absent at latitudes higher than about 60° in both hemispheres. Antarctica is the only continent on which tornadoes have not been observed. This is because incursions of warm, moist (and originally potentially unstable) air are strongly modified by the time they reach these latitudes. The surface layers are cooled as they travel over relatively cold ocean or land surfaces, and so surface-based convection is suppressed. Cold air also holds less moisture than warm air; consequently, particularly cold climates are also usually arid climates. As in other arid regions, population density tends to be low. In these respects, the polar regions represent the extreme case; intensely cold, dry conditions, and weak solar heating entirely prohibit surface-based convection, while vast tracks of land are entirely uninhabited.

Inspection of Figure 1 also shows a general minimum in tornado activity over tropical regions. This is perhaps surprising, given the fact that thunderstorm activity is frequent and widespread there. A major limiting factor for tornadoes in tropical regions is the lack of significant wind shear. The tropics are well removed from the upper level jet streams which are found at higher latitudes, and the associated baroclinic disturbances which act to periodically increase vertical wind shear. This means that environments conducive to supercell thunderstorms do not generally occur. This likely explains an apparent lack of strong and violent tornadoes in the tropics. A further result of the distance from baroclinic disturbances is that well-marked air mass boundaries associated with frontal systems, one important environment for the development of non-supercell tornadoes, also seldom occur in the tropics. On the other hand, the presence of widespread instability and weak wind shear suggests that, despite the lack of recorded events, non-supercell tornadoes do occur from time to time. Again, population bias likely plays a role; underreporting could contribute significantly to the apparently low tornado frequencies in some tropical regions. For example, the lack of violent supercell tornadoes may have resulted in a general lack of awareness of the phenomenon, reducing the chances that events will be reported. It remains to be seen whether tornado reports increase in the future as awareness and documentation of tornado events improves.

Areas of high tornado frequency

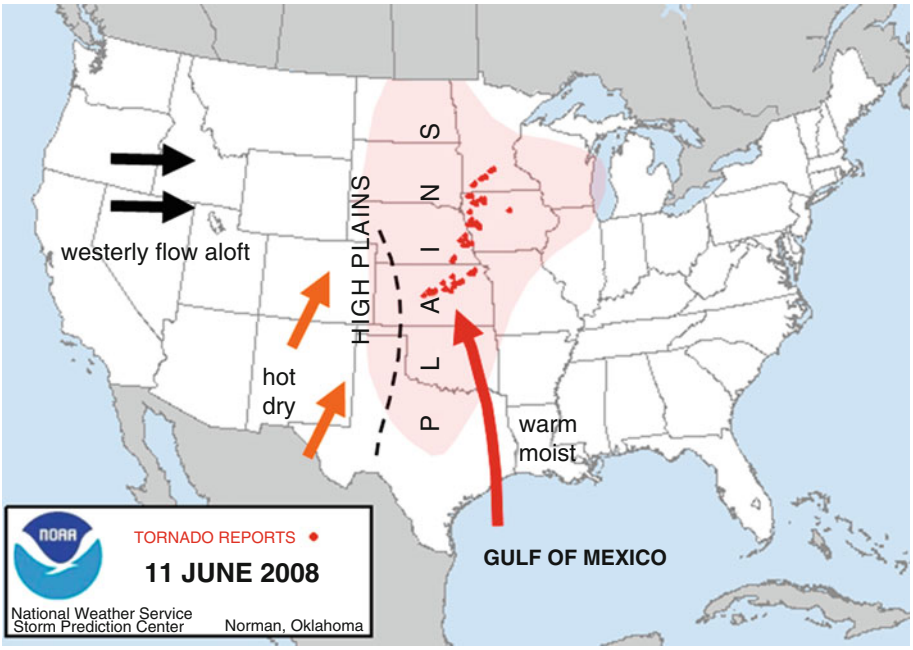
Northwest Europe

Some of the highest frequencies of tornadoes are to be found over northwestern Europe, including countries such as the UK and the Netherlands. In this area, the prevailing wind is off the Atlantic Ocean which results in a reliable and abundant supply of moisture throughout the year. Midlatitude depressions (low pressure systems) also affect this region with a high frequency. These baroclinic systems, deriving additional energy from warmth and moisture provided by the Atlantic Ocean, are often well developed and vigorous as they reach northwest Europe. They are frequently associated with strong vertical wind shear, sufficient for supercell storms. Instability in the maritime air masses is generally small, however, which often limits the potential for supercells. Nevertheless, such storms do occasionally occur. With the abundance of low pressure systems also comes an abundance of well-defined air mass boundaries, such as cold fronts. Strong cold fronts, along which lines of convection develop, are characterized by strong low-level convergence and vertical vorticity. Tornadoes are frequently observed in association with such cold fronts and, less commonly, post-frontal squall lines. In some cases, the development of small-scale (diameter $\leq$ 4 km) vortices and tornadoes may be associated with horizontal shearing instability along the vertical vortex sheet associated with the narrow zone of wind veer at the cold front (e.g., Carbone, 1982; Smart and Browning, 2009). However, in general, these cold frontal and post-frontal squall lines are not well understood from a dynamical perspective, and much remains to be discovered about tornadogenesis in this type of environment.

A substantial number of the UK's tornadoes occur in association with cold fronts and post-frontal squall lines (Bolton et al., 2003). Such tornadoes tend to be rather weak and short-lived, which largely explains why deaths resulting from tornadoes are very rare despite the high overall tornado frequency. For example, only two tornado fatalities were documented in the UK between 2000 and 2009, though approximately 30 injuries were recorded during the same period (G. T. Meaden, personal communication 2011). Strong tornadoes have, however, been documented in this type of situation. An example is the T5 (F2) tornado which affected northwest London on December 7, 2006 (Clark, 2011). Tornadoes associated with cold fronts also occur rather frequently in other midlatitude west coastal localities, including parts of western Canada, California, and the west coast of Australia. Island nations of the midlatitudes may also be susceptible to such events; examples include Japan and New Zealand.

Another potentially relevant factor in parts of northwest Europe is the coastline. Relative to the size of each country, the coastlines of the UK and Netherlands, for example, are very long, which means that sea breeze boundaries commonly affect substantial areas, especially in the summer months. Such boundaries frequently act as focal regions for the development of deep, moist convection. It is likely that tornadoes are also favored in such situations, owing to the strong vertical vorticity often present, associated with strong shear of the horizontal wind across the sea breeze front. However, no clear link has yet been demonstrated between areas of frequent sea breeze formation and elevated tornado frequencies. In the winter, cold air outbreaks moving south over the relatively warm waters (the Gulf Stream ensuring that waters close to northwest Europe are unusually warm for their latitude) result in strong instability at low levels. Deep convection is often observed in such situations, and occasionally tornadoes have been documented. Again, it could be speculated that coastline-generated convergence lines provide environments favorable for tornado development. However, such cold air outbreaks are also frequently associated with rather strong vertical wind shear; consequently, small supercell storms may also be responsible for some of these tornadoes. Therefore, further research is required in order to elucidate the relevant physical processes in these situations. Strong instability generated by cold air flowing over relatively warm waters also occurs quite regularly over places such as the Mediterranean Sea and the waters surrounding Japan, which can help explain more frequent cool-season tornado activity in areas adjacent to these water bodies.

US Great Plains and Midwest



Parts of the central third of the USA, including the Great Plains and much of the Midwest, have the dubious distinction of experiencing the highest documented frequency of strong and violent tornadoes in the world. Within this region tornadoes constitute a substantial hazard to life and property. As a result, tornadoes and tornadic storms in this area have been the subject of a tremendous amount of scientific study in recent decades. This has led to a much greater understanding of the types of situation in which tornadoes occur. Public awareness of the tornado hazard in this region is high, and this, together with an established and comprehensive forecasting and warning infrastructure significantly reduces the number of deaths and injuries sustained as a result of tornadoes. Within this region, tornado activity reaches a well-defined maximum in the spring and early summer months. In basic terms, this is because increasing solar elevation raises instability, while the upper level midlatitude jet stream, though on average retreating gradually northward at this time of year, is still far enough south to permit episodes of sufficiently strong vertical shear over the region. Therefore, the required combination of instability and strong wind shear occurs most frequently at this time of year. As the mean position of the jet stream moves northward through spring and into early summer, so the location of maximum tornado activity tends to shift northward across the region. Peak activity in Oklahoma and northern Texas, for example, typically occurs in May, while the peak occurs in June and July over the Dakotas and other northern States (Brooks et al., 2003).

The combination of instability and substantial vertical wind shear favorable for supercell thunderstorms occurs from time to time across many continental regions of the midlatitudes, especially during the warm season. Accordingly, tornadic supercell storms occasionally occur in these regions too; for example, over central and eastern Europe (e.g., Caspar et al., 2009) and the Canadian Prairies (Kumjian and Ryzhkov, 2008). However, there are a number of additional factors which set the central US region apart from other midlatitude continental regions. One is the presence of the Rocky Mountains to the west. A consequence of westerly flow across the Rockies in middle and upper levels of the troposphere is the development, at the surface, of a lee trough over the high Plains region. This results in southerly flow over the Plains to the east, which transports warm and very moist air originating over the Gulf of Mexico hundreds or even thousands of miles northward (Figure 2). Instability is further increased by the frequent presence of an elevated mixed layer over the same region. This warm, dry layer of air originates over the high Plateaux of the southwestern USA and parts of Mexico and is advected northeastward over the Plains above the surface layer of moist air (Lanicci and Warner, 1991). This initially caps convection, thus allowing the instability associated with the surface moist layer to build further over the Plains, until it is released explosively as convection is triggered by the approach of atmospheric disturbances from the west.

Because the land slopes gently upward toward the west over the whole region, the depth of the moist surface layer decreases to the west. The western boundary of the moist air is marked by a feature called the "dryline." This boundary frequently acts as a focus for the initiation of deep convection, which then typically moves northeast over the Plains. This kind of setup sometimes favors concentrated "outbreaks" of severe thunderstorms and tornadoes over parts of the Plains, especially when stronger middle and upper level disturbances arrive from the west. These outbreaks occasionally result in the occurrence of several tens or even in excess of 100 tornadoes, within the space of 24–48 h. Such outbreaks have the potential to cause significant loss of life, but fortunately they can now usually be forecast in general terms several days in advance. To give an example of a significant, though unexceptional, tornado outbreak over the US Plains, Figure 2 also shows the locations of tornado reports on June 11, 2008. Forty-six separate tornadoes occurred on this day, resulting in 7 deaths, 52 injuries, and over $24 million of damages in total (NCDC, 2009).

Bangladesh and Northeast India

It is interesting to note that some of the features which make parts of the USA favorable for violent tornado development may also be found in one or two other regions around the world. One example is Bangladesh and the northeast region of India. In this area, the Bay of

Tornadoes, Figure 2 Schematic illustration of a typical synoptic setup for severe thunderstorm and tornado outbreaks over the US Great Plains region. *Red circles* show the locations of tornado reports received by the Storm Prediction Center (SPC) during the outbreak of June 11, 2008.

Bengal provides a source of warmth and abundant moisture at low levels. Elevated terrain to the west of the region allows for the development of an elevated mixed layer which, when advected into the region from the west, helps to cap instability associated with low level moisture allowing it to build until it may be released explosively, in the same way that an elevated mixed layer originating in the southwestern US Plateaux helps to cap instability over the US Plains. A lee trough also frequently occurs east of this elevated terrain inducing surface flow off the Bay of Bengal and transporting high moisture further inland. Locations at such low latitudes as Bangladesh and northeast India are normally well removed from the midlatitude westerly jet streams. However, in this region, the Himalayas and Tibetan Plateau to the north act as a huge barrier, diverting a portion of the jet stream well to the south of its typical latitudes. This not only increases wind shear to levels which may support supercell thunderstorm development, but larger-scale ascent associated with disturbances within the jet stream, also occasionally diverted over the region, act to trigger severe thunderstorm systems periodically. A brief but well-marked period of tornado activity occurs over the region, peaking in April as the pre-monsoon heat and humidity begin to build, but before the upper level jet stream retreats well to the north of the Himalayas. Singh (1981) also notes that tornadoes have very occasionally been associated with landfalling tropical cyclones (hurricanes) over Bangladesh.

As mentioned previously, violent tornadoes have been documented in this region (Singh, 1981; Mandal and Saha, 1983). Although the total number of such tornadoes in a typical year is not as great as that in the US Plains and Midwest, a combination of high population density in parts of the region, low public awareness of the hazard, and an absence of warning systems means that such events occasionally result in extremely high numbers of fatalities. The worst recent example occurred in Daultipur, Bangladesh, on April 26, 1989. This event is estimated to have resulted in around 1,300 deaths. In the period 1978–1998, nine tornadoes have been documented which resulted in over 100 deaths each (Finch, 2009). Tornadoes resulting in this many deaths are comparatively rare in the USA. Unfortunately however, such events still occur on occasion, as demonstrated most recently on May 22, 2011 when a violent tornado struck the city of Joplin, Missouri, resulting in 158 deaths.

Forecasting and warning

History

Given the hazards associated with tornadoes, it is desirable for weather forecasting agencies to attempt to predict them. Tornado forecasting could be said to have had its roots in the nineteenth century, largely out of the work undertaken by J.P. Finley (Galway, 1985). European settlers advancing into the frontier land of the US Great Plains would have started to experience thunderstorms and tornadoes of ferocity far greater, in general, than they had ever witnessed beforehand. However, it was not until the 1950s that tornado forecasting really began to be taken seriously, and

scientifically (Doswell et al., 1993). Prior to this, the word "tornado" was banned from public forecasts. Perhaps the most famous early attempt at a tornado forecast by meteorologists was undertaken by Major Ernest Fawbush and Captain Robert Miller (of the US Air Force), who went on to produce pioneering work on the subject.

Their initial forecast was issued on March 25, 1948, for Tinker Air Force Base, Oklahoma. Five days prior to this, a tornado had torn through the base, causing more than $10 million damage (in 1948 dollars), injuring several men, and destroying aircraft. It was estimated by Miller that the odds of another tornado hitting the base within a few days of this were around 20 million to 1. On the day of this initial tornado, the forecast had been for gusty winds, and an Air Force inquiry the next day ruled that a tornado "was not forecastable given the present state of the art." On March 22, and for the next 3 days, Fawbush and Miller made a highly concentrated effort to observe and document every piece of available meteorological information which had preceded the March 20 tornado, including as much data as they could find about the upper air. In addition, they scrutinized data surrounding previous tornado outbreaks to attempt to ascertain which parameters were present, and whether there was any set "pattern" to the weather beforehand. The weather maps for March 25 showed remarkably similar patterns to those which had turned up in their research. Based on this information, at 2.50 pm on that afternoon, they issued a prediction for a tornado. This triggered emergency procedures, which included rolling as many aeroplanes as possible into the hangers, and locations such as the control tower were evacuated. Incredibly, at 6 pm another tornado did hit Tinker Air Force Base. It did $6 million damage, but thanks to the warning, no one was injured. From that point on, the Air Force began to use this so-called Fawbush and Miller technique to issue tornado forecasts, and this attracted attention from the media. Several subsequent forecasts were deemed successful.

To put this into perspective, it must be appreciated that it is extremely unusual to have successfully predicted a tornado *for a specific site*. Modern forecasters would not attempt to predict a tornado strike for a specific site, 3 h hence; this is despite a much greater understanding of the atmosphere and the processes involved in severe storms and tornadogenesis. Ironically, it is for this very reason that tornadoes are not predicted for specific sites – meteorologists understand that this is simply not possible beyond guesswork and luck. So, although pioneering in many respects, the successful outcome of this initial tornado forecast also relied very heavily on chance. However, an important outcome of this, and subsequent successful Air Force forecasts was in making many people's minds up: tornado forecasts should be made publicly available so that people and businesses can take evasive and protective action. In 1952, the US Weather Bureau was forced to establish a tornado forecasting center. This was the forerunner of today's Storm Prediction Center (SPC; www.spc.noaa.gov).

Modern forecasting

Formal forecasting of severe weather for civilian use started in the 1950s. A specialized unit was set up in March 1952, and in early 1953 this became known as the Severe Local Storms (SELS) Center, and moved to Kansas City, Missouri in 1954. This is what subsequently became the Storm Prediction Center (SPC).

Early forecasts by SELS was a largely empirical process. It had been observed by forecasters and researchers that certain meteorological elements in the larger scale were apparent in several tornado outbreaks. Examples of these include the presence of significant areas of low pressure (extratropical cyclones), abundant low-level moisture, and the proximity jet streams. However, it soon became apparent, even in these early days, that no single set of features was present in each case. Certain features were present in certain groups of cases, and this led to pattern recognition in forecasting severe weather.

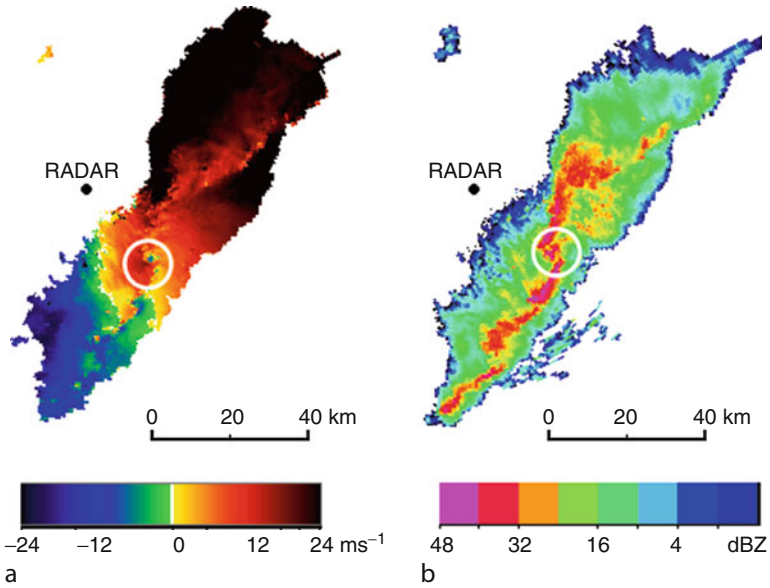
While, undoubtedly, some major outbreaks of severe weather across the Great Plains region have very similar features present, pattern recognition is not a desirable method of severe weather forecasting, since it will not reliably identify all outbreaks of severe weather.

With the advent of numerical weather prediction and hugely powerful computers, day-to-day weather forecasting has become much more accurate than was the case even 15–20 years ago. A trend away from pattern recognition and empirical techniques, toward more physical principles, has taken place. However, tornadoes are very small-scale and transient phenomena and so cannot be resolved by current computer modeling, and certainly not from a forecasting point of view. This is unlikely to improve soon, not least because the processes which cause tornadoes are still not fully understood. For these reasons, the method of severe thunderstorm and tornado forecasting typically employed today uses an "ingredients-based" approach for identifying areas at risk of severe storm or tornado development. The forecaster will use a number of weather forecast models, along with current weather observations at both the surface, and in the upper atmosphere. In simple terms, the forecast is based on identification of the four key ingredients required for severe thunderstorm formation: moisture, instability, lift, and wind shear. Where these are coincident in space and time, severe thunderstorms and tornadoes *might* occur. However, there are no thresholds over which the values of these parameters guarantee the development of severe weather; the forecaster is charged with quantifying the *risk* of severe weather for a particular area, based on all the available information.

As the USA suffers from severe thunderstorms and tornadoes on a regular basis, it is no surprise to find that this is the country with the most advanced severe weather forecast dissemination system. The Storm Prediction Center (SPC – a division of the National Weather Service), in Norman, Oklahoma, is responsible for the forecasting of organized severe thunderstorms and tornadoes across the

contiguous 48 states. It is also responsible for monitoring heavy rain, heavy snow, and fire weather events, and warning the public as necessary.

The SPC issues a range of forecasts which cover varying timescales in order to give timely notice of possible severe weather. "Outlooks" cover the 1–8 day period. There is one forecast product covering the 4–8 day period. This typically highlights possible risks in the medium term, but at that range, detail on the exact locations, timing, and nature of the threat is usually not possible. There are also individual outlooks for days one, two, and three. The "Day Three" forecast is updated once per day; "Day Two," twice per day; and "Day One," five times daily. The "Day One" Convective Outlook provides guidance in technical meteorological language along with maps to highlight areas at risk from organized severe thunderstorms. The text provides information regarding the specific nature of the threats, timing of the threads, and their expected severity. Graphics include a categorical forecast of the severe risk, broken down into regions of slight, moderate, and high risk, along with an area depicting 10% or greater chance of thunderstorms. There are separate maps depicting the probabilities for severe hail, wind, and tornadoes.



During a typical severe weather day, as conditions become more favorable for severe weather, the SPC may issue a *mesoscale discussion (MCD)*. Once conditions become favorable for the development of organized severe thunderstorms and tornadoes, the SPC issues a severe thunderstorm or tornado watch. Although tornadoes can develop in both types of watch, tornado watches are usually issued when conditions become favorable for multiple tornadoes or strong tornadoes. These watches are designed to alert the public to the risk of rapidly changing weather conditions, and to review severe weather safety rules, as well as listening out for possible warnings. For storm spotters, broadcast media, and emergency managers, watches can allow time to bring in extra staff and gear up operations. A watch does not guarantee severe weather, and is certainly not a warning of imminent danger. The watch area covers specified counties within one or more states and typically covers an area of 50,000–100,000 square kilometers (20,000–40,000 square miles), although this can vary rather widely. Even in a successful case, only a tiny fraction of the area covered by the tornado watch would be expected to experience a direct tornado "hit." Typically, between 800 and 1,000 severe thunderstorm and tornado watches will be issued each year. They are numbered sequentially starting afresh on January 1 each year.

When severe weather is either imminent or actually underway, weather warnings will be issued to alert communities in the projected path of the severe weather-producing storm or storms. One of the most useful tools for deciding when and where to issue warnings is Doppler weather radar. Doppler radar is capable of the detection of rotation within a storm, something which may be a precursor to tornado development. To this end, tornado warnings are often issued when strong rotation has been detected in the storm, even if no tornado has yet been reported. However, such remote sensing techniques are not fail-safe. Radar-based warning relies on detectable rotation, or other known severe weather "signatures," developing before tornado occurrence, something which does not occur in every event. On the other hand, false alarm rates may be high since the development of storm rotation does not guarantee the development of a tornado. Also consider that it typically takes an operational weather radar unit around 5 min to complete a full volume scan of the sky around it, while tornadoes can develop within seconds. Despite these limitations however, Doppler radars are probably the most useful tool available to forecasters to aid in the warning making process, in real time. For this reason, and because of the existence of other applications for radar data, Doppler radar networks are now being set up in many countries worldwide. Figure 3 shows an example of Doppler radar data from the UK Met Office, showing an area of rotation associated with the tornado of December 7, 2006 which affected parts of London.

Warnings may also be issued based on actual reports of severe weather. In the USA, *Storm spotters* will be activated when severe weather is expected. These are trained individuals who voluntarily observe conditions during periods of heightened risk. They are charged with calling or radioing-in severe weather reports, and are coordinated by a meteorologist at the local NWS office. Law enforcement officials also act as storm spotters, as do some storm chasers. In a rapidly developing situation, such reports are essential to maintain real-time monitoring of the storms.

Warnings are issued via NOAA Weather Radio, as well as to broadcast media, and to government officials. Emergency managers in towns and cities will usually sound civil defense sirens when a tornado warning has been issued. In addition, many TV stations and radios will switch to continuous severe weather coverage, with their own storm chasers/spotters in the field, and sometimes helicopters. These can all bring live footage of tornadoes to viewers' TV screens. Indeed, in many of the more tornado prone parts of the USA, severe weather coverage is deemed a ratings-winner, and the stations make a big point of advertising their coverage as "the best."

There are a number of other organizations around the world who attempt to forecast severe thunderstorms and tornadoes in their own countries. In the UK and Eire, the Tornado and Storm Research Organization (TORRO) is one such organization. Severe thunderstorm and tornado watches have been issued since 1992, and since 2006 they have been publicly available of the TORRO website (www.torro.org.uk). Being a voluntary organization means that coverage is not provided 24 h per day, but forecasts are issued as often as is necessary, and possible, by professional meteorologists. Across Europe, a group of meteorologists and meteorology students have set up the European Storm Forecast Experiment (Estofex). The group issues daily forecasts of severe thunderstorms

Tornadoes, Figure 3 Doppler radar observations of a tornadic squall line in the UK. (**a**) radial winds: positive (negative) values indicate a component of wind directed away from (toward) the radar, and (**b**) radar reflectivity (precipitation intensity) at 1056 UTC December 7, 2006. At this time, a T5 tornado was on the ground in west London. The parent circulation associated with this tornado is shown by the region of strong inbound and outbound winds located in close proximity to each other (*circled*). Radar location is shown by the *black dot* in each panel (**a**) (Crown Copyright Met Office 2009).

Tornadoes, Figure 4 The Baca County, Colorado, tornado of May 31, 2010. This tornado was rated EF2 following a damage survey by the US National Weather Service. Fortunately, since the tornado moved over open ground, the damage was mostly to power poles and no injuries were reported (Copyright Matthew Clark 2010).

across Europe, in a similar manner to the SPC's "Day One" outlooks. Much like TORRO, this is a voluntary group.

The future of tornado forecasting will likely focus on attempting to determine which thunderstorms have the best potential for producing tornadoes, with the aim of reducing warning false alarm rates. Currently, many supercells which do not produce tornadoes become tornado warned due to the detection of rotation. Higher resolution radar and a denser network of radars may help to

discriminate between tornadic and non-tornadic supercells in future. Future forecasting will also likely focus on trying to better anticipate those areas most likely to see thunderstorm development in the short term (i.e., the next few hours) as this will allow more targeted watches to be issued. However, given that we are far from understanding the full complexity of the tornado, storm spotters in the field, issuing real-time reports, will likely be required for many years to come and possibly indefinitely.

For more information about tornado forecasting in the USA, the reader is referred to Doswell et al. (1993) (Figure 4).

Summary

Although even the largest outbreaks of tornadoes do not generally result in widespread destruction and large death tolls on the scale sometimes associated with other natural hazards, such as earthquakes and volcanic eruptions, the relatively high frequency of tornadoes, the locally intense nature of their damage, and their possible occurrence in many of the inhabited regions on the planet ensures that they are justifiably considered as one of the Earth's primary natural hazards. Owing to their small scale and short lifetimes, observing and forecasting tornadoes remains a challenging task. In spite of some remarkable advances in these areas in recent decades, much remains to be discovered. Continued improvements in our understanding of the exact mechanisms responsible for tornadogenesis, the range of environments in which tornadoes can occur, and more accurate and complete observation and documentation of events, amongst other things, are vital if further advances are to be made.

To this end, tornado research is still very much an active and developing area of meteorological science. In the USA, where much of the tornado research conducted thus far has been based, dedicated field campaigns continue (e.g., VORTEX2; www.vortex2.org/home/), with the aim of observing tornadoes and their immediate environments at higher temporal and spatial resolution than has yet been possible. For example, the use of phased array, polarimetric radars, capable of providing data at very high temporal resolution, has provided additional insight into sub-storm scale processes whose evolution is typically very rapid (e.g., Heinselman et al., 2008; Heinselman and Torres, 2011). High-resolution numerical models, used in conjunction with polarimetric radar observations, provide insight into microphysical aspects of severe storms (i.e., processes taking place on the scale of individual aerosol or precipitation particles), which also likely influence the potential for severe weather, including tornadoes (e.g., Dawson et al., 2010; Bryan and Morrison, 2012). Collectively, these efforts will help to address some of the remaining questions regarding tornadogenesis, in particular. Outside of the USA, interest in tornadoes and severe convective weather has also increased in recent years. Advances in observing capability and development of warning procedures are now occurring in some countries; the benefits of these improvements in terms of reduction of injury and death tolls should soon be realized. In other countries however, little, if anything has yet been done to address the hazard posed by tornadoes.

TRIGGERED EARTHQUAKES

Harsh K. Gupta
Government of India, NDMA Bhawan, New Delhi, India
National Geophysical Research Institute, Hyderabad, India

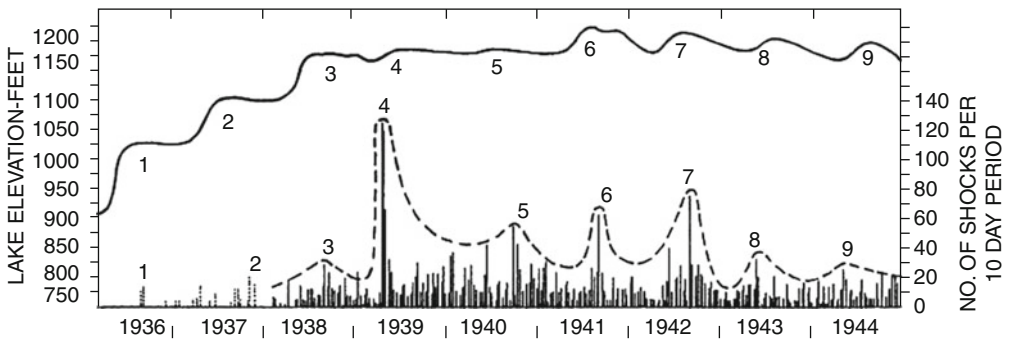
Introduction

Under certain suitable geological conditions, anthropogenic activity can trigger or induce earthquakes. The triggered/induced earthquakes are known to have occurred due to gold and coal mining, petroleum production, filling of artificial water reservoirs, high-pressure liquid injection into ground, and natural gas production. The largest triggered, scientifically accepted earthquake of magnitude 6.3 occurred on December 10, 1967 in the vicinity of Koyna Dam near the west coast of India. It is debated whether the M 7 Gazli earthquakes of May 1976 and

March 19, 1984 were induced due to the production of large quantities of gas at the Gazli Oil Field in Uzbekistan. A good account of the above and the mechanism of triggered/induced seismicity can be found in a review by McGarr et al. (2002).

Triggered vis-a-vis induced earthquakes

For a long time, the adjectives "induced" and "triggered" were used interchangeably whenever one talked of artificially simulated earthquakes. McGarr and Simpson (1997) have addressed this question and suggested that it would be important to draw a distinction between the two. They proposed that the adjective "triggered seismicity" should be used only when a small fraction of stress change or energy associated with earthquakes is accounted for by the causative activity. The term "induced seismicity" should be used where the causative activity is responsible for a substantial part of the stress change. In case of triggered seismicity, tectonic loading plays an important role. The stress level changes associated with filling of some of the deepest artificial water reservoirs are only of the order of 1 M Pa or so, whereas the stress drop associated with the earthquakes is much larger. Therefore, all cases of earthquakes occurring subsequent to filling of the artificial water reservoirs fall in the category of "triggered earthquakes," and hence it is appropriate to call it "reservoir triggered seismicity" (RTS).



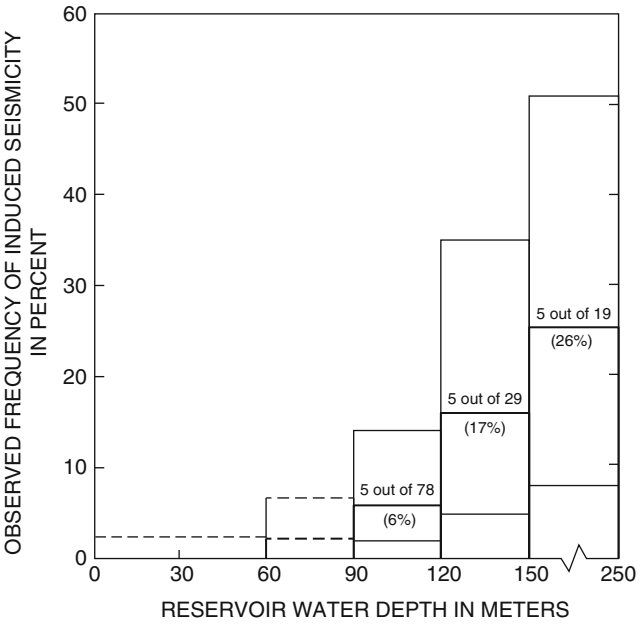
In the present entry, we concentrate on triggered earthquakes caused by the filling of the artificial water reservoirs.

Reservoir triggered seismicity (RTS)

Generation of hydroelectric power, irrigation, and flood control has necessitated creation of artificial water reservoirs globally. Triggering of earthquakes was for the first time pointed out by (Carder, 1945) at Lake Mead in the USA. Figure 1 depicts Lake Mead water levels and local seismicity. The rise in water levels and the corresponding bursts in seismicity are numbered. The correspondence is indeed remarkable.

Over 100 reservoir sites are now known globally, where triggered earthquakes occurred after filling of the artificial water reservoirs (Gupta, 2002, 2008). Earthquakes exceeding magnitude 6 have occurred at Kariba, Zambia-Zimbabwe border; Hsinfengkiang, China; Kremasta, Greece and Koyna, India. Koyna earthquake of M 6.3 that occurred on December 10, 1967 is so far the largest triggered earthquake. It claimed over 200 human lives, injured about 1,500 and rendered thousands homeless. The occurrence and potential of triggered earthquakes has caused major modification of civil works and engineering projects. Anticipating a large triggered earthquake, the Hsinfengkiang Dam was strengthened twice before the occurrence of M 6.1 earthquake on March 20, 1962 (Shen et al., 1974). The disposal of waste fluid through injection into the ground at Rocky Mountain Arsenal had to be discontinued due to triggered earthquakes (Evans, 1966). The possibility of high magnitude triggered seismicity was responsible for terminating the Auburn Dam project in California (Allen, 1978). A number of researchers believe that the M 7.9 Wenchuan earthquake of May 12, 2008 in China, which claimed around 90,000 lives, may have been triggered by the near by Zipingu reservoir (Kerr and Stone, 2009).

In Table 1, the reservoir sites where triggered earthquakes exceeding M 4 occurred are listed. Many studies examined the correspondence among several possible correlates such as the size of the reservoir, time interval for the largest RTS event to occur from the first filling of the reservoir, height of the water column in the reservoir, rate of loading, and the RTS. The most important correlate is the depth of the water column in the reservoir (Baecher and Keeny, 1982). Figure 2 shows that when the water column depth exceeds 150 m, a quarter of reservoirs experienced RTS. A review of recent global review supports this finding. Artificial water reservoirs with water column exceeding 100 m and/or volume exceeding 1 m^3 are called large reservoirs (ICOLD, 2008). There are over 1,000 large reservoirs in the world and only a small percentage of these reservoirs have evidenced RTS. One should remember, however, that many pre-1990s hydroelectric



Triggered Earthquakes, Figure 1 Lake Mead water levels and the local seismicity. For 1936 and 1937, only the felt shocks are plotted. The rises in water levels and the corresponding bursts of seismic activity are numbered. General trend of tremor-frequency variation is shown by *dotted lines* (After Carder, 1945).

Triggered Earthquakes, Table 1 Reported cases of reservoir-triggered seismicity (RTS) where M ≥ 4 earthquake occurs.

Name of the dam/ Reservoir	Country	Height of dam (m)	Reservoir volume (10^6 m^3)	Year of impounding	Year of the largest earthquake	Magnitude/ Intensity	References
Sites where earthquakes having magnitude ≥ 6.0 were triggered

Triggered Earthquakes, Figure 2 Height of water column is the most important correlate (After Alexander and Mark, 1976).

developments did not have seismographic capacity to detect small induced earthquakes. Hence, one cannot discard the possibility that small earthquakes below the detection threshold of some areas could have been triggered.

How to assess the RTS potential and what would be the largest RTS event at a given reservoir site, is frequently debated. Although the phenomenon of RTS is not yet fully understood, it is clear that the stress changes caused by the reservoir are small and that the region must be stressed close to critical for triggered earthquakes to occur. It is possible to estimate the likelihood of RTS by measuring the in situ stresses at a site at depth and see how close to failure it is. Such experiments were conducted by (Zoback and Hickman, 1982) at Monticello Reservoir at South Carolina, USA, and are still used. The magnitude of an RTS event would not exceed the maximum credible earthquake of the concerned region. The possibility of mitigating triggered earthquakes through the manipulation of the water levels in the reservoirs was first demonstrated by (Simpson and Negmatullaev, 1981) at the Nurek dam in Tajikistan and (Gupta, 1983) at Koyna, India. Similar suitable approaches can be made at other sites taking into consideration the locale specific situations and parameters.

Koyna, India, continues to be the most significant RTS site where since the impoundment of the reservoir in 1962, 22 $M \geq 5$ earthquakes (including the December 10, 1967 M 6.3 earthquake), over 200 $M \geq 4$ and several thousand smaller earthquakes have occurred. All this RTS is confined to a small area of 30 × 20 km, and there is no other seismically active area within 50 km of the dam site (Gupta, 2008).

Summary

Anthropogenic activities can trigger/induce earthquakes. Earthquakes triggered by filling of the artificial water reservoirs have been damaging at several locations. Proper geoscientific evaluation of site conditions and in situ stress measurements can help in finding safer sites.

Definition

Tsunami. From Japanese *tsu*, harbor, and *nami*, wave. A wave, or series of waves, generated when a large volume of water is vertically/horizontally displaced by an impulsive disturbance such as an earthquake, landslide, or volcanic eruption. Tsunami are distinguished from regular sea waves by their long wavelength and period. "Tsunami" and "tsunamis" are both used for the plural in

English. There is no pluralizing suffix "s" used in the Japanese language.

