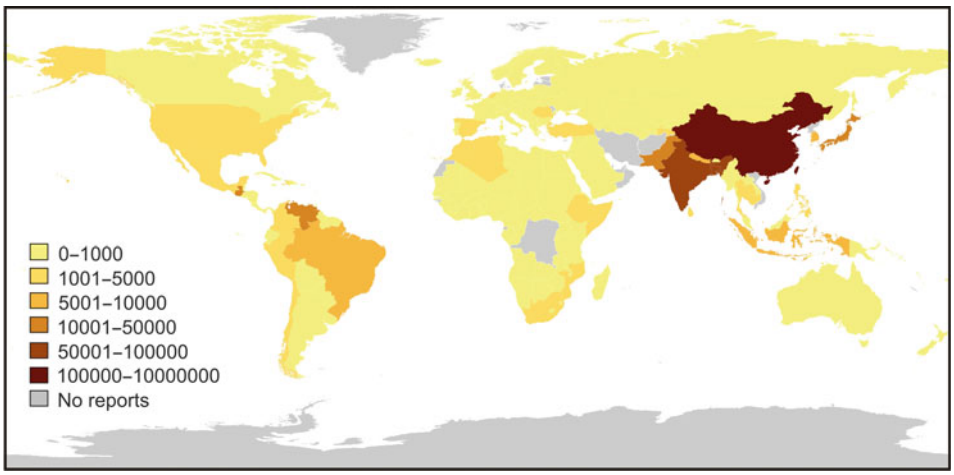
On July 10, 1949, a massive (245 Mm^3) loess flow (landslide) travelled through the Yasman valley in Tajikistan on slopes of only 2° following the M_W 7.4 Khait earthquake. The landslide travelled over 20 km and buried 20 villages in its path. The death toll from that single event was about 4,000 people, but landslides in adjacent valleys raised the regional magnitude of the disaster, increasing the death total to over 7,000 people, making this event one of the most devastating landslides of the twentieth century (Evans et al., 2009b).



Floods

Floods occur when land that is normally dry becomes saturated, submerged, and underwater. Floods are caused by rainfall (convective as well as cyclonic), snowmelt, tidal and storm surges, dam creation (natural and man-made), dike and dam breaches (both natural and man-made), and glacial lake outburst floods (GLOFs). Floods are one of the most widespread hazards, and flood disasters have affected nearly every country at one time or another (Figure 14). The Pacific Asian region is particularly vulnerable to flood disasters, both because of constant exposure to tropical cyclonic weather patterns and because of high population densities in flood-prone regions.

Flood disasters in China have been especially destructive; in the twentieth century alone, almost seven million residents have been reported killed by floods. In fact, the deadliest geophysical disaster on record is the 1931 flooding of the Yellow River, which occurred between July and November of that year, killing 3.7 million people (EM-DAT, 2010). China had repeated flood disasters in the twentieth century, including 1911 (100,000 killed), 1931 (3.7 million killed), 1933 (18,000 killed), 1935 (142,000 killed), 1939 (500,000 killed), 1949 (57,000 killed), 1954 (31,000 killed), and 1959 (two million killed). The 1959 flood, also along the Yellow River, coincided with experimental (and ultimately unsuccessful) changes in agricultural practices; in addition to the two million persons lost directly to flooding, the agricultural losses contributed to an ongoing famine that killed between 15 and 43 million

Geological/Geophysical Disasters, Figure 13 A cross marking the dead following the Guinsaugon landslide disaster on Leyte island in the Philippines (Photo by R.H. Guthrie).

Geological/Geophysical Disasters, Figure 14 The total number of reported deaths due to flooding disasters worldwide (1900–2010) (Data from EM-DAT, 2010). Most countries are affected by some level of flood disasters. Canada, for example, reports 168 flood disasters between 1900 and 1997, killing at least 198 and costing several billion dollars (Brooks et al., 2001). However, the devastation due to floods in China is particularly severe. The total number of deaths reported for China for that period is about 6.7 million.

people. Such unintended consequences are not limited to developing countries during certain periods of history.

The 2005 flooding in New Orleans, United States was made worse by the catastrophic failure of a man-made dike, normally used to protect houses from just such an event. The total damage from Hurricane Katrina and subsequent floods was over 80 billion dollars, making it the most expensive disaster in the country to date.

Glacial lake outburst floods (GLOFs), also known as jokulhlaups, occur when there is a sudden release of water from beneath or behind a glacier. The outflow suddenly and often catastrophically can incorporate sediment and

often become hyper-concentrated flows. In 1954, for example, a GLOF occurred in the Yarlung Zangbo basin of Tibet, releasing up to 10,000 m^3/s of water and damaging cities up to 200 km away (SAARC, 2010). As glaciers retreat worldwide, thousands of glacial lakes are forming and growing in size. The threat of GLOF disasters is increasing as a result.