Tsunami run-up height. The elevation above sea level at a point along the maximum inundation extent of a tsunami. The sea level datum should be specified; often the ambient sea level at the time of the tsunami is used.

Tsunami run-up distance. The horizontal distance from the coast line to a point along the maximum inundation extent of a tsunami.

Tsunami wave height. The height of a tsunami wave, measured either relative to the ambient sea level or from the peak to the trough of the wave. These are referred to as the *zero to peak wave height* or the *peak to trough wave height*, respectively.

Introduction

Tsunami are a natural process recorded every year on tide gauges around the world. They can occur in any ocean, sea, or lake provided there is some way the water body (or a connected water body) can be suddenly displaced vertically/horizontally, usually by an *earthquake*, and less often by a *volcanic eruption* or *landslide*. Tsunami large enough to cause injury to people and damage to property recur globally on the order of years to decades. Tsunami are often mistakenly called "tidal waves" and although tides play no part in the source of tsunami, the arrival of a tsunami at high tide can be significantly more hazardous than if it arrives at low tide – especially on coasts with a large tidal range. The word "tsunami" is adopted from Japanese – tsunami disasters have punctuated Japan's history due to that country's proximity to large faults associated with plate boundaries and the presence of many volcanoes. For example, in 1792 a volcanic earthquake on Mt Unzen triggered a landslide that descended into the nearby bay causing a tsunami with run-up heights of 35–55 m in Shimbara; the tsunami and landslide killed approximately 15,000 people in total (Lockridge, 1990). In recent years, the Indian Ocean tsunami of December 26th, 2004, and the Tohoku, Japan, tsunami of March 11, 2011, have raised public awareness of the hazard from very large subduction zone earthquake-generated tsunami.

Tsunami can propagate across the deep ocean at high speed, sometimes exceeding 700 km/h, and with relatively little dissipation of energy. They can consequently be dangerous far from the source, for example, the tsunami caused by the giant Chilean earthquake of 1960 claimed 61 lives in Hawaii and 138 in Japan (Atwater et al., 2005). Despite the high propagation speed there is still the potential to provide warning ahead of a long-range tsunami, as it takes, e.g., 12–24 h for a tsunami to travel across the Pacific basin. A Pacific-wide tsunami warning system has been in operation since the late 1960s.

The primary geological causes of tsunami are earthquakes, landslides, and volcanic eruptions. Earthquakes initiate tsunami principally through coseismic uplift or subsidence of the seafloor, which displaces the water above. Submarine landslides cause tsunami by displacing water to make way for the descending landslide material, and leaving a volume to be filled by water in the landslide's wake. Volcanic events displace water by a wide variety of mechanisms, some of which involve gravitational collapse similar to landslides, whereas others are associated with explosive events. Weather systems are also capable of creating tsunami-like waves, known as storm-surges or "meteorological tsunami" (Monserrat et al., 2006). The flooding of New Orleans associated with Hurricane Katrina in 2005 was one such event (Fritz et al., 2007). Although frequent and sometimes devastating events, they are generally regarded as a different category of event to tsunami, because they have no geological cause.

Physical properties of tsunami

When a body of water is suddenly displaced vertically, gravity acts to try and restore equilibrium. The dynamics of this process cause waves to propagate away from the initial disturbance. Tsunami waves are thus an example of gravity waves, for which the restoring force is gravity. In a tsunami these waves are able to propagate long distances with little dissipation, and this property of tsunami means that, for example, a tsunami caused by an earthquake on one side of the Pacific can be destructive to people and property on the other side of the Ocean.

A distinguishing feature of a tsunami is the long period of its waves; these can last from several minutes to an hour or more, in contrast to wind waves which have periods ranging from a few seconds to about a minute. One consequence of this is that tsunami inundation can be much more dangerous than inundation caused by wind waves of the same amplitude. Another distinguishing feature of tsunami waves is that they involve the motion of water all the way from the seabed to the surface, whereas shorter period waves typically only involve the first few tens of meters. This contributes to the large amount of energy that can be transferred within a tsunami.

The propagation speed of a tsunami is controlled by the water depth. Provided the wavelength is long compared to the water depth, as it is for most earthquake-generated tsunami, the speed, c, is given by:

$$c = \sqrt{gh}$$

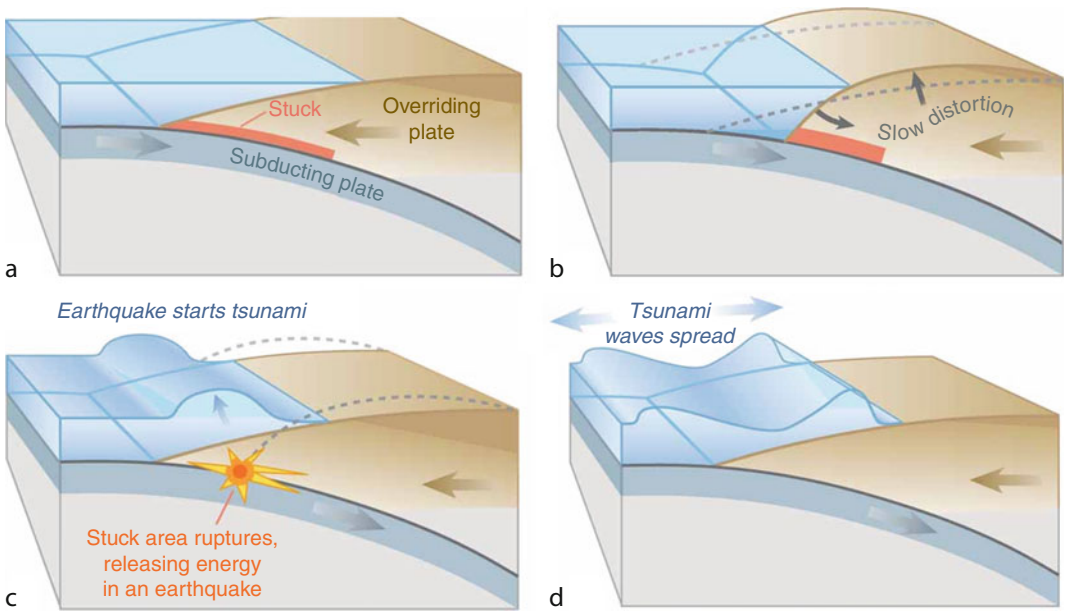
where g is the gravitational acceleration and h is the water depth. In deep water very high propagation speeds are possible, e.g., in 4,000 m of water the speed is approximately 200 m/s. It should be noted that this is the speed with which the wave propagates, rather than the speed of individual particles within the wave (which is generally much slower, except in shallow water where it may be comparable).

When a tsunami approaches land its speed reduces causing the wave to "bunch-up," increasing in amplitude as it does so. This is known as shoaling, and is the reason that a tsunami that goes unnoticed by ships at sea can rise to be tens of meters high at the shore. Overland speeds for tsunami

inundation flows have been measured in the 10–75 km/h range (Matusutomi et al., 2006; Choowong et al., 2008).

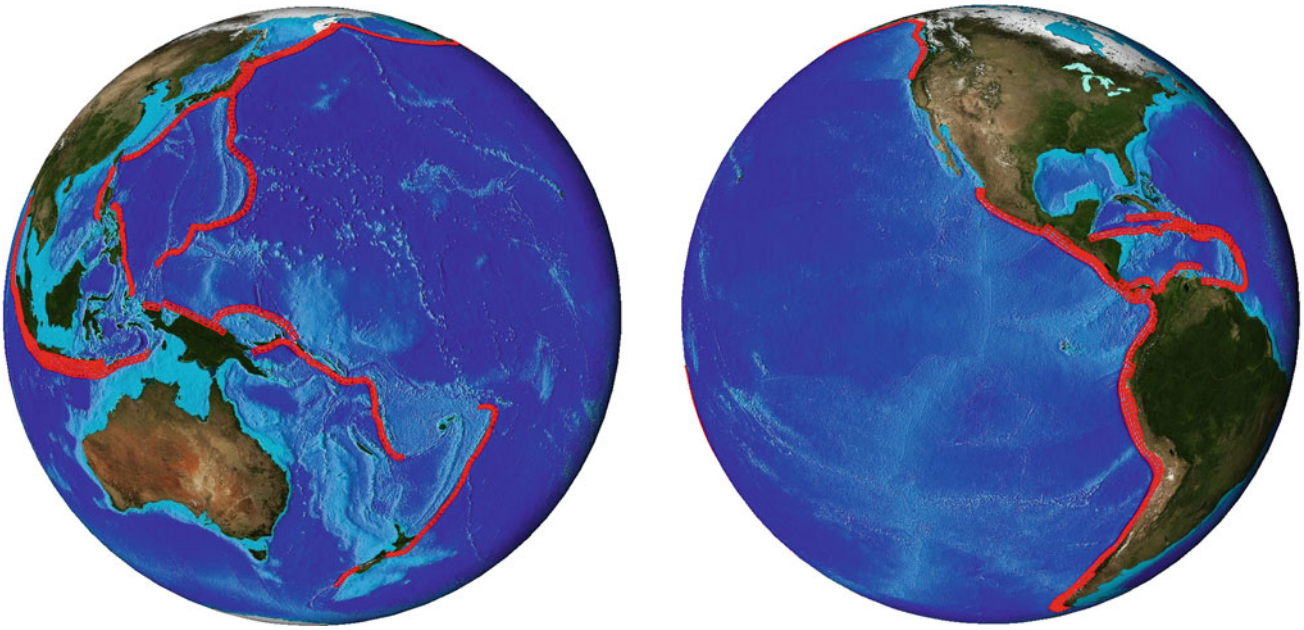
Because the tsunami speed is controlled by water depth, the tsunami waves are subject to processes familiar from optics such as reflection, refraction, and wave-guiding, but for tsunami it is the bathymetric profile that controls the direction of propagation rather than the refractive index as in the case of light waves. The effects of bathymetry on tsunami propagation have been studied extensively by Mofjeld et al. (2000).

Sources of tsunami



Since tsunami involve the motion of large volumes of water they require similarly large sources of initial displacement. The most frequent and well-known source of tsunami are earthquakes, but landslides and volcanic eruptions can also cause them, as well as more exotic phenomena such as asteroid impacts.

Earthquakes



The majority of destructive tsunami are caused by earthquakes; in a typical year there may be one or two damaging earthquake-caused tsunami, and many more nondestructive smaller events. The process by which an earthquake initiates a tsunami is principally one in which the earthquake dislocation causes sudden and persistent uplift or subsidence to the seabed over a wide area. This lifts (or lowers) the water column above the seabed, putting the water out of equilibrium and causing a tsunami to propagate away (Figure 1). A variety of factors determine the area, timing, and degree of coseismic vertical displacement; these include depth, dip-angle, slip-distribution, rupture velocity, and the rigidity of surrounding rock. The influence of factors such as these on the tsunamigenic potential has been studied in depth by Geist (1999).

The most well-known examples of an earthquake-caused tsunami, and indeed of any tsunami, are the 2004 Sumatra-Andaman Islands tsunami and the 2011 Tohoku, Japan tsunami. The former was caused by an earthquake on the subduction zone boundary between the India plate and Burma microplate that lies in the northeast of the Indian Ocean. In this earthquake, which had an estimated moment magnitude of 9.3 (Stein and Okal, 2007), the average slip was over 9 m along a 1,300–1,600 km segment of plate boundary, with a maximum slip of 25–30 m near northern Sumatra. The subsequent tsunami produced run-ups in excess of 30 m along part of the Sumatra coast (Borrero, 2005), devastated the city of Banda Aceh, and caused huge loss of life (>220,000 deaths) and damage to property around the Indian Ocean.

One particular type of earthquake that causes tsunami is worthy of special mention is known as a "tsunami-earthquake" (Kanamori, 1972; Bilek and Lay, 2002) as it causes large tsunami relative to the felt shaking. This is particularly problematic in situations where the earthquake shaking is relied upon to provide a natural early warning of tsunami, as tsunami-earthquakes are liable to go unnoticed or ignored by much of the population. Seismic characteristics of tsunami-earthquakes include long-rupture durations, shallow locations close to the trench, low rupture velocities, and disproportionate energy release at low frequencies. A recent example of

Tsunami, Figure 1 Stages in tsunami generation by a subduction zone earthquake: (**a**) coupling between plates, (**b**) strain accumulation, (**c**) strain release during earthquake, and (**d**) tsunami propagation (Credit: USGS; not subject to copyright).

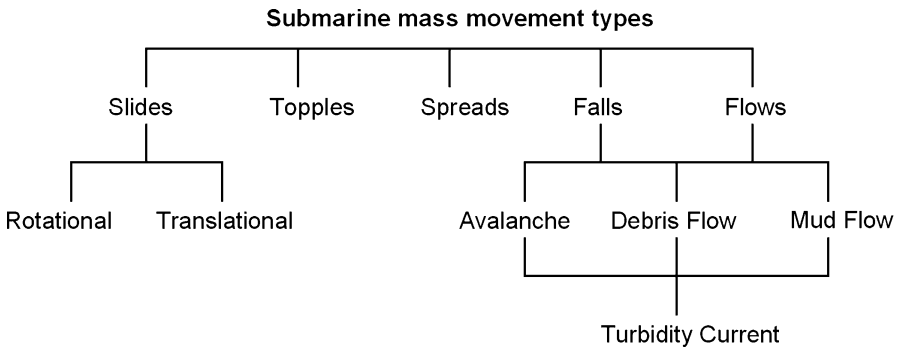
Tsunami, Figure 2 International tsunami source map. Identified subduction zone source locations are shown in *red* (Credit: NOAA; not subject to copyright).

a tsunami caused by a tsunami-earthquake is the 2006 M7.7 south Java tsunami (Reese et al., 2007).

Most major tsunami-generating earthquakes occur on subduction zones (Figure 2). In general, earthquakes with moment magnitudes of less than 6.5 are unlikely to cause tsunami directly. However such smaller events may still cause ground shaking sufficient to act as a trigger for landslides, especially in areas where large earthquakes are rare.

Landslides

Landslides are generally believed to be less frequent causes of tsunami than earthquakes, but as most large landslides are likely to be triggered by earthquakes it is not always possible to determine the ultimate source. A well-known instance of a landslide-caused tsunami is the Grand Banks tsunami of 1929; in this case although there was a triggering earthquake, we know that a substantial submarine landslide took place because of the sequential severing of a sequence of telephone cables (Heezen and Ewing, 1952).



Tsunami-causing landslides may be entirely submarine, or they may be subaerial, i.e., starting above the water surface but descending into it. In both cases it is the displacement of water by the descending body of dense material that initiates the tsunami. The classification of landslides is quite complicated which reflects the variety of different failure mechanisms and the physical properties of the landslide material (Figure 3).

The scale of earthquake-generated tsunami is limited by the size of the largest earthquakes which is itself constrained by the length of subduction zones (McCaffrey, 2008). Landslides, on the other hand, appear to have fewer constraints on the maximum size, and consequently may become the dominant source of tsunami at scales beyond the reach of tectonic sources. While it is simplistic to reduce the scale of a landslide source to just the volume of material in the landslide, it does provide a first approximation. The 1929 Grand Banks tsunami, which produced waves 3–8 m high and claimed 29 lives, was estimated to be caused by a turbidity current of volume 200 km^3 (Fine et al., 2005). This is dwarfed by comparison to the volumes of material implied by submarine paleo-landslides: the Ruatoria debris flow in New Zealand is estimated to have a volume of 3,000 km^3 (Collot et al., 2001) and the Storegga debris flow in the North Sea is thought to be similar (Haflidason et al., 2004). Fortunately, the timescales between such events is estimated to range from tens to hundreds of thousands of years. The Nuuanu slide near Hawaii is estimated to have contained more than 5,000 km^3 of material (Moore et al., 1989), but is thought to have occurred more than 1.5 Ma years ago (Moore et al., 1989).

The largest recorded tsunami run-up heights are due to a subaerial landslide source, namely, the Lituya Bay (Alaska) landslide in 1958 (Miller, 1960). The landslide was triggered by an earthquake, and although the volume of material was relatively small at about .04 km^3 the sudden, fast, descent into the confined body of the Bay caused water to rush to over 500 m elevation on the opposite banks.

Volcanoes

Volcanic eruptions are an infrequent, but occasionally catastrophic source of tsunami. There are thought to be many

Tsunami, Figure 3 Classification of submarine mass movements (Locat and Lee 2000).

different possible modes by which a volcanic event can trigger a tsunami (Latter, 1981), and it is often difficult to establish the mechanism for historical events due largely to the self-destruction of the volcanoes involved and the limited prospects for eyewitnesses. The most well-known tsunami following a volcanic event was that which followed the eruption of Krakatau in 1883 (Verbeek, 1884). The tsunami was the principal cause of loss of life in this eruption, waves which ran-up to about 40 m in the Sunda Strait caused a similar level of devastation to that of the 2004 Sumatra-Andaman Islands tsunami. Other notable tsunami-causing eruptions are that of Santorini in the Aegean Sea in about 1470 BC, and the eruption of Mt Unzen in southern Japan in 1792.

Proposed mechanisms by which a volcano can create a tsunami are varied, Latter (1981) lists ten: earthquakes accompanying eruptions, displacement of water by submarine explosions, displacement of water by pyroclastic flows, caldera collapse and subsequent in-filling with water, landslides on volcano flanks, shock waves caused by base-surges, hot-rock avalanches, lahars entering the water, air waves following explosions, and lava avalanches.

Others

In addition to the three main source types of earthquakes, landslides, and volcanoes, there are some additional sources of tsunami. The impact of extraterrestrial objects such as asteroids and comets (collectively referred to as bolides) into the ocean has the potential to create tsunami. These tsunami could conceivably be larger than those due to any terrestrial source, though such large events are believed to be extremely infrequent. The extinction of the dinosaurs is linked to the impact of a large comet near Chicxulub in Mexico approximately 65 million years ago (Bryant, 2001), but tsunami are just one of the many devastating global consequences of such an event.

Impacts of tsunami

Tsunami damage and casualties are usually caused by five main factors:

The impact of a swiftly flowing torrent (up to 70 km/h), or traveling bores, on vessels in navigable waterways, canal estates and marinas, and on buildings, infrastructure and people where rivers break their banks or coastal margins are inundated. Torrents (inundating and receding) and bores can also cause substantial erosion both of the coast and the seafloor. They can scour roads and railways, land, and associated vegetation. The receding flows, or "out-rush," when a large tsunami wave recedes, are often the main cause of drowning, as people are swept out to sea.

Debris impacts – many casualties and much building damage arise from the high impulsive impacts of floating debris picked up and carried by the in-rush (inundating) and out-rush (receding) flows. Building materials, boats, cars, and other vehicles are some of the most common and destructive debris in urban areas.

Fire and contamination – fire may occur when fuel installations are floated or breached by debris, or when home heaters are overturned. Breached fuel tanks, and broken or flooded sewerage pipes or works can cause contamination. Homes and many businesses contain many harmful chemicals that can be spilled.

Inundation and saltwater-contamination – by the ponding of potentially large volumes of seawater will cause medium to long-term damage to buildings, electronics, fittings, and to farmland.

Sedimentation and erosion – advancing and retreating tsunami pulses can be highly erosive, removing large amounts of sand, soil, and even loose rock. This material is then deposited as sediments in other locations. Material, especially sand, eroded from the sea floor can be deposited on land, and vice versa. Changes in the coastal seabed due to erosion and deposition can change shipping channels and affect the operability of ports.

Buildings

The response of buildings to tsunami varies widely depending on building construction and wave dynamics. In general, reinforced concrete buildings fare far better than unreinforced buildings. For example, in Samoa in 2009 flow heights of 3–4 m caused the complete destruction of many unreinforced timber buildings, whereas those built nearby with cement and reinforcing iron, often schools and churches, often remained standing. Water depth and velocity are important; there is less structural damage from

slow moving deep water, or faster moving but shallow (a fraction of wall height) water. Unreinforced buildings are often destroyed by the force of water alone, whereas the majority of structural damage to reinforced buildings comes from debris impact (especially vehicles and boats). Buildings with reinforced structural members and unreinforced in-fill walls (often brick) usually have partial or complete loss of the walls with relatively little damage to the structure, even with water depth greater than one story. For multistory buildings, this means that people often survive unscathed on the roof or upper stories (Figure 4).

People

Even shallow (depth less than knee-height) tsunami inundation can be very dangerous or deadly. Water velocity and turbulence means that it is hard to remain standing; drowning is a significant risk. Additionally, the water usually contains sharp or heavy debris, such as roofing iron or cars, and fine sand and silt. This leads to a high incidence of cut, crush, and abrasion injuries, all of which can be lethal through internal or external bleeding and shock (e.g., Prasartritha et al., 2008). Disease and infection are a high risk in the hours and days following a tsunami, compounded by the entrainment of sewage and the damage to health and sanitation facilities.

Infrastructure

Tsunami can damage anything they touch, and infrastructure and lifeline utilities are often significantly impacted. Even buried utilities are vulnerable due to the erosion generated by advancing and retreating tsunami. Roads, bridge approaches, foundations, and airport runways are often eroded; utility poles, bridge structures, wharves and piers are damaged by erosion and debris impacts; water and sewage pipes are broken, and electrical and communications lines severed, especially where they cross bridges; water supply, storage, and treatment facilities are damaged or filled with material; lifeline service buildings are damaged or contaminated (e.g., hospitals) and emergency responders and their vehicles may be directly impacted making them unavailable for relief efforts. Dependant services are also affected, for example, an ambulance may be undamaged but the roads are not drivable, or a hospital intact but without power or water.

Boats and shipping

Boats in shallow water and marinas are often damaged by collision with other boats, debris, wharves, or buildings. They are also often rafted inland and stranded, lost out to the open water, capsized or otherwise swamped and sunk. Even undamaged boats, and especially larger ships, may have difficulty usefully operating due to damage to wharves and piers. Loss of the use of boats and ships can have flow on consequences such as hindrance of relief efforts and aid supply, and loss of trade (from commodity shipping to local fishing).

Historical tsunami and paleotsunami

Historical tsunami databases are an important source of information on past events. The National Geophysical Data Center (NGDC) maintains an online database of historically recorded tsunami from 2000 BC to 2008 (NGDC, 2008). The database contains over 2,300 events, of these 1,126 are considered to be of high validity

Tsunami, Figure 4 Damaged house in Leone, American Samoa 2009. The ground floor has been destroyed by the tsunami apart from the reinforced pillars. The occupants survived the tsunami on the upper floor (Credit: GNS Science).

(probable or definite tsunami), and 902 have taken place since 1800 (Power and Downes, 2009). Approximately 73% of source events were in the Pacific Ocean, 14% in the Mediterranean Sea, 6% in the Caribbean Sea and Atlantic, and 5% in the Indian Ocean (NGDC, 2008). NGDC also maintains a database of tsunami run-up measurements covering approximately 7,000 locations. The Novosibirsk Tsunami Laboratory (NTL) also maintains a comprehensive historical tsunami database (NTL, 2010).

Prehistoric tsunami may be studied via their geological impacts, for example, by the inland deposition of sand and other materials from the coast. It is however difficult to distinguish between inundation events with geological sources from those arising from weather events. Many smaller tsunami do not leave paleotsunami traces, and those that do may be hard to detect due to the shifting coastal environment. Consequently the known record of paleotsunami is much less complete than the recent historical record of tsunami. A well-studied paleotsunami event is the Cascadia tsunami of 1700, which was also observed in Japan and recorded in the myths of Native Americans (Atwater, 2005).

Tsunami modeling

Tsunami modeling allows us to reconstruct, and better understand, past tsunami; and to look into the consequences of possible future events. Creating a model of a tsunami can be achieved both through scaled-down physical models and more commonly via numerical calculations of the processes involved using a computer.

Tsunami modeling can be performed for all stages in the generation, spreading and impact of a tsunami. Numerical modeling of earthquake sources is a fairly mature field; typically Okada's (1985) formulae are used to estimate the seabed deformation following slip on portions of a fault plane. A large area of uncertainty here is in estimating the initial slip-distribution, as this is often poorly constrained by real data and can have a big influence on the resulting tsunami, especially close to the source (Geist, 1999). Landslide and volcanic source modeling does not follow a single well-established procedure and to some extent this reflects the variety of mechanisms by which they can initiate tsunami. In the case of landslide sources a sliding-block approach is sometimes used to represent the failure of large blocks, at the other extreme the landslide may be described as a dense, viscous fluid flow. Real landslides form a continuum between these extremes, with, for instance, debris avalanches, having some properties of both solid and fluid.

Numerical modeling of tsunami propagation is usually achieved by solving the shallow-water wave equations. These algorithms may include nonlinear terms in situations where the tsunami propagates over shallow water, and additional corrections may be included to account for Coriolis effects and to approximate frequency-dispersion effects. Inundation modeling is often carried out in conjunction with propagation modeling, as once an area becomes wet the evolution is described by similar equations. Key differences include the optional incorporation of bottom-friction, and equations to describe the wetting and drying processes at the front of a tsunami. Examples of software packages that combine propagation and inundation modeling are MOST (Titov and Gonzalez, 1997), COMCOT (Liu et al., 1995; Wang and Liu, 2006) and ANUGA (Roberts et al., 2008).

Tsunami mitigation

Hazard assessment

Important precursors for efficient tsunami mitigation are *risk assessment* and *hazard and risk mapping*, to establish the likelihood and probable consequences for a tsunami to impact a particular area. This helps to ensure that mitigation measures are applied where they can have the greatest benefit. The approach used to achieve this is combination of vulnerability cataloging (where people and assets are located and how susceptible to tsunami they are), and tsunami hazard assessment (Power and Downes, 2009).

Tsunami hazard assessment can take two main forms. It can be based on a scenario approach, where models are made to represent one or more likely situations; or it can be based on a probabilistic approach, in which a spectrum of possible events are analyzed and weighted according to their likelihood. This latter approach is in its infancy for tsunami modeling, but allows for a more systematic comparison of hazards between different locations and across different types of phenomena.

Whether scenario or probabilistic, it is usually important for a hazard assessment to also estimate the likely consequences of the tsunami impact. This is then usually referred to as a risk assessment, and takes into consideration the fragility of buildings and people; that is how likely they are to be damaged by the impact of a tsunami wave of a particular height or velocity. Tsunami *risk management* is often best conducted through a combination of *land-use planning* and *building codes*, possibly *structural mitigation* (with some caveats) and *warning systems* (e.g., Jonientz-Trisler et al., 2005; NTHMP, 2001). Deciding on the exact tsunami hazard at a location is very difficult, because future tsunami inundations are models, and there is usually only a short historical record, and incomplete geological record, for calibration.

Land-Use planning and building codes

Land-use planning for tsunami can greatly reduce the risk, if people do not live near the coast. However, coastal land is some of the most desirable and expensive because of access to the coast, attractive views, and lifestyle factors. Some areas are of high tsunami risk to most people (e.g., beach-front facing a subduction zone fault line), but deciding on the line inland/above which the risk is acceptable is very difficult due to uncertainties in modeling tsunami hazard. As a result

virtually no place has instituted tsunami land-use planning rules. Buildings can in theory be built to codes that will protect people inside them from tsunami, or be built to be elevated above the tsunami risk height (FEMA, 2008). Such buildings would need to be water-proof and very strong. Tall reinforced buildings can be used as evacuation structures in tsunami warnings, where evacuation routes to higher ground require travel too far. Specific tsunami evacuation structures and dual use buildings with evacuation access have been implemented in Japan and recently Indonesia, for example.

Structural mitigation

Barrier *structural mitigation*, such as sand dunes and sea walls may be effective against tsunami of a similar or lower height. Because of the large volume of sand dunes they can also act as a sacrificial barrier, being eroded by a tsunami and reducing velocity and distance of inundation. Sea walls tend to create a high level of perceived landward safety, leading to increased development. Walls can still fail or be exceeded and the additional development has in the meantime added vulnerability, increasing the consequences in these larger events. Walls are typically very expensive and also have major cultural (community division), life quality (view and access) and safety (barrier to evacuation) problems.

Warning

In most cases *warning systems* are the default option relied upon to mitigate tsunami risk, but do not mitigate against other damage – they only aim to ensure life safety. Tsunami can reach the shore from sources only minutes away (e.g., a local fault or landslide) or take 12 h or more to arrive as they travel across an ocean. Warnings can come from natural, informal, or official sources (Gregg et al., 2006). Natural and informal warnings may be the only warnings for sources close to the impact location, as there may not be enough time for official warning systems to activate and communicate, or if the official system fails to notify people (due, for example, to equipment fault, or patchy coverage). Natural warnings for tsunami are usually:

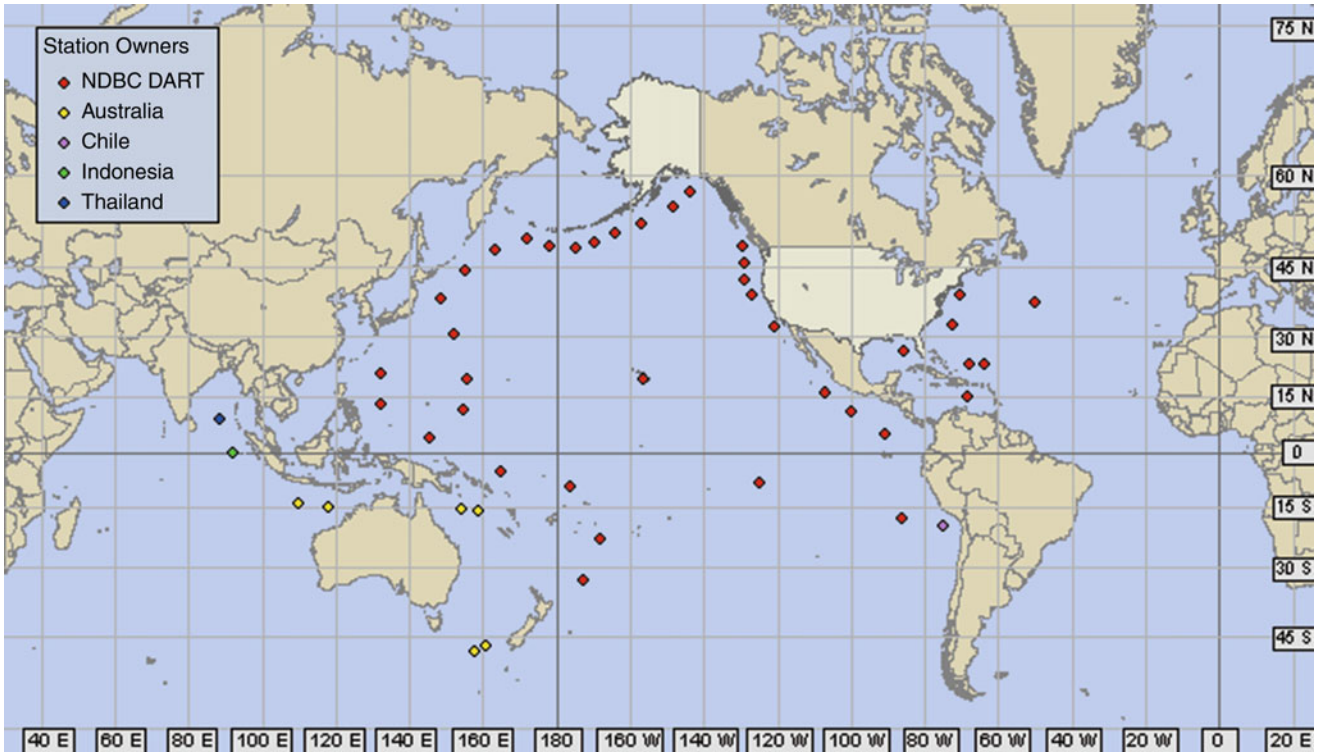
Earthquakes – either strong earthquakes that it is difficult to stand up in or gentler rolling earthquakes that last for a minute or more (indicative of large earthquakes farther away, and of "tsunami-earthquakes")
Unusual ocean behavior – water rushing in or out
Unusual noises from the ocean – often described as "roaring like a jet engine," or "like an animal roaring"

Informal warnings may propagate from one person to another after natural signs have been observed, or an official warning message is received.

Forecasting

Official warning systems are typically technological and rely on geophysical monitoring and scientific evaluation to generate tsunami forecasts. The precursor to the Pacific Tsunami Warning Center (PTWC) in Hawaii was established in 1949 in response to the 1946 Aleutians tsunami, and its remit extended to cover the Pacific Basin in 1968. The West Coast and Alaska Tsunami Warning Center (WC/ATWC) was established in 1967 in response to the 1964 Alaskan tsunami. The WC/ATWC also acts as a backup for PTWC within the wider Pacific Basin. Since the 2004 Indian Ocean tsunami PTWC has also taken responsibility for the Indian Ocean, South China Sea, and parts of the Caribbean. The Japan Meteorological Agency has operated a tsunami warning system since 1952.

The initial basis for tsunami warnings comes from seismic data alone, since seismic waves propagate much faster than tsunami waves. This provides information on the location and magnitude of the source earthquake, from which an initial evaluation of tsunami threat can be made. More accurate modeling requires time and detailed earthquake parameters.



Subsequent information comes in the form of DART buoy (Gonzalez et al., 1998; Figure 5) and tide gauge measurements, which can be used to confirm the presence of a tsunami and then to refine estimates of the tsunami size. Software such as SIFT (Gica et al., 2008) is under development to provide more accurate tsunami forecasting using DART buoy data.

Communication and response

For warnings to be effective they must reach an aware and prepared public with enough time to take protective actions. Protective actions for tsunami are usually to evacuate, either to higher ground and inland or up a tsunami evacuation structure. Warning systems only activate a decision-making process, so for an appropriate decision to be made the public must be aware of the hazard, believe the potential consequences, know the appropriate protective actions and know that they will be effective (Gregg et al., 2007). They must believe that their actions will mitigate the risk and that they (the public) are capable of completing these actions in time.

The official warning process always includes a lead time comprised of the time taken to detect tsunami data (e.g., earthquake location and magnitude, wave arrivals), to decide on the message to deliver, to prepare the message, and to communicate the message to the public. To keep this lead time as short as possible detailed planning of the system, decision-making thresholds, and evacuation are needed. The public need to know where the official message is coming from, be able to get that message at any time of the day or night, regardless of what they are doing, know if the message is trustworthy, and know what to do in response. Evacuation zones, routes, and safe areas need to be preplanned and widely known.

Given that evacuation is the usual protective action for tsunami, and that destructive tsunami are infrequent (often decades or more apart at a given location) evacuation exercise drills are essential to (1) test the system for reliability and effectiveness and (2) maintain a high level of awareness as to the correct actions. For successful evacuation

Tsunami, Figure 5 Worldwide distribution of DART buoys (Credit: NOAA; not subject to copyright).

from tsunami the mode of transport is an important criterion. Cars may be effective with many hours between warning and impact, but quickly jam roads in short time-frame events. For sources less than a few hours away it is probably best to aim for evacuation on foot and bicycle wherever possible, to avoid congestion.

Summary

Tsunami are naturally occurring long period waves in oceans, seas, and lakes generated by vertical displacement of water. They are most-often driven by earthquakes, and less often by volcanic eruptions and landslides. Earthquake sources tend to displace water over a larger area and so generate tsunami that are hazardous at a much larger distance from source. Tsunami can be highly destructive, reaching up to tens of meters above sea level on steep coastal land, and up to several kilometers inland over flat land. They can travel up to 200 m/s in the open ocean and go virtually unnoticed, shoaling and slowing down as they reach shallow coastal waters. Damage is caused by the force of water, entrained debris (cars and building materials) and fine particles (sand, etc.), erosion and sedimentation by withdrawing water, and fouling, contamination or salination from the water and impurities in the water. Land-use planning and structural mitigation (such as dune restoration rather than sea walls) can be effective, and warning systems are often implemented. It is hard to achieve high warning effectiveness and reliance on warning hardware often reduces the focus on community planning and options such as land-use planning, natural and informal warnings, and evacuation exercises, to the detriment of risk reduction.

Definition

Tsunami. The Japanese word for "harbor wave."
Coastal bathymetry. The study and mapping of the submarine ocean floor in near-shore areas.
Inundation. The overflowing of water onto normally dry land.
Loading combinations. The summation of individual force components occurring simultaneously.

Introduction

Tsunami, meaning "harbor wave" in Japanese, is the outcome of a vertical displacement of a large body of water. It can be triggered by various geological or astronomical phenomena, including: underwater earthquakes occurring along tectonic boundaries, volcanic eruptions, submerged or aerial landslides, and impact from asteroids or comets. In deep, open waters, tsunamis have small amplitudes (wave height), but very long wavelengths. However, as tsunami waves advance toward shorelines they transform. First, the amplitude of the tsunami wave increases due to shoaling, which occurs as the wave is "squeezed" by the up-sloping seabed. Second, the celerity and the wavelength decrease. However, the wave period remains constant. Depending on coastal bathymetry, tsunami waves can break offshore and advance in the form of a hydraulic bore, which is a turbulent, foamy wall of water, or surge in the form of a sudden increase in water level. Both bores and surges cause inundation of low-lying coastal areas. This in turn can significantly impact infrastructure located in the path of the advancing tsunami. The risks associated with tsunami hazard have increased in recent years due to the rapid development of coastal regions. The risk is more severe in low-lying coastal areas in developing countries, as shown in Figure 1, where structures, specifically residential, are often nonengineered and inadequately designed and constructed, thus prone to extensive damage when subjected to extreme events such as earthquakes, wind storms, and tsunamis. Even in developed countries, however, where structures are typically designed for gravity loads, wind-induced lateral loads, and earthquake excitations, they are not generally designed for tsunami-induced loading.

Tsunami forces on infrastructure

The impact of tsunami-induced forces on coastal protection structures, such as breakwaters, seawalls, reefs, etc., has been previously analyzed by researchers and engineers, particularly in Japan. However, understanding of the adverse effects of the impact of tsunami-induced flooding on near-shoreline infrastructure, such as bridges and buildings, is significantly less developed. Building codes do not explicitly consider tsunami loading, as it is understood that inland structures can be protected by proper site planning and site selection. Therefore, forces generated by tsunami are often neglected in structural design practice. Furthermore, code developers consider tsunami to be a rare event with a long return period. However, depending on the geographical location and tectonic characteristics of the underlying fault lines, major tsunamis can have a recurrence in the order of tens to hundreds of years; therefore, they should be given more attention in building codes. Recent catastrophic events (2004 Indian Ocean Tsunami; 2007 and 2010 Solomon Islands Tsunamis; 2010 Chile Tsunami; 2011 Tohoku, Japan Tsunami) have brought to light the destructive power of tsunami-induced flooding on near-shoreline structures. These events caused major structural damage to infrastructure, devastating coastal communities and resulting in widespread fatalities. Figure 2 illustrates the damage sustained by reinforced concrete structures during the 2004 Indian Ocean Tsunami. The research community has been responding with significant efforts to better understand the phenomenon of tsunami-induced forces and the interaction with structures to provide guidelines for engineers to design or assess infrastructure against such actions. Recent research indicates that forces imposed on structures due to impact of tsunami-induced flooding can be significantly higher than those associated with wind and comparable to or in excess of forces due to earthquake ground shaking (Nouri et al., 2007; Palermo and Nistor, 2009; Saatcioglu, 2009).

Tsunami Loads on Infrastructure, Figure 1 Overall damage after the 2004 Indian Ocean tsunami (Saatcioglu et al., 2006a).

Existing design guidelines

While several design codes explicitly provide guidelines for flood-induced loads (UBC, 1997; ASCE, 2006; IBC, 2006), a survey of current design codes, design standards, and design guidelines indicates that limited attention has been given to tsunami-induced forces. Four pioneering design documents specifically account for tsunami-induced forces, namely: the Federal Emergency Management Agency Coastal Construction Manual, FEMA 55 (FEMA, 2003), which provides recommendations for tsunami-induced flood and wind wave loads; the City and County of Honolulu Building Code (CCH, 2000), which contains regulations that apply to districts located in flood and tsunami-risk areas; the Structural Design Method of Buildings for Tsunami Resistance (SMBTR) proposed by the Building Center of Japan (Okada et al., 2005), outlining structural design for tsunami refuge buildings; and Guidelines for Structures that Serve as Tsunami Vertical Evacuation Sites, prepared by Yeh et al. (2005) for the Washington State Department of Natural Resources to estimate tsunami-induced forces on structures. Recently, the Federal Emergency Management Agency published Guidelines for Design of Structures for Vertical Evacuation from Tsunamis, FEMA P646, (FEMA, 2008). This document focuses on high-risk tsunami-prone areas, and provides design guidance for vertical evacuation structures. Conservative assumptions have been incorporated in FEMA P646 to ensure safety and security for the public requiring shelter from tsunami flood waters.

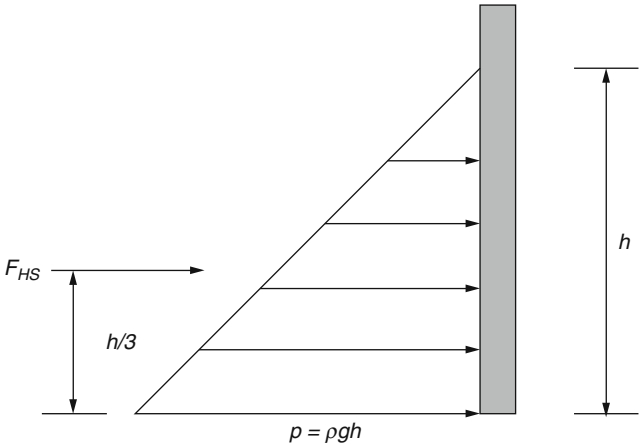
Tsunami-induced force components

A tsunami wave imposes significant loading on structures. The parameters defining the magnitude and application of these forces include inundation depth, flow velocity, and flow direction. These parameters mainly depend on tsunami wave height and wave period, near-shore bathymetry, coastal topography, and roughness of the coastal inland. The inundation depth at a specific location can be estimated using various tsunami scenarios (magnitude and direction) and by numerically modeling coastal inundation. The estimation of flow velocity and direction, however, is much more difficult to quantify. Flow velocities can vary in magnitude, whereas flow directions can vary due to onshore local topographic features, as well as soil cover and obstacles. The force components associated with tsunami-induced flows consist of: (1) hydrostatic force, (2) hydrodynamic force, (3) buoyant and uplift forces, (4) impulsive force, (5) debris impact and damming forces, and (6) gravity forces. The reader is referred to Nistor et al. (2009) and FEMA P646 for a comprehensive review of the individual force components.

Hydrostatic force

The hydrostatic force, generated by still or slow-moving water, acts perpendicular to the surface of the structural element of interest. The hydrostatic force, F_{HS}, can be calculated using the expression in Equation 1, where ρ is the seawater density, g is the gravitational acceleration, h is the maximum water depth or flood level, and b is the width of the structure or structural element. The force arises from a difference in water levels on opposite sides of the structural element. Equation 1 is based on water being present on one side of a structural element; however, it can be applied for cases where there is a difference in water elevation on two sides of an element.

Tsunami Loads on Infrastructure, Figure 2 Damage to reinforced concrete buildings after the 2004 Indian Ocean tsunami (Saatcioglu et al., 2006b).



$$F_{HS} = \frac{1}{2}\rho g h^2 b \tag{1}$$

Equation 1 is based on a triangular pressure distribution, as shown in Figure 3, with height of h and maximum pressure of pgh at the base. The point of application of the resultant hydrostatic force is located at one third from the base of the pressure distribution. In the case of a hydraulic bore, the hydrostatic force has a smaller magnitude compared to the hydrodynamic and impulsive forces. However, for surge-type tsunamis, the hydrostatic force may be substantial.

Hydrodynamic (drag) force

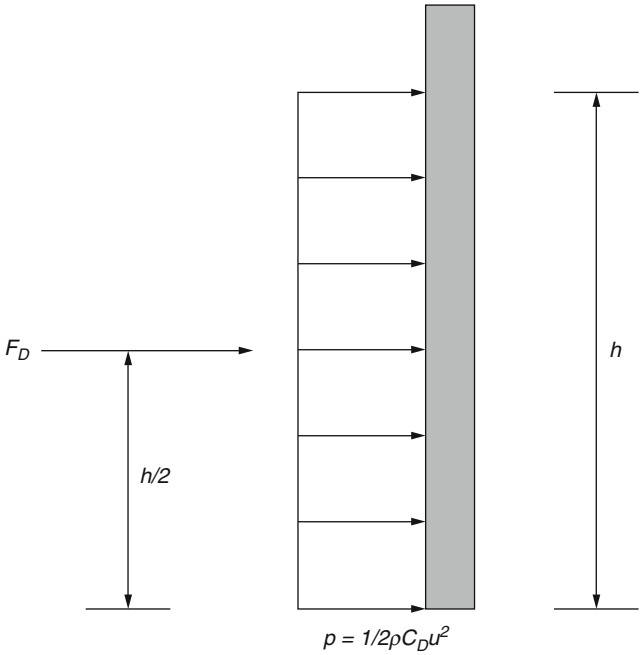
As tsunami-induced flow encounters a building or structural element, hydrodynamic forces, F_D, are applied to the building. The force includes the effect of the flow velocity on all sides of the building or structural element. The general expression for this force is given in Equation 2. Existing codes suggest different drag coefficient, C_D, values.

$$F_D = \frac{\rho C_D h u^2 b}{2} \tag{2}$$

Tsunami Loads on Infrastructure, Figure 3 Hydrostatic force.

where u is the tsunami-induced flow velocity (see section "Tsunami Flow Velocity" below). The flow is assumed to be uniform, and therefore, the pressure is constant through the depth of the flow. The resultant force is applied at the centroid of the projected area. The FEMA 55 document permits the hydrodynamic force to be converted to an equivalent hydrostatic force for flow velocities not exceeding approximately 3.0 m/s. Figure 4 illustrates the hydrodynamic force on a structural element.

Buoyant and uplift forces



The buoyant force, F_B, is a vertical force acting through the center of mass of a submerged or partially submerged structure. Its magnitude is equal to the weight of the volume of water displaced by the structure. Buoyant forces can induce stability problems by reducing the resistance of a structure to sliding and overturning. The buoyant force is calculated as follows:

$$F_B = \rho g V \tag{3}$$

where V is the volume of water displaced by the submerged or partially submerged structure. The effect of buoyancy in combination with hydrodynamic forces result in uplift forces on horizontal structural elements that have been submerged by tsunami inundation. The contribution of the hydrodynamic force occurs from the rapidly rising water level. It can be estimated using Equation 2 by replacing the flow velocity with the vertical component of the flow velocity, and applying an appropriate hydrodynamic coefficient. Figure 5 demonstrates the effects of uplift forces on concrete slab panels after the 2004 Indian Ocean Tsunami due to buoyant and hydrodynamic forces.

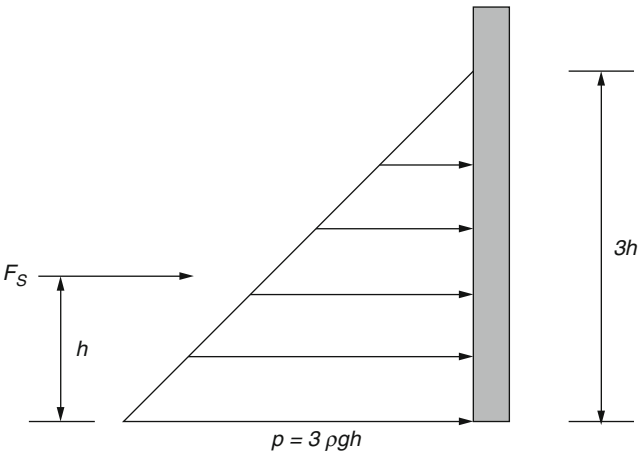
Impulsive force

The impulsive force, F_S, is a short duration load generated by the initial impact of the leading edge of a tsunami bore on a structure. Due to a lack of detailed experiments specifically applicable to tsunami bores running up the shoreline, the calculation of the impulsive force exerted on a structure is subject to substantial uncertainty and has not been universally validated. Dames and Moore (1980) suggested an impulsive force, known as surge force, as follows:

Tsunami Loads on Infrastructure, Figure 4 Hydrodynamic force.

$$F_S = 4.5\rho g h^2 b \tag{4}$$

where h is the surge height, usually assumed equal to the inundation depth or flood level. This expression is based on a triangular pressure distribution, as illustrated in Figure 6, extending $3h$ in height, with a corresponding maximum pressure of $3\rho g h$ at the base. Thus, the point of application of the resultant surge force is located at a distance h from the base of the pressure distribution. The surge force as given in Equation 4 results in excessively large forces. Conversely, FEMA P646 proposes an impulsive force equal to 1.5 times the hydrodynamic force, based on experimental results reported by Ramsden (1996) and Arnason (2005), as provided in Equation 5:



$$F_S = 1.5 F_D \tag{5}$$

Debris impact and damming forces

Tsunami-induced flooding traveling inland carries debris such as floating automobiles (as illustrated in Figure 7), floating pieces of buildings, drift wood, boats, and ships. The impact of floating debris can induce significant forces on a building, leading to structural damage or collapse (Saatcioglu et al., 2006a). The debris impact forces, F_i,

Tsunami Loads on Infrastructure, Figure 5 Displaced slab panels due to uplift forces (Saatcioglu et al., 2006b).

Tsunami Loads on Infrastructure, Figure 6 Surge force.

in its simplest form, can be estimated from the following momentum expression:

$$F_i = m\frac{u}{\Delta t} \tag{6}$$

where m is the mass of the body impacting the structure, u is the approach velocity of the impacting body (assumed equal to the flow velocity), and Δt is the impact duration taken equal to the time between the initial contact of the floating body with the building and the time the floating body comes to rest. FEMA P646 provides additional methods for calculating the debris impact force. The impact force acts horizontally at the flow surface or at any point below it. The impact force is to be applied to the structural element at its most critical location. Depending on the assumed debris mass, this force may not represent a significant contribution to the total lateral tsunami load relative to the other force components. However, it is significant in the design of the structural member that is subjected to the impact.

Debris impacting a structure can cause accumulation of debris, as depicted in Figure 7, leading to a damming effect. The forces generated due to damming can be estimated from the hydrodynamic force (Equation 2) by replacing b with the width of the debris dam.

Gravity forces

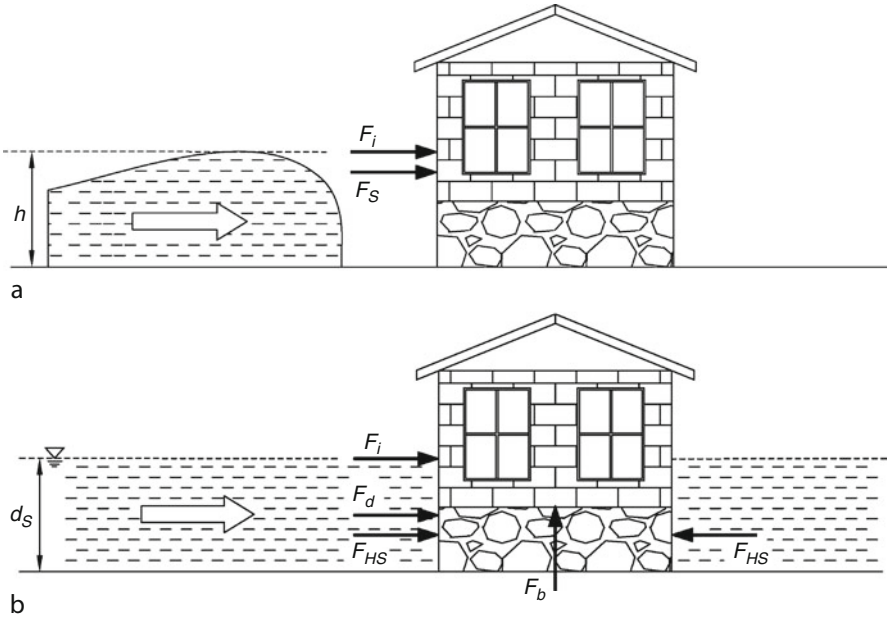
Drawdown of the tsunami-induced flooding can result in retention of water on structural flooring systems. This phenomenon imposes additional gravity loading on the structure, which must be considered in design.

Wave-breaking

Classic wave-breaking formulas are applicable for the case of wave breaking directly onto coastal structures, such as breakwaters, piers, and docks. Tsunami waves, however, depending on the near-shore bathymetry, tend to break offshore and approach the shoreline in the form of a rapidly moving hydraulic bore. Furthermore, inland infrastructure is generally not affected by the action of wave breaking occurring at the shoreline.

Tsunami flow velocity

The hydrodynamic force is proportional to the square of the flow velocity. Thus, uncertainties in estimating velocities result in large differences in the magnitude of



Tsunami Loads on Infrastructure, Figure 7 Impact of a floating vehicle during 2004 Indian Ocean tsunami (Saatcioglu et al., 2006a).

the resulting hydrodynamic force. Tsunami inundation velocity magnitude and direction can vary significantly during a major tsunami. Current estimates of the velocity are crude; a conservatively high flow velocity impacting the structure at a normal angle is usually assumed. Also, the effects of run-up, backwash, and direction of velocity are not addressed in current design documents. A number of guidelines and researchers have proposed estimates of velocity for given tsunami inundation levels, such as Murty (1977), Camfield (1980), FEMA 55 (Dames and Moore, 1980), Kirkoz (1983), CCH (2000), Iizuka and Matsutomi (2000), Bryant (2001), and FEMA P646 (2008).

Tsunami-induced loading combinations

The design documents previously discussed do not explicitly provide loading combinations to estimate the maximum tsunami load for design. In the case of SMBTR, the tsunami load is determined from a single force component that is equivalent to the surge force. FEMA 55 provides load combinations for flood loads, which include wave breaking. However, modifications are necessary to derive loading combinations that are directly applicable to tsunamis. Yeh et al. (2005) recommended that tsunami shelters located in the inundation zone, but inland, be designed for hydrodynamic (drag) and debris impact. The surge force that is generated due to the formation of a turbulent bore is neglected, since Yeh et al. (2005) consider dry-bed test conditions only where the initial impulsive force does not exceed the drag force. Dias et al. (2005) proposed two loading combinations: point of impact and post-submergence. The point of impact considers the initial impact of the tsunami wave and is estimated as the sum of hydrodynamic (drag) and hydrostatic force components on the upstream face of the structure. The post-submergence includes hydrodynamic (drag) on the upstream face, hydrostatic forces on the upstream and downstream faces, and buoyancy. The impact of debris is not explicitly included in either of the load combinations. Pacheco and Robertson (2005) analyzed structures to various inundation levels. In the estimation of the tsunami load, FEMA 55 was followed and wave-breaking forces were omitted. For columns directly exposed to the tsunami wave, the load was estimated as a combination of hydrodynamic and debris impact forces. The tsunami load for structural walls placed parallel to the shoreline, (and perpendicular to the flow of the tsunami), was considered as the maximum of two combinations: (1) The combined effect of hydrodynamic and debris impact forces, and (2) the surge and debris impact forces. Nouri et al. (2007) proposed loading combinations specifically for turbulent bores generated by tsunamis, as shown in Figure 8. Two combinations were developed, which were based on modifications of those recommended by Dias et al. (2005). The first combination (Initial Impact) considers the first arrival of the tsunami bore on a structure, and includes the combined effect of surge and debris impact forces. The second combination (Post Impact) considers the flow of the tsunami bore around the structure. Hydrodynamic, debris impact, and hydrostatic forces are combined to determine the lateral loading. Consideration is also given to buoyancy, which can cause sliding and overturning instability. The more recent FEMA P646 document provides separate tsunami force combinations for a structure and the individual structural

Tsunami Loads on Infrastructure, Figure 8 Tsunami loading combinations: (**a**) Initial impact; (**b**) Post impact (Nistor et al., 2009).

elements. For the structure as a whole, three loading combinations are described. The first is a combination of the impulsive forces on structural members located at the leading edge of the bore and drag forces on all previously submerged members behind the leading edge. The second combines a single impact force with drag forces on all structural members. Finally, the third considers the effect of debris damming with drag forces on all structural members. In, addition, the buoyant and hydrodynamic uplift forces should be considered in all load combinations. The design of tsunami load can be readily incorporated in building codes and combined with other loads. Given that a tsunami is considered to be an extreme event, load cases adopting the philosophy of seismic loading have been suggested (Palermo et al., 2009). FEMA P646 has also provided load combinations consistent with ASCE (2006).

Design considerations

Appropriate construction and layout design of a structure located in a tsunami-prone area can reduce the risk of damage during a tsunami event. Tsunami forces increase proportionally with exposed area and nonstructural elements that remain intact during the impact of the tsunami-induced flooding. Therefore, it is prudent to orient buildings with the shorter side parallel to the shoreline. Further, structural walls should also be oriented, if possible, to minimize the exposed area. Exterior nonstructural elements located at lower levels should be designed with a controlled failure mechanism that is triggered by the initial impact of the tsunami. This concept, known as *breakaway walls*, reduces the amount of lateral load that is transferred to the lateral force resisting system of the structure. Conversely, however, breakaway walls may result in an increase in debris loading. The use of rigid nonstructural exterior components, while providing protection to buildings from flooding, increases the lateral loading.

Summary

Recent catastrophic tsunamis (2004 Indian Ocean Tsunami, 2007 and 2010 Solomon Islands Tsunamis, 2010 Chile Tsunami, 2011 Tohoku, Japan Tsunami) have emphasized the destructive power of tsunami-induced flooding as it propagates overland and impacts near-shoreline infrastructure. As a result, research has evolved to improve our understanding of the forces associated with tsunamis and the interaction between tsunami-induced flow and infrastructure. Currently, force components and loading combinations have been proposed to assess and design structures against tsunami forces. The force components include hydrostatic, hydrodynamic, buoyant and uplift, impulsive, debris impact and damming, and gravity. There is, however, uncertainty in both the estimation of the component forces, as well as the total tsunami load that should be considered. Future efforts, including experimental and analytical studies, are being directed toward a better understanding of the forces that should be considered in design of infrastructure located in tsunami-prone areas.

Definition

Uncertainty encompasses all factors of the lack of knowledge towards the exact probability, the timing, magnitude and potential frequency of return of a natural hazard event.

Discussion

Uncertainty extends to the imprecise knowledge of the risk, that is, the precise knowledge of vulnerabilities at any given time of a hazardous event. Uncertainty comprises all unknown inaccuracies. The term is not unanimously defined but it certainly comprises a larger concept than error, the statistical expression for known inaccuracies. Natural hazards are complex phenomena that cannot be forecasted precisely. Allegedly one of the most descriptive manners to describe the risk types attached to natural hazards, including uncertainty aspects, was developed by the German Advisory Council on Global Change – WBGU (2000). WBGU risk types are based on prominent figures from the Greek mythology, and most natural hazards fall into the "cyclope" type risks. Cyclopes are mighty giants with only one eye, meaning that the extent of damage is well known but that the perspective is lost, that is, the probability (or timing) of occurrence. Beyond this, uncertainty is a concept that includes imperfect knowledge, inaccuracy, lack of reliability and inconsistency, and so on of the data (Pang, 2008). Uncertainty is mainly grouped into two types: (1) Aleatory (external) uncertainty is the unpredictability and randomness of the precise moment of an event or process (rock fall, climate change), and (2) Epistemic (internal) uncertainty is the inaccuracy of data and the shortcomings in the understanding of complex processes (models). According to this distinction epistemic uncertainty can be encountered by improving data sets and models. Aleatory uncertainty is subject to probability analysis (e.g., return periods) and epistemic uncertainty is encountered by expert knowledge.

The complexity of uncertainty plays a vital role in the design and estimation of mitigation and adaptation efforts. The cost-benefit analysis of measures to minimize risks related to natural hazards, or the potential impacts of climate change, is greatly dependent on data accuracy. The higher the uncertainty the higher is the potential to invest in inappropriate measures or to take unsustainable decisions. There are several approaches to visualize uncertainty in hazards to better inform about the complexity of the problem and ultimately to support decision making (Pang, 2008). The integration of uncertainty in hazard maps has direct effects on, and may be used to support, the delineation of hazard zones (zoning (further reading: Bostrom et al., 2008), Hoffmann & Hammonds, 1994). Traditionally hazard maps have sharp borders between for instance, "high" and "medium" hazard areas. Since natural events seldom follow strict borders introduced by human concepts, the introduction of uncertainty concepts into hazard maps assists the perception of the potential spatial extent and impacts of hazards such as floods (see also MacEachren et al., 2005).

UNITED NATIONS ORGANIZATIONS AND NATURAL DISASTERS

Badaoui Rouhban
UNESCO, Paris, France

Introduction and historical background

The content of this entry does not necessarily reflect the views of the United Nations Educational, Scientific, and Cultural Organization (UNESCO). The United Nations (UN) and its system of organizations is an international ensemble that addresses various areas of concern to Member States and member communities. The UN system includes specialized agencies, autonomous bodies, and programs having specific mandates and carrying out varied missions. This entry provides an overview of different United Nations entities' involvement in activities related to natural disasters. One of the UN's key roles is managing international partnerships and promoting multilateral cooperation with respect to disaster risk attenuation and post-disaster situations. The UN plays a leading role in global collaboration for the understanding and assessment of natural hazards, the mitigation of their consequences, as well as the provision and coordination of disaster relief and emergency response. Through their expertise in social, health, economic, environmental, and technical sectors, including disaster management and emergency response, UN organizations have responsibilities for creating an enabling environment to promote the study of natural hazards such as earthquakes, windstorms (cyclones, hurricanes, tornadoes, typhoons), tsunamis, floods, landslides, volcanic eruptions, droughts, and wildfires and in the development of techniques and measures to mitigate risks arising therefrom. They engage in supporting and implementing activities aimed at assisting disaster-prone countries, notably developing ones, in disaster risk reduction and advancing integrated approaches to building disaster resilient communities. They help countries to set up national strategies and plans of action and programs for disaster risk reduction including prevention, prediction, early warning, and preparedness and to develop their institutional and technical capacities in this field. They encourage stronger linkages, coherence, and integration of disaster risk reduction elements into the humanitarian and sustainable development fields. The responsibilities of the UN system of agencies encompasses coordination of disaster relief. Disaster response is an integral part of the humanitarian mandate of the UN which enjoys representatives and resources around the world ready to get mobilized rapidly in the aftermath of disasters. The system provides logistical coordination of relief efforts; assists with needs assessments to ensure that help is directed where it is needed; and uses its own resources to deliver food, medicine, and other emergency supplies. The UN actively plans the rehabilitation of areas affected by disaster. This part of the mandate includes support for risk reduction activities in post-disaster recovery and rehabilitation processes and sharing of good practices, knowledge, and technical support. Natural hazards do not recognize geographical or political boundaries. When disaster affects people on a multinational scale, it is the mission of the UN to coordinate response activity and perform disaster-response planning across borders.

The engagement of the UN in activities related to natural disasters may be traced back to the early 1970s with the launch of initiatives related to both hazard surveys and disaster relief coordination. In December 1987, the General Assembly of the UN decided to "designate the 1990s as a decade in which the international community, under the auspices of the United Nations, will pay special attention to fostering international co-operation in the field of natural disaster reduction." This decision was behind the International Decade for Natural Disaster Reduction (IDNDR), 1990–2000, (A/RES/42/169 of 11 December 1987), which had mobilized the UN system around the objective of reducing losses from natural hazards. The strategic focus at the start of the Decade was on disaster reduction through the scientific understanding of natural disasters; the assessment of their damage potential; and the mitigation and reduction of damage through technical assistance and technology transfer, education, and training. The IDNDR did serve as a global partnership for the development of disaster reduction activities among different stakeholders inside and outside the United Nations. Several actors concerned with natural hazards have enhanced disaster reduction efforts that had already been in place prior to the Decade. At the same time, and in the early 1990s, the General Assembly of the United Nations underlined the need to strengthen the coordination of emergency humanitarian assistance of the United Nations system. It therefore designated a high-level official as emergency relief coordinator. Subsequently, the UN Department of Humanitarian Affairs was established to "mobilize and coordinate the collective efforts of the international community, in particular those of the UN system,

to meet in a coherent and timely manner the needs of those exposed to human suffering and material destruction in disasters and emergencies. This involves reducing vulnerability, promoting solutions to root causes, and facilitating the smooth transition from relief to rehabilitation and development."

At the conclusion of the IDNDR, it was generally accepted that the momentum generated by it must be maintained. The global mobilization that occurred during the Decade confirmed that the United Nations is well placed to offer "a suited framework for bringing the various interests together" in the mutual interest of all concerned with the reduction of effects of natural hazards. Furthermore, the rise in the occurrence of natural disasters and the evolution in their intensity and complexity compel the UN system to adapt and strengthen its mandate and intervention with respect to natural hazards. This mandate is progressively evolving. In 1999, the UN General assembly initiated the International Strategy for Disaster Reduction (ISDR) to succeed the program of the IDNDR. The Strategy aims at "building disaster resilient communities by promoting increased awareness of the importance of disaster reduction as an integral component of sustainable development, with the goal of reducing human, social, economic and environmental losses due to natural hazards and related technological and environmental disasters." It is thus crucially important that a platform such as the ISDR be maintained and in place for cooperation through coordination, and to promote synergy among stakeholders, rather than compartmentalize them.

Over the past decade, the involvement of the United Nations system in activities related to natural disasters has increased markedly. A number of UN system entities carry out active programs in support of disaster reduction and many of them have strengthened their disaster reduction capacity in their respective areas of competency during recent years. All work with regional, national, or local authorities and in many cases with civil society organizations and groups. Coordination and cooperation among these entities are progressing well. Still improved coherence and cooperation is needed among United Nations entities in disaster risk reduction and disaster response.

Overview on role of United Nations Organizations

An overview is given of the role of the main UN players in relation to natural disasters. The essence of this text is derived from a recent reference publication produced by the Inter-Agency Secretariat of the International Strategy for Disaster Reduction, ISDR, 2009: *Disaster Risk Reduction in the United Nations- Roles, mandates and areas of work of key United Nations entities* (Geneva, Switzerland, UNISDR). The description does not provide an exhaustive inventory of all relevant activities of the UN. The purpose is to illustrate the work rather than be comprehensive. Relevant website citations are given as sources of further information.

United Nations General Assembly

http://www.un.org/ga/

The General Assembly is the chief deliberative, policymaking, and representative organ of the United Nations and is composed of representatives of all Member States. It determines the policies and the main lines of work of the UN. It provides a unique forum for multilateral discussion of the full spectrum of international issues covered by the Charter of the UN. The Assembly recognized in 1971 the need to reduce the impact of disasters and created the Office of the United Nations Disaster Relief Coordinator (UNDRO) for the improved coordination of "assistance in cases of natural disaster and other disaster situations," including disaster mitigation. The Assembly recognized in 1987 the need to focus on disaster reduction as an activity in itself and launched the IDNDR in 1989, followed by ISDR in 1999.

Deliberations concerning natural disasters take place under diverse items of the Assembly's agenda. Disaster risk reduction is generally discussed under the segment *Environment and Sustainable Development* whereas the Humanitarian segment of the Assembly covers discussions related to coordination of humanitarian and disaster relief assistance.

Economic and Social Council (ECOSOC)

http://www.un.org/en/ecosoc/

ECOSOC was established under the United Nations Charter as the principal organ to coordinate economic, social, and related work of the 14 UN specialized agencies, functional commissions, and five regional commissions. ECOSOC serves as the central forum for discussing international economic and social issues, and for formulating policy recommendations addressed to Member States and the United Nations system.

ECOSOC promoted and approved the establishment of an Office of the Emergency Relief Co-ordinator, the subsequent UN Department of Humanitarian Affairs (DHA) and the current Office for the Coordination of Humanitarian Affairs (OCHA). It endorsed the founding documents of the IDNDR and the ISDR. Post-disaster responses and disaster risk reduction are issues which are regularly covered by deliberations and decisions of ECOSOC. Furthermore, the ministerial declarations of the high-level segment (Annual Ministerial Review) of ECOSOC deal with these issues. ECOSOC Commissions work actively in humanitarian assistance aspects and disaster risk reduction.

United Nations System Chief Executives Board for Coordination (CEB)

http://www.ceb.unsystem.org

The Chief Executives Board (CEB) brings together the executive heads of all United Nations organizations to further coordination and cooperation on the whole range of substantive and management issues facing the United Nations system. In addition to its regular reviews of

contemporary political issues and major concerns facing the UN system, CEB approves policy statements on behalf of the UN system as a whole.

In its work, CEB periodically considers disaster reduction, humanitarian assistance, and related development and environmental issues. It issues statements and takes decisions regarding the coordination among agencies and organizations active in these areas. It ensures that disaster risk reduction is mainstreamed into the UN system's policies and practices.

United Nations Development Group (UNDG)

http://www.undg.org

UNDG is a committee composed of the 33 UN funds, programs, agencies, departments, and offices. It supports the work of CEB, providing a framework for greater coherence and cooperation in United Nations development operations, notably at the country level. As most of the UNDG members carry out activities toward disaster reduction, this group offers a mechanism to integrate disaster reduction into other areas of concern, in particular sustainable development.

Inter-Agency Standing Committee (IASC)

http://www.humanitarianinfo.org/iasc/

The Inter-Agency Standing Committee (IASC) is a forum for coordination, policy development, and decision making involving key UN and non-UN agencies and entities concerned with humanitarian assistance. It develops system-wide humanitarian policies and ensures effective response to post-disaster needs at the onset of a crisis.

Office for the Coordination of Humanitarian Affairs (OCHA)

http://ochaonline.un.org/

OCHA is a department of the United Nations whose mission is to mobilize and coordinate humanitarian action in partnership with national and international actors in order to alleviate human suffering in disasters and emergencies, advocate for the rights of people in need, promote preparedness and prevention, and facilitate sustainable solutions. OCHA is led by the Under-Secretary-General for Humanitarian Affairs and Emergency Relief Coordinator, who serves also as the Chair of the ISDR system.

One of OCHA's objectives is greater incorporation of disaster risk reduction approaches and strengthened preparedness in humanitarian response.

International Strategy for Disaster Reduction (ISDR)

http://www.unisdr.org

The ISDR is a global framework in which countries, institutions, and individuals can cooperate in order to promote and achieve disaster risk reduction. It is a global platform for the United Nations and other organizations to coordinate and guide disaster risk reduction and its integration into development planning and action and to ensure synergy among the activities of partners concerned with disaster risk reduction. The guiding document behind the ISDR is the Hyogo Framework for Action 2005–2015: Building the Resilience of Nations and Communities to Disasters which was adopted in January 2005 by 168 countries.

The ISDR is coordinated within the United Nations by an Inter-Agency Secretariat located in Geneva, Switzerland.

Department of Economic and Social Affairs (UN/DESA)

http://www.un.org/esa/desa/

The DESA multidimensional program promotes broad-based and sustainable development through an integrated approach to economic, social, environmental, population, and gender-related aspects of development. The Department serves as the secretariat for the UN Commission on Sustainable Development. Many of its divisions are concerned with disaster reduction, particularly the Division for Sustainable Development (DSD).

Food and Agriculture Organization (FAO)

http://www.fao.org

The FAO's general mandate is to raise the levels of nutrition, to improve agricultural productivity and the condition of rural populations. Based in Rome, Italy, FAO develops programs to strengthen the capacity of communities and local institutions in preparing for and addressing natural disasters, notably in order to reduce the vulnerability of agricultural production systems to disasters. It helps alleviate the impact of emergencies that affect food security and therefore strengthens programs for agricultural relief and rehabilitation in the aftermath of disasters.

International Telecommunication Union (ITU)

http://www.itu.int/en/pages/default.aspx

ITU, with its headquarters in Geneva, Switzerland, is an international organization where governments and the private sector coordinate global telecommunication networks and services. ITU work emphasizes the importance of telecommunications for disaster mitigation and disaster relief operations. It addresses the impact of disasters on communication facilities and information flows and works toward rapid availability and access to telecommunication resources.

United Nations Educational, Scientific and Cultural Organization (UNESCO)

http://www.unesco.org

The main objective of UNESCO is to promote collaboration among States through education, science, culture, and communication. UNESCO is based in Paris, France. The Organization provides intergovernmental coordination, advice to governments, and policy support for the

establishment and operation of monitoring networks and early warning and risk mitigation systems for natural hazards, with particular emphasis on earthquakes, tsunamis, floods, volcanoes, and landslides. It promotes activities to develop a better scientific understanding of natural hazards and the mitigation of their effects. It promotes joint multi-stakeholder strategies for enhancing disaster education. Integrated approaches and synergy between natural sciences, social sciences, culture, education, and information systems lay the basis for interdisciplinary platforms to manage disaster risks. UNESCO provides technical advice on the construction of hazard-resistant schools and for the protection of cultural heritage. Through its Intergovernmental Oceanographic Commission, UNESCO coordinates tsunami early warning systems.

In the aftermath of disasters, UNESCO contributes to the rehabilitation of the educational establishment and the restoration of cultural heritage and to long-term reconstruction processes in its fields of competence.

The World Bank Group

http://www.worldbank.org

The mandate of the World Bank Group, based in Washington, D.C., USA, is to alleviate poverty and improve quality of life. It furthers strategies and procedures to promote proactive ways to integrate disaster prevention and mitigation into its development work. The Group promotes disaster risk management as a priority for poverty reduction, linked to environmental management. It concentrates on reconstruction measures that strengthen resilience to future disaster and identify innovations in risk transfer and financing.

The World Bank's work in integrating disaster risk reduction in development is carried out primarily through its Global Facility for Disaster Reduction and Recovery (GFDRR). It offers a model for advancing disaster risk reduction based on ex ante support to high-risk countries and ex post assistance for accelerated recovery and risk reduction after a disaster. Interventions of the World Bank catalyze greater cooperation between the humanitarian and development actors for accelerated recovery and risk reduction.

World Health Organization (WHO)

http://www.who.int/en

The World Health Organization is the directing and coordinating authority for health within the United Nations system. Based in Geneva, Switzerland, WHO deals with disaster preparedness connected with health. Its purpose is to reduce avoidable loss of life and the burden of disease and disability in disaster-affected countries. It works for emergency preparedness and response, as well as for advocacy for health and humanitarian action. WHO is concerned with the safety of hospitals in hazard-prone areas.