Landslide dams create flooding in watersheds where the impound lakes and streams form, and when breached, they may fail catastrophically devastating everything in their path, similar to GLOFs. For example, in the United States in 1925, the 38,000,000 m^3 Gros Ventre landslide created a 60-m-high dam that backed up the Gros Ventre River and created a temporary lake. Two years later, a partial failure of the dam generated a flood that travelled for 40 km downstream, destroying the town of Kelly, 10 km along its path.

In 1786, in Sichuan, China, a landslide dam was breached on the Dadu River, flooding lands 1,400 km downstream and killing approximately 100,000 people.

At the time of writing, workers are trying to construct a spillway and mitigate the potential threats caused by a massive landslide that dammed the Hunza River in Pakistan. The current water level is 86 m above the valley floor and rising. Overtopping of dam is expected to occur on or about June 8, 2011. Downstream resources include a man-made dam and populated communities.

Subsidence

Subsidence is the lowering of land relative to some datum such as sea level, due to the removal of underlying support or by compression of the soil. Subsidence may produce an overall lowering (the sinking of Venice for example), or it may produce sudden catastrophic sinkholes. Sinkholes and subsidence may result from mining, the dissolution of limestone or underground salt, the removal of sediment by water, melting of permafrost, or any other mechanism that removes underlying support. Fortunately, there are relatively few instances of disasters related to ground subsidence.

In February 2007, a large (100 m deep) sinkhole appeared in Guatemala City, resulting in the evacuation of 1,000 people and the death of three people.

In the state of Florida, United States, public work officials struggle with sinkholes on a regular basis including a large (50 m deep) sinkhole that appeared beside a gypsum stack in 1994. Hazardous waste from the failure contaminated 90% of the drinking water in Florida.

In 1986, a sinkhole appeared in Berezniki, Russia at the location of 10% of the world's potash production. The sinkhole has been growing wider every year. The hole is currently 200 m deep, 80 m long by 40 m wide and threatens the nearby rail system.

Asteroids and near-earth objects

The understanding that humans are potentially threatened by comets and asteroids (near-Earth objects) careening through space is a fairly recent occurrence; however, it is not without precedent. In the geologic record, impacts of near-Earth objects (NEOs) have changed the global climate, food supply, and ultimately preceded global mass extinctions. The consequences are so potentially devastating that NASA maps all NEOs that approach the earth and ranks them accordingly to the Torino scale (a 1–10 logarithmic scale of probability and magnitude; Binzel, 2000). Should a NEO of a category 8 or higher be on a collision course with the Earth, it is likely that humans would use technology to intercept the object. In this manner, NEOs are the one potential devastation that is expected to be fully preventable.

Other disasters

There are other geophysical hazards that may lead to a disaster. In 1998, the North American ice storm killed 35 and cost several billion dollars in damages. Snow avalanches in 218 BC killed 20,000 soldiers and numerous elephants of Hannibal's army as they tried to cross the Alps. Lightning during electric storms kills people and starts fires that do millions of dollars of damage on a yearly basis. In 1281, 100,000 people died in a typhoon (cyclone) that inundated Japan. In March 2010, over 6,000,000 people were impacted by drought in Thailand.

Summary

Geophysical disasters will occur whenever humans and things that human's value are exposed to geophysical hazards. In the end, it is a matter of scale: Humans and human structures are small relative to the workings of the planet, and even small perturbations in the geophysical world can have devastating effects to humankind. However, humans have a responsibility for awareness, prevention, and mitigation. Much of the devastation from the world's most calamitous disasters is ultimately avoidable through good planning, engineering, avoidance, and improved geophysical science. As we move forward into the twenty-first century, humans will face new geophysical challenges and disasters will become more expensive. However, enacting procedures and policies to mitigate these disasters will ultimately save lives.

GLACIER HAZARDS

John J. Clague
Simon Fraser University, Burnaby, BC, Canada

Definition

Glacier hazards are natural Earth processes associated with alpine glaciers, ice caps, or ice sheets that threaten people or property.

Introduction

About 10% of Earth's surface is covered by glacier ice, and about 99% of this glacier cover is in Greenland and Antarctica. The other 1% comprises ice fields, ice caps, and cirque, valley, and piedmont glaciers, mainly in mountains of northwest North America, Arctic Canada, and Asia. Glaciers provide many benefits or natural service functions. For example, meltwater from alpine glaciers augments stream runoff during summer, which is important for agriculture, municipal water supply, and hydroelectric power generation. However, processes associated with glaciers can also be hazardous. In addition, some glacier hazards may be amplified by climate change.