World Meteorological Organization (WMO)

http://www.wmo.ch

Based in Geneva, Switzerland, WMO is an intergovernmental organization mandated to facilitate international collaboration in meteorology, including coordinated observations and standardized instruments. It provides world leadership in expertise and international cooperation in weather, climate, hydrology, and water resources and related environmental issues. The Organization deals with hazards related to weather, climate, and water and coordinates global scientific activity to provide the advance warnings.

United Nations Children's Fund (UNICEF)

http://www.unicef.org

UNICEF is mandated by the United Nations General Assembly to advocate for the protection of children's rights, to help meet their basic needs. UNICEF generally works on warning, prevention, preparedness, relief, and recovery activities for the care of children and women in disaster-prone areas. The Fund sustains and enhances its support of national risk reduction efforts, specifically, those most directly related to threats to children, both in noncrisis and emergency situations. Policy and procedural guidelines for UNICEF staff in emergencies include both emergency response and preparedness/prevention activities.

United Nations Development Programme (UNDP)

http://www.undp.org

The United Nations Development Programme (UNDP) is the main development branch of the United Nations. It plays a coordinating role at country level. UNDP considers crisis prevention and disaster mitigation as integral parts of sustainable human development strategies. It therefore helps countries prevent and recover from natural disasters through advocacy, capacity building, conflict sensitive development, development of tools and methodologies, gender equality, knowledge networking, strategic planning and programming, and policy and standard setting. The UNDP has operational responsibilities at national level for natural disaster mitigation, prevention and preparedness, as well as disaster response. It works to ensure that disaster risk considerations are factored into national and regional development programs, and that countries take advantage of disaster recovery to mitigate future risks and vulnerabilities. UNDP focuses on the national and sub-national levels, where it assists the national and local governments in implementing disaster risk reduction activities.

United Nations Environment Programme (UNEP)

http://www.unep.org

Based in Kenya, Nairobi, the United Nations Environment Programme (UNEP) is the environmental agency of the United Nations. UNEP provides worldwide environmental information about the necessity of a viable

sustainable ecosystem and early warning about the hazards to ecosystem health and environmental hazards. Objectives of its action are to minimize environmental threats to human well-being from the environmental causes and consequences of existing and potential natural and man-made disasters. It deals with emergency prevention, preparedness, assessment, mitigation, and response and implements programs on disaster reduction at all levels.

UN-Habitat

http://www.unhabitat.org

With its headquarters in Kenya, Nairobi, the United Nations Human Settlements Programme, UN-HABITAT promotes socially and environmentally sustainable towns and cities with the goal of providing adequate shelter for all. As such the Programme contributes to reducing the vulnerabilities of human settlements and to strengthening their capacities for managing disasters at all levels as well as to responding to immediate needs in the aftermath of crises that are linked to Agency mandated interventions supporting sustainable human settlements (they help rebuild a settlement after a disaster).

World Food Programme (WFP)

http://www.wfp.org/

WFP is mandated by the United Nations to combat global hunger. Based in Rome, Italy, the Programme meets emergency needs regarding food security, and provides the necessary logistics to deliver food. The consolidated framework of the WFP policies emphasizes the mitigation of the effects of recurring disasters in vulnerable areas. WFP assesses measures to prevent and mitigate disasters that pose threats to food production or livelihoods as part of country programming in areas subject to recurring disasters. WFP develops standard procedures jointly with government counterparts for borrowing from and replenishing national food stocks.

United Nations Population Fund (UNFPA)

http://www.unfpa.org/

UNFPA is an international development agency "that promotes the right of every woman, man and child to enjoy a life of health and equal opportunity." UNFPA has a main goal to ensure adequate emergency preparedness and contingency planning at country level and to improve environmental protection. Its strategy for emergency preparedness, humanitarian response, transition, and recovery includes various measures to strengthen technical and institutional capacities to incorporate population, reproductive health, and gender concerns into overall emergency preparedness, response, transition, and recovery.

United Nations Institute for Training and Research (UNITAR)

http://www.unitar.org

UNITAR is an autonomous body within the United Nations with a mandate to enhance the effectiveness of the United Nations through training and research activities. Its headquarters is located in Geneva, Switzerland. Training and capacity-building programs are organized for policy and institutional development. Its environmental program addresses risk issues in the areas of chemical and waste management, climate change, biodiversity, land degradation.

United Nations University (UNU)

http://www.unu.edu/

United Nations University (UNU) is an autonomous organ whose overall mission is to contribute, through research and capacity building, to efforts to resolve the pressing global problems that are the concern of the United Nations Member States. It mobilizes an international community of scholars, engaged in research, postgraduate training, and dissemination of knowledge to provide alternative perspective on sustainable development challenges. UNU, with headquarters in Tokyo, Japan, provides useful knowledge about, and effective training on, important issues related to human-environmental-climate security, peace, and development including crises and disasters.

United Nations Centre for Regional Development (UNCRD)

http://www.uncrd.or.jp/

The UNCRD head office, located in Nagoya, Japan, encourages training and research in regional development as well as information dissemination. The Centre's work includes basic research programs for the design of community-based projects for disaster management planning, and disaster management capacity building introducing best practices case studies in developing countries.

United Nations Office for Outer Space Affairs (UNOOSA)

http://www.oosa.unvienna.org/

The United Nations Office for Outer Space Affairs (UNOOSA) is responsible for promoting international cooperation in the peaceful uses of outer space, and assisting developing countries in using space science and technology. Space applications and space-based services are used for disaster mitigation, relief, and prevention and space technologies can play important roles in the reduction of disasters. The use of such technologies can be particularly useful in the risk assessment, mitigation, and preparedness phases of disaster management. Space technologies are also vital to the early warning and management of the effects of disasters.

International Labor Organization (ILO)

http://www.ilo.org

ILO is the United Nations agency specialized in matters related to labor. ILO established a special In-Focus Programme on Crisis Response and Reconstruction that concentrates on various types of crises including natural disasters. The Programme promotes employment in post-disaster situations.

United Nations Volunteers (UNV)

http://www.unv.org/

The United Nations Volunteers program contributes to peace and development through volunteerism worldwide. UNV mobilize volunteers and strengthen volunteerism initiatives in support of disaster risk reduction and management, especially to strengthen community capacity to respond to and prevent disasters. In emergency and post-disaster situations, it also mobilizes and places national and international UNV volunteers in response to requests from UN entities and government partners. UNV also works with partners to integrate volunteerism into programming for disaster risk reduction and management. UNV works in disaster response, risk reduction, crisis prevention, and community-based adaptation to climate change.

International Atomic Energy Agency (IAEA)

http://www.iaea.org

The IAEA is the world's center of cooperation in the nuclear field. The IAEA Secretariat is headquartered in Vienna, Austria. The agency is concerned with the zoning of nuclear power plants in areas prone to seismic activity, and it has been actively concerned with the design of reactors that can withstand the most severe natural disasters. A core element of the IAEA's work is to help countries to upgrade nuclear safety and to prepare for and respond to emergencies.

Conclusions

The UN system is widely acknowledged as the central multilateral framework through which the international community can address global challenges, including by providing a coherent approach to global climate change, preparing for, and responding to natural disasters. Action in these fields increasingly depends on the active involvement and support by all major stakeholders.

UNIVERSAL SOIL LOSS EQUATION (USLE)

Armand LaRocque
University of New Brunswick, Fredericton, NB, Canada

Synonyms

Revised Universal Soil Loss Equation (RUSLE); RUSLE2; USLE

Definition

The Universal Soil Loss Equation (USLE) is a mathematical model developed to predict the soil erosion by rainfall and surface runoff on a field. The empirical result of the USLE corresponds to a long-term average annual rate of soil losses under a variety of climatic conditions, soil types, topographic characteristics, crop systems, and conservation practices. However, USLE only predicts the amount of soil loss resulting from sheet or rill erosion on a single slope and does not account for additional soil losses that might occur.

Discussion

The USLE is based on soil erosion data collected from experiments in erosion plots and rainfall simulators since the 1930s by the USDA (United States Department of Agriculture) Soil Conservation Service (now the "USDA Natural Resources Conservation Service"). The main purpose of this model was to preserve cropland from erosion and the diminution of the agricultural productivity by devastating drought, wind erosion, and dust storms, such as the famous "Dust Bowl," affecting the American and Canadian prairie lands between 1930 and 1940. The Revised Universal Soil Loss Equation (RUSLE and now RUSLE2), which is a computerized version of USLE, includes improvements in many of the factor estimates.

The USLE is composed of six major factors used to predict the long-term average annual soil loss (A), in tons per acre per year for a specific site. The equation takes the simple product form as follows:

$$A = R \times K \times L \times S \times C \times P.$$

The potential soil loss (A) is calculated using the rainfall erosivity factor determined for each geographic location (R), the soil erodibility factor (K), which is mainly based on the soil texture, the slope length factor (L), the slope steepness factor (S), the cover type and management factor (C), and the conservation practices factor (P). Each of these factors is a numerical estimate of specific conditions affecting the severity of soil erosion at the studied site. In the case of factors K, L, and S, the estimates are based on measures realized on a "standard" slope (steepness of 9% and slope length of 22.1 m or 72.6 ft).

The calculated soil loss (A) can then be compared with a tolerable soil loss that is the maximum annual amount of soil that can be removed before the natural productivity in the long term of soil may be affected. This comparison allows determining the adequacy of conservation measures in farm planning. USLE is also used to guide conservation planning of land use for nonagricultural conditions such as construction sites.

UNREINFORCED MASONRY BUILDINGS

Fabio Taucer
European Commission – Joint Research Centre,
Ispra (VA), Italy

Synonyms

Unreinforced concrete block masonry (UCB) (Jaiswal and Wald, 2008); Unreinforced fired brick masonry (UFB); URM

Definition

A structure whose load-bearing system consists of an assemblage of masonry units generally made of stone, brick, or concrete blocks laid in a specific pattern and joined together with mortar.

Discussion

Unreinforced masonry (URM) buildings are found all over the world and have been used since ancient times for providing shelter with a number of advantageous properties, such as thermal and acoustic insulation, fire resistance, and weather protection. URM buildings are commonly used for the construction of low-rise residential and office buildings with the floor area subdivided into a large number of spaces that repeat along the height from the foundation to the roof level (Hendry et al., 1997). This allows for a flexible arrangement of the load-bearing walls, which form the backbone of the structural system of resisting forces.

The structural performance of the masonry fabric depends on the performance of the masonry units, the mortar, and their composite behavior. Modern building

codes provide guidelines for the optimum combination of these, namely, the quality of bond between bricks and mortar, the connection among the width of brick walls, the connection among the walls at the corners and junctions, and the connection between the walls and the roof and floor structures (D'Ayala, 2010).

In spite of their good performance in resisting vertical loads, URM buildings are particularly vulnerable to seismic loading, due to their intrinsic low capacity in resisting tensile stresses that develop during an earthquake. The collapse of URM buildings was responsible for most of the 242,000 people killed during the 1976 Tangshan earthquake in the People's Republic of China (Grossi et al., 2010). In Italy, the 115,619 deaths registered between 1900 and 2010 (EM-DAT, 2010) were due in large part to the collapse of URM buildings that constitute a large part of the building stock constructed in Italy before the 1950s.

The damage patterns commonly observed in URM buildings range from the collapse of chimneys and plaster cracks, to the development of cracks in the walls starting at window openings and corners, to the partial or total collapse of the building due to the out-of-plane collapse of walls. The lack of effective connections between the walls and the horizontal structures of roofs and floors that act as diaphragms that keep together the masonry fabric has been associated as the main factor in leading to the collapse of URM buildings. The use of heavy reinforced concrete roofs and floors to replace older horizontal structures made of light wood construction has exacerbated the amount of damage suffered by these structures.

Possible ways to strengthen and retrofit URM buildings to enhance their seismic performance include ensuring adequate connections of the masonry fabric, efficient connections between the walls and the horizontal structures, stitching and grouting of cracks, installation of steel ties for anchoring the walls, reinforced concrete or composite polymer coating, and the addition of new members to prevent the out-of-plane collapse of walls.

URBAN ENVIRONMENTS AND NATURAL HAZARDS

Pat E. Rasmussen
University of Ottawa and Health Canada, Ottawa, ON, Canada

Definitions

Chronic obstructive pulmonary disease (COPD). A respiratory disease characterized by a gradual loss of lung function.

Elephantiasis. Symptom of an infectious tropical disease filariasis (philariasis) caused by parasitic nematodes and spread by mosquitoes.

Natural hazard. Any naturally occurring event or agent that has the potential to negatively impact human and environmental health.

Slums. A socioeconomic term describing intensely populated parts of cities characterized by poverty, inadequate housing, water, and sanitation.

Introduction

Natural hazards have disastrous consequences when they impact cities. Recent examples are the tens of thousands of Americans left homeless when Hurricane Katrina flooded 80% of the city of New Orleans, Louisiana, on August 29, 2005; the widespread destruction of schools, hospitals, and factories caused by the May 12, 2008, earthquake in Sichuan Province, China; and the death of some quarter million Haitians in the city of Port-au-Prince caused by the earthquake of January 12, 2010.

Natural hazards in the urban environment may be physical, climatic, biological, or chemical in origin, and often occur in combination with anthropogenic hazards. For example, extreme weather conditions such as *heat waves* further aggravate the negative health effects of urban air pollution. Degradation of the urban environment by *flooding* is another example, where the natural hazard triggers increased pollution of surface water and groundwater from sewage and surface runoff. Therefore, when we consider natural hazards in urban environments, we must consider the additive effects of interactions between human activities and natural forces.

Large-scale urbanization

In his book "Crucibles of Hazard: Mega-Cities and Disasters in Transition" Mitchell (1999) warned that the world's large cities were rapidly becoming more exposed and more vulnerable to natural hazards. By the dawn of the millennium, the world had changed from predominantly rural to predominantly urban: at the time, more than 300 cities counted a million or more inhabitants. In Europe more than 70% of the population had moved to urban areas, whereas in the USA, an estimated 90% of the population resided in cities (Santamouris, 2001). Mitchell (1999) warned that rapid large-scale urbanization would be a major contributor to the rising global toll of disaster losses.

By 2010 the United Nations recognized the increasing urban population at risk, and undertook to engage city mayors and other local authorities in designing and building disaster-resilient cities, schools, and hospitals as a priority under the 2010–2011 World Disaster Reduction Campaign (United Nations, 2009). Preventative measures, emergency preparedness, and sound environmental management practices, which are put into place prior to the occurrence of a natural disaster, help to reduce the probability of damage, minimize deaths, illnesses and economic loss, and assist the city in its recovery (see *Disaster Risk Reduction*, and *Recovery and Reconstruction After Disaster*).

Natural physical hazards

The construction of human settlements on hazardous lands represents an interaction between the natural and urban environment which creates an increased risk to humans. Examples include practices such as locating schools on slopes with high risks of *landslides*; building residential developments on ocean cliffs or *floodplains*; and situating high-rise office buildings in *earthquake* zones. Earthquakes strike violently and suddenly, causing extensive property damage and many deaths and injuries when they occur in or near cities (FEMA, 2010a).

Extreme weather conditions, such as *heat waves* and *hailstorms*, are important natural physical hazards affecting urban environments. Inadequate protection from the elements is a common cause of death in cities all over the world, whether it is the urban homeless facing the extreme cold of a winter night in northern cities; homes collapsing during monsoon rains in tropical cities; or the combination of stifling heat and air pollution in underventilated slums of southern and temperate climates.

Degradation of air quality

The impact of air temperature on urban environments is an example of the interaction between natural and anthropogenic hazards. Many cities are located in valleys where thermal inversions cause air pollutants to become trapped, increasing both the concentration of pollutants and the duration of exposure. The combination of high temperatures and air pollution affects the health of vulnerable groups living in cities, especially the elderly, small infants, and people with respiratory disorders. In general, densely built urban environments experience elevated temperatures compared to the rural surroundings, a phenomenon known as the "urban heat island" (Santamouris, 2001). The "urban heat island" effect is caused by the radiation of heat from surfaces of building and pavement surfaces.

According to a World Health Organization (WHO, 2006) assessment of the burden of disease due to air pollution, more than two million premature deaths each year can be attributed to the effects of urban outdoor air pollution and indoor air pollution (caused by the burning of solid fuels). Globally, more than 40% of all pulmonary disease (COPD) cases, and 41% of all cases of lower respiratory infections, are attributed to air pollution, both indoors and outdoors (WHO, 2006).

Where cities are located in the vicinity of *volcanic eruptions*, increased respiratory problems occur in vulnerable populations who inhale ash particles and acidic gas vapors. Even distant cities may experience problems, as wind can carry ash particles from volcanic eruptions that occur hundreds of kilometers away (FEMA, 2010b). *Volcanic ash* also damages engines and electrical equipment, and ash accumulations mixed with water become heavy and can collapse roofs (FEMA, 2010b).

Biological hazards in the urban environment

The World Health Organization attributes 94% of the global burden of disease to poor urban environmental management practices, mainly unsafe water, sanitation, and hygiene (WHO, 2006). Natural physical disasters such as *flooding*, *hurricanes*, and *earthquakes* interrupt urban services, leading to further degradation of environmental conditions in cities. The result is increased transmission of diseases from food and water, including diarrhea, gastroenteritis, cholera, dysentery, hepatitis-A, hepatitis-E, and typhoid fever. Overcrowded and poorly ventilated slums suffer inordinately from these diseases (United Nations, 2003).

A large proportion of deaths caused by malaria (42% of all cases globally) are attributed to poor management of water resources, housing, and land use, which result in a failure to control *insect* populations effectively (WHO, 2006). For example the malaria-spreading *Anopheles* mosquito breeds in standing water and the elephantiasis-spreading *Culex* mosquitoes breed in blocked drains, latrines, and septic tanks.

Urban geochemical hazards

The United Nations General Assembly declared 2008 as the International Year of Planet Earth. One of the main themes "Earth and Health – Building a Safer Environment" served to inspire earth scientists and medical researchers to work together toward understanding and mitigating geochemical hazards (Rasmussen and Gardner, 2008).

There is a long history of health effects related to urban exposures to metals and minerals, the most famous being

lead plumbing used by the ancient Romans (Skinner and Berger, 2003; Selinus et al., 2005). Mielke et al. (2003) describe the neurological effects of childhood exposures to lead-contaminated soil in modern cities, and make the case for urban geochemical mapping efforts. Concentrations of lead and other metals are commonly higher in urban house dust than in soil, partly caused by the tendency for house dust to accumulate metals that are tracked indoors from outside sources (Rasmussen, 2004). Radon from underlying bedrock is a natural household source of radiation in air and tap water (Appleton, 2005). Lung disease caused by inhalation of asbestos fibers is mainly related to occupational exposures, but urban environmental exposures have been documented, notably during the demolition of buildings following the 1995 earthquake in Kobe, Japan (Nolan et al., 2001).

Summary

- Natural hazards are most likely to become catastrophic when they hit populated urban environments.
- In urban environments, natural hazards are interactive processes that involve both people and natural systems.
- Natural hazards disproportionately hurt the urban poor.
- Natural hazards have the greatest impact in cities that are vulnerable due to location and/or inadequate attention to prevention and mitigation.
- When natural hazards strike a city, they cause further degradation of the urban environment and exacerbate preexisting biological and chemical hazards.
- Interrupted urban services and destruction of urban infrastructure increase the transmission of disease, contamination of surface and groundwater, and human exposures to toxic wastes and chemical spills.
- Urban geochemical hazards include radon, soil and dust contaminated with lead and other metals, and environmental pollution caused by destruction of buildings and factories following earthquakes and other physical disasters.
- The rapid growth of large cities has contributed to the increased rate of death and destruction when natural hazards interact with urban settlements.

CASE STUDY

USOI LANDSLIDE AND LAKE SAREZ

Alexander Strom
Geodynamic Research Center – Branch of JSC "Hydroproject Institute", Moscow, Russia

Introduction

On February 18, 1911, a strong *earthquake* in Pamirs (Tajikistan) caused a catastrophic failure of about 2.2 km^3 (six billion tons) of rock (Figure 1) and resulted

Usoi Landslide and Lake Sarez, Figure 1 Headscarp of the Usoi landslide.

Usoi Landslide and Lake Sarez, Figure 2 Google Earth image of Lake Sarez.

in the formation of the Usoi landslide dam named after the small village buried by the *landslide*. Fifty eight inhabitants lost their lives in this event. The Usoi landslide located at 38°16.5′N, 72°36′E is the world's largest non-volcanic landslide ever recorded in historical times. Despite the remoteness and inaccessibility of the site, Russian researchers performed their first studies of this feature soon after the event (Bukinich, 1913; Shpilko, 1915; Preobrajensky, 1920). Regular studies started in the 1960s (Sheko and Lekhatinov, 1970; Agakhanjanz, 1989).

Main parameters of the dam and the lake

The Usoi *landslide* occurred in bedrock and formed a 567-m-high, 5-km-long (across the valley), and 3.75-km-wide dam in the Murgab River valley. The upper part of the dam's body is composed of rocky blocks about 1.5 × 1.5 km in size, intensively fractured but, at the same time, retaining original layering. Distal and proximal parts of the dam are composed of heavily crushed material. No direct data on the structure and grain size composition of the dam's interiors are available (Ischuk, 2011). The downstream slope of the dam is cut by the deep canyon eroded by the filtering water and by debris flows that originate from the glaciers remaining above the headscarp (in 1947, these flows were diverted toward the lake by rockfall from the headscarp wall). The lake that has been impounded was named after the Sarez village submerged by rising water. Three years after the dam formation, in 1914, water was detected to seep through the blockage. Annual mean discharge passing through the dam is 47 m^3/s at present. During the flood periods when water rises to about 5 m above the mean annual level, it increases up to 85 m^3/s (Alford and Schuster, 2000; Ischuk, 2011). According to regular observations, lake level increases gradually (up to 20 cm/year) and is now 3261 m.a.s.l., only 38 m below the lowermost part of the blockage at maximal water level (Ischuk, 2011). The 500-m-deep and 60-km-long Lake Sarez contains almost 17 km^3 of water and is the world's deepest existing landslide-dammed lake (Figure 2).

Right-bank landslide

In the 1960s A.I. Sheko (Sheko, 1968; Sheko and Lekhatinov, 1970) hypothesized that a large-scale slope failure may occur on Lake Sarez' right bank, 4–5 km from the blockage, which could cause a huge *displacement wave* that could spill over the dam at its lowermost section, resulting in the dam's partial or complete breach and a downstream *flood* as happened, for example, in the Las Conchas valley (Argentina) in prehistoric times (Hermanns et al., 2004). Many researchers estimated the volume of this "right-bank landslide" to range from 0.3 to 2.0 km^3. However, the possibility of such a large-scale failure, its volume, and velocity are still controversial and require additional studies (Alford and Schuster, 2000; Ischuk, 2011). Additional uncertainty of this slope stability assessment is due to the high seismic activity of the Central Pamirs.

Safety measures

Though studies performed since 1960s revealed that the dam in its present state should be considered as a stable feature that could not be destroyed by water pressure or by gradual overtopping (Ischuk, 2011), an *early warning system* has been installed recently aiming to detect various indicators of the dam's instability (seismic strong motion, rapid increase of water level, etc.) and to allow people living downstream to escape to shelters constructed above the flood level calculated for outburst scenarios (Zaninetti, 2000).

Nevertheless, in a long-term perspective, Lake Sarez endangers sustainable development of the communities living in the Bartang, Pianj, and Amu-Daria River valleys in Tajikistan, Afghanistan, Uzbekistan, and Turkmenistan with a population over 5.5 million people (Gaziev, 1984; Alford and Schuster, 2000; Schuster, 2002). Thus, since the potential risk of the landslide dam breach and of a devastating outburst flood exists, special measures

should be undertaken to ensure long-term safety of Lake Sarez regardless of any dynamic effects such as strong *earthquake*s or the impact of a landslide-triggered *displacement wave* caused by large-scale slope failure.

Possible long-term solutions, which are under discussion, envisage not only risk reduction measures but also use of the Lake Sarez water for irrigation and power production. Construction of a spillway tunnel system through the left-bank bedrock massif seems to be the most reliable variant that allows not only lowering of the lake up to the safe level but also the integration of a powerhouse.

Synonyms

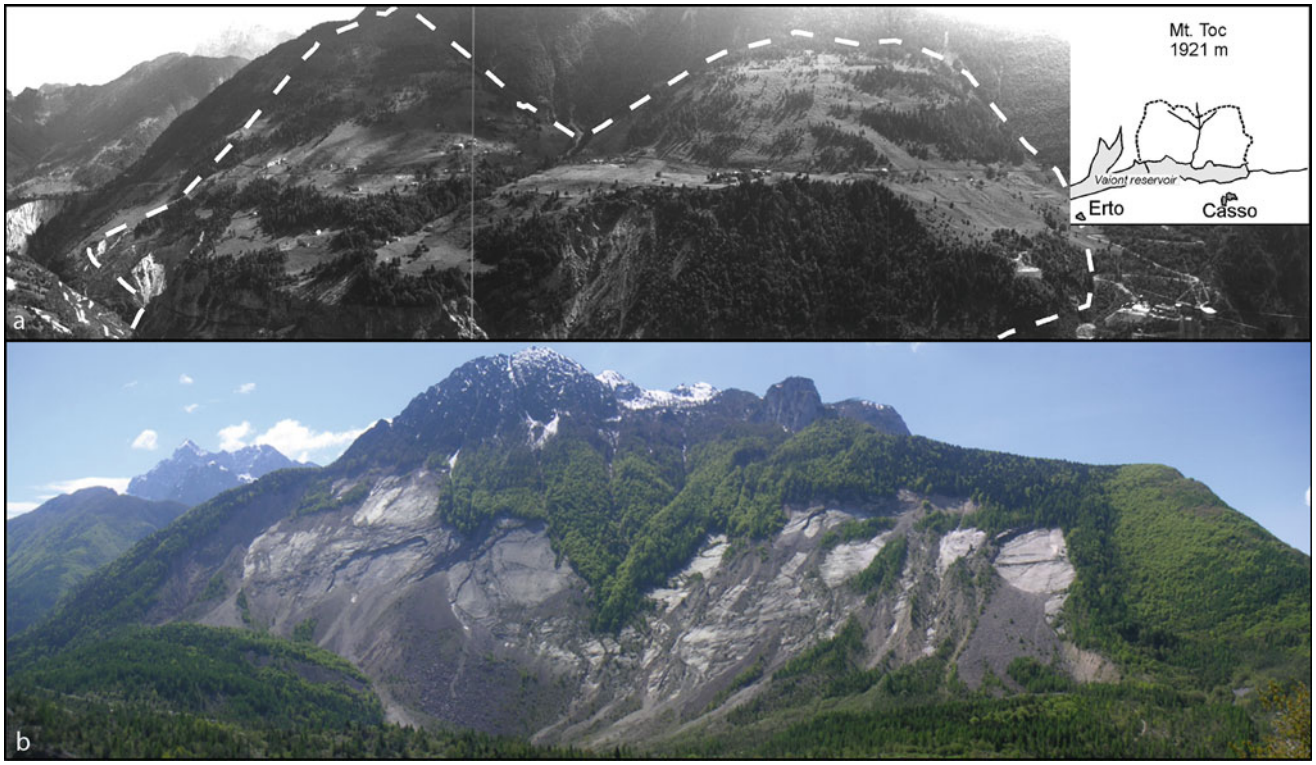
Vajont landslide

Definition

The Vaiont landslide (northern Italy) is one of the best known and most tragic examples of a natural disaster induced by human activity. On October 9, 1963, a catastrophic landslide occurred on the northern slope of the Mount Toc; a rock mass of approximately 270 million m^3 collapsed into the reservoir at velocities up to 30 m/s generating a wave that overtopped the dam and swept into the Piave valley below, with the loss of about 2,000 lives.

Introduction

Landslides, as major natural hazards, account for extremely significant property damage/losses in terms of direct/indirect costs, especially in hilly or mountainous areas. Triggering factors can be intensive rainfall, earthquake shaking, groundwater changes, or rapid stream erosion promoting a sudden decrease in the shear strength and stability of slope-forming materials. Landslides induced by reservoir impounding can also damage dams and result in considerable loss of life. The Vaiont reservoir landslide is one of the best-known examples of a natural disaster induced by human activity.



Many questions have been posed and remain concerning the legal, economic, social, and scientific issues associated with the history of the dam and in particular emergency management of the instability in the Vaiont reservoir slope up to the time of catastrophic failure. The global impact of the event has been to stimulate a large body of research on the stability of natural rock slopes and in particular the development of geotechnical risk protocols for the construction of hydroelectric projects in mountainous topography. The 1963 Vaiont rock slide represents a dramatic example of the consequences of limitations in available data (parameter uncertainty) and our understanding of slope failure processes (model uncertainty). It provides a clear example of the importance of fully understanding the complex mechanics and dynamics of large rock slope instabilities.

Chronology of events

The Vaiont Dam, constructed between 1957 and 1960, is located on the Vaiont River in northern Italy, about 100 km north of Venice. The double-curved arch dam, at 265.5 m above the valley floor, was in 1963 the highest thin arch dam in the world. Its abutments were founded on the steep flanks of a deep canyon cut into dolomitic limestones of Malm and Dogger age. The planned full reservoir capacity was to reach a volume of 169 million m^3.

The slopes of Mount Toc underwent nearly 3 years of intermittent, slow slope movements, beginning at the time of the first filling of the reservoir. On October 9, 1963, at 22.39 local time, during the third reservoir emptying event, a catastrophic landslide (Figure 1) suddenly occurred on the southern slope of the Vaiont dam reservoir (northern slope of Mount Toc) and the whole mass collapsed into the reservoir in less than 45 s. The failed mass drove the water of the reservoir forward, giving rise to

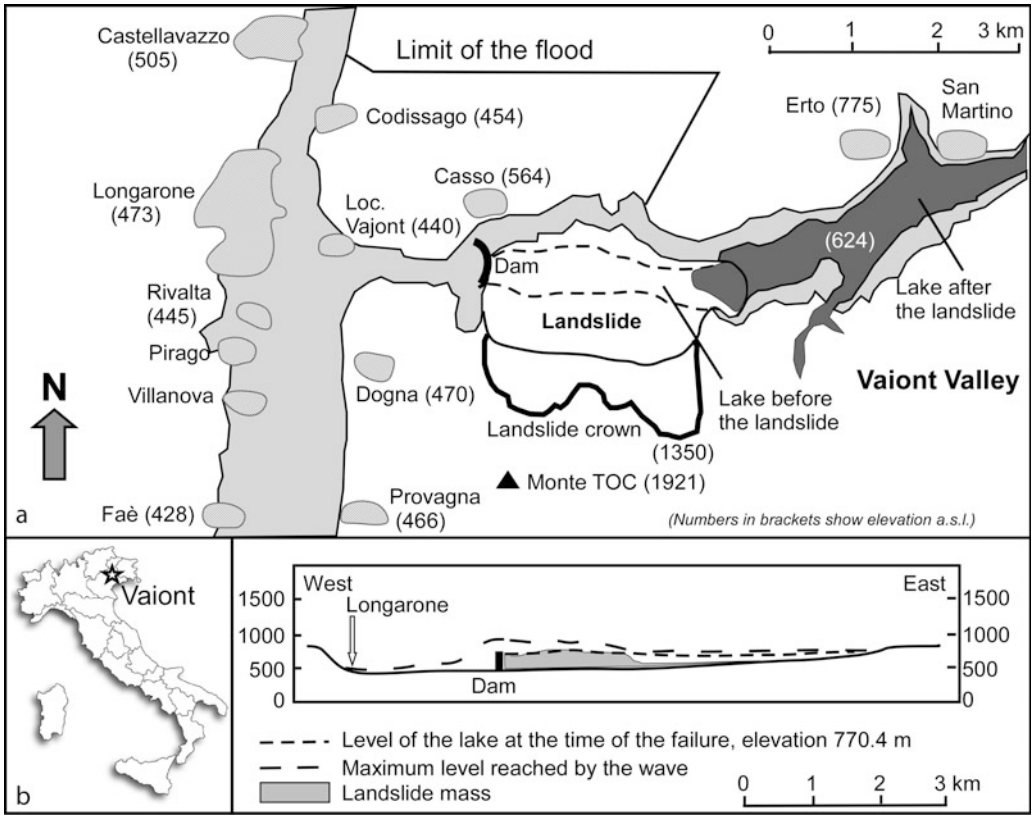
Vaiont Landslide, Italy, Figure 1 (**a**) Mount Toc before October 9, 1963 (Semenza and Ghirotti 2000); (**b**) the failure scar of the 1963 Vaiont landslide (Mount Toc behind)

a wave, which overtopped the dam at a height of more than 100 m above the crest and hurtled down the Vaiont Gorge to the bottom of the Piave River. The flood destroyed the villages of Pirago, Villanova, Rivalta, and Faé and most of the town of Longarone; almost 2,000 people lost their lives (Figure 2). The event produced seismic shocks which were recorded throughout Europe. Remarkably the dam remained relatively intact, with only minor damage at the dam crest. The landslide was characterized by a long-term phase of creep deformation lasting 2–3 years, clearly related to the reservoir water levels and followed by the catastrophic failure. Three years prior to the catastrophic failure, the presence of an M-shaped tension crack on Mount Toc, 1 m wide and 2.5 km long, delineated the eventual failure.



However, even if Mount Toc provided clear important evidence to suspect the instability of its northern slope, technicians and experts of the time incorrectly hypothesized a very large and slow-moving landslide that could be controlled by reservoir operations (Müller, 1964, 1968, 1987).

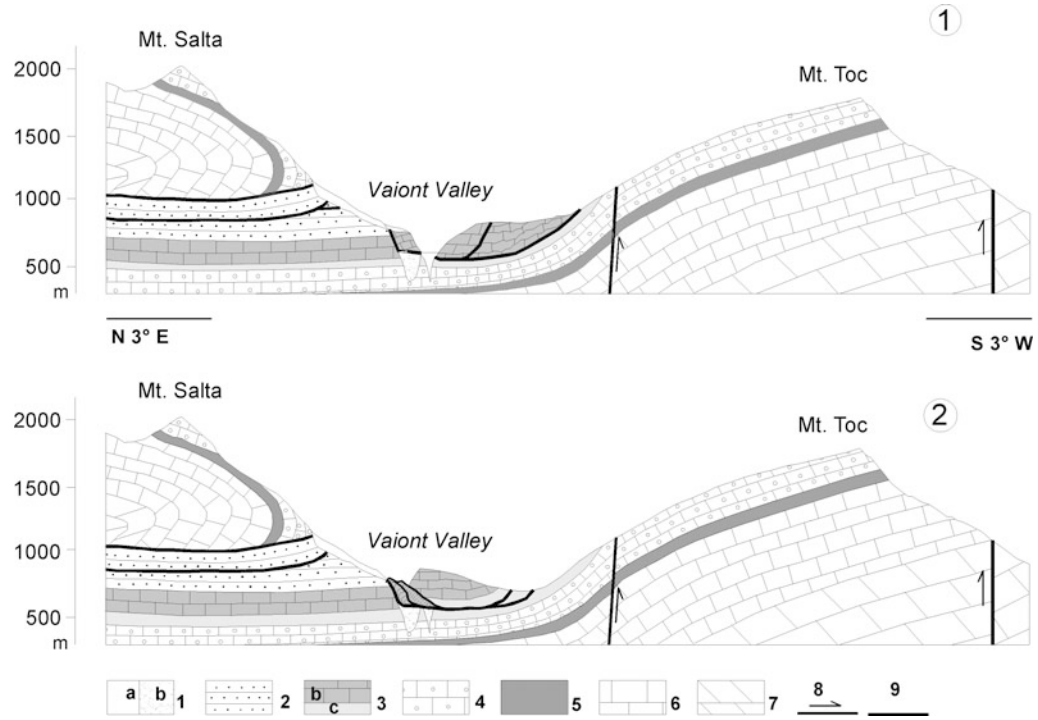
The landslide

The landslide involved Jurassic and Cretaceous rocks (limestones and marls) showing varying degrees of fracturing. Movement occurred along a chair-shaped failure surface (Figure 3) in part corresponding to a preexisting slip surface at or close to residual strength, as indicated by the geological evidence recognized before 1963 (Semenza and Ghirotti 2000). The failure surface was largely confined within 0.5–18-cm-thick clay-rich layers (Hendron and Patton, 1985) which were observed to be continuous over large areas of the failure surface.

Geological and tectonic evidence suggests that parts of both the 1963 landslide perimeter and the prehistoric slide closely correspond to one or more faults (Hendron and Patton, (1985).

During the third reservoir emptying operation, the southern rock slope of Mount Toc failed suddenly over a length of 2 km and a surface area of 2 km^2. The slide moved a 250-m-thick mass of rock some 300–400 m horizontally with an estimated velocity of 20–30 m/s, before running up and stopping against the opposite side of the Vaiont Valley. The majority of the slide moved as a whole and reached the opposite side of the valley without any change in shape apart from a general rotation evident from both the surface morphology and the stratigraphic sequence that remained essentially unchanged after the movement. Kinematic release of the rock mass is suggested to have required internal yielding and fracturing with surface faults and a graben forming within the rock slope (Mencl, 1966; Hutchinson, 1987).