Glaciers, climate change, and sea-level rise

Glaciers around the world have grown and receded in response to climate change throughout the Holocene. Most alpine glaciers achieved their maximum Holocene size during the late stage of the "Little Ice Age" in the eighteenth and nineteenth centuries (Grove, 1988). In marked contrast, alpine glaciers have thinned and receded during the twentieth century and the first part of the current century, a response to the warming that has occurred over the past 150 years. Today, ice cover in most mountain ranges is one-half to two-thirds of what it was in the mid-nineteenth century. The response of the large ice sheets in Greenland and Antarctica to climate warming is less clear, although large amounts of ice are now being lost in Greenland due to accelerated flow of outlet glaciers, and ice shelves in Antarctica are showing signs of instability (Howat et al., 2008; Rignot et al., 2008).

Sea-level rise, which is a hazard in its own right, is being caused by glacier melt and thermal expansion of upper ocean waters, both driven by climate warming. Some of the current global sea-level rise of about 3 mm/year is due to retreat of alpine glaciers, mainly in western North America and Eurasia (Larsen et al., 2007; Leclercq et al., 2011), and ice loss in Greenland and Antarctica is increasingly contributing to the rise in sea level (Rignot et al., 2011). If all alpine glaciers were to disappear sea level would only rise several tens of centimeters, but even that rise would displace people living along some shorelines and would threaten or damage infrastructure. A large reduction in ice cover in Greenland or Antarctica would be catastrophic. Enough freshwater is currently stored in glacier ice in Greenland and Antarctica to raise sea level, respectively, about 7 m and 70 m (National Snow and Ice Data Center).

Landslides and other mass movements

Thinning and retreat of alpine glaciers appear to be responsible for some catastrophic rock-slope failures in high mountains (Evans and Clague, 1994, 1999; Holm et al., 2004). Many marginally stable slopes that were buttressed by glacier ice during the Little Ice Age failed after they became ice-free in the twentieth century (Figure 1). An ancillary factor that may have contributed to the failures is steepening of rock slopes by cirque and valley glaciers during the Pleistocene Epoch.

Landslides related to glacier debuttressing are most common in mountain ranges with the greatest ice cover (Himalaya, St. Elias Mountains, and Coast Mountains), because those ranges have experienced the largest ice losses in the twentieth century. An extreme example is Glacier Bay, Alaska, which until the end of the eighteenth century was completely occupied by glacier ice. Since then, the bay has become deglaciated, with the loss of over 1,000 km^3 of ice. Ice loss in Glacier Bay is so great that the land is rising due to glacio-isostatic rebound (Larsen et al., 2005).

Other climate-related mechanisms besides debuttressing cause or trigger landslides. Temperatures in high-glacierized mountains are normally below freezing. They may rise rapidly, however, during warm spells, accompanied by melting snow and ice. The water generated by melting may infiltrate fractures in marginally stable rock masses (Davies et al., 2001). When temperatures again fall below freezing, water within the fractures freezes or freezing at the surface may seal the fractures. In either case, pore water pressures rise, producing extensional forces in an already weak rock mass. A related process is thawing of permafrost beneath high-elevation rock slopes (Gruber et al., 2004; Fischer et al., 2006; Gruber and Haeberli, 2007). The lower limit of alpine permafrost has risen in most or all mountains in the twentieth century due to climate warming (Zhang et al., 2006). Thawing of previously frozen slopes has lowered the strength of stratified or fractured rock, because water along bedding planes or in the fractures melts (Deline et al., 2011).

The importance of these processes is illustrated by the unusually large number of rock falls in the European Alps during the summer of 2003, which was one of the warmest summers in European history. The rockfalls posed a significant hazard to climbers, and they attracted the attention of scientists and the public. Larger landslides have also occurred more recently, for example in 2004 at Thurwieser Peak in the central Italian Alps and in 2007 at Monte Rosa in the northwestern Italian Alps, both areas heavily trafficked by tourists.

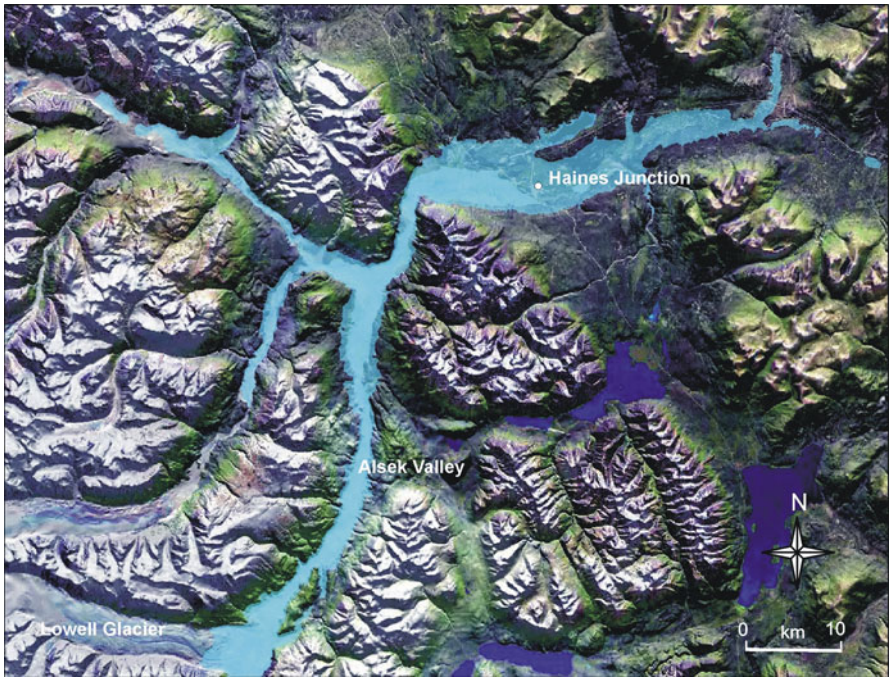
Another glacier hazard with possible links to climate is ice avalanches. The heavily crevassed snouts of glaciers that terminate on steep slopes are prone to avalanching, in part because of the large gravitational forces exerted on the ice and in part because rates of ice flow on steep slopes are high and accompanied by enhanced basal sliding. In such environments, ice avalanches can occur any time. Many ice avalanches occur during warm or wet weather, when there is abundant water flowing at the base of the glacier. This water can accelerate glacier flow and locally elevate pore pressures. It is no coincidence, then, that many notable ice avalanches have occurred during summer. Examples include a snow and ice avalanche from Glaciar 511 on the summit of Nevados Huascaran, Peru, in January 1962, which destroyed the town of Yungay, killing an estimated 4,000 people; an avalanche from the toe of Allalin Glacier in August 1965, which killed 12 men at a dam construction site in Switzerland; an avalanche of 2–3 million cubic meters of ice from the snout of Diadem Glacier in British Columbia in July 2007; and a 1.1 million cubic meters ice avalanche on the east face of Monte Rosa in August 2005.

Glacial outburst floods

Many glaciers impound large water bodies that drain suddenly, causing downvalley floods, termed jökulhlaups, that are far larger than normal nival and rainfall-triggered floods (Costa and Schuster, 1988; Clague and Evans, 1994). Water may be trapped on top of, within, beneath, or at the margins of glaciers. Some lakes at the margins of alpine glaciers may hold 100,000,000 m^3 of water or more.

Glacier Hazards, Figure 1 Jubilee rock avalanche, New Zealand. This landslide, which occurred in the austral summer of 2008, is an example of a landslide that may have been caused, in part, by glacial debuttressing.

The largest of these lakes, and commonly those most prone to sudden emptying, are situated in low-gradient trunk valleys at the toes of glaciers that flow out of tributary valleys, and in a few fiords at the margins of calving tidewater glaciers. Subglacial lakes form beneath Vatnajökull, an ice cap in Iceland, during eruptions of Grimsvötn and other active volcanoes, and generally drain suddenly to produce large jökulhlaups. When climate is stable and glaciers neither advance nor retreat, few glacier-dammed lakes drain. The situation is different, however, when climate changes over periods of decades or longer. During the Little Ice Age, for example, new lakes formed when glaciers advanced across streams and blocked drainage (Figure 2). When these lakes first formed, their glacier dams may have been weak and many of the lakes probably drained repeatedly. As these glaciers continued to advance, both the dams and the impounded lakes stabilized. Most Little Ice Age lakes drained one or more times in the twentieth century when their dams weakened due to glacier thinning and retreat (Figure 3; Costa and Schuster, 1988; Clague and Evans, 1994; and references therein). In each case, a critical threshold of instability was reached, at which time the dam failed. The most common drainage mechanism is rapid development of one or more subglacial channels that serve as conduits for outflowing water. Glacier dams may also fail by mechanical collapse after glacier surges that block streams or fiords. Many former glacier-dammed lakes no longer exist, because the glaciers that dammed them have wasted so much that they no longer impound water. However, lakes have formed in new locations at the margins of some receding glaciers, typically at higher elevations than former lakes, and pose new risks to downvalley areas (Geertsema and Clague, 2005).