Vaiont Landslide, Italy, Figure 2 General plan showing the Vaiont landslide and the limit of the flood (**a**); schematic longitudinal section showing the original lake level and the elevation of the flood wave (**b**) (After Selli et al. 1964).



Summary

Considerable engineering geological research has been undertaken as a consequence of both the dramatic scientific and human impact of the Vaiont landslide disaster and the complex dynamics involved. In spite of the volume and number of research investigations undertaken to date, the Vaiont landslide continues to provide an engineering case study of great scientific interest and technological challenge. As emphasized by Mencl in 1966: "Anyone working in the field of slope stability may meet a similar problem and no pains should be spared to discover an explanation of the Mount Toc landslide."

Papers on the Vaiont landslide, published in the international literature after 1963, can be schematically subdivided into the following groups: papers based on geological and geomorphological data collected or providing detailed engineering geological and rock engineering descriptions of the Vaiont landslide (Müller, 1964; Selli et al., 1964; Semenza, 1965; Broili, 1967; Müller, 1968, 1987; Semenza and Ghirotti, 2000); papers mainly dealing with specific aspects including the geotechnical properties of the failure material, the physical and rheological behavior of the failure mass, and the use of varied methods of stability analysis (limit equilibrium and numerical modeling) as a means to understanding the complex role of the many factors involved in the triggering and development of the landslide (Mencl, 1966; Skempton 1966; Voight and Faust, 1982; Hendron and Patton, 1985; Hutchinson, 1987; Tika and Hutchinson, 1999; Vardoulakis, 2002; Crosta and Agliardi, 2003; Helmstetter et al., 2003; Sitar et al., 2005; Veveakis et al., 2007); papers on microseismic and other instrumentation data (Belloni and Stefani, 1987; Kilburn and Petley, 2003); and papers on the landslide-generated impulsive wave (Tinti et al., 2002; Panizzo et al., 2005).

Several interpretations of the event have been attempted during the last 45 years, but a comprehensive and convincing explanation of both the triggering and dynamics of the phenomenon remains elusive, the most comprehensive work to date being by Hendron and Patton (1985) who notwithstanding noted the need for further research. A review of all research on the Vaiont landslide has been published (Genevois and Ghirotti, 2005). Readers are referred to Superchi et al. (2010) who provide a comprehensive electronic bibliographic database on the significant number of publications to date on the Vaiont landslide.

At present, the area affected by the 1963 landslide is subject to environmental and town planning restraints.

Vaiont Landslide, Italy, Figure 3 North-South geological sections of the Vaiont landslide: (**1**) before October 9, 1963; (**2**) after October 9, 1963 (Semenza and Ghirotti 2000). (Lower and Middle Liassic); 7. Dolomia Principale (Upper Triassic); 8. faults and overthrusts; 9. failure surfaces of landslide

Numerous initiatives have been carried out in order to assess this territory and contribute to keeping the memory of the catastrophic disaster alive. Among these are included the creation of a permanent laboratory for the study of hydrogeological hazards, the dissemination of information concerning these kinds of risk, and the creation of a "multicenter museum," consisting of historical-natural science paths, permanent (e.g., memorial chapel) exhibitions, and other educational and/or popular multimedia material concerning the sites where the catastrophe occurred.

Somma-Vesuvius

Introduction

Vesuvius is the only volcano on the European mainland to have erupted within the last 100 years, although it has currently been inactive for more than half a century. The volcano is best known for its catastrophic 79 AD eruption, during which a number of Roman settlements and buildings, including Pompeii and Herculaneum, were buried in ash and pumice. Since its discovery in 1748, excavations at Pompeii have provided a unique view of a first century Roman town frozen in time.

Europe's most dangerous volcano

Vesuvius (40.821°N 14.426°E) is located on the Bay of Naples, directly to the southeast of the city of Naples in the Italian province of Campania. It is a 1,281-m high composite or stratovolcano, constructed from the products of both explosive (ash and pumice) and effusive (lava flows) eruptions. Vesuvius is also the type example of a *Somma* volcano, in which the active center is built up within a caldera resulting from the collapse of an earlier center of activity. Vesuvius is sometimes allocated to a so-called "Campanian volcanic arc," which includes Campi Flegrei to the west of Naples and the island of Ischia in the Bay of Naples itself. Vesuvius and neighboring volcanic centers sit close to the northern, steeply dipping edge of a subducting slab reflecting the northwestward subduction of the Ionian Sea plate beneath southern Italy. In the Bay of Naples region, the subducting slab has become detached, contributing to the somewhat anomalous chemistry and mineralogy of the volcanic products. These range from mafic basalts to trachytes and phonolites and are particularly rich in potassium, resulting in the occurrence of distinctive minerals such as leucite, hauyne (nosean), and nepheline.

Volcanic activity in the Vesuvius area stretches back to 400,000 years, although the Somma-Vesuvius central edifice has been constructed over just the last 25,000 years. The ancestral Somma volcano was built largely from effusive eruptions interspersed with mildly explosive eruptions of ash and other pyroclastic materials. At 18,300 y BP, the style of eruption changed dramatically with the first of several *Plinian* eruptions – major, explosive events named after Pliny the Younger, who described such an eruption in 79 AD. The 18,300 y BP eruption was probably the largest eruption in the history of the volcano, and it deposited the widespread marker horizon known as the Pomici di Base (basal pumice). Collapse of the Somma edifice was also initiated during this eruption, forming a caldera within which the current Vesuvius cone has developed. Between 18,300 y BP and 79 AD, there occurred a further three major Plinian eruptions, together with six sub-Plinian events. One of the most notable and violent was the Pomici di Avellino event at 3,800 y BP, which deposited pyroclastic flow and surge deposits up to 3 m deep in the Naples area, and left half a meter of pumice in the vicinity of what is now the city of Avellino, 35 km away. Archeological excavations reveal that the eruption had a considerable and detrimental impact on a flourishing Bronze Age society in the region.

The 79 AD "Pompeii" eruption is the first to be historically documented in any detail, thanks to descriptions of the event contained in two letters sent by observer Pliny the Younger to the Roman senator and historian Tacitus. Little is known about precursory signs, but earthquake

swarms seem to have begun on August 20 and increased over the next 4 days. After 800 years of quiescence, the eruption started on August 24, first with steam blasts as rising magma came into contact with groundwater and then with the development of an eruption column that reached a height of 15 km. Following a pause, a second phase ensued involving a major Plinian eruption. Gravitational collapse of the eruption column generated pyroclastic flows and surges that devastated the towns of Herculaneum (Ercolano), Pompeii, and Stabia to the south and west. Pyroclastic flows and heavy pumice and ash fall continued until the eruption ended during late morning of the 25th, further burying the inundated communities. During the 19 h of the eruption, the volcano ejected an estimated 4 km^3 of ash and pumice, registering the event at 5 on the volcanic explosivity index (VEI). The numbers of people killed in the eruption are not known, although estimates vary from 10,000 to 25,000. To date, the remains of some 1,500 bodies have been recovered from Pompeii and Herculaneum, most showing evidence of having died due to the intense heat of pyroclastic surges.

Following the 79 AD event, less violent explosive eruptions continued sporadically, to be replaced in the eleventh century by predominantly effusive events. A period of quiescence, which started in the thirteenth century, was ended by a large (VEI 4 or 5) sub-Plinian eruption in 1631, which took more than 3,000 lives. The volcano was in almost continuous eruption over the next 300 years, culminating in lava-dominated eruptions in 1906, which led to more than 100 deaths, and in 1944, which destroyed several villages. Vesuvius has since been quiet for 66 years – the longest period of quiescence in more than half a millennium.

Looking ahead, Vesuvius presents one of the greatest volcanic threats to a major urban center on Earth. This is becoming increasingly recognized, and an emergency plan is in place, based upon a future eruption on the scale of 1631. The plan assumes that monitoring will provide an early warning of between 14 and 20 days, during which time 600,000 people will require evacuation from a *zona rossa* (red zone) that is most at risk from pyroclastic flows and surges. In order to reduce the numbers requiring evacuation, financial incentives are being offered to inhabitants of the red zone, and new building is banned. Whether this can have any significant impact before the next eruption is, however, questionable.

Summary

Because of the resulting inundation, and subsequent exhumation, of Pompeii, the 79 AD eruption has arguably helped to make Vesuvius the most famous of all the world's volcanoes. At present, the volcano has the dubious distinction of presenting the greatest potential volcanic threat to a major urban center in the developed world. The current, long period of quiescence will ultimately be terminated by an eruption that is liable to be moderately violent and that will test the emergency plans of the civil authorities to the limit.

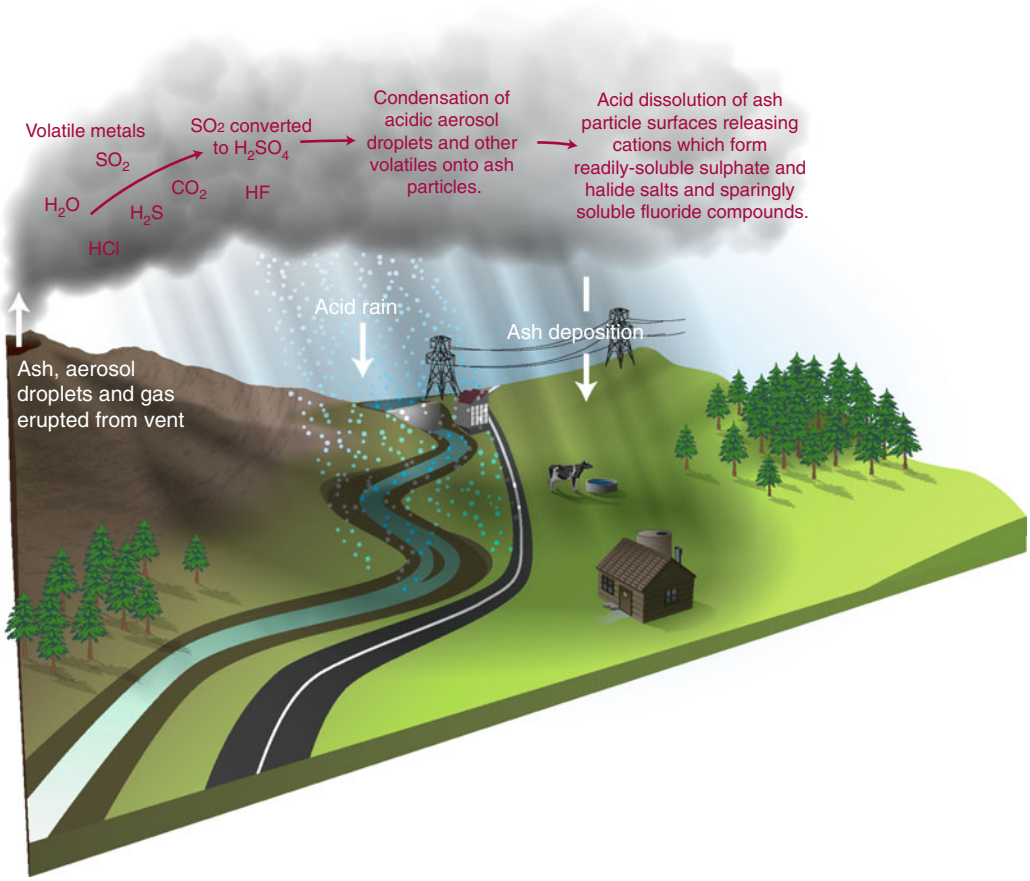
Definition

Volcanic ash is the material produced by explosive volcanic eruptions that is <2 mm in diameter. Fine ash is <0.063 mm; coarse ash is from 0.063 to 2 mm.



Generation

Volcanic ash is formed during explosive volcanic eruptions. Explosive eruptions occur when magma decompresses as it rises, allowing dissolved volatiles (dominantly H_2O and CO_2) to exsolve into gas bubbles.

Volcanic Ash, Figure 1 A volcanic ash particle (vesiculated glass).

These expand the fluid magma into foam and accelerate its ascent to the surface. A *magmatic eruption* occurs when the foamy magma fragments at the volcanic vent, with violently expanding gas bubbles tearing the silicate lattice apart to erupt into the atmosphere, where it then solidifies into fragments of volcanic rock and glass (Figure 1). Ash can also be produced when rising magma contacts water (e.g., surface water, groundwater, snow, and ice). The water explosively flashes into steam, causing shattering of the magma and resulting in a *phreatomagmatic eruption*. A single eruption may be driven by both the release of magmatic gases and interaction with water. The violence of the eruption is determined by the viscosity of the magma (a function of silica content, crystallinity, temperature, and the dissolved volatile content) and the exsolved volatile content (Heiken and Wohletz, 1985; Sigurdsson et al., 2000).

Volcanic Ash, Figure 2 The principal gases released by volcanic eruptions are water, carbon dioxide, sulfur dioxide, hydrogen sulfide, carbon monoxide, hydrochloric acid, and hydrofluoric acid. Volcanic ash particles are thought to have a very thin surface coating comprised of readily soluble sulfate and chloride salts, and more sparingly-soluble fluoride compounds. These are thought to be formed following the condensation of acidic aerosols (H_2SO_4, HCl and HF) onto ash particles, followed by the rapid acid dissolution of Mg, Ca, Na, and K from the ash surface, and then precipitation of the salts at the ash/liquid interface (Witham et al., 2005; Delmelle et al., 2007). Recent work suggests gas/aerosol–ash interactions scavenge around 30–40% of the emitted sulfur and 10–20% of the emitted chlorine in the volcanic plume (Delmelle et al., 2007).

Dispersal and deposition

Volcanic ash is the most widely distributed product of explosive volcanic eruptions. Ash particles ejected from an eruption vent are typically incorporated into an eruption column that may buoyantly rise tens of kilometers (and up to 50 km) into the atmosphere. Eruption plumes are dispersed by prevailing winds, and the ash can be deposited hundreds to thousands of kilometers from the volcano, depending on wind strength, ash grain size, and eruption magnitude.

Ash deposit thicknesses and median grain size generally decrease exponentially with distance from a volcano (Pyle, 1989). Ash deposit thicknesses can be measured, plotted on a map, and contoured. Lines of equal ash thickness are termed *isopachs*. Unconsolidated ash deposits may be subject to remobilization by fluvial or wind processes.

Characteristics

Due to their violent and rapid formation, volcanic ash particles are made up of various proportions of vitric (glassy, noncrystalline), crystalline or lithic (non-magmatic) particles. They are typically very hard and angular, making them abrasive. Vitric particles typically contain small voids formed by expansion of magmatic gas before the enclosing magma solidified, known as vesicles (Figure 1). Ash particles can have varying degrees of vesicularity. Vesicular particles can have extremely high surface area-to-volume ratios. Exsolved magmatic gases condense onto ash particle surfaces while they are in the conduit and ash plume (Figure 2). Surface coatings on fresh ash can be highly acidic, due to the presence of strong mineral acids H_2SO_4 (formed from the oxidation of SO_2), HCl, and HF. Over 55 soluble components have been measured in volcanic ash leachates. Freshly deposited volcanic ash is, therefore, potentially corrosive and electrically conductive. Some components, such as fluoride, may be toxic (Witham et al., 2005; Stewart et al., 2006; Cronin et al., 2003).

Impacts

Volcanic ash can affect many people because of the large areas that can be covered by ashfall. Although ashfalls rarely endanger human life directly, respiratory health hazards of volcanic ash, disruption of critical infrastructure such as electricity and water supplies, transport routes, wastewater treatment and drainage systems and communications networks, disruptions to aviation, building damage and impacts on crops and livestock can all lead to significant societal impacts (Horwell and Baxter, 2006; Johnston et al., 2000; Stewart et al., 2006; Wilson et al., 2010). VOLCANIC GAS

Travis W. Heggie
University of North Dakota, Grand Forks, ND, USA

Synonyms

Volcanic emissions; Volcanic fumes

Definition

Volcanic gases refer to a range of substances emitted by volcanoes during and between eruptive phases.

Discussion

Origins: Volcanic gas is contained within magma. The gases are originally dissolved in magma under high-pressure conditions deep beneath the surface of the Earth. As magma rises to lower pressure conditions near the surface of the Earth, gases held in the magma form tiny bubbles that increase in volume. The increasing volume taken up by gas bubbles makes the magma less dense than the surrounding rock which in turn allows magma to continue rising to the Earth's surface.

Composition: The most common volcanic gases released into the atmosphere are water vapor (H_2O), carbon dioxide (CO_2), sulfur dioxide (SO_2), hydrogen chloride (HCl), hydrogen sulfide (H_2S), hydrogen fluoride (HF), carbon monoxide (CO), nitrogen (N_2), hydrogen (H_2), helium (He), methane (CH_4), radon (Rn), and heavy metals such lead and mercury (Hansell et al., 2006; Heggie, 2009).

Hazards: Volcanic gases can impact the climate at local, regional, and global scales. For example, sulfur aerosols in the atmosphere can lead to lower surface temperatures and ozone depletion. Volcanic gases are also harmful to humans, animals, and agricultural crops. SO_2 can produce acid rain and contribute to air and water pollution downwind of volcanoes, CO_2 is heavier than air and may flow into low-lying areas and collect in soil, and a collection of volcanic gases can instantly corrode aircraft engines (Heggie, 2005).

Direct Health Hazards: Human death resulting from volcanic gases is usually the result of asphyxiation and/or acidic corrosion (Baxter, 1990). Volcanic gases are estimated to account for <1–4% of recorded volcano-related fatalities (Hansell and Oppenheimer, 2004). However, these figures are likely underestimated as reported studies tend to focus more on fatalities during volcanic eruptions and neglect degassing events between eruptive phases. CO_2 is particularly dangerous because it is odorless and poses the risk of asphyxiation, vomiting, dizziness, visual disturbances, headaches, sweating, mental depression, and tremors (Heggie, 2009). H_2S is a colorless gas with a sewer or rotten egg smell than can cause upper respiratory irritation and pulmonary edema at higher concentrations and irritate the eyes and act as a depressant at lower concentrations (Heggie, 2009). Common gases such as SO_2 and HCl are irritating to the eyes, throat, mucous membranes, and respiratory tract (Heggie et al., 2009). HCl can also be irritating to the skin and those with asthma can suffer severe consequences to SO_2 (Heggie et al., 2009).

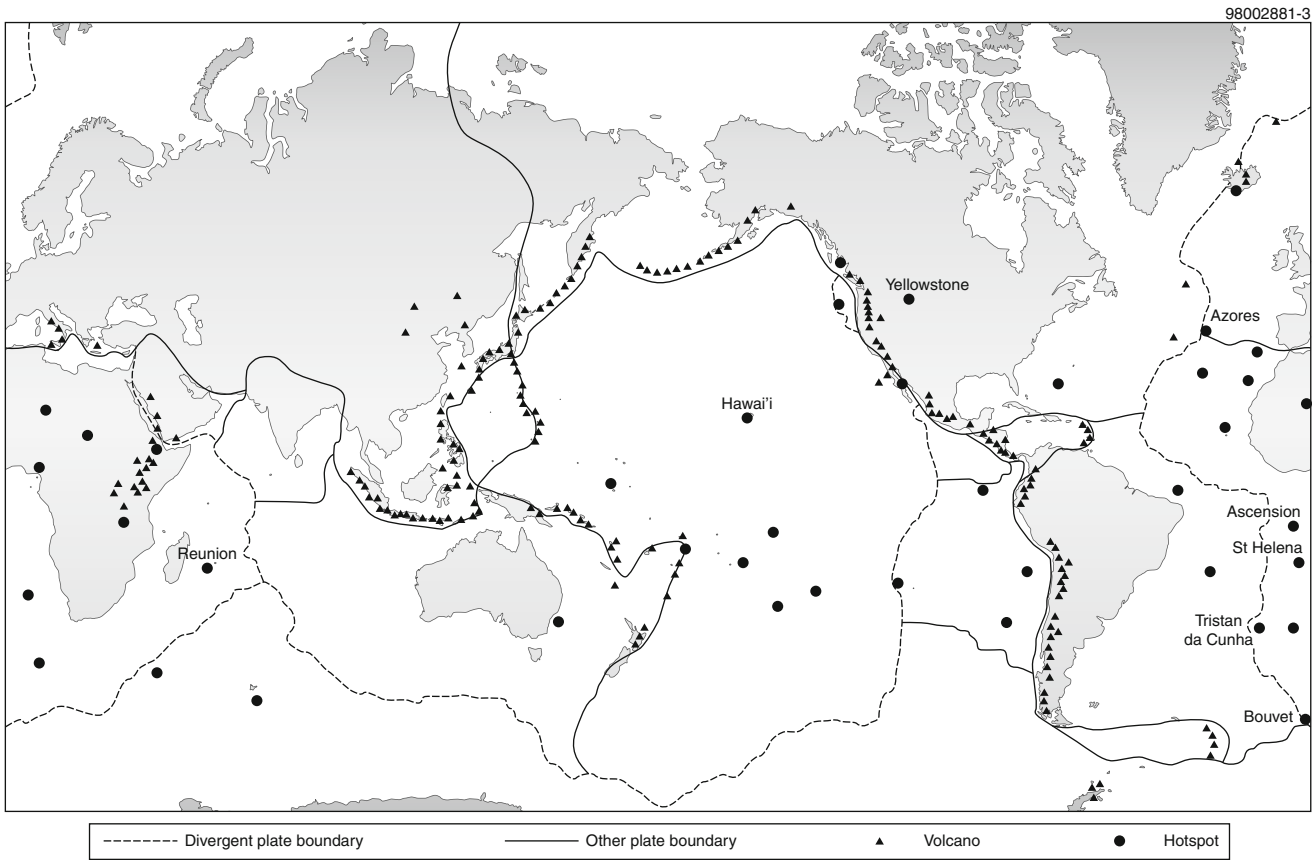
VOLCANOES AND VOLCANIC ERUPTIONS

Sue C. Loughlin
British Geological Survey, Edinburgh, UK

Definitions

Volcano: There are volcanoes wherever magma rising from the Earth's interior reaches the surface. In terms of landforms, a single dome, cinder cone, tuff cone, or maar may be described as a volcano, but these are *monogenetic volcanoes* arising from a single eruption. They may form on the summit and flanks of larger, long-lived volcanic edifices (*polygenetic volcanoes*) or as part of extensive volcanic fields that result from several eruptive periods. Here, in order to report numbers of active volcanoes (i.e., those that have erupted in the last 10,000 years and could erupt again), we follow the same broad definition as the Global Volcanism Program (Simkin and Siebert, 2002–2009) where all products of a single magmatic system are considered part of one "volcano" or "volcanic system." So, a volcanic field tens to hundreds of kilometers across, comprising hundreds or thousands of monogenetic volcanoes, is here considered to be a single volcanic system.

Eruption: An eruption is usually described as the explosive expulsion of fragmental material (tephra) and/or lava from a volcano (Simkin and Siebert, 2002–2009). An eruption may last for hours, days, years, decades, or, in the case of Stromboli, Italy, thousands of years. A pause in an eruption longer than 3 months would constitute the end of the eruption (Simkin and Siebert, 2002–2009). Periods of dormancy between eruptions may extend to thousands of years.



Introduction

Volcanoes are awe inspiring, beautiful, and deadly. They may provide benefits such as good quality agricultural soils, geothermal energy, stunning landscapes, and tourist attractions, but equally they may cause devastating destruction and numerous fatalities. In the twentieth century, 91,724 people were killed by volcanic phenomena (see *Casualties Following Natural Hazards*), and the best estimate for people affected is 5.6 million (Witham, 2005). Almost one in ten people live within possible range of an active volcano, and most of these people are in urban centers in the developing world (Chester et al., 2001). As the world's population increases and urban populations increase, the number and proportion of vulnerable people will also increase.

Some communities have learned to live alongside and benefit from frequently erupting volcanoes (e.g., Mauna Loa in Hawaii and Etna in Italy). Typically, such volcanoes are well monitored, and emergency plans and communication networks are well established (see *Emergency Planning*). However, more commonly, volcanoes are dormant for hundreds or thousands of years and then awaken suddenly to the surprise of local populations. All too often, emergency plans and monitoring networks are established in response to the onset of volcanic activity, and this lack of preparedness can have deadly consequences.

Distribution of volcanoes

The distribution of volcanoes is strongly controlled by plate tectonics (see entry *Plate Tectonics*) which is driven largely by convection of the Earth's mantle (Figure 1). Volcanoes occur mainly at plate margins: above subduction (see entry *Subduction*) zones (destructive plate margins), or at mid-ocean ridges and continental rifts (constructive plate margins). They also occur within plates and/or associated with "hot spots." Each tectonic setting results in unique processes of magma (see entry *Magma*) generation resulting in differing types and styles of volcanic eruption (see entry *Eruption Types (Volcanic Eruptions)*). The most dangerous volcanoes tend to be associated with subduction zones (island arcs and continental margins) where two tectonic plates collide and one is forced underneath the other.

Volcanoes and Volcanic Eruptions, Figure 1 Global distribution of historically active volcanoes (Simplified from Simkin and Siebert, 2000).

Magma generation, storage and transport

Basaltic magma is generated in the Earth's mantle when rocks undergo partial melting by decompression, hydration, or heating. The exact composition of primitive basaltic magma varies depending on the tectonic environment and consequent depth and degree of partial melting although it always has low silica content (<52% SiO_2) and low viscosity. As magma moves toward the surface, it is modified by a variety of processes (see papers in Sigurdsson, 2000) and can evolve into magma of very different composition. At mid-ocean ridges, where minimal magma modification occurs, large volumes of basaltic lava are erupted at the surface, whereas at subduction zones, high silica magmas are more commonly erupted. In magma chambers, basaltic magma cools and crystallizes various minerals, some of which are dense and sink (fractional crystallization), leaving magmas of more silicic composition. Additional processes may contribute to magma evolution such as the partial melting of crustal rocks (heat supplied by the hot primitive magmas) and mixing of different magma compositions (e.g., Blake, 1981; Marsh, 2000). The evolution to silicic compositions can only take place if the magma is stored for some time; so long repose periods between eruptions facilitate the process. Silicic magmas such as dacite (e.g., Mount St. Helens, USA), trachyte (e.g., Fogo, Azores), or rhyolite (e.g., Chaitén, Chile) have higher potential for cataclysmic volcanic explosions.

Eruptions are commonly triggered when basaltic magma enters the base of a long-lived cooling magma chamber. As well as a space problem, the fresh magma supplies heat and volatiles that trigger convection and mixing (e.g., Murphy et al., 1998). Magma makes its way toward the surface along zones of high deformation (at depth) and fracturing (near the surface). Some volcanoes develop on large rift systems where lava (see entry Lava) is erupted along dyke systems; other volcanoes have a near-surface cylindrical conduit, often where two fracture zones intersect.

Number of active volcanoes

Based on the records at the Smithsonian Institution, 50–70 volcanoes are in eruption each year and about 160 each decade. There are at least 1,300 (and possibly more than 1,500) volcanoes known to have erupted in the Holocene (last 10,000 years) and 550 of these have had historically documented eruptions (Simkin and Siebert, 2002–2009). Based on the definition of a "volcano" given above, Simkin and Siebert (2002–2009) suggest that there are at least 1,000 known magma systems on land that might erupt in the future. It is entirely possible that there are active volcanoes (volcanoes with the potential to erupt) that have not yet been identified due to ice or vegetation cover. If a volcano has not erupted for hundreds or thousands of years, our understanding of it is entirely dependent on geological mapping and the dating of eruption products. There are volcanoes that have not been mapped in detail (and some not at all), and the products of many past eruptions remain to be identified let alone dated.

The number of volcanoes on the seafloor and ocean rift system is unknown, but it far exceeds the number on land. A seamount is defined as an edifice at least 50–100 m above the seafloor of which there are more than one million; highly productive seamounts form ocean islands of which there are a few thousand (Schmidt and Schmincke, 2000). It is estimated that three-fourths of the magma reaching the Earth's surface is erupted along submarine ocean ridges (Crisp, 1984).

Morphology and volcano type

Volcanoes have a significant variety of forms from ice-capped symmetrical cones like Mount Fuji (see *Stratovolcanoes*) and broad shield volcanoes (see entry *Shield Volcano*) like Mauna Loa to potentially devastating caldera (see entry *Calderas*) volcanoes (e.g., Toba, Sumatra) which have barely any topography; so despite their great size, some were only identified from space (e.g., Francis, 1993).

The shape, size, and type of volcano depend on tectonic setting, magma supply rates, and eruption frequency. The features and deposits generated by a single eruption depend on several factors including lava chemistry, gas content, and eruption style which may change through the lifespan of a volcano or even during a single eruption. Sector collapse and eruption into, or erosion by, water or ice also significantly modify volcano shape, giving an enormous variety of volcanic forms (see papers in Sigurdsson, 2000; Smellie and Chapman, 2002; Francis and Oppenheimer, 2003).

The simplest forms are monogenetic volcanoes created during a single eruption. They include scoria (cinder) cones (often associated with lava flows), lava domes, maars, and tuff cones. Monogenetic landforms may form on the summit or flanks of a large polygenetic volcano (e.g., cinder cones on Etna, Italy), as part of a volcanic field (e.g., Michoacan-Guanajuato filed, Mexico), or independently (e.g., Inyo craters, California).

Polygenetic volcanoes have undergone repeated eruptive episodes. Large complex, constructional features that are long-lived and comprise both lava and fragmentary eruption products (tephra) are termed composite volcanoes (Davidson and Da Silva, 2000). This broad category includes stratovolcanoes (see *Stratovolcanoes*), central volcanoes, shield volcanoes (see *Shield Volcano*), and compound volcanoes. Their eruption products are diverse in type and composition, and many have experienced sector or caldera collapse. They are widely distributed, developing above subduction zones (e.g., Pinatubo, Philippines; Mount St. Helens, Washington, USA) but also in intraplate environments (e.g., Mount Kilimanjaro, Tanzania) and associated with "hot spots" (e.g., Hekla, Iceland). Intrusive dykes and sills build up the edifice from the inside. Klyuchevskoy in Kamchatka, Russia, is one of the tallest composite volcanoes, standing 4,725 m above sea level.

If a magmatic system supplying a composite volcano shifts a limited distance during the volcano's lifetime,

a compound volcano is formed. It is asymmetric and generally has the appearance of one or several cones superimposed upon one another. The result may be an elongated ridge (e.g., Lascar, N. Chile), or a more complex massif with nonsystematic migration of the eruption center (e.g., Ojos del Salado, Chile). In some cases, two distinct composite volcanoes are formed much closer than average volcano spacing (<10 km) and one cone is commonly older than the other (e.g., Nevado de Colima and Volcán de Colima, Mexico).

A "volcanic field" may be active for up to 5 Ma and contain thousands of individual monogenetic volcanoes. Clusters or extensive fields of monogenetic volcanoes may extend for tens or hundreds of kilometers.

Small summit calderas on basaltic volcanoes (e.g., Piton de la Fournaise, Réunion Island) form when magma from a shallow summit chamber is ejected laterally into dykes, leaving the summit to collapse, often incrementally rather than catastrophically. A *caldera* (*cf*) like Crater Lake, Oregon, formed when a Plinian explosion rapidly evacuated a large, shallow magma chamber and resulted in collapse of the roof of the magma chamber along ring fractures. Such eruptions are usually associated with a preexisting edifice; in the case of Crater Lake, it was originally Mount Mazama. In contrast, resurgent calderas are the largest volcanic structures on Earth formed by enormous volcanic eruptions. They are up to 100 km across, dwarfing any preexisting structure, and are characterized by post-eruption resurgence of the caldera floor, sometimes by up to 1 km (e.g., Cerro Galan (Argentina), Long Valley (California, USA), and Yellowstone (Wyoming, USA)).

Eruption style

The style of eruption depends mainly on the gas pressure in bubbles growing in the magma as it moves toward the surface, the rheology of the magma, and magma ascent rates (see *Eruption types (Volcanic Eruptions)* and papers in Sigurdsson, 2000). Magma ascent rate and decompression in the last few km below the surface has a significant effect on the properties of magma and dynamics of conduit flow (e.g., Massol and Jaupart, 1999; Melnik and Sparks, 1999, 2002, 2005, 2007). It is in the shallow subsurface that gas exsolution and degassing occurs, controlling whether a volcanic eruption is effusive (lava flows) or explosive. If gases are unable to separate effectively during ascent, the pressure in the bubbles increases and then may blow the magma apart during explosive eruptions (e.g., see papers in Gilbert and Sparks, 1998; Freundt and Rosi, 1998).

A volcano may switch between effusive and explosive styles during a single eruption (e.g., Vesuvius 1944; Soufrière Hills 1995-ongoing). Melnik and Sparks (2005, 2007) have shown that nonlinear dynamic processes in volcanic conduits at andesitic volcanoes can lead to substantial changes in style simply as a result of a change in a single parameter such as volatile content. The same nonlinear dynamics may make volcanoes inherently unpredictable although many volcanoes exhibit repetitive cyclic patterns of activity on various timescales that can assist with effective forecasting (e.g., Voight et al., 1998, 1999; Druitt et al., 2002a; Sparks and Young, 2002).

Scale of eruptions

It is useful to compare eruptions, even though they cover an enormous range of types and impacts, and several scales have been developed for this purpose (see *Intensity Scales* and *Magnitude Measures*).

The Volcanic Explosivity Index (VEI) is a commonly used logarithmic scale devised by Newhall and Self (1982) that is useful to compare magnitudes of explosive eruptions (Table 1). Most volcanic eruptions are explosive to some degree, and although the eruptive products are different, the dynamics are the same. The VEI scale includes eruption column height, erupted volume of tephra (which may be controlled by eruption duration), and qualitative descriptions to define eruptions. On the VEI scale, fire fountaining might score 0–1, strombolian explosions 1–2, vulcanian explosions 2–4, and plinian explosions 4 and above (see *Eruption Types (Volcanic Eruptions)*). The VEI scale is often used to compare recent explosive eruptions (defined by erupted tephra volume and/or column height) and historic or prehistoric explosive eruptions (defined by erupted tephra volume only).

Volcanoes and Volcanic Eruptions, Table 1 The VEI based on Newhall and Self, 1982, showing approximate frequencies of eruptions based on the Smithsonian Institution Holocene database (Simkin and Siebert, 2000)

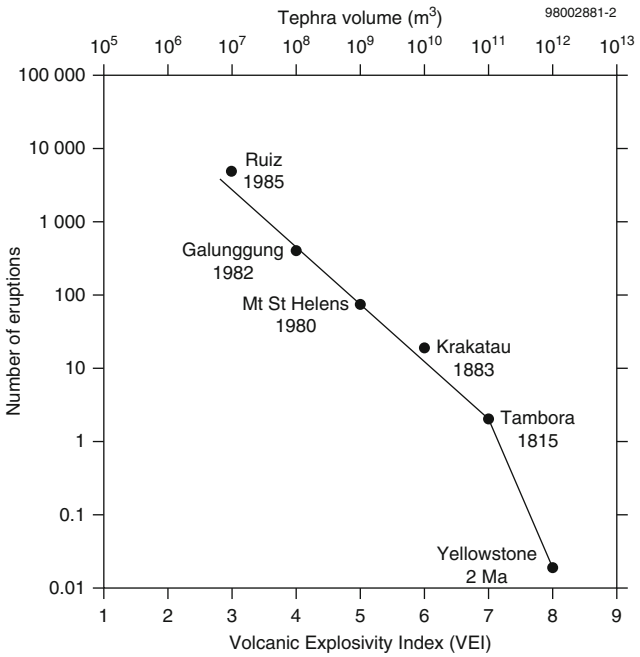
VEI	Maximum volume of erupted tephra m^3	Eruption column height	Description	Approximate frequency
0	10^4	<0.1	Nonexplosive	
1	10^6	0.1–1	Small	
2	10^7	1–5	Moderate	
3	10^8	3–15	Moderate-large	10/year
4	10^9	10–25	Large	1/year
5	10^{10}	>25	Very large	1/10 years
6	10^{11}	>25		1/100 years
7	10^{12}	>25		1/1,000 years
8	10^{13}	>25		1/100,000 years

There are also logarithmic scales to define magnitude and intensity (e.g., Pyle, 2000) which are useful to compare effusive and explosive eruptions:

Magnitude = $\log_{10}$(erupted mass, kg) − 7
Intensity = $\log_{10}$(mass eruption rate, kg/s) + 3

For example, the Rosa lava flow which is a single lava flow from the Columbia River basalts (USA) had a magnitude of 8.5, and the explosive Toba caldera-forming eruption of 75 ka had a magnitude of 8.8.

Another way to compare otherwise dissimilar events is a destructiveness index: = Log_{10}(total area affected by lava, lahar, pyroclastic flows, debris avalanche, or tephra accumulations exceeding 100 kg/m^2).



The Taupo eruption of 180 AD affected 45,000 km^2 of land, whereas the Mount St. Helens eruption of 1980 affected 710 km^2 (Pyle, 2000).

Magnitude, frequency, duration and interval

Based on the Smithsonian Institution Holocene database, small to moderate size eruptions are frequent (in geological time) but large eruptions are not, in other words, there is a link between eruption magnitude and eruption frequency (Figure 2, Simkin and Siebert, 2000). Nevado del Ruiz (1985) was a small eruption with devastating consequences, but about10 eruptions of this size could be expected every year. Human civilization has not yet experienced the largest possible explosive eruptions (VEI 8+: super-eruptions, see below) which occur on average every 100,000 years (Simkin and Siebert, 2000).

Long repose periods (hundreds to thousands of years) precede large eruptions (e.g., Mason et al., 2004). The repose period is often longer than documented history at that volcano; so communities may be unprepared. Simkin and Siebert (2000) pointed out that of the 16 largest explosive eruptions of the nineteenth and twentieth centuries, 11 were the first historical eruptions known from that volcano (e.g., Santa Maria, Guatemala, and El Chichon, Mexico).

Some volcanic eruptions have a "paroxysmal" explosive phase, and these tend to cause fatalities. In recent history, such eruptions include Mount St. Helens (1980; Lipman and Mullineaux, 1981) and Pinatubo (1990; Newhall and Punongbayan, 1996), both of which reached their cataclysmic stage after months of precursory activity. However, Simkin and Siebert (2000) showed that more than 40% of well-documented explosive volcanic eruptions reached their peak in the first day of the eruption, and where detailed data exist, half reached the climax within 1 h of the start of the eruption (e.g., Tarawera, 1886; Hekla, 1947; Shiveluch, 1964). Such rapid development was demonstrated at Chaitén (Chile) in 2008 when only 1 day of seismic unrest was felt before a large Plinian eruption. The apparent rapid ascent rate of silicic magmas had been a dilemma to geologists due to the assumption that they are highly viscous – we now know that near-liquidus hydrous rhyolite is in fact very fluid (Castro and Dingwell, 2009). There had been no historical eruptions at Chaitén, and so the eruption was not expected, and this scenario will be repeated at other volcanoes in the future.

Volcanoes and Volcanic Eruptions, Figure 2 Magnitude and frequency of Holocene eruptions normalized to show eruptions per 1,000 years. Data for VEI 8 eruptions is based on geological not historical data.

For those historical eruptions in the Smithsonian Institution database with start and end dates, there is a median eruption duration of about 7 weeks, most last for less than 3 months and a few last for longer than 3 years (Simkin and Siebert, 2000–2009). Some ongoing long-lived eruptions include Santa Maria (Guatemala) and Arenal (Costa Rica).

Super-eruptions

A super-eruption is defined as an eruption of at least 100 km^3 of magma (equivalent to about 250 km^3 of volcanic ash) that has global consequences (Sparks et al., 2005). Super-eruptions are up to hundreds of times larger than the biggest eruptions of the last 200 years (Tambora, 1815; Krakatoa, 1883) that both caused major global climatic anomalies for several years after the eruptions (see *Global Dust*). The most recent super-eruption was at Toba (Sumatra, Indonesia) 73,500 years ago which may have released up to 6,000 km^3 of tephra and up to five million tons of sulfuric acid (Rampino and Self, 1994). The largest flood basalt province (Ontong Java plateau) reached emplacement rates of up to 12 km^3 per year, and the global impacts of such large-scale magmatism and volcanism must be severe (White and Saunders, 2005; Thordarson et al., 2009).

It is tempting to link these catastrophic events to biotic extinctions (e.g., Rampino and Self, 2000), but conclusive evidence is lacking (see *Extinction*). The impacts of a super-eruption would include the devastation of world agriculture, severe disruption of food supplies, social unrest, mass starvation, disease, and financial collapse.

Volcanic hazards and impacts

Volcanic ash (*cf*) fall has significant impact on agriculture (see *Challenges to Agriculture*), human health, and environment (e.g., Hansell et al., 2006; Martin et al., 2009) and has led to the greatest number of volcano-related fatalities (by famine and disease) in the last 400 years (Table 2; e.g., Baxter, 2000). Volcanic ash (see entry *Volcanic Ash*) was also responsible for the highest numbers of people made homeless/evacuated or otherwise affected by volcanic eruption in the twentieth century (Witham, 2005). It can disrupt critical infrastructure, such as power, communication, and aviation (see *Aviation (Hazards to)*) (e.g., Miller and Casadevall, 2000), and contaminate water. Volcanic ash is likely to have cross-border impacts (e.g., Watt et al., 2009), making countries which may not have a volcano vulnerable if *emergency planning* (*cf*) is not in place. As an example of unexpected impacts, the total losses to global GDP of the small-moderate 2010 eruption of Eyjafjallajökull in Iceland were US$5 billion (Oxford Economics, 2010).

When considering numbers of immediate fatalities, pyroclastic flows/surges (commonly referred to as "pyroclastic density currents," Druitt, 1998; Branney and Kokelaar, 2002) are the most devastating hazards (Figure 3; Table 2). Recent eruptions have provided many opportunities to observe pyroclastic flows (see *Pyroclastic Flow* and *Nuée Ardente*) and study their behavior and deposits (e.g., Fujii and Nakada, 1999; Ui et al., 1999; Druitt and Kokelaar, 2002; Saucedo et al., 2002). Pyroclastic surges (see "*Surge*") are highly mobile; they do not necessarily follow valleys and may travel uphill or across the surface of the ocean catching observers by surprise (e.g., Fisher, 1995; Loughlin et al., 2002; Trofimovs et al., 2006). An additional hazard known as surge-derived pyroclastic flows was identified at both Mount St. Helens and Soufrière Hills (e.g., Druitt et al., 2002b). The best risk reduction strategy for *pyroclastic flows* (*cf*) and *surges* (*cf*) is to identify areas at risk and then avoid them (e.g., Crandell et al., 1984). However, identification of potentially affected areas is nontrivial, and various statistical methods and dynamic models have

Volcanoes and Volcanic Eruptions, Table 2 Fatalities greater than 1,000 in the last 400 years (Data from Fisher et al., 1997; Blong, 1984)

Year	Volcano	Pyroclastic flows/surges	Lava flows	Debris flows/lahars	Tsunami	Famine
1586	Kelut, Indonesia			10,000		
1600	Huaynaputina, Peru	>1,000				
1631	Vesuvius, Italy		<4,000			
1669	Etna, Italy		?			
1711	Awu, Indonesia			3,200		
1741	Oshima, Japan				1,480	
1741	Cotopaxi, Ecuador			1,000		
1772	Papadian, Indonesia	2,960				
1783	Laki, Iceland					9,340
1783	Asama, Japan	1,150				
1792	Unzen, Japan				15,190	
1814	Mayon, Philippines	1,200				
1815	Tambora, Indonesia	12,000				80,000
1822	Galunggung, Indonesia			<4,000		
1825	Mayon, Philippines			1,500		
1826	Awu, Indonesia			3,000		
1845	Nevado del Ruiz, Columbia			1,000		
1856	Awu, Indonesia			1,530		
1877	Cotopaxi, Ecuador			1,000		
1883	Krakatau, Indonesia				36,417	
1892	Awu, Indonesia			1,532		
1902	Soufriere, St. Vincent	1,680				
1902	Pelee, Martinique	29,025				
1902	Santa Maria, Guatemala	6,000				
1911	Taal, Philippines	1,335				
1919	Kelut, Indonesia			5,110		
1930	Merapi, Indonesia	1,300				
1951	Lamington, New Guinea	2,942				
1963	Agung, Indonesia	1,900				
1982	El Chichon, Mexico	1,700				
1985	Nevado del Ruiz, Columbia			25,000		

Volcanoes and Volcanic Eruptions, Figure 3 Block-and-ash flows entering the sea off the coast of Montserrat 20 May 2006. The surges traveled across the water surface.

so far been employed (e.g., Calder et al., 1999; Denlinger and Iverson, 2001; Patra et al., 2005; Esposito Ongaro et al., 2005; Charbonnier and Gertisser, 2009; Wadge, 2009). The essential parameters needed for effective dynamic modeling of flows, especially the surge (see entry *Surge*) component, remain elusive.

Pyroclastic density currents (see *Pyroclastic Flow* and *Nuée Ardente*) are also formed during lateral blasts when part of a volcanic edifice collapses to (a) expose pressurized magma (e.g., Mount St. Helens, 1980, Lipman and Mullineaux, 1981) or (b) remove support for a pressurized lava dome (e.g., Soufrière Hills, Montserrat, 1997, see papers in Druitt and Kokelaar, 2002). The enormous impact of such events may not be immediately recognizable in the geological record when only localized hummocky debris avalanche deposits may remain. The Mount St. Helens collapse was preceded by an obvious bulge (cryptodome) on the southern flank. At Soufrière Hills, open fractures and frequent rock falls (see Rockfall) were evident signs of instability 14 months before the collapse. It was also obvious that the southern part of the growing lava dome was resting on a deeply hydrothermally altered flank. The longest known debris avalanche occurred associated with an eruption at Volcán de Colima 4,000 years ago; even at a distance of 90 km, it was estimated to have had a velocity of 44 m/s (158 km/h) (Stoopes and Sheridan, 1992). Debris avalanches can cause tsunami (see entry *Tsunami*) if they enter the sea.

Lahars (see *Lahar*) have also been devastating in terms of fatalities. There were 25,000 fatalities at *Nevado del Ruiz* (*cf*) volcano, Columbia, in 1985 (Voight, 1988; Table 1). A *lahar* (*cf*) is controlled by topography; it may be hot or cold and can precede, accompany, or follow volcanic activity. They are particularly voluminous and hazardous at volcanoes where pyroclastic deposits are generated. Lahars typically travel much farther than pyroclastic flows; 30 km is not unusual at larger volcanoes, and so towns and cities developed on a coastal plain or river delta tens of kilometers from a volcano may be at risk. This is especially the case if the volcano is snow or ice-covered (e.g., Mount Rainier, USA, Fisher et al., 1997). GIS has been used effectively to deal with potential lahar inundation zones (e.g., Schilling, 1998; Iverson et al., 1998). A *jökulhlaup* (*cf*) is a flood of meltwater generated at a subglacial volcano; it is similar to a lahar but may be more dilute and often carries large blocks of ice.

Basaltic lavas (see *AA-Lava* and *Pahoehoe-lava*) typically travel at several kilometers per hour; so an observer can walk away (but there have been fatalities when flows advance over wet ground causing small explosions) (Manga and Ventura, 2005). Slowly advancing lava nevertheless destroys everything in its path. Alkaline basaltic lavas erupted in continental environments have very different properties. In 1977, at Nyiragongo in Congo, lava flows generated by draining of the lava lake traveled at 60 km/h (and possibly up to 100 km/h) and hundreds of people were killed in Goma. In 2002, another eruption killed over a 100 (see papers in Capaccioni and Vaselli, 2004). Walker (1973) determined that effusion rate is the single most important factor in determining the morphology and length of lava flows. The largest basaltic eruption of the last 1,000 years was from the Laki fissure in 1783 which extruded at a rate of 5,000 m^3/s, produced lava flows that spread over 565 km^3, and flowed for distances up to 65 km (e.g., Thordarson and Self, 2003). Quaternary basalt lavas have been reported with lengths of up to 181 km (Pasquare, 2008). Mauna Loa's axial rift has been the source of numerous lavas in the recent past that have extended for over 30 km to Hilo.

Andesitic to rhyolitic lava tends to be viscous and forms either short lava flows or lava domes. They are often associated with explosive eruptions and pyroclastic flows. Extrusion rates are highly variable and lava domes at different volcanoes show differing morphologies (e.g., Fink and Anderson, 2000; Watts et al., 2002). At Soufrière Hills Volcano, distinct cycles relating to magma depressurization, degassing and crystallization were recognized (Voight et al., 1999). Each pulse generated a recognizable shear lobe in the dome, facilitating assessment of the most likely direction of dome-collapse pyroclastic flows (Calder et al., 2002). At Soufrière Hills Volcano (*Montserrat eruptions*), several lava dome

collapses have taken place during heavy rainfall and have lacked other precursors such as seismic activity. In these cases, rainfall has been implicated in the triggering of the collapse. Several mechanisms have been proposed, and it was apparent that most collapses took place during the first heavy rains after a long dry season (e.g., Matthews et al., 2002; Elsworth et al., 2004).

Volcanogenic tsunami (see entry *Tsunami*) may be caused by voluminous pyroclastic flows and/or debris avalanches entering the sea, underwater explosions, or submarine caldera collapse. Pyroclastic flows entering the sea may be accompanied by hydrovolcanic explosions (e.g., Edmonds and Herd, 2005). During the eruption of Krakatau in 1883, many were killed on Sumatra and Java by tsunami up to 40 m high. The caldera-forming eruption at Santorini in about 1620 BC generated tsunami in the eastern Mediterranean up to 50 m high and probably contributed to the downfall of the Minoan civilization (see entry *Santorini, Eruption*).

Potentially hazardous volcanic gas (see entry *Volcanic Gas*) is released at elevated concentrations almost continuously from active volcanoes and at lower levels from fumaroles (see *Fumarole*) when there is no eruption. Volcanic gases include sulfur dioxide, hydrogen sulfide, carbon dioxide, and hydrogen fluoride, all of which can have significant environmental and health impacts. Human fatalities have been mainly caused by carbon dioxide and hydrogen sulfide both of which are denser than air and so collect in dangerous concentrations in depressions (e.g., Baxter, 2000). At Lake Nyos in Cameroon, carbon dioxide seeping up into the lake bed was dissolved in lake waters in huge quantities. The gas suddenly exsolved causing the lake waters to overturn on 21 August 1986, and killed at least 1,700 people. The conversion of volcanic gases to acid aerosol in the atmosphere can result in acid rain (see entry *Acid Rain*) and damage to agriculture, environment, and water supplies.

Climate and volcanoes

There is evidence that major volcanic activity can cause a change in the Earth's climate for several years after an eruption (e.g., Rampino and Self, 1994; Rampino and Self, 2000; Robock and Oppenheimer, 2003; Thordarson et al., 2009). In 1783, a dry fog across much of Europe and a severe winter has been attributed to gases and the resulting sulfate aerosols from the Laki eruption of 1783 (Thordarson and Self, 2003; Oman et al., 2006). There were severe environmental and health impacts (e.g., de Boer and Sanders, 2002). Similar effects such as a dry fog and reduced sunlight were reported in 1816 after the plinian (VEI 7) eruption of Tambora in 1815. The average global temperature fell by 0.4–0.7°C, and there is a clear acidity spike in the Greenland and Antarctic ice cores. The summer of 1816 in the northern hemisphere was known as the "year without a summer." Crop failure was widespread and famine resulted in epidemics of cholera (India) and typhus (Europe) and mass migrations. More recently, the 1982 eruption of El Chichon and the 1991 Pinatubo eruption (McCormick et al., 1995) both added considerable masses of sulfate aerosol to the stratosphere.

It is the release of sulfur dioxide and hydrogen sulfide and production of sulfuric acid aerosols that have significant impact on the atmosphere, and in general, these gases are more abundant in basaltic eruptions. The impact of a given eruption on the climate depends on the height of the eruption column, the erupted mass of gas (which relates to erupted volume of magma), the geographical location, composition, and eruption duration (e.g., Parfitt and Wilson, 2008). Flood basalt eruptions could repeatedly inject large masses sulfur dioxide into the stratosphere over years or even decades giving little opportunity for recovery, whereas the aerosol injection of a cataclysmic silicic eruption might just last several days (Thordarson et al., 2009).

The impact of changes in sea level and varying degrees of glacial loading on crustal dynamics is a growing area of research.

Volcano observatories and international collaboration

The first volcano observatory was established at Vesuvius in 1841 (Krafft, 1993). Since then, significant advances in volcanology have tended to follow major volcanic eruptions and also technological advances. There are now more than 70 institutes signed up to the World Organization of Volcano Observatories (a commission of the International Association of Volcanology and Chemistry of the Earth's Interior), some with extremely sophisticated monitoring equipment enabling scientists to forecast volcanic activity and thus enabling populations at risk to take action (e.g., Scarpa and Tilling, 1996). Nevertheless, most potentially active volcanoes are not monitored.

The monitoring of inactive volcanoes is essential in order to establish long-term baseline measurements for each volcano so that precursory signs can be identified (see Monitoring Natural Hazards). Technological advances have increased the reliability and sensitivity of monitoring equipment and allow real-time collection, interrogation (e.g., Mader et al., 2006), and communication of vast datasets. Nevertheless, equipment and monitoring comes at a cost; at many volcanoes, access to effective, durable, low-cost monitoring techniques is more practical. International, interdisciplinary collaboration has been successful and, combined with more focused use of remote sensing capability (see *Remote Sensing of Natural Hazards and Disasters*), may in time facilitate improved monitoring of more volcanoes.

Data gathered by volcano observatories is being collated in a database of volcanic unrest (WOVOdat) which is facilitating international collaboration in identifying eruption precursors. Other international, web-based initiatives include "VHub" focusing on the development of computational models of volcanic processes and

"VOGRIPA" which will focus on collating and building volcanic hazards databases. Another valuable international initiative includes the International Volcanic Health Hazard Network (IVHHN). An effort to provide a platform for global hazard and risk assessments is underway called the Global Volcano Model.

Hazards, risk and uncertainty

Effective hazards assessments require a combination of detailed geological mapping and dating of historic and ancient deposits, recognition of all possible hazards, good dynamic modeling, and effective expert elicitation. A thorough hazard analysis must also be combined with a consideration of vulnerability in order to constitute a *risk assessment* (*cf*) (e.g., Blong, 2000). Effective volcanic *risk management* (*cf*) involves strong partnerships between scientists, communities, and various authorities. There are many opportunities for the reduction of risk posed by volcanic hazards (e.g., Blong, 2000), but many volcanoes still require basic monitoring and mapping (e.g., Scarpa and Tilling, 1996). In the twentieth century, there were notable "successes" for the volcanological community (e.g., Pinatubo, 1991) and failures (e.g., Nevado del Ruiz, 1985). Long-lived eruptions like Soufrière Hills (see *Montserrat Eruptions*) have brought different challenges and offer the opportunity to develop and test new methodologies in probabilistic hazard and risk assessment (e.g., Aspinall et al., 2002; Aspinall, 2006). Probabilistic methods are also being developed elsewhere (e.g., Newhall and Hoblitt, 2002; Marzocchi et al., 2007; Neri et al., 2008). Nevertheless, the communication of the findings in a way that is useful and meaningful to the community stakeholder remains a challenge (e.g., Johnston and Ronan, 2000) (see *Risk Perception and Communication*). The concept of uncertainty (see entry *Uncertainty*) remains a major difficulty to overcome.

Summary

The most significant volcanic eruptions of the last 50 years have led to great advances in understanding how volcanoes work. Nevertheless, there is still a great deal to be done in terms of short-term forecasting of eruption onset and dynamic changes in an eruption, understanding how eruptions are triggered and sustained, and how magma is supplied to the surface, and improving multiparameter monitoring to track magma movement and to identify when unrest will become an eruption. Recognizing all potential hazards and delineating the likely impact areas of pyroclastic flows, surges, and lahars in particular remains an elusive goal with potential for more sophisticated modeling.

In order to reduce volcanic risk, baseline monitoring at the very least should be established at all volcanoes with potentially at-risk populations. During periods of dormancy, scientists, policy and decision makers, emergency managers, and communities potentially at risk can build relationships, knowledge, and preparedness planning. The importance of effective communication between these groups cannot be understated (see *Risk Perception and Communication*).

The concept of "multi-hazards" requires a more holistic view of volcanic hazards. For example, heavy rainfall is known to trigger collapse of lava domes, and hence planning for a hurricane should include preparation for a possible concurrent volcanic collapse, lahars, landslides, and tsunami.

The planet is undergoing significant rapid environmental change at the same time as great population growth; so it is urgent that we understand the short- and long-term effects and consequences of volcanic activity in order to mitigate the risk (see entry *Risk*) as far as we can (Sparks and Aspinall, 2004). We need to appreciate our vulnerability (see entry *Vulnerability*) in the face of volcanic hazards and reduce that vulnerability wherever possible.

VULNERABILITY

Susan L. Cutter
University of South Carolina, Columbia, SC, USA

Synonyms

Exposure; Susceptibility

Definition

Vulnerability is potential for harm or loss.

> The characteristics and circumstances of a community, system, or asset that make it susceptible to the damaging effects of a hazard (ISDR 2009:30).

Introduction

Vulnerability is a key concept in natural hazards and disasters research. It is used to describe the potential for harm or loss in a physical system (e.g., erosion of beaches, glacial melting); the fragility of the built environment and infrastructure; or the susceptibility to harm in social and economic systems. Vulnerability can be studied at the individual level, for example, an individual person, a house, a bridge. It can also be aggregated to the group level to study the vulnerability of low-income populations, commercial establishments, and infrastructure systems such as the transportation networks. Vulnerability can also be examined spatially with a focus on particular places such as communities, regions, or nations. From the spatial vantage point, vulnerability examines the potential for harm at the place as a function of the intersection between the built environment and infrastructure, social and economic systems, and physical systems (Cutter, 2010).

Moving from risk-hazards to vulnerability

There is a rich multidisciplinary tradition that focuses on disasters, risk, and hazards. As noted elsewhere in this volume, natural hazards arise from the interaction between society and natural systems (earthquakes and tsunamis, for example). Risk is another widely used term, and here we use it to define the likelihood of incurring harm from a particular hazard event. This risk–hazard concept permeated the early work in the field and has now given way to vulnerability, which recognizes the degree to which an individual or system is likely to experience harm to due to some exposure from natural, technological, or human-induced sources (National Research Council 2007).

While there are numerous definitions, frameworks, conceptual models, and assessment techniques used for understanding vulnerability (Turner et al., 2003b; Wisner et al., 2004; Kasperson et al., 2005; Adger, 2006; Eakin and Luers, 2006) several common principles or understandings have emerged. First, vulnerability is examined from a social-ecological perspective. In this viewpoint, natural processes by themselves do not create hazards, rather it is the intersection with human system that produces the potential for harm, and ultimately the vulnerability to the natural hazard. Second, there is a clear recognition of the importance of place-based studies in examining vulnerability. Finally, vulnerability is seen as an equity concern, who is vulnerable is equally important as what is vulnerable. There are three important concepts emerging in the vulnerability literature: exposure, sensitivity, and resilience. Exposure primarily relates to the proximity to the source of the threat and environmental characteristics. Sensitivity focuses on the characteristics of individuals, social groups, or places and examines the differential susceptibility to harm. Resilience pertains to both the physical system and the social system and is used to describe the coping capacity of individuals, communities, or places, and their ability to respond and recover after a hazard event (Wood et al., 2010).

There are differences in the literature on the underlying causes of vulnerability. For some, the causal structure is exposure to the hazard, which is often measured in terms of proximity (Alexander, 1993). A different perspective suggests that vulnerability is caused by the underlying social conditions that give rise to unsafe conditions (Wisner et al., 2004). The third perspective incorporates elements from both. This view suggests that vulnerability includes both the exposure from the physical system, and the social response and how these are produced locally to create hazardousness of places (Hewitt and Burton, 1971; Cutter et al., 2000; Turner et al., 2003b).

Vulnerability assessments

A solid body of evidence exists on how vulnerabilities in physical systems interact with social conditions to produce hazard vulnerability (Birkmann, 2006). Many of these examine single stressors such as drought (Polsky, 2004) or earthquakes and tsunamis (Rashed and Weeks, 2003; Wood et al., 2010), but multi-stressor vulnerability assessments, while more difficult, are slowly emerging (O'Brien et al., 2004; Boruff and Cutter, 2007). In each case, the assessments begin with an understanding of the interactions between physical systems, human systems, and the built environment, and how these vary locally – the differential exposure of people and places to natural hazards.

Practical applications

The value of vulnerability assessments for emergency preparedness is increasing as local, regional, and national governments are more focused on risk reduction in preparedness and planning. The delineation of hazard zones (exposure) has a long tradition within the research community and as the science of hazards improves as well as our computational power, we are increasingly adept at mapping such high-risk zones from the perspective of the threat. However, the science of vulnerability vis-à-vis social vulnerability is less advanced. Social vulnerability frames hazards and their impacts within broader social contexts (Tierney, 2006; Laska and Morrow, 2007) and is equally important in understanding the differential impacts of natural hazards on people and places (Yarnal, 2007; Zahran et al., 2008). Yet, the development of social vulnerability metrics and models is still in its infancy. There are a variety of social vulnerability indices available, among the most significant are the Prevalent Vulnerability Index (PVI) developed by Cardona and colleagues (http://www.iadb.org/exr/disaster/pvi.cfm?language=EN&parid=4); the Environmental Vulnerability Index (EVI) developed by South Pacific Applied Geoscience Commission (SOPAC) (http://www.vulnerabilityindex.net/); and the Social Vulnerability Index (SoVI) developed by Cutter and colleagues (http://webra.cas.sc.edu/hvri/products/sovi.aspx).

Conclusion

The study of vulnerability to natural hazards is one of the emerging fields within the hazards and disasters community. New advancements in our conceptual understanding and measurement are rapidly occurring. The need for such information is critical as localities and nations cannot develop disaster risk-reduction strategies in the absence of knowing who and what is most vulnerable.

Alerting system; Early warning systems; End-to-end warning system; Immediate warning system; Short fuse warning

Definition

A *warning system* is a network of interrelated sensors and processes that detect signals of a possible or imminent dangerous event and provide *information* that people can use to make protective action decisions before the moment of impact.

A *natural hazard warning system* is usually technology based, monitors signs of a natural hazard, evaluates the signs against rules and notifies people, triggering a human response.

End-to-end warning systems consider, or are owned by, responding communities.

Early warning systems are often synonymous with warning systems.

Public notification systems are the mechanisms by which the public are notified within a warning system.

Natural warnings are provided by nature. They are often synonymous with *environmental* cues, but are distinguished from them in that some geological or meteorological phenomena, for example, serve as a warning of an event, whereas other phenomena serve only as a cue that an event may occur.

Informal warnings are provided by people not acting in an official warning capacity (e.g., a friend calling another friend to alert them of a dangerous event).

Official warnings are provided by people acting in an official warning capacity.

Social warnings or social cues are provided via observations of other people's behavior.

Introduction

Warnings are a natural part of everyday life for humans. When we detect fear or pain our built-in biological warning system is letting us know something unusual is happening and that it may be detrimental to our health. *Natural hazard warning systems* are usually technological, designed to detect hazardous events and inform us of those events in a time frame that permits us to take protective action, perhaps through evacuation, sheltering, or protecting property (see Lindell and Perry, 2004). The use of a canary to detect gas in a coal mine is one early and well-known warning system. In this case, a miner's canary encapsulates two core components of most warning systems: monitoring (canary biology) and notification (the canary stops singing). Warning system research has increasingly recognized the need for "people centered" warning systems (summarized by Basher, 2006), which are not considered effective unless they trigger appropriate human behavior. This requires that the hazard detection and monitoring aspects of a warning system be integrated with emergency management and the public. Such an integrated warning system focused on reaching at-risk communities, ideally managed and owned by those communities, is often referred to as an "end-to-end" warning system.

A warning system is only as effective as its weakest link. That is, a failure of one component may render the whole system ineffective. An effective warning system requires the integration of several features of warnings in

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

the design of the system. These include (a) Standard Operating Procedures (SOPs) of scientists and emergency managers, (b) channels of message dissemination, and (c) public response (Sorensen, 2000). Redundancy, especially in communication and notification technologies and SOPs, reduces the chance of a broken link. Warning systems that are solely "hardware based" with no focus on community response or participation have proven ineffective.

Warning systems and risk management

Warning systems are one *risk management* option available to reduce the *risk* posed by a *hazard*. It is therefore advisable to complete a *risk assessment* before embarking on developing a warning system. A 100% reliable warning system does not exist for any hazard, which leaves some level of residual risk (Sorensen, 2000). This is especially true in the case of infrequent, difficult to detect, or short lead-time hazards. Development of a warning system may also increase risk by perpetuating the occupation of marginal land (Sorensen, 2000). A flood warning system, for example, may encourage development in the floodplain where it would otherwise not be desirable. *Land use planning* and *structural mitigation* are additional risk reduction options, which for some hazards have the potential to remove the risk entirely. For example, in the case of land use planning, if a hazardous location is not developed or otherwise occupied then risk is reduced or eliminated. In such a situation, no warning system is needed. Some combination of land use planning, structural mitigation, and warning systems is often recommended to maximize risk reduction and use of land. Increasing development and population growth in coastal areas and increasing diversity in global travelers, especially visitors to coastal areas, demands that warnings are issued for multiple languages, a point underscored by the loss of life of visitors from some two dozen countries in the 2004 Indian Ocean tsunami. This requires additional complexity in warnings and other risk communications.

Monitoring, forecasting, and prediction

A warning system is dependent upon reliable *detection and monitoring* of an event or hazardous processes. In order to provide maximum response time, a warning system is designed to detect a change in a monitored parameter and provide a clear indication (forecast or prediction) when a hazardous event is expected to occur. Warning for natural hazards relies on lead-time between detection of a precursory sign(s), or the event or hazards themselves, and the impact of the hazard. Longer lead-times correspond to improved decision making, notification, and human response. The "lead-time" of a hazard varies considerably across hazards. For example, hurricanes have a particularly long lead-time measured in days, whereas earthquakes have little lead-time, often measured in a few seconds at best. Onset of the hazard event must be able to be predicted with a degree of certainty, and within a relatively small time window, to be of use in decision making concerning response. Some hazards, such as earthquakes, can only be predicted to within decades or centuries. Although this is not considered to be a traditional warning system, it can be very useful to inform other risk management strategies with enough time for changes, such as land use planning, to be implemented (Sorensen, 2000).

Hazards with warnings

A given warning system is often proposed and developed for a single natural hazard, despite the fact that most communities are exposed to multiple hazards. Warning systems and other risk management strategies should be considered in an all-hazard context wherever practical to achieve maximum community resilience (Paton, 2003). Only a few hazards regularly have no currently detectable precursors: earthquakes; dry landslides; landslide-induced tsunamis; and mud volcanoes, for example. Other hazards usually have detectable precursors, but in some cases such as small volcanic eruptions, the precursors are below detectable levels. Warnings based upon the onset of the hazard event itself, as opposed to a precursor, are theoretically possible for all hazards. These post-onset warning systems have typically short lead-times with the extreme case being earthquakes. Several countries (e.g., Mexico City, Japan, USA, and Taiwan) have implemented or are testing an earthquake warning system that gives seconds of lead-time once an earthquake is detected by issuing warnings after non-damaging seismic Primary waves are detected but in advance of the damaging Secondary and Surface waves (Cyranoski, 2004). This may provide sufficient time to shut down critical infrastructure such as trains or gas lines, or start alternate generators in hospitals and for people to drop, cover and hold. Such warnings are more likely to be useful with increasing distance from the epicenter, but only up to a distance where the intensity of ground shaking is potentially damaging. It is not very useful for near source areas because the time between the arrival of the Primary waves and subsequent damaging waves is too short.

Decision to warn

For a warning system to notify the public, a specific warning message needs to be generated and a notification disseminated. Issuing a warning notification requires that a criteria or threshold within monitored parameters must usually be reached. Such criteria often include geographic location and magnitude, or the expected intensity. Determination as to whether or not the criteria have been met must be rapid, but some decision time is nearly always needed and this should not be underestimated. The most effective warning system will minimize the frequency of warnings for events that either do not happen or are much smaller in magnitude or intensity than expected. Emergency managers are often overcautious of the potential to "cry wolf." However, research has shown that only repetitive false alarms will begin to reduce human behavioral response rates, as long as the reason for false alarms

is disclosed by officials and understood by recipients (Dow and Cutter, 1998).

Interpretation of initial data for the purpose of evaluating whether an event will actually occur may have high uncertainty. As time progresses more data often become available; but the time until the impact of the event is also reduced during this time. There is a minimum time period before an event within which a warning must be given if it is to achieve the expected response actions, such as evacuation of a population. Setting criteria for the decision to warn involves a trade-off over time between decreasing uncertainty or error and decreasing the time remaining to respond once a warning is issued. These criteria influence critical response actions such as evacuation. Emergency managers often find the criteria particularly difficult to set. This can be compounded in cases where a decision is either "yes" (evacuate) or "no" (do not evacuate), because scientists usually often provide information to emergency managers in the form of probabilities. Decision support systems, with preplanned probability thresholds and critical timeframes, reduce the time required to make decisions and issue warnings or evacuations.

Dissemination of warning messages

The process of detecting and monitoring a hazardous event and disseminating a notification requires time, which must be allowed for when planning response times. Notifications are usually technological and sent through telephone, radio, television, etc., but warnings may also be perceived directly from natural processes in one's environment. With the correct prior knowledge, a wide range of natural phenomena can be interpreted by members of the public either as a warning of an imminent event or as a cue to simply be alert. These notifications are termed "natural warnings" or "environmental cues" and include earthquake-generated ground shaking preceding the arrival of a tsunami and heavy rainfall or a high rate of *river stage* rise preceding a flood. If the time between onset of precursor signs and a hazard is too short for official warnings to be issued or if a warning system does not exist or fails to disseminate a warning message, natural warnings or environmental cues may be the only warning (Gregg et al., 2007).

Warnings from one person to another can be classed as either "official" or "informal." Official warnings are those communicated by people acting in an official capacity to do so. They are preplanned and the most likely to be accurate. Informal warnings are warnings communicated by individuals not acting in an official capacity. They may increase the reach of, or occur in place of, official warnings (which may have failed or been too slow to be useful). Informal warnings are often diffused through a population in advance of official warnings (Sorensen and Mileti, 1989; Gregg et al., 2007). Because natural warnings or environmental cues sometimes provide the first and only warning of an event and informal warnings are often received before official warnings, it is significant that those developing official warning systems understand how receipt of different warnings and cues in time and space influences response.

Technological notification systems can be grouped into either "third party" systems that are usually used for a non-warning-related purpose or "dedicated" systems that exist for the specific purpose of warning notification, such as those used in industrial settings where hazardous material is handled. There are wide ranges of warning notification technologies available and new possibilities continuously emerge.

Third party systems include:

- Radio and television station broadcasts
- Break-in broadcast
- Landline telephone
- Mobile telephone/device (Short Message Service (SMS) text message, broadcast, multicast)
- Pagers
- Websites
- Inserted website banners
- E-mail
- Emergency responders and their hardware (e.g., route alert with car/appliance loud-hailers)
- GPS receiver messaging
- Power-line messaging
- Loudspeakers (e.g., those separately used for public address or prayer calls)

Dedicated systems include:

- Tone-activated alert radio
- Private radio
- Sirens
- Flares and explosives.

The advantage of third party systems is that they are often self-maintaining and self-testing through regular use (e.g., telephones). Dedicated notification systems generally have a higher rate of failure, unless very regularly tested in realistic conditions and designed with redundancy (Gruntfest and Huber, 1989). Notifications that catch a person's attention even though they are focused on something else (e.g., telephone or siren) are more effective than those where the target person will only get the message if they are actively using the notification pathway (e.g., watching television, viewing a website). A person's location and activity changes throughout the day, so one notification technology that might reach them at work might not reach them while they are recreating or asleep at home. Warnings at night are also more slowly disseminated and acted upon (Sorensen, 2000). Transient populations, especially tourists, may need notification via different means than local residents. This can be accentuated from season to season as tourists visit coastal areas in summer months or snowy mountains in winter months.

Weather conditions can alter the effectiveness of a system. Loud-hailers are harder to hear in wind, and cold weather may mean more people are inside insulated from outdoor notification systems. Mobile technologies

provide an obvious opportunity to reach large numbers of people regardless of their location. SMS text messages have been used to warn of many hazard events in recent years, with mixed success. Generally, delivery time may increase as the number of messages increases, and delivery is not guaranteed (Sillem and Wiersma, 2006). Lists of phone numbers need to be created through either a voluntary preregister, with typically very low uptake, or generated for an area at the time of warning, which introduces a further time lag. Mobile "cell broadcast" and "multicast" protocols can be implemented to send a message to all devices on that network in a geographic area. The advantages over SMS appear to be high speed, low traffic volume, geographic control, and avoidance of requiring phone number lists. These protocols are currently being tested (e.g., Sri Lanka, Samarajiva and Waidyanatha, 2009; Netherlands, Jagtman, 2010). Break-in broadcasting takes precedence over standard radio and television channels via an automated protocol. In the United States this is a cornerstone of the Emergency Alert System and is mandated by legislation. Land-line telephones, when used in warning systems, are usually utilized by auto-dialer equipment, by people enacting prearranged phone trees or as call-in phone lines. Computer control of notification systems has enabled greater speed and geographical control for many of the warning technologies listed, especially mobile and landline-based telephones (Sorensen, 2000).

Warning systems should also consider other populations with special needs including groups based on gender, age, language, and disability. For example, perceptual changes in older adults can impair their ability to notice warnings during the alerting phase, whereas limitations in cognitive abilities, such as text comprehension and memory, might limit their understanding in the decision-making and response phase. These issues also apply to other disabled groups, who may need special assistance to compensate for their physical and/or cognitive disabilities. Special consideration is needed for notification of institutional populations including hospitals, prisons, nursing homes, large worksites, and tourist facilities. Warning systems can specifically utilize community networks (e.g., church, ethnic social groups, volunteer fire fighters), capitalizing on their already-established communication networks and also aiding in reaching those who might otherwise be isolated (e.g., by geography, language).