Lakes also developed behind Little Ice Age terminal moraines as glaciers retreated in the late nineteenth and early twentieth centuries (Costa and Schuster, 1988; O'Connor and Costa, 1993; Clague and Evans, 1994, 2000). Some of these moraine dams are unstable and vulnerable to failure because they are steep-sided and consist of loose sediment. Irreversible rapid incision of moraine dams may be caused by a large overflow triggered by an ice avalanche or a rockfall (Figure 3). Other failure mechanisms include earthquakes, slow melt of buried ice, and removal ("piping") of fine sediment from the dam.

Many outburst floods from glacier and moraine-dammed lakes display an exponential rise in discharge, followed by an abrupt decrease to background levels when the water supply is exhausted. Peak discharges are controlled by lake volume, dam height and width, the material properties of the dam, failure mechanism, and downstream topography and sediment availability. Floods from glacier-dammed lakes tend to have lower peak discharges than those from moraine-dammed lakes of similar size because enlargement of tunnels in ice is a slower process than overtopping and incision of sediment dams.

Floods from glacier and moraine-dammed lakes may transform into debris flows as they travel down steep valleys. Such flows can only form and be sustained on slopes greater than 10–15° and only where there is an abundant supply of sediment in the valley below the dam (Clague and Evans, 2000). Entrainment of sediment and woody plant debris by floodwaters may elevate peak discharges, which has important implications for hazard appraisal, because debris flows are more destructive than floods of the same size.

Outburst floods from lakes dammed by glaciers and moraines erode, transport, and deposit huge amounts of sediment over distances of tens of kilometers (Figure 4). They alter river floodplains far from the flood source. They broaden floodplains, destroy preflood channels, and create a new multichannel, braided planform. The changes can persist for decades after the flood, although rivers quickly reestablish their preflood grades by incising the flood deposits.

A relation exists between climate and the stability of moraine and glacier dams. Most existing moraine-dammed lakes formed in the twentieth century when glaciers retreated from bulky terminal moraines constructed during the Little Ice Age. The lakes soon began to fail as climate warmed. If warming and glacier retreat continue, the supply of moraine-dammed lakes susceptible to failure in most mountain ranges will decrease and the threat they pose will diminish (Clague and Evans, 2000). The relation is different for glacier-dammed lakes. Typically, a glacier-dammed lake goes through a period of cyclic or sporadic outburst activity, lasting up to several decades. The cycle of outburst of floods from a lake ends when either the glacier advances and forms a stronger dam or retreats so much that it can no longer trap water behind it.

Glacier Hazards, Figure 2 Glacial Lake Alsek formed repeatedly during the Little Ice Age when Lowell Glacier, a large valley glacier in the St. Elias Mountains of southwest Yukon Territory, advanced across Alsek River alley and blocked the flow of the river. This figure depicts the lake in the mid-nineteenth century, when it reached to the present site of Haines Junction on the Alaska Highway, and earlier when the site of Haines Junction was inundated by water about 70 m deep (Courtesy of Jeff Bond, Yukon Geological Survey).

Glacier Hazards, Figure 3 Breached Little Ice Age terminal moraine of Diadem Glacier, British Columbia. About 6 million m^3 of water flowed out of moraine-dammed Queen Bess Lake on August 12, 1997, after an ice avalanche from the toe of Diadem Glacier entered the lake and produced a displacement wave that overtopped and incised the moraine (Photo courtesy of Interfor).

Glacier Hazards, Figure 4 Floor of the west fork of Nostetuko River valley, British Columbia several years after the 1997 outburst flood from moraine-dammed Queen Bess Lake. The flood transported and deposited large amounts of coarse sediment and destroyed the preexisting river channel and floodplain on the valley floor (Photo: J. J. Clague).

Changes to streams

A sustained advance or retreat of a glacier will change the amount of water and sediment delivered to its snout. These changes impact the stream in the valley below the glacier snout. During glacier advance, for example, meltwater streams aggrade their channels as sediment supply increases (Maizels, 1979). Sediment stored within and beneath the glacier, and that previously stored in the valley, is delivered at an increasing rate to the fluvial system as the glacier advances (Karlén, 1976; Maizels, 1979; Leonard, 1986, 1997; Karlén and Matthews, 1992; Lamoureux, 2000). At the same time, the areas of subglacial erosion and rockfall onto the glacier increase and meltwater may carry more sediment into the river valley than at times when the glacier is more restricted. A sediment pulse may propagate rapidly downstream in a narrow mountain valley as the glacier approaches and reaches its maximum extent.