Warning messages

The format and content of an official warning message is critical to its effectiveness. The most effective messages: are detailed, contain local information, are specific, explain the event, specify location, give instructions, are time-stamped with a time frame for the next message, are verifiable; come from a specific authoritative source, are frequent, and are consistent across notification media (Mileti and Beck, 1975; Lindell and Perry, 1983; Mileti et al., 2004; Sorenson and Mileti, 1989). Templates allow for consistent warning information to be given, reducing the chance that important content is forgotten. Data interoperability is of increasing importance to propagate a warning message through multiple technological systems. The Common Alerting Protocol (CAP; Oasis Open, 2005), for example, provides consistent machine-readable headings and metadata; therefore, a message generated by a CAP-compliant system can be propagated through and notified via all other CAP-compliant systems. Protocol-based interoperability reduces the chance of parts of the message being dropped or changed, increasing consistency of the message, as well as reducing any time required to retype and edit messages.

Education, participation, and response

Social aspects of warning systems are often underemphasized compared to the scientific and emergency management aspects. This focus on the science of detecting and monitoring hazards and the hardware and software linking scientists to emergency managers limits a system's ability to ultimately deliver messages to end-users or motivate the public to comply with warning messages (Sorensen, 2000; OEM and ODGAMI, 2001; Twigg, 2002; Mileti et al., 2004). For example, engaging community members at large in the development of warning systems, and maintaining adequate levels of public education about the dynamics of warning messages including expected human responses, seldom occurs. Passive education through brochures and advertisements has been shown to have only limited effect (Paton 2006). Community-based planning for effective warning responses is needed to help ensure that people understand messages and know what to do. For warning systems to be effective they must ensure that factors beyond knowledge and understanding are incorporated into education. Individuals first need to become motivated to confront hazards they face in their local environment, and then form intentions to actually make preparations. Improved preparedness is likely to result from enhancing community members' beliefs in the feasibility of successfully responding to a warning through personal actions (i.e., to counter beliefs that hazards have totally catastrophic effects) and enhancing beliefs in personal competency to implement these activities (i.e., self-efficacy). Changing these factors requires a mix of public education, social policy, training, and empowerment strategies. Full scale exercises that allow people to experience the breadth of warnings and response, such as that obtained during evacuation or sheltering drills, are rare. However, exercises are one of the most effective means of education and are most important for hazards with long time periods between events (years to decades).

Summary

Warning systems for natural hazards provide notification of potential hazard events through the monitoring of natural processes. Monitoring is usually technological with

a wide range of detection and notification hardware available and in use. Warning sources can be natural, informal, or official and if available time to respond is short, natural and informal warnings may be the only source of information before impact of a hazard. In recent years there has been an increasing focus on end-to-end warning systems, which focus heavily on community involvement, preparedness, and warning response actions. Response actions are usually to either evacuate or shelter in place, with the added complexity of sometimes protecting valuables. Decisions to disseminate a warning are often difficult to make, especially if the desired response is to evacuate, because as certainty of the onset or specifics of a hazard such as location, magnitude, and intensity increases over time the time remaining to respond decreases. The delivery and content of a warning message has been heavily studied and there are a range of characteristics of effective warning messages. Warning systems are often not fully effective, so they should be considered along with a range of risk management options, especially land use planning.

WATERSPOUT

Miquel Gayà
Agencia Estatal de Meteorología, Palma, Spain

Synonyms

Whirlwind

Definition

Waterspout is an intense vortex of air, linked to convection, with small horizontal dimension (tens of meters to a few hundred meters), which occurs on a surface of water, usually on the sea. With this definition, waterspouts are no different than tornadoes, except in the area on which they occur.

Discussion

Tornadoes and waterspouts can be formed in association with a supercell cloud (containing mesocyclone) or linked to a "fair" weather. When the vortex is generated by a supercell, its damage, intensity, duration, and path length normally increase. However, waterspouts usually are generated in an environment with weak convection, with low level unstable air, and in conjunction with a convergence zone that had an inherent vorticity. Because these convergent areas are very common close to shores, many waterspouts can be seen from the coast, sometimes reach land and continue inland as a tornado. Often, the land roughness perturbs and destroys one of the ingredients to form the waterspout and this new tornado vanishes quickly. The other essential ingredient to form a waterspout is the instability of the low-level atmosphere. This instability comes from a high lapse rate at low troposphere (difference of temperature between the air closest to the sea and 3,000 m height) and from its high moisture content.

Because warm seas provide the air its high water vapor, and also can produce a large lapse rate of temperature, such warm seas will be the most frequent waterspout generators. Thus, when cold air overrides a warmer sea, waterspouts can appear. For these reasons, the tropical and subtropical seas are those water surfaces with a high incidence of waterspouts. Still, sometimes waterspouts have been observed over cold waters if the unstable air is much colder. On the polar seas, such vortices cannot occur.

Waterspout, Figure 1 A waterspout over the Mediterranean sea, close to the coast of Formentera, Balearic Islands (Spain), on September 20, 2009 (Courtesy of Barbara Klahr).

Converging air intensifies its vertical vorticity when the condensation is produced. A convective cloud (not necessarily a *Cumulonimbus*) grows at the same time as the funnel cloud seems to be pendant: the waterspout is typically developed early in the *Cumulus* life cycle. When the parent cloud produces its first drops, the downflow can destroy the convergence line and the vorticity starts to diminish. Then, the waterspout initiates its last step before termination. If the conditions are similar, the front produced by the precipitation can generate another focus of convergence and the process of another waterspout can start again. Often, over the same convergence boundary or front, it can be possible to see a family of waterspouts.

Although the rough surface of the sea can be observed, the water itself is not lifted to the cloud. The funnel is a cloud of droplets produced by the condensation of the water vapor. The dimensions and the maximum velocity that a waterspout reaches can be dangerous to small boats or to ships. People may be displaced and thrown into the sea. The masts can be broken and the objects that were on the deck can become projectiles with fatal consequences (Figure 1).

CASE STUDY

WENCHUAN, CHINA (2008 EARTHQUAKE)

Zhengwen Zeng[1], Chenghu Wang[1,2]
[1]University of North Dakota, Grand Forks, ND, USA
[2]China Earthquake Administration, Beijing, China

Introduction

On May 12, 2008, at 14:28:04 (Beijing Time), an Ms 8.0 earthquake struck Wenchuan, a small county of Sichuan Province in southwest China. The quake lasted for about 18 s. The geographic coordinates of the epicenter were N30°57′ and E103°24′; and the focal depth was estimated at 14–19 km. The Wenchuan Earthquake sequences included one major shock (Ms 8.0) and many fairly large aftershocks (Yuan, 2008). Within 3 months after the major shock, over 20 aftershocks exceeded Ms 5.4. The main shock and the aftershock sequences were scattered along the seismic faults, as indicated in Figure 1 (USGS, 2008; China Earthquake Administration Monitoring and Prediction Division, 2009).

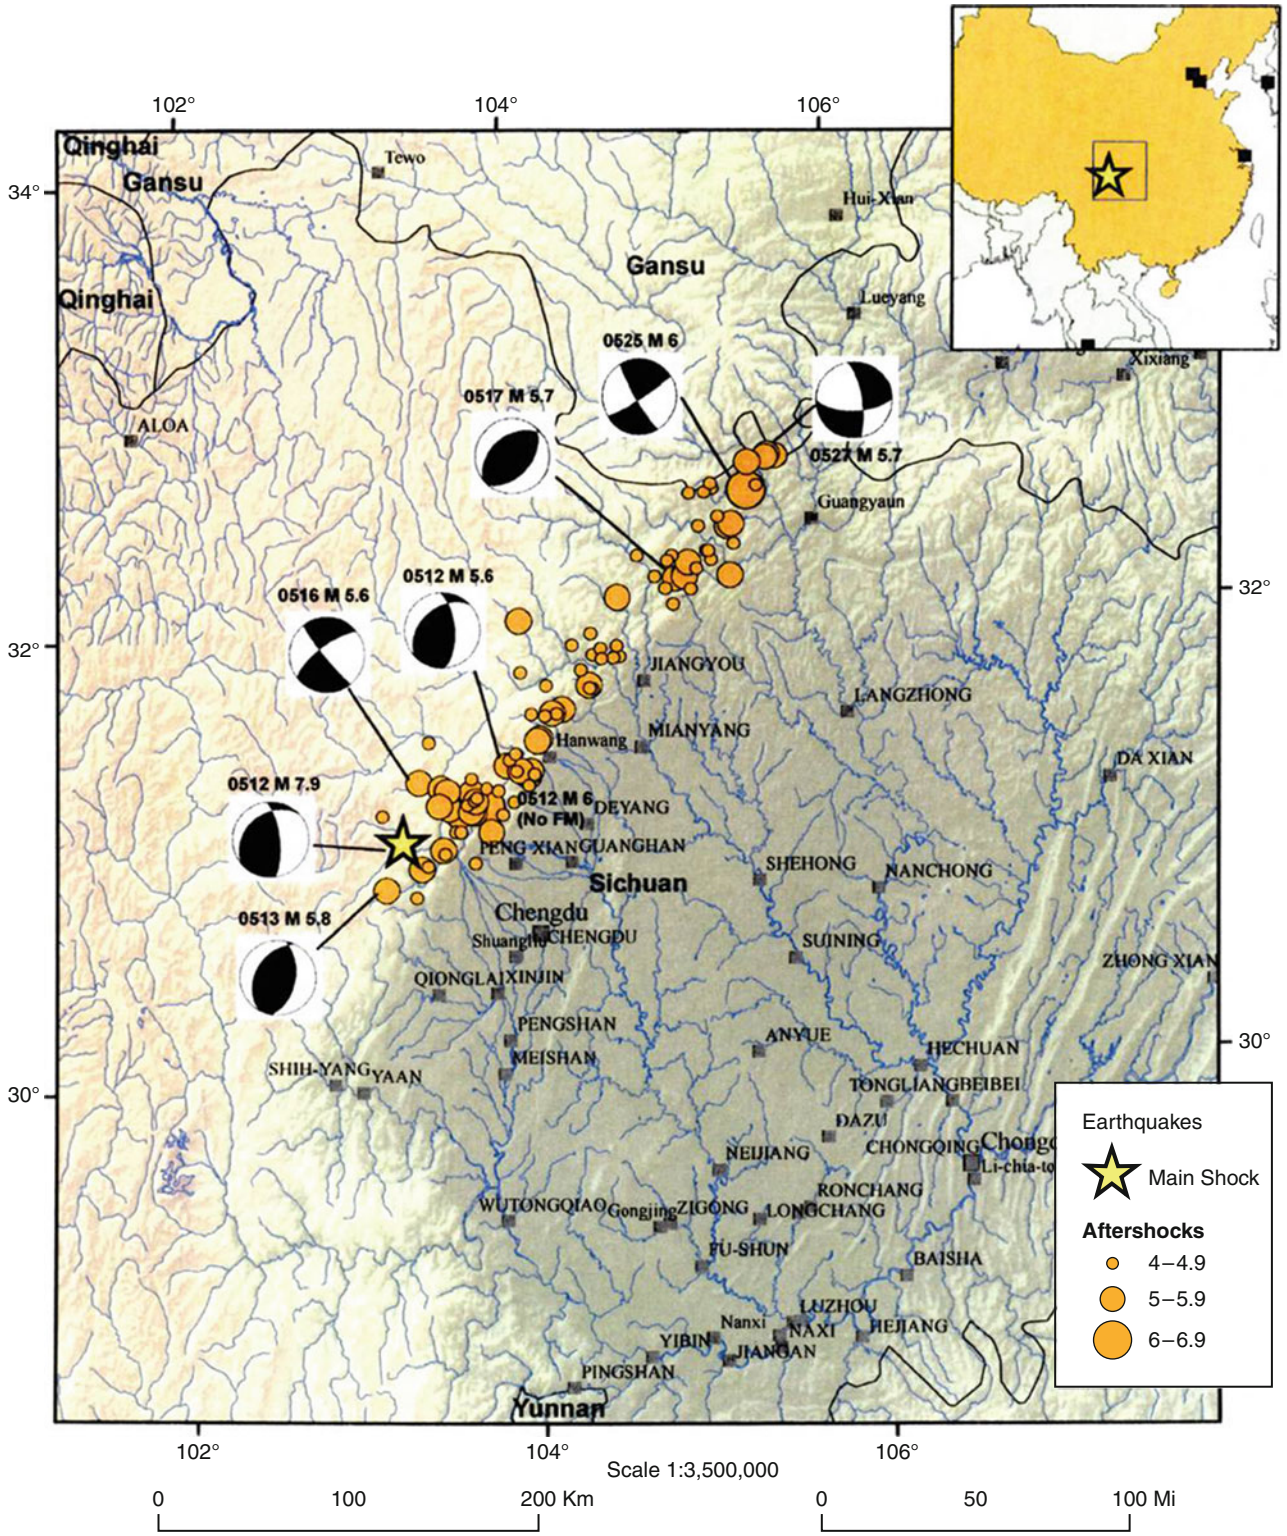
Geologically, the Ms 8.0 Wenchuan Earthquake occurred on the Longmenshan faulting belt, a large, active, partly strike-slipping, partly thrust-faulting belt in the middle of the north-to-south seismogenic zone and on the eastern edge of the Qinghai-Tibet Plateau in China. The instrumental epicenter was in the middle of the Longmenshan faulting belt, below Yinxiu Township at the west of Dujiangyan and the south of Wenchuan County (Figure 1). The northeast trending Longmenshan faulting belt belongs to a fault system that was formed by the Mesozoic orogenesis. It is 500 km long and 40–50 km wide. The fault belt starts at Luding and Tianquan, at its southwest end, passes through Baoxing, Guanxian, Jiangyou, and Guangyuan, all in Sichuan Provinces, and finally enters into Ningqiang and Mianxian in Shaanxi Province at its northeast end.

The Ms 8.0 Wenchuan Earthquake created two new surface fractures inside the Longmenshan faulting belt, that is, the Wenchuan Earthquake fractures. The major surface fracture is over 250 km in total length, extending parallel to the middle and northern sections of the Longmenshan faulting belt. The secondary surface fracture extends along the Guanxian-Jiangyou fault of the Longmenshan faulting belt, with a discontinuous length of 90 km.

The Wenchuan Earthquake was shallow-focused, and thus caused significant damage and loss. The relative location of the earthquake epicenter inside China is shown in Figure 2. This earthquake affected almost all the population within a radius of 200 km around the surface epicenter. Except Heilongjiang, Jilin, and Xinjiang, all provinces in mainland China were shocked by this terrible earthquake, with Sichuan, Shaanxi and Gansu suffering the most. The shock was also felt in several countries in eastern Asia, including Thailand, Vietnam, Philippines, and Japan. Based on the Chinese Seismic Intensity Scale (CSIS), the intensity of the Wenchuan Earthquake is shown in Figure 3 (China Earthquake Administration Monitoring and Prediction Division, 2009).

According to detailed investigations after the earthquake, the disaster area was classified into four categories of damage: (1) extremely severe, (2) severe, (3) heavily affected, and (4) slightly affected (National Disaster Relief Commission, 2008). The distribution of the four categories and the demographical statistics are shown in Table 1.

Casualties

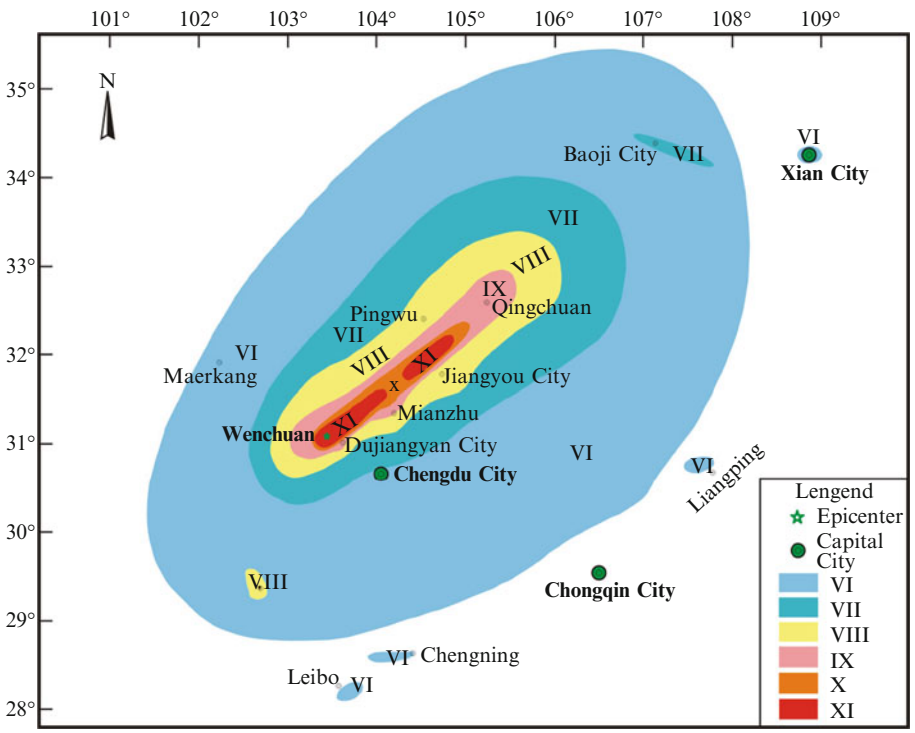


As of May 5, 2009, 69,220 people died, 374,643 people were injured, and 17,923 people were missing as a result of the Wenchuan Earthquake. The casualty statistics of each province are shown in Table 2 (National Disaster Relief Commission, 2008). Table 3 indicates the extent to which the extremely severe areas suffered in the categories of casualties and building collapses (National Disaster Relief Commission, 2008).

Economic losses

The Wenchuan Earthquake caused a direct economic loss of 845.14 billion RMB, approximately US$122.85 billion (2008 dollars) (National Disaster Relief Commission, 2008). Among all the losses, Sichuan Province suffered the most, accounting for 91.3% of the total losses; Gansu Province accounted for 5.8%; and Shaanxi Province accounted for 2.9%. The combined losses of other provinces were about two billion RMB (US$0.29 billion).

Among all the losses, buildings and infrastructures accounted for the most, up to almost 70% of the total losses. Ranked by the percentage share of the total losses, losses of civil buildings were ranked the first, at 24.7% of the total losses; infrastructure, including roads, bridges, and other municipal facilities, ranked second at 21.9%. Nonresidential buildings, including schools, hospitals, and other public buildings held third at 20.4% of the total losses.



The direct economic losses of the disaster areas comprised 2.81% of China's GDP in 2007. The losses of Sichuan Province alone accounted for 58.80% of the provincial GDP in 2007, and 2.51% of China's total GDP.

Earthquake prediction and preparation

Seismic zoning and earthquake preparation

China's Code for Earthquake Resistant Design of Buildings and the Seismic Zoning Map (State Seismological Bureau, 1992) have been put into force to set standards for the buildings and infrastructures all over the country, but adherence to these codes and regulations were not compulsory in less-developed areas until 2006 because of economic factors. Before this earthquake, these codes and regulations set the maximum seismic intensity at CSIS VI for all the extremely severe disaster areas and at CSIS VII for a few of the more potentially severe disaster areas (Shi and Li, 2001), because there had been no large earthquakes in this area before these codes was established.

According to these earthquake resistant design codes, infrastructure in areas of CSIS VI and below would be built with no earthquake-resistant design. Earthquake-resistant design was only mandatory in areas of CSIS VII and above. Therefore, seismic resistant capabilities of buildings designed by such standards would not have met the required strength to withstand such a shallow focused Ms 8.0 earthquake.

Earthquake prediction

Whether the Wenchuan Earthquake was predicted or not aroused many controversies and rumors in both international and Chinese societies. Unlike the 1976 Tangshan earthquake in China, the middle section of the Longmenshan faulting belt – the meizoseismal area of the Wenchuan Earthquake – had been considered inactive before this earthquake according to analyses of Chinese mainstream earthquake experts. Compared with the middle section of the Longmenshan faulting belt, the Xianshuihe faulting belt, the Anninghe-Zemuhe-Xiaojiang faulting belt, and the Songpan-Ganzi faulting zone in the southwest China had more tectonic activities, and attracted much more research attention; thus, many seismic monitoring measures and research efforts were applied to those areas. However, prior to the Wenchuan Earthquake, a few Chinese specialists and American experts did give a fairly accurate middle-term prediction for the possible earthquake, and some advice for future research. Unfortunately, such predictions and research findings were not accepted by the mainstream earthquake experts in China. Obviously, earthquake prediction is still not an exact science and remains an unsolved world-class challenge. A large gap still exists between the actual problem-solving ability of scientists and the need for community disaster preparation.

Emergency responses and relief measures

After the occurrence of the Wenchuan Earthquake, the Chinese government immediately began an emergency rescue and relief program (China Earthquake Administration, et al., 2010). Headquarters for victim rescue and disaster relief were established all around the affected areas.

According to statistics issued by the Headquarters at the State Council, all relevant ministries and organizations of the Chinese central government had allocated a large amount of resources and exerted many efforts during the disaster relief campaign. As of May 24, 2008, the Headquarters had mobilized 111,278 soldiers, 22,970 armed policemen, 24,401 special policemen, 4,000 specialized earthquake rescue workers, 88,341 medical workers, and 6,013 volunteers to help in the disaster areas. As of June 14, 2008, the central government and the local governments had allocated 1.31 million tents, 4.82 million quilts, 14.09 million articles of clothing, 1.04 million tons of liquid fuel, and 2.23 million tons of coal to the disaster area. As of August 4, 2008, the central government and the local governments had devoted 64.16 billion RMB to the disaster areas, and about 59.41 billion RMB was received from public and private donations for the disaster relief.

After the occurrence of the Wenchuan Earthquake, the international society expressed its sincere sympathy to the Chinese people through the central government, together with various kinds of support. As of July 18, 2008, the Chinese Ministry of Foreign Affairs and other Chinese embassies and diplomatic missions all over the world had received about 1.71 billion RMB in donations, including 0.77 billion RMB from foreign governments, international, and regional organizations; 1.99 million RMB from foreign embassies, diplomatic missions, and individuals in China; and 0.94 billion RMB from foreign civilian organizations, foreign enterprises and individuals, overseas Chinese, Chinese scholars and students living overseas, overseas branches of China-based companies and organizations, and other individuals.

Recovery and reconstruction after the earthquake

One month after the Wenchuan Earthquake, the Chinese central government began to implement recovery and reconstruction work by establishing basic guidelines (Wen, 2008). At the same time, the relevant ministries jointly issued specific instructions to direct the recovery and reconstruction work. In September 2008, the State Overall Planning for Post-Wenchuan Earthquake Restoration and Reconstruction (SOP) was issued (State Planning Group, 2008).

According to the statistics issued by the China Ministry of Finance, by May 4, 2009, the Chinese central government had supplied almost 85 billion RMB to the disaster area for the recovery and reconstruction. By the end of 2009, 160 billion RMB from the central government and 17 billion RMB from the provincial government were allocated to the affected areas in Sichuan province. In addition, a total of 250 billion RMB was available from other provincial governments through the "Twin Assistance" program, social donations, contributions from Hong Kong, Macao, and Taiwan, and rehabilitation funds from the county and city governments of the affected areas.

Following the SOP, 29,704 recovery and reconstruction projects were planned for Sichuan Province, the worst-struck province, including 1,500,000 rural dwelling houses, 259,000 urban dwelling houses, 3,002 schools, 1,362 medical and health institutes (including hospitals), and 38 towns and cities.

As of March 2010, 95% of these projects were being implemented, and 74% were completed; special efforts were made to care for the most vulnerable groups (China Earthquake Administration, et al., 2010).

Parallel to the Chinese central government's efforts, recovery projects assisted by international loans were also being implemented. The World Bank loaned a total of US $710 million to the Chinese central government for recovery and reconstruction projects in Sichuan and Gansu Provinces for a period of 5 years from March 2009 to March 2014 (World Bank, 2009). As of June 2010,

US$116 million had been disbursed for infrastructure, health, and educational projects (World Bank, 2010). One year later, the cumulative disbursement reached 35% of the total loan, and the progress on the project was moderately satisfactory (World Bank, 2011).

In March 2012, the Chinese central government announced that the SOP recovery and reconstruction tasks were completed; the basic working and living conditions and the level of economic and social development in the disaster areas were significantly better than that before the earthquake (NDRC, 2012).

WILDFIRE

Brigitte Leblon, Laura Bourgeau-Chavez
University of New Brunswick, Fredericton, NB, Canada

Synonyms

Burn; Bush fire; Fire; Forest fire; Natural fire; Wildland fire

Definition

A wildfire is an unplanned or unwanted natural or person-caused fire occurring in a natural setting or wilderness (Merrill and Alexander 1987: 44). A fire is a simultaneous release of heat, light, and flame generated by the combustion of flammable material (Merrill and Alexander, 1987: 12). It requires the so-called fire triangle elements: fuel, oxygen, and a heat source. Naturally occurring wildfires are less frequent than man-made wildfires, but usually burn large areas.

Types of wildfires

Several types of wildfires can be defined as a function of the fuel layer involved:

Type	Fuel layer	Remark
Ground or *subsurface*	Below the litter layer of the forest floor (duff, roots, buried punky wood, peat)	Difficult to detect
Crawling or *surface*	Low-lying vegetation (leaf and timber litter, debris, herbaceous vegetation, low-lying shrubbery)	Control depends on the type of fuels involved
Ladder	Between low-level vegetation and tree canopies (medium shrubs, tree seedlings, stumps, small trees, downed-dead logs)	Control depends on the type of fuels involved
Crown, canopy, or *aerial*	Suspended combustible material at the canopy level (tree crowns, vines, mosses)	Difficult to control because it depends on wind; Three types can be defined depending on whether it is dependent or independent of a surface fire
Spotting	Firebrands that are thrown ahead of the main fire by the wind	Difficult to control because it depends on wind

Fire regime

Fire regime refers to the general type of fire activity and pattern of burns that characteristically occur in a given region. Some important elements of fire regimes include fire frequency, fire intensity, type of fire, and burn severity (Merrill and Alexander, 1987). Fire regimes can range from low-intensity, high-frequency surface fires to high-intensity, low-frequency stand-replacing fires. The fire regime is determined by fire climate, lightning incidence, physiography, ecosystem type, and a balance between dry matter production and decay.

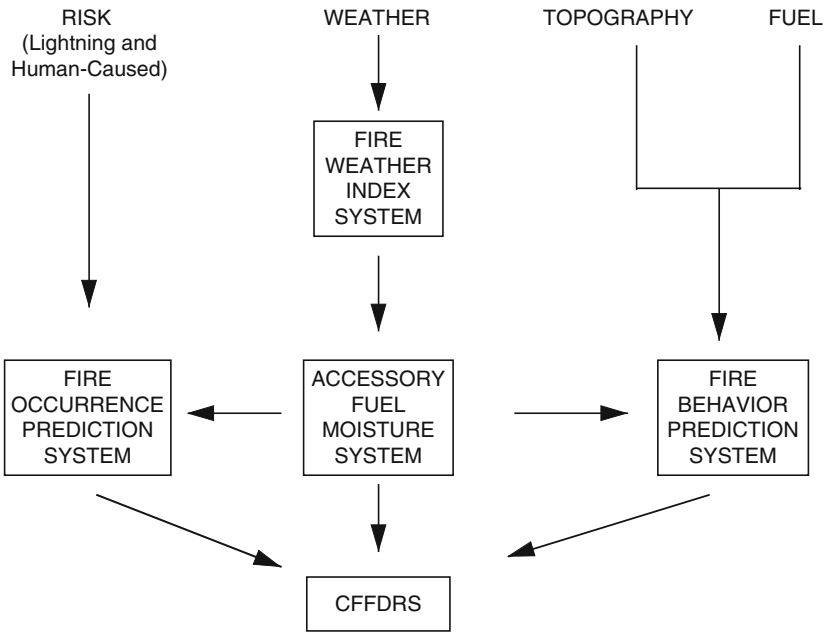
Fire risk, hazard, and danger

Ignition and spread of wildfires depends on four main types of factors (Leblon, 2005):

1. The state and nature of the fuel: proportion of live and dead vegetation, compactness, morphology, species, density, stratification, fuel arrangement, continuity of fuel, and moisture content;
2. The physical environment: weather conditions and topography
3. Causing factors: human or nature (lightning)
4. Fire prevention and suppression means

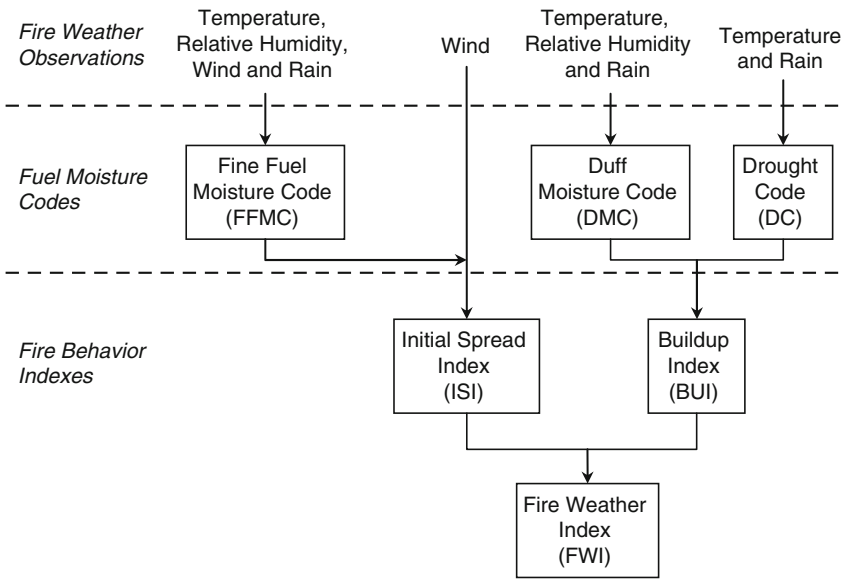
The first two factors define *fire hazard*, whereas the last two factors define *fire risk*. *Fire danger* includes both hazard and risk.

Fire danger rating systems



Wildfire is the one of the dominating disturbances in the world's forests and grasslands. Wildfire is part of the natural cycle. For some species, it is necessary to their reproductive cycle. For example, jack, pitch, red, yellow (ponderosa), and lodgepole pines, as well as sequoia and black spruce store for years live seed in their crown cones that are glued by resin. The resin will melt by heat from a fire, allowing the cone opening. Seed germination for red and white pines, white spruce and Douglas fir require ground that has been exposed by fire creating a good seed bed. Exposure to fire smoke promotes seed germination in some plants, like *Eragrostis tef (Zucc.) Trotter*, by inducing production of butenolide (3-methyl-2H-furo[2,3-c]pyran-2-one) (Ghebrehiwot et al., 2008). Despite their ecological benefits, wildfires can also become a threat to property, human life, and economy. For this reason, fire danger predicting systems have been developed for use in fire management, among others for fire suppression. Among others, there are the National Fire Danger Rating System (NFDRS) in USA (see the review of Hardy and Hardy, 2007) and the Canadian Forest Fire Danger Rating System (CFFDRS) in Canada (Van Wagner, 1987; Stocks et al., 1989; Taylor and Alexander, 2006). The CFFDRS is also used in Alaska and in some other parts of the world (see the review of Taylor and Alexander, 2006). It is a semiempirical modular system that has the structure shown in Figure 1.

The relative mid-afternoon fire potential is rated using the Fire Weather Index (FWI). It represents the intensity of a spreading fire. It is computed daily from noon standard time weather records (dry-bulb temperature, relative humidity, 10 m high open wind speed, 24-h precipitation), by one of the *CFFDRS* subsystems, the Fire Weather Index (FWI) system. It considers, as forest type, a generalized pine forest similar to the jack pine and lodgepole pine forest, but three fuel layers (Van Wagner, 1987; Stocks et al., 1989), each of them being characterized by its moisture content represented by a code: (1) *Fuel Moisture Code (FFMC)* for the 1–2 cm depth fine surface litter and other cured fine fuels (mosses, needles, small twigs) having a time lag of 2/3 day (16 h); (2) *Duff Moisture Code (DMC)* for the loosely compact duff of moderate depth (5–10 cm) having a time lag of 15 days; and (3) *Drought Code (DC)* for the deep (15–20 cm) compacted duff layer (organic matter of the soil, large logs) having a time lag of 52 days. *FFMC* determines the potential for fire ignition, *DMC*, the resistance to control of fire and the ability of the fire to spread, and *DC*, the seasonal drought, the smoldering in deep duff or large logs and the resistance to extinguishment and ability to mop-up. These fuel moisture codes are combined into two fire behavior indices: (1) *Initial Spread Index (ISI)* representing the relative fire spread expected immediately after ignition and (2) *Build-Up Index (BUI)* indicating the total amount of fuel available for combustion by a moving flame front. It is used in pre-suppression planning, indicates fire's resistance to control. *ISI* and *BUI* are combined together to produce *FWI* (see Figure 2).

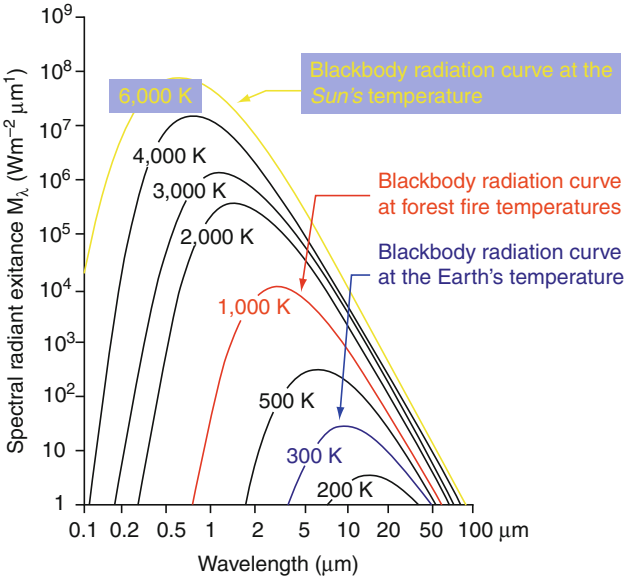


Another *CFFDRS* subsystem, the *Fire Behavior Prediction* (*FBP*) system, predicts the fire behavior in 17 specific fuel types (Stocks et al., 1989; Forestry Canada Fire Danger Group, 1992; Wotton et al., 2009).

Use of remote sensing in wildfire management

The availability of remote sensing technology coupled with the development of geostatistics and spatial analyses using geographic information technology allows moving fire danger rating from point-based estimates based on weather stations to spatially explicit estimates. Indeed, remote sensing has the advantages of larger sampling areas, lack of destruction of the studied resource, gathering data on less accessible areas and is representing, in essence, the integrated response of vegetation to environmental influences. Such a technology can be first used for fire danger monitoring. The first fire danger variable that can be derived from remote sensing is the fuel type, which can be mapped from high spatial resolution optical or radar images, as in classical land use (see the review of Leblon, 2005). Such maps can then be linked within a wildfire threat system, to other fire danger parameters, such as topography, proximity to roads and to urban areas (see the review of Leblon 2005). Fuel moisture is another fire danger parameter, which can be estimated by remote

Wildfire, Figure 1 The Canadian Forest Fire Rating System (CFFDRS) (After Stocks et al., 1989).



Wildfire, Figure 2 The Fire Weather Index of the CFFDRS (Adapted from Van Wagner, 1987).

sensing. Remote sensing–based fuel moisture monitoring has been done primarily using indices derived from *NOAA-AVHRR* normalized difference vegetation index (NDVI) images, like the *relative greenness* (Burgan et al., 1998) or the *Vegetation Condition Index* (Kogan, 1990). They were also used to estimate the degree of curing, which is an important fuel behavior variable for herbaceous fuel type (e.g., Paltridge and Mitchell, 1990). Thermal infrared data were better correlated than *NDVI* to fire danger codes (see the review of Leblon, 2005; Oldford et al., 2003; Oldford et al., 2006; Leblon et al., 2007) and to foliar moisture content (see the review of Leblon, 2005). There were also studies using indices that combine *NDVI* and thermal infrared *NOAA-AVHRR*

images, like the *Vegetation and Temperature Condition Index* of Kogan (2001) and the index of Chuvieco et al. (2001). However, both *NDVI* and thermal infrared images have limited image availability during cloudy days. By contrast, active microwave (or radar or Synthetic Aperture Radar (*SAR*)) images can be acquired in any weather conditions. Good correlations were obtained between *CFFDRS* fuel moisture codes and backscatter images from *ERS-1* (Bourgeau-Chavez et al., 1999; Leblon et al., 2002) or *RADARSAT-1* (Abbott et al., 2007) single-polarized SAR images acquired over boreal forests. The operational use of *SAR* images in fuel moisture monitoring is limited by the influence of interfering factors, including the type, species, structure, and biomass of the vegetation, as well as the topography and surface roughness (see the review of Leblon, 2005). It has been shown that polarimetric *SAR* images are better for estimating the surface roughness independently from the soil moisture and vice versa in the case of agricultural bare soils or crop canopies (Mattia et al., 1997; Hajnsek et al., 2003; Hajnsek et al., 2009). Polarimetric *SAR* images are provided by several existing satellites, for instance, *RADARSAT-2* and *ALOS-PALSAR*. These images are currently being tested for fuel moisture mapping in boreal forests of the interior Alaska (Bourgeau-Chavez et al., 2009). Fuel moisture mapping is not only needed for assessing fire danger probabilities, but also for post-fire regeneration assessment, because vegetation regrowth highly depends on soil moisture availability.