Such climatically induced changes in stream discharge and sediment yield have been documented in the Coast Mountains of British Columbia. Streams responded to increased sediment delivery during the Little Ice Age by aggrading their channels and braiding over distances up to tens of kilometers down valley from glaciers in their headwaters (Church, 1983; Gottesfeld and Johnson-Gottesfeld, 1990; Wilkie and Clague, 2009). Subsequently, during the twentieth century, the streams incised their Little Ice Age deposits and reestablished single-thread channels characteristic of periods of lower sediment flux.

Summary

Warming of climate during the twentieth century has caused massive deglacierization of high mountains around the world. The loss of glacier ice, in tandem with permafrost thaw, has destabilized many steep slopes and triggered rockfalls, rock slides, and ice and rock avalanches. Glacier downwasting and retreat also have triggered outburst floods from glacier- and moraine-dammed lakes. These floods, which have peak discharges much larger than normal nival and rain-on-snow floods, pose a serious threat to downvalley communities and infrastructure in many mountain ranges. Melting glaciers are also contributing to sea-level rise, which will accelerate in the future if warming continues.

GLOBAL CHANGE AND ITS IMPLICATIONS FOR NATURAL DISASTERS

Gonéri Le Cozannet, Hormoz Modaressi,
Nicolas Desramaut
BRGM – French Geological Survey, Orléans, France

Definition

Global change refers to environmental and societal transformations, including those affecting the Earth system as a whole such as climate change (Field et al., 2012)

or ozone hole depletion (Farman et al., 1985), but also more direct impacts of human activities that affect environmental systems worldwide, such as urbanization (see entry "*Urban Environments and Natural Hazards*") and environmental degradation (Verstappen, 2011). Hence, global change includes the dynamic of society and socioeconomic factors (Clark, 1988; Gallopin, 1991) and their interactions with environmental changes (Slaymaker et al., 2009). A *disaster* is defined by the International Strategy for Disaster Reduction (ISDR) as "a serious disruption of the functioning of a community or society, causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources" (ISDR, 2004). The term "natural" can be disputed because human vulnerability and exposures are essential components of disasters induced by natural phenomenon (O'Keefe et al., 1976; Turner, 1976; Pelling, 2001). *Global change implications of natural disasters* (Pelling, 2003) (see "*Natural Hazard*") thus include all components of risk: hazard, exposure, vulnerability as well as the communities' capacity to respond. Responses to global change as a factor of aggravation of natural disasters (Alexander, 1993) address at least three major policies with implications from local to global decision levels: disaster risk management (see "*Disaster Risk Management*"), adaptation to climate change (see "*Adaptation*"), and sustainable development as a response to environmental degradations (UN (United Nations), 2009).

Discussion

Global change affects natural disasters through three major components: (1) climate change, which is influenced by human activities (Hegerl et al., 2007); (2) more local human-induced pressures on the environment that constitute a global issue either because they occur worldwide, or because the magnitude of change is increasing (Turner et al., 1990); and (3) global societal transformations (see "*Humanity as an Agent of Natural Disaster*").

Global change affects or is expected to affect the following components of natural disasters:

- Hazard, which may be affected by climate change (Field et al., 2012) and inappropriate land use planning, such as deforestation affecting landslides (Glade, 2003; Huggel et al., 2012).
- Exposure, which has considerably grown recently because of population growth and urbanization (see "*Urban Environments and Natural Hazards*").
- Vulnerability (see "*Vulnerability*"): as an example, disorganized urbanization that does not take into account building regulation contributes to increasing physical vulnerability (as defined in Douglas, 2007). Another example is economic development causing environmental degradations that reduce the capacity of natural systems to protect against disasters (World Bank, 1992). This is the case, for example, for the mangrove that plays a role in protecting coastal areas against marine submersions and coastal erosion (Othman, 1994).
- The capacity to respond to disasters may be worsened by environmental degradation and population growth pressure (Adger et al., 2005), as there may already be a stress on basic resources such as food, water, or even land (see "*Land Use, Urbanization, and Natural Hazards*").