Remote sensing can also be used for detecting active fires. Such detection is based on the detection of either a smoke plume produced by fire emissions, hot surface temperatures above normal environmental temperatures, or hot surface temperatures with respect to the surroundings. Detection of smoke plumes is achieved by optical sensors that are sensitive to atmospheric interferences. The detection of hot surface temperatures due to wildfires is done first using satellite sensors (*NOAA-AVHRR*, *MODIS*) operating in the mid-infrared (3–5 μm) spectral window. Indeed, as shown in Figure 3, wildfires have surface temperatures around 1,000 K leading to a peak of the spectral radiant exitance around 3 μm. By comparison, the Earth has a surface temperature of 300 K (leading to a maximum of exitance around 9.7 μm) and the Sun has a surface temperature of 6,000 K (leading to a maximum of exitance around 0.5 μm). The thermal infrared (8–12 μm) spectral window can also be used, but confusion with the Earth exitance peak can occur. A detailed description of the methods used for detecting active fires on satellite images can be found in the review by San-Miguel-Ayanz et al. (2005).

Finally, remote sensing technology can also be used to map burn scars, either from optical images, such as LANDSAT-TM or SPOT-HRV or from *SAR* images. Burned areas are mapped on the image either as spectrally homogeneous areas that are distinct from the surroundings or by comparison of prefire and postfire satellite imagery. In the optical and mid-infrared spectral bands, burned

Wildfire, Figure 3 Spectral distribution of the emitted radiation of black bodies computed by Planck's law.

areas have usually a significant low spectral reflectance. Based on these observations, Fraser et al. (2000) designed the *Hotspot And NDVI Differencing Synergy (HANDS)* algorithm that uses *NOAA-AVHRR NDVI* and mid-infrared images to map burn scars. In their algorithm, the burned area mapping is helped by identifying potential active fires based on satellite-detected hot spots. However, similarly for other remote sensing applications, the use of optical and thermal infrared images is limited, when fire smokes or clouds mask the observed areas. For this reason, the use of single-polarized *SAR* imagery has been successfully tested both in the case of Mediterranean forests (Gimeno and San-Miguel-Ayanz, 2004a, b) and boreal forests (Bourgeau-Chavez et al., 1997). Both the optical and *SAR* images are also used for postfire regeneration assessment.

Summary

A fire is a simultaneous release of heat, light, and flame generated by the combustion of flammable material. The fire is a wildfire, when it corresponds to an unplanned or unwanted natural or person-caused fire, occurring in a natural setting or wilderness. Types of wildfires include ground, surface, ladder, crown, and spotting fires. Although wildfires have an ecological benefit for some species, they can also become a threat to property, human life, and economy. For this reason, fire danger predicting systems, including the National Fire Danger Rating System (NFDRS) in USA and the Canadian Forest Fire Danger Rating System (CFFDRS) in Canada, have been developed for use in fire management, among others in fire suppression. Fire danger is determined as a function of the state and nature of the fuel, of the physical

environment, of the causing factors, and of the fire prevention and suppression means. With the availability of remote sensing technology coupled with the development of geostatistics and spatial analyses using geographic information technology, fire danger rating systems have been moved from point-based estimates from weather stations to spatially explicit estimates. Remote sensing can be used to map fuel types and fuel moisture, as well as to detect active fires and to map fire scars and post-fire regeneration.

WORLD ECONOMY, IMPACT OF DISASTERS

Ilan Noy
University of Hawaii, Manoa, Honolulu, HI, USA

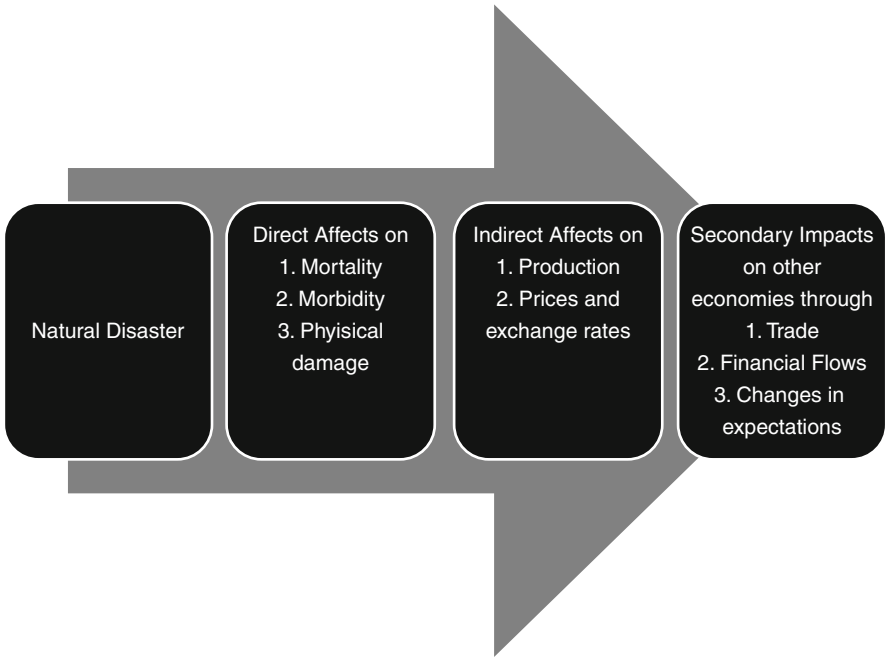
Definition

Human and economic catastrophes that are associated with natural hazards are by no means new. Recent very larger events, such as the Indian Ocean tsunami of 2004 or the 2005 Kashmir earthquake on the de facto Pakistan-India border, have also been experienced across national boundaries. Most of our current and rapidly evolving understanding regarding their relevance to economic dynamics is focused on the domestic economic and socioeconomic impacts (Cavallo and Noy, 2009, survey this literature). Here, the focus is on the international dimension of such economic and socioeconomic impacts, specifically the channels through which a disaster in one region/country can have an impact elsewhere.

Introduction

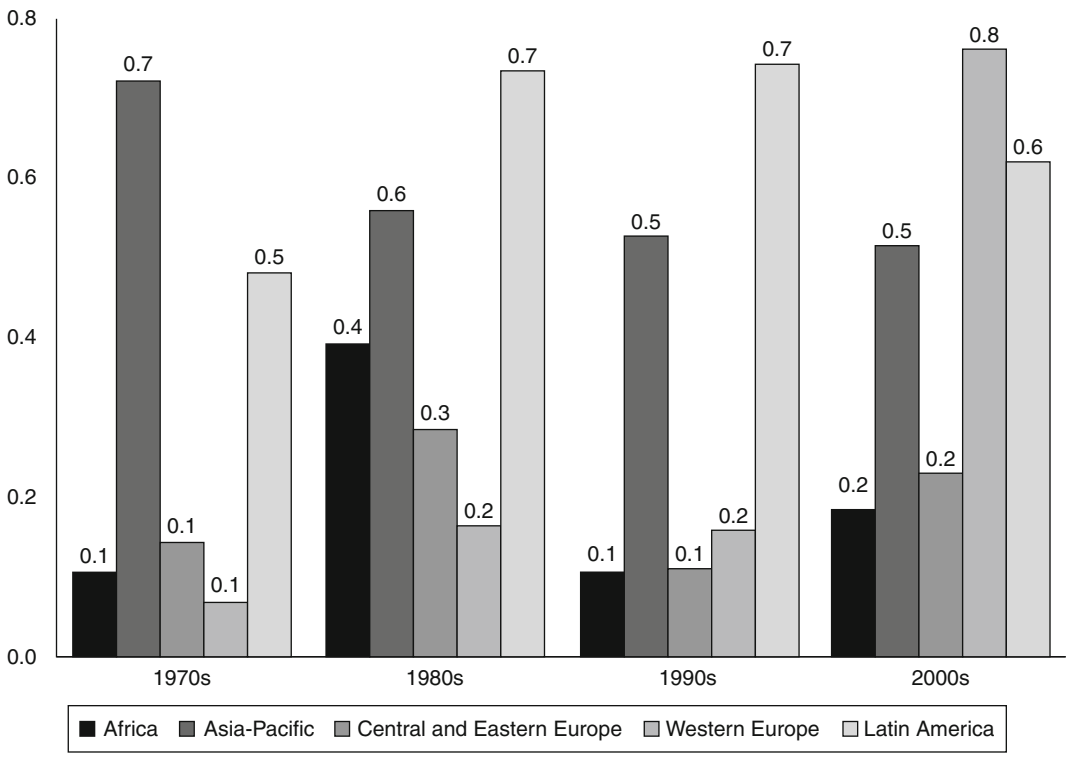
Barro (2006) has shown that the occurrence of infrequent economic disasters has a much larger welfare cost than continuous economic fluctuations of lower amplitude. For less developed countries, which suffer from a larger propensity to disasters of all types, and of disasters of larger magnitude than advanced economies, such events have an even greater effect on the welfare of the average citizen. These very large events are also the ones that are bound to have repercussions beyond the national borders of the affected countries.

In analyzing the economics of disasters, one typically distinguishes between direct damages, indirect damages, and secondary effects. Direct damage is the damage to fixed assets and capital, to raw materials and extractable natural resources and, of course, the mortality and morbidity that are a direct consequence of the natural hazards. Indirect impacts may be caused by the direct damage to physical infrastructure and productive capacity, or be a consequence of the fact that reconstruction pulls resources away from normal production. Such indirect damages also include the additional costs that are incurred because of the need to use alternative and less efficient means of production and/or spend dire resources for the provision of basic goods and services. At the household level, indirect costs include the loss of income resulting from the non-provision of goods and services or from the destruction of previously used means of production.



The "secondary effects" are in essence the aggregate measures of the secondary impact of the indirect effects, that is, the effects on other geographical regions, or at a later date, which originate from the indirect impact on the economy. In these secondary effects, one can identify the potential impact of disasters on the world economy, and the latter's effect on the secondary impacts of the disaster. These can, potentially, be even more severe than the initial negative disaster shock.

The secondary consequences of disasters can affect or be affected by other economies through two channels: (1) trade in both goods and services, and (2) flow of capital as aid, debt, or investment. Each of these channels is discussed in turn. An additional potential channel is migration. Disasters, however, have rarely generated large-scale migration; it is likely that only slow climate-related environmental changes, such as extended drought or desertification, will result in future migrations, but rapid-onset disasters most likely will not have such effects. Disasters, however, do frequently lead to internal displacement.



The only publicly available dataset on the economic impact of disasters worldwide is the Emergency Events Database (EM-DAT), maintained by the Center for Research on the Epidemiology of Disasters (http://www.emdat.be). The EM-DAT data reports on the number of people killed, the number of people affected, and the dollar amount of direct damages for each recorded disaster. The amount of damage reported in the database, however, consists only of direct damages (e.g., immediate damage to infrastructure, crops, and housing) and does not include either indirect or secondary damages. Thus, much of the following discussion is speculative, and the few research projects that have attempted to shed a more rigorous light on this issue rely on statistical analysis that is not always robust to permutations and changes in underlying assumptions. Much work remains to be done.

The often-cited data from EM-DAT appears to suggest that the frequency of disasters has been increasing rapidly in the last couple of decades (see, e.g., Figure 1 in Strömberg, 2007). However, much of the apparent increased incidence of disasters is due to an increase in the number of reported "small events." Figure 2 shows the frequency of large events with no apparent trend over time. Whether the reason for the increased frequency in the number of reported disasters is because small events are happening more frequently or because they are reported more often remains an open question.

Disaster fatalities are not distributed evenly across geographical regions, with a large majority occurring in the Asia-Pacific region. The Asia-Pacific region is an important region for the global economy: It includes more than 60% of the world population and more than 60% of world fatalities from disasters; it trades heavily in both goods and services (trade is 64% of the region's GDP, whereas the comparable figure for the United States is 25%); and it is

World Economy, Impact of Disasters, Figure 1 Disasters and their global impacts.

the largest recipient of capital flow outside the richest countries, and increasingly also a source of capital outflow to other regions (especially Africa).

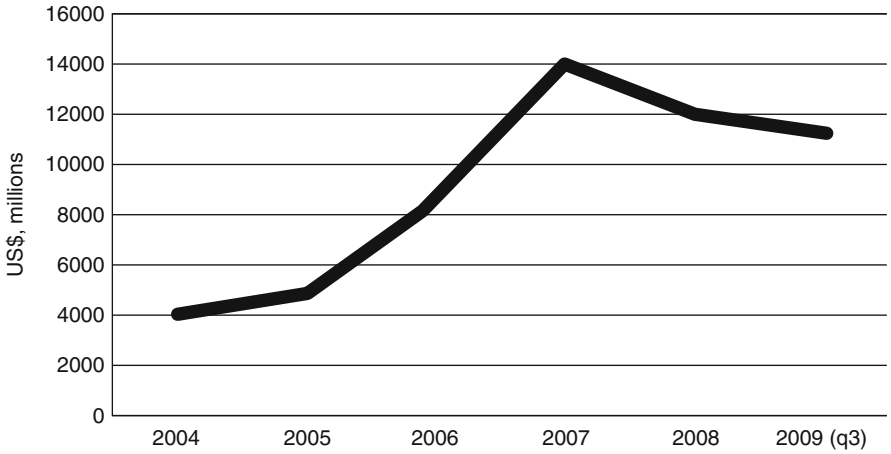
Trade

The initial disaster impact leads to mortality, morbidity, and loss of physical infrastructure (housing, roads, telecommunication and electricity networks, and other infrastructure). The main issue here is how these initial direct effects lead to changes in trade patterns. There is some evidence that the trade deficit increases in the aftermath of a disaster. A disaster is unlikely to generate increases in output; it is also likely that a decrease in output will result in decrease in exports. Service exports, especially tourism, are uniquely vulnerable and will likely decrease in a post-disaster period. However, there may be a boost to exports if the disaster causes the local currency to depreciate. Currency depreciation decreases the price of exports and can therefore lead to an increase in their volume. Because of these contradictory effects, empirical work has not yet reached any conclusions regarding the "export channel."

There is some evidence that post-disaster reconstruction leads to an increase in import. Imports, especially of machinery and reconstruction materials, but also potentially of non-aid foodstuffs, are all likely to increase in the post-disaster reconstruction period. In that case, a disaster may have potential benefits for trading partners since demand for their products will increase. This is especially true if there is no discernible impact on the exchange rate that negates some of the increase in demand.

The possibility of major disasters in oil-exporting regions, such as the North Sea or the Arabian Gulf, is another concern that can have a dramatic impact on the world economy. Previous crises that led to a decrease in oil supplies for export have led to dramatic increases in oil prices, and to contractions in economic activity (e.g., 1973 or 1979–1980). A major disaster event in a large oil-exporting region is likely to have a similar detrimental impact on the world economy.

Noy (2009) concludes that countries that are more open to trade (measured by the amount of trade they conduct, relative to the size of their economies), but that have less open capital accounts, are better able to withstand the initial disaster shock and prevent further spillovers. This may be because countries that have been more open to trade historically may find it easier to absorb and finance the additional imports that are normally necessary for reconstruction. The reason why countries that are less open to capital flows may be less vulnerable is less obvious.



Capital flows

As for trade flows, one can identify several ways in which disasters may have an impact on the flow of financial capital and vice versa. One obvious impact is that a *large* disaster generates inflows of official and private aid. In some cases, these aid flows can be quite sizable, especially if the disaster has been widely reported in the international media (see Eisensee and Strömberg, 2007). For example, the 2004 South-East Asian tsunami led to an initial inflow of $US 6 billion in foreign aid to the affected countries (Economist Intelligence Unit, 2005). There is some evidence that, as happened in this case, aid inflows are useful in reducing the indirect damage to the national economy that may result from a disaster. This is unlike the very mixed evidence as to the effect of aid flows at "normal" times.

Beyond an increase in post-disaster aid, it is less clear what will be the effects of a disaster on other types of capital flows. Official lending may also increase as a form of aid to finance reconstruction; however, private lending may decrease if the disaster has destroyed infrastructure, so that the productive capacity of the country/region decreases. Other types of investment such as direct foreign investment – both in the form of purchases of existing productive assets and in new "green-field" investment creating new production facilities – may increase or decrease, depending on the actual range of damages and their implications for economic opportunities in the affected regions. The same can be expected for capital outflows. Whereas domestic residents may see new opportunities as a result of the destruction, the disaster may also generate capital flight if it changes perceptions regarding the likelihood of future similar events.

Yang (2008) and Bluedorn (2005) have both attempted to investigate the evolution of capital flows following disasters empirically, and both conclude that disasters generate some inflow. Bluedorn finds that, in the case of Caribbean hurricanes, the post-disaster inflow is quite large (5% of GDP). Yang, using a broader dataset, argues that the magnitude of these inflows is relatively small. He observes that international aid and remittances to poorer countries increase, whereas other types of flows are rarely affected in empirically observable magnitudes. He also finds that there is some increase in private capital outflows from the affected countries. This reported increase in capital outflows may be the reason why a closed capital account, and specifically limitations on capital outflows, may enhance an economy's resiliency in the face of a natural hazard.

Given the beneficial impact of foreign capital in financing post-disaster reconstruction and assistance, it is not surprising that governments may be interested in insuring against disaster onset, in order to guarantee this flow of funds. The simplest way to guarantee the availability of post-disaster reconstruction funding is with precautionary savings. However, Borensztein et al. (2008) argue that, in the case of less developed countries exposed to large natural disasters, insurance – or debt contracts with insurance-like features – provides an attractive alternative to a fiscal rainy-day funds. To illustrate this, they examine the vulnerability of Belize's public finance to the occurrence of hurricanes and the potential impact of insurance instruments on reducing that vulnerability. Through numerical simulations they show that the provision of catastrophic risk insurance has the potential to significantly improve Belize's debt sustainability.

World Economy, Impact of Disasters, Figure 3 Cat bonds outstanding.

Implementing disaster insurance faces two types of obstacles: paucity of markets and political resistance (Kunreuther and Pauly, 2009). For a number of reasons, certain markets have traditionally been insufficiently developed, whereas elsewhere they are simply nonexistent. Recently, however, advances such as the development of parametric insurance policies, in which payments are based on externally verifiable disaster magnitude indices (such as the Richter measure for earthquakes), have the potential of increasing the availability of insurance. Political reluctance to engage in insurance purchase derives from the fact that there is little benefit for a political leadership with short-term interests from entering into insurance contracts. Insurance involves immediate costs and a possible payoff in an undetermined future when the government may already have changed hands (Healy and Malhotra, 2009). Since disasters are natural phenomena, and politicians cannot be blamed for their occurrence, the incentives to take relatively complex measures, such as insurance, to offset some of the costs are indeed weak. Political incentives to invest in *ex ante* mitigation are even weaker if the perceived likelihood of the disaster is relatively small.

In less developed countries, an additional obstacle to any *ex ante* preparation that includes the provision of insurance is an inadequate institutional framework – this relates to low government policymaking capabilities, opaque and potentially corrupt management practices of public assets, and systems that may be unable to provide efficient post-disaster disbursing of funds.

Catastrophe debt instruments (cat bonds) are another recently introduced means to transfer risks to the international capital markets. The main difference between a cat bond and a plain-vanilla bond is that if a prespecified disaster strikes, the creditor's claim is extinguished and the issuer's debt is essentially erased. The use of cat bonds is increasing rapidly, as can be seen in Figure 3, using data from GC Securities. However, it is not clear whether the increased use of these assets is indeed motivated by a demand for insurance or is merely speculative.

Conclusion

It seems clear that a large disaster, such as the Indian Ocean tsunami of 2004, will also cause people to change their evaluation of the probability of a future disaster occurring. In Hawaii, for example, the fear of a tsunami has increased markedly since 2004, but whether that has led to behavioral changes is still an open question. Disasters, thus, may have an impact on the global economy, not only because of what they do, but also because of the expectations they modify.

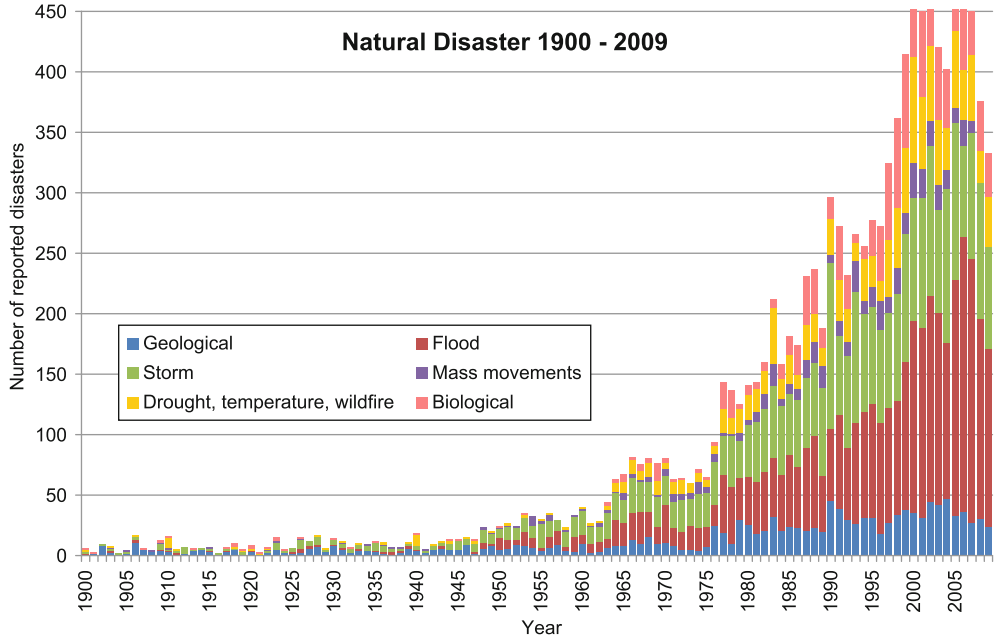
WORLDWIDE TRENDS IN NATURAL DISASTERS

Margreth Keiler
Duke University, Durham, NC, USA

Definition

Multiple definitions of the term "disaster" exist, which is rooted in different conceptualizations (authorities, scientists, journalists) and the context in which these definitions are used (Perry and Quarantelli, 2005; Perry, 2007). In the context of worldwide trends in natural disasters, the United Nations define disaster within the "International Strategy for Disaster Reduction" (UNISDR, 2010a) as "a serious disruption of the functioning of a community or a society involving widespread human, material, economic, or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources." This UNISDR definition provides the base for different worldwide databases on natural disasters, although it does not provide the basis for NatCat and Sigma, whereas the Centre for Research on the Epidemiology of Disasters (CRED) declares more precisely when the local capacity is exceeded by "necessitating a request to a national or international level for external assistance" (CRED, 2010a).



Background: Worldwide database

Worldwide databases of disasters and losses are maintained by, e.g., the Centre of Research on Epidemiology of Disasters in Brussels (CRED) with the sponsorship of the USAID's Office of Foreign Disaster Assistance (OFDA), the Emergency Events Database (EM-DAT), as well as by reinsurance companies, such as Munich Reinsurance Group (NatCatSERVICE) and Swiss Reinsurance (Sigma). These databases contain essential core data on the occurrence and effects (casualties, people affected, economic losses) of disasters over the globe. While the focus of EM-DAT is to serve the purposes of humanitarian action (disaster preparedness, vulnerability assessment, priority setting) at national and international levels as well as scientific research (CRED, 2010b), the reinsurance companies give more emphasis to economic loss and especially to insured losses. Therefore, due to different foci and, above all, due to a lack of clear internationally accepted standards, definition, and criteria for the disaster data compilation, these global databases are limited by inconsistent reliability and poor interoperability (Below et al., 2009). The following table (Table 1) gives a short overview on the different information contained and criteria applied by taking the EM-DAT and NatCatSERVICE databases as examples.

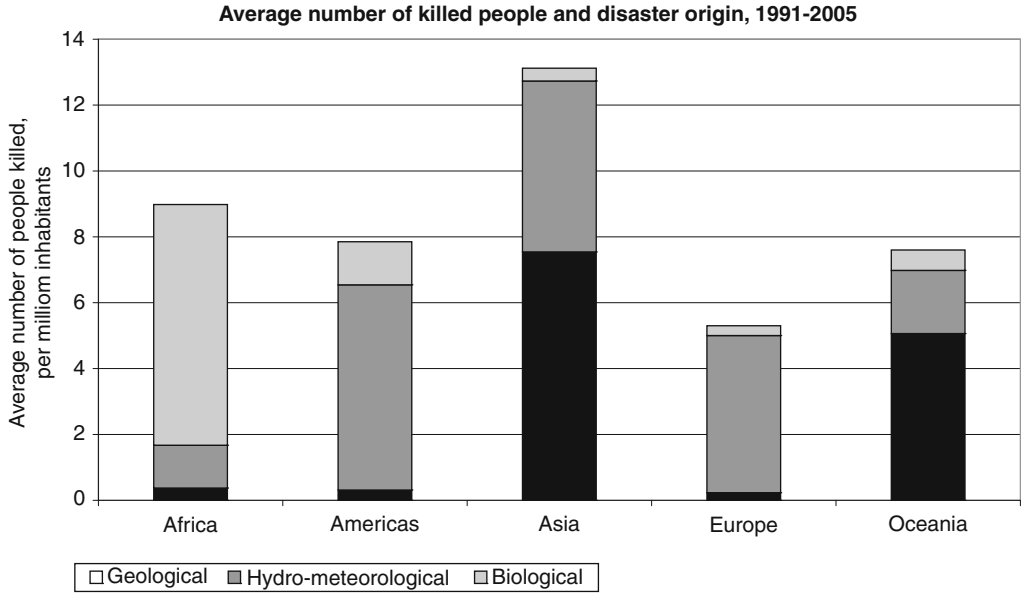
Recent efforts were undertaken between the provider of global and regional databases by comparing the datasets in the different databases to identify inconsistencies and gaps, to improve data quality, and to allow for a comparison and exchange of data on a detailed level (Guha-Sapir and Below, 2002). The result of a comparative study between data of EM-DAT, NatCatSERVICE, and Sigma, carried out on four countries, showed that the data collected vary significantly (up to 37% difference for casualties, 66% for people affected, and 35% for economic damage according to Guha-Sapir and Below, 2002; Peduzzi et al., 2005). One result to overcome the above-mentioned limitations is an agreement (between CRED and Munich Re) on a common hierarchy and terminology on natural disasters and on a definition of disaster groups. It should be

Worldwide Trends in Natural Disasters, Table 1 Information and criteria applied in worldwide databases EM-DAT (CRED) and NatCatSERVICE (Munich Re), after Guha-Sapir and Below (2002) and Below et al. (2009).

	EM-DAT	NatCatSERVICE
Type of disasters	Natural and technological disasters	Natural disasters
Entry criteria	$\geq$ 10 deaths and/or $\geq$ 100 affected and/or declaration of a state of emergency/call for international assistance	Entry if any property damage and/or any person sincerely affected (injured, dead) It is distinguished between six categories (two loss events, four catastrophes) Only major events prior to 1970
Methodology	Country entry	Country and event entry, all disasters geo-coded for GIS evaluation
Main sources	UN agencies, US Government agencies, official governmental sources, IFRC, research centers, Lloyd's, reinsurance sources, press, private	Munich Re branch offices; insurance associations, insurance press, scientific sources, governmental and nongovernmental organizations
Priority source	UN agencies	For monetary losses, priority is given to Munich Re branch offices and insurance associations
Period covered	1900–present	0079–present
Number of entries	17,000	26,000
Access	Public	Partially accessible

Worldwide Trends in Natural Disasters, Figure 1 Number of natural disasters from 1900 to 2009 classified in geological (earthquakes and volcanic eruptions), flood, storm, mass movement, drought (including extreme temperature and wild fire), and biological (epidemics, insect infestations) triggers (Source: CRED, 2010b).

mentioned that a common understanding about the regional scope and the time scale (start and end) of a disaster would also be required to harmonize data. The natural disaster categories are divided into six groups: biological, geophysical, meteorological, hydrological, climatological, and extraterrestrial, and each group includes several disaster main types and subtypes (Below et al., 2009). Still, after redistribution of datasets, differences between the databases exist as a result of the different entry criteria.



Worldwide trends

Disaster events

The analysis of the data recorded in the EM-DAT database indicates the following worldwide trend (CRED, 2010b). The number of reported disasters has increased, from about 10 per year between 1900 and 1949, 60 per year in the 1960s, 180 per year in the 1980s, almost 300 per year in the 1990s to about 440 per year for the decade 2000–2009. A similar exponentially rising trend is presented by Munich Re (Munich Re, 2009). In the last two decades, 64% of the total disaster numbers were recorded (Figure 1). The high increase in the number of hazardous events reported is probably mainly due to significant improvements in information access and reporting, especially after the establishment of EM-DAT in 1988. The most frequent triggers for disasters are floods (32%) and storms (28%, including hurricanes, typhoons, tornadoes, mid-latitude winter storms); earthquakes and volcanic eruptions (geological) caused about 12% of the disasters.

Disaster mortality and people affected

The related losses due to these natural disasters are concentrated in a small number of infrequently occurring events (UNISDR, 2009). The number of people reported killed by disasters since 1900 has been decreasing since the 1940s, whereas the reported number of people affected, defined as those requiring survival needs such as medical care, food, and shelter during and in the wake of disasters, increased strongly since the 1960s. The average number of people affected rose from about 25 million per year in the 1960s to 300 million in the 2000s due to floods, storms, and droughts (CRED, 2010b; UNISDR, 2010b). Regarding the time period between 1975 and October 2008 (with a more comparable global reporting coverage), 8,866 natural disaster events which were recorded by EM-DAT (excluding epidemics) caused more than two million killed people (UNISDR, 2009). However, only 23 M-disasters (0.26% of the events) accounted for 78.2% of the mortality, mostly in developing countries. Half of the 10 disasters with the highest death tolls since 1975 have occurred between 2003 and 2008 (UNISDR, 2009). For the period between 1975 and 2009, earthquakes (36%) are largest cause of natural disaster mortality, followed by storms (27%), droughts (23%), and floods (9%) (CRED, 2010b). The average number of people reported killed per million inhabitants is presented in Figure 2, indicating the highest number in Asia caused by "geological disasters" (earthquakes and volcanic eruptions) and "hydrometeorological disasters," including floods, storms, droughts and related disasters (extreme temperatures and wild fires), and mass movements

Worldwide Trends in Natural Disasters, Figure 2 Average number of people killed per million inhabitants by continent and disaster origin (Source: UNISDR, 2010b).

(UNISDR, 2010b). Africa shows the highest contribution to biological disasters covering epidemics and insect infestations. The greatest portion of individuals killed in Europe and the Americas are related to hydrometeorological disasters.

Economic losses

Economic losses due to natural disasters highlighted an exponentially rising trend since the mid-1970s regarding the period 1900–2009 (CRED, 2010b). The recorded economic losses in EM-DAT added up more than US$ 1.5 trillion between 1975 and 2008, with high peaks about US$ 160 billion in 1995 (Kobe earthquake), US$ 220 billion in 2005 (hurricane Katrina), and US$ 190 billion in 2008 (Sichuan earthquake and hurricane Ike). Only 25 M-disasters representing 0.28% of the events accounted for 40% of that loss which were located mainly in developed countries (UNISDR, 2009). The annual average of economic damage for the years 2000–2008 was about US$ 94 billion (CRED, 2010b). According to inflation-adjusted data from Munich Re, the average annual losses from the period 1977–1986 to the period 1997–2006 increased at a decadal rate of about 125% (Bouwer et al., 2007). Furthermore, Bouwer et al. (2007) highlighted that global economic losses caused by weather-related disasters have increased from an annual average of US$ 8.9 billion (1977–1986) to US$ 45.1 billion (1997–2006) based on the Munich Re database. The highest economic losses occurred since the 1990s in Asia by hydrometeorological (about 60%) and geological disasters (about 40%), followed by the Americas whose losses were dominated by hydrometeorological disasters (UNISDR, 2010b).

Discussion and conclusion

Trends of the disaster numbers, mortality, and people affected by disaster as well as economic losses show different developments or rate of increase especially if the records are analyzed by different "hazards" and regions. UNDP/BCPR (2004) highlighted the disproportionate impact on developing countries, that while only 11% of those exposed to hazards live in low human development countries, 53% of disaster mortality is concentrated in those countries. Mortality and direct economic losses appear to be highly clustered geographically; these are areas with a major concentration of people and economic assets and associated with a very small number of disaster events (UNISDR, 2009). More frequently occurring lower impact events are often not covered by the global databases, but in contrast, these widespread low-intensity losses are coupled to a large number of affected people and damage to housing and local infrastructure (McBean and Ajibade, 2009; UNISDR, 2009). The following example will illustrate the geographical disparity of disasters due to exposure and vulnerability. A comparable hazard event of a similar severity will generally result in lower mortality and smaller losses in countries with higher income and higher human development levels than in a less developed country when measured against the country's total wealth, despite the higher economic losses in absolute terms (UNISDR, 2009).

Beside the fact that a part of worldwide trends in natural disasters can be explained by improved disaster reporting (UNISDR, 2009), drivers for rising trends of affected people and economic losses are population growth (Strömberg, 2007) and increase in population and housing

units in vulnerable areas (Pielke et al., 2008), particularly in urban and coastal areas. The Intergovernmental Panel on Climate Change concluded that the rising number of disasters triggered by hydrometeorological events is likely to have been partly driven by anthropogenic global climate change altering the hazard pattern. Furthermore, it is very likely that hot extremes, heat waves, and heavy precipitation events will continue to become more frequent and future tropical cyclones will become more intense (Solomon et al., 2007). Nevertheless, the increasing trend of weather-related disaster losses such as stated by Bouwer et al. (2007) should be carefully considered, as already indicated earlier by Downton and Pielke (2005). Even if flood damages continued to increase despite extensive flood management efforts since 1900, particularly when measured in constant currency units, the trend is not as obvious once normalized. If flood data related to the United States of America are presented in terms of damage per unit wealth, a slight and statistically insignificant downward trend is observed (Loucks and Stedinger, 2007), which suggests that floods might have a lessening or neutral impact on the overall personal wealth of citizens in the United States of America over the course of the past decades. Similarly, no significant loss trends were found for flood and wind storm in Europe (Barredo, 2009; Barredo, 2010), tropical cyclones in India (Raghavan and Rajesh, 2003), and weather-driven disasters in Australia (Crompton and McAneney, 2008) if they were normalized by eliminating the socioeconomic influence of growing exposure in areas affected.

In summary, multiple, interacting drivers and records of disaster that are of poor quality, inhomogeneous, and collected using a wide range of methods for different purposes make the analysis of worldwide trends in natural disasters extremely challenging.

Definition

Natural hazard zoning is the division of any determined space into areas which could be affected by hazardous phenomena to variable degrees.

Discussion

Zoning is used as an instrument in land use planning to regulate land use in areas affected by specified hazard patterns. Usually, the determination of hazard zones vary gradually from imminent hazard zones, with very restrictive land use or determined building regulations, toward zones that are considered outside the statistically relevant reoccurrence or magnitude of a given hazard, which do not require land use regulations that pay special attention to a defined hazard. There are different national approaches on the definition and the use of hazard zones. The legal binding of hazard zones depends not only on the potential occurrence of hazards, but also on land planning regulations and respective responsibilities in the case of the occurrence of a hazard. In some countries, a municipality issuing land use plans can be held responsible in the case of a natural hazard, whereas in other countries the land developer has to ensure and guarantee safety.

Hazard zoning aims mainly at influencing or avoiding future developments in affected areas, but is less effective for existing structures due to private property rights. For that purpose, there are different options in the insurance sector. In some areas, official hazard zones and respective risk patterns of insurance companies do not match, whereas in other countries legal institutions tightly cooperate with the insurance sector. Since the second half of the twentieth century, hazard maps have increasingly been incorporated into legal acts that regulate land use, for instance, in Austria and Switzerland, hazard zones related to avalanches have been mapped since the 1960s and following legal regulations were installed officially as a practice in the 1970s. The rapid rise of costs related to damages caused by natural hazards since the 1990s have led to an increase in national activities to regulate land use in hazard-prone areas. This development is in line with a continued population pressure and land take toward hazard-prone areas, a general understanding that natural hazards cannot be fully mitigated by technical means, as well as growing demands from the insurance industry to lower vulnerabilities related to hazards.

The determination of hazard zones depends on the nature of a hazard. In the case of avalanches, usually return periods, maximum run out extensions, and magnitudes are used to determine the borderlines. Mass movements (landslides, rock falls, soil creep, etc.) are influenced by many factors such as the steepness of slopes, the underlying geology, potential run out areas, and shear zones. Flood and storm surge hazard zones are also related to reoccurrence, e.g., 100 year floods, the potential depth of inundation and the runoff velocity (the latter is especially important in mountainous areas). Tsunami hazard zones follow elevation above ground for potential inundation areas. Volcanic hazard zoning focuses on potential pathways of lava, pyroclastic flows, and/or lahars. Depending on the type of volcano, main wind directions influencing the directions of ashfall may be taken into account. Earthquake zones are related to the potential magnitudes,

tectonics (location of fault lines), and the underlying geology (liquefaction and ground acceleration potential). Storm hazard zones depend on peak wind speeds and forest fire hazard zones potentials of ignition and spreading.