1. *Widespread anthropogenic environmental changes and their influence on natural disasters:* Anthropogenic changes such as land use (Dale, 1997), urbanization (Parnell et al., 2007), and some agriculture practices may modify all components of risk, including the hazard itself in certain cases. However, they primarily affect exposure, vulnerability, as well as, the capacity to respond of communities. EM-DAT (www.emdat.net) reports a significant increase in the number of natural disasters since 1900 (See "*Worldwide Trends in Natural Disasters*"). These data should be considered cautiously because of observational bias and the improvements in disaster reporting. However, such a trend would be the expected consequence of increased vulnerability and exposure in the context of social and economic development barely taking into account disaster risk prevention and mitigation.
2. *Climate change* (see "*Climate Change*") *influence on natural disasters:* Climate change is expected to primarily affect the heat wave hazard and secondarily hydrometeorological hazards (see "*Hydrometeorological Hazards*"), such as heavy precipitation, flooding, and drought. Finally, it is assumed that climate change will modify hazards that are related to hydrometeorological processes (Meehl et al., 2007) such as landslides. Coastal risks, in particular coastal erosion (see "*Coastal Erosion*") and storm surge hazard (see "*Storm Surges*"), should increase as a consequence of sea-level rise (Nicholls and Cazenave, 2010). Whereas the consequences of climate change on hazard are expected to be important in the future, observations of current extreme events are rarely attributed unambiguously to climate change. Recently, a notable advance in this field has been to investigate how heat waves can be attributed to climate change (Yiou et al., 2007). However, many of the significant trends that have been observed in recent decades are the manifestation of decadal or multi-decadal climate variability (Schneider et al., 2007). Moreover, the assessment of climate change influence on natural disasters is limited by a scaling issue: Global climate models produce projections at spatial scales and timescales that are barely appropriate for many extreme events. Thus, projections from global models are downscaled to identify or track indices of extreme events trends for climate change scenarios. This regionalization adds an additional layer of uncertainties to those of global climate models

(Van Aalst, 2006). Climate change influences on cyclonic hazard in the Caribbean are an example of these difficulties. The scientific community not only debates the possibility of attributing recent cyclonic patterns changes to climate change (Holland and Webster, 2007), but they are also debating what could finally be the impact of climate change on cyclonic (see "*Hurricane (Typhoon, Cyclone)*") patterns and genesis in the future. For many hazards such as landslides (see "*Landslide (Mass Movement)*"), the relative importance of temperature and hydrometeorological forcing with respect to other processes and features, such as geomechanics, is still a research topic. Because of this limited knowledge of the influence of climate change on natural disasters, methods are being developed within climate change adaptation strategies to support decision making in an uncertain future (Hallegatte, 2009).

3. *Links between climate change adaptation, disaster reduction, and sustainable development:* The question of climate change influence on natural disasters includes several major issues: disaster risk management, adaptation to climate change, and sustainable development as a response to environmental degradations. Connecting these policies also increases the complexity of finding suitable strategies because of different understanding of concepts such as vulnerability (see "*Vulnerability*"): For climate change communities, vulnerability is defined as the losses to be expected because of global changes minus the benefits of adaptation, whereas in communities concerned with disaster risk management, it is a component of risk (Romieu et al. 2010). Beyond the semantic difficulties, the connection of these three major policies raises major questions for decision-making authorities. For example, it is presently often unclear whether short-term reduction of present risks is a sufficient measure of adaptation to climate change or if new approaches need to be developed.
4. *Extreme events and long-term trends:* Over a certain threshold, the poorest societies are unable to manage the consequences of extreme events, recovery is limited, and so these societies are kept in the loop of underdevelopment (Schipper and Pelling, 2006). Since the influence of climate change on natural disasters remains uncertain, there is no evidence whether the worldwide impact of global change will be limited to part of the gross domestic product or if a threshold may be passed leading to a new pathway of underdevelopment (Hallegatte et al., 2007). A relatively open research issue is the question of which kind of interactions between short-term effects, such as extreme events, and long-term trends, such as climate and global changes, are implied in terms of human development and livelihood.
5. *Global change as a hazard in itself:* The above highlighted examples also lead to consideration of global change as a hazard in itself (ISDR, 2008). This is supported by possible future abrupt changes of climate, such as collapse of large Greenland or Antarctic ice sheets, major changes in the oceanic thermohaline circulation, or major changes in the carbon cycle (Schneider et al., 2007). This raises again the question of the robustness of human societies to global changes. The collapse of the Akkadian empire in the context of Mesopotamia becoming more arid (4000 BC) (De Menocal, 2001) and the rise of the Egyptian civilization in the context of Sahara's desertification and population growth around the Nile (5300 BC to 3500 BC) (Kuper and Kröpelin, 2006) are two of many historical examples of major environmental changes affecting human societies. In these two examples, environmental stress creates a crisis in a society, which may adapt to the new conditions or not, for example, by creating a more complex and structured culture (Brooks, 2006). While such research provides a perspective on the ongoing global change consequences, there are major differences between the present situation and historical analogues. Despite the uncertainties, there is presently some knowledge of the expected changes. In addition, while the expected climax of the environmental crisis has probably not been already reached, human societies are now investigating how they can anticipate adverse effects of contemporary global change and reduce their vulnerability to the forecasted future disasters.

Summary or conclusion

The environmental impact of human development and climate change are two major components of global change. It is widely recognized that fast population growth and disorganized urbanization has led to increasing vulnerability and exposure to natural disasters during the twentieth century. With respect to climate change, our ability to understand and predict its actual impact to natural disasters is limited, for example, by the difficulties in capturing natural disasters triggering factors in global climate models. In addition, Roe and Baker (2007) showed that our ability to predict future changes due to climate change is limited by intrinsic uncertainties of climate models. This supports the idea that the suspected implications of global change for natural disasters should be anticipated through mitigation and adaptation measures to climate change (see "*Climate Change*"), which should be consistent with disaster risk reduction policies (see "*Disaster Risk Reduction*") and sustainable development policies (ISDR, 2005; Adger et al., 2007; Field et al., 2012).

GLOBAL DUST

Edward Derbyshire
Cheltenham, Gloucestershire, UK
Royal Holloway, University of London, Egham, Surrey, UK

Definition

Global dust refers to palls or plumes of solid particles suspended in the troposphere, to be transported for thousands of kilometers by the action of strong, turbulent winds in source regions characterized by dry land surfaces with little or no vegetation cover. Other notable sources include the volcanic ash (tephra) emitted during eruptions and organic matter and elemental carbon derived from forest fires and industrial sources (Gieré, 2010). A large proportion of global dust particles have aerodynamic diameters finer than 20 micrometers (μm).

Introduction

Erosion, airborne transport and deposition of solid dust particles have occurred throughout geological time. Evidence of such events includes wind transport and deposition of mineral dust over the past 2.6 Myr in the form of the thick clayey-silt formation, known as *loess*, found on all inhabited continents. Long range (hemispherical and global) transport of dust involves atmospheric turbulence in source areas such as occurs along air-mass frontal systems, the finer dust particles being lifted into the upper troposphere (up to about 10 km). The stronger volcanic dust plumes, ejected at speeds greater than those of the local winds, reach the upper atmosphere (the stratosphere) (Durant et al., 2010). Information on the relative proportions of global dust emitted by three of the primary processes (dust storms, volcanic eruptions, and forest fires) is sparse but fine volcanic ash and dust from biomass burning may make up only 12% and 3% by weight, respectively, of the dust storm total (Gieré and Querol, 2010). The written record of visible atmospheric dust dates back to some 3,000 years in China (Zhang, 1984), since classical and medieval times in the Mediterranean region (e.g., Homer's "blood rain" referred to in the *Iliad* (eighth century BCE); Georgius Agricola (1556), cited in Guthrie, 1997) and since the eighteenth century in North Atlantic ships' logs (e.g., Darwin, 1846).

Airborne dust and its entrainment

Mineral particles, a major component of global dust, are products of physical and chemical weathering of rocks, biochemical processes involved in soil formation, and volcanic eruptions. Detachment of loose mineral dust from such dry surfaces (deflation) varies with particle size, degree of particle exposure, soil surface moisture content and roughness, lower atmosphere dynamics, and the wind speed (threshold velocity) required to detach the dust. Some dust particles, including sulfates, form within the atmosphere.

Global dust consists mainly of silt-size particles (>2 μm); its mineral composition is dominated by oxides of silicon, aluminum, iron, and calcium, as well as carbonates, the relative proportions reflecting the average composition of the upper continental crust. However, composition varies with dust source. Fibrous materials (including the fibrous amphibole minerals and organic fibers) can be transported long distances. The finer mineral fractions (clay-size grains: <2 μm) are not easily detached from soil surfaces as single particles because of their high interparticle cohesive charges; most detachment occurs as a result of impact on soil surfaces by larger, sand-size particles (the process of saltation). Clay-size material commonly occurs as attachments to silt-sized grains and also as silt-sized aggregates.

The entrainment of dust from barren or sparsely vegetated terrain varies with numerous factors, but the particle size, density, and shape exert a strong influence on the process of entrainment of particles by a critical wind speed known as the threshold velocity at the surface of the dust source. Dust particles held in suspension in the atmosphere over global distances are generally finer than 20 μm.

Volcanoes with silica-rich magma tend to have more violent eruptions, in which the thrust of volcanic gases may reach a velocity of 600 m s^{-1}, slowing with increase of altitude and with progressively finer particles in the upper part of the plume. About one quarter of such emissions reach the stratosphere and strong, high magnitude plumes can sustain global atmospheric impacts for months to years (Sparks, 1986; Durant et al., 2010).

Dust sources

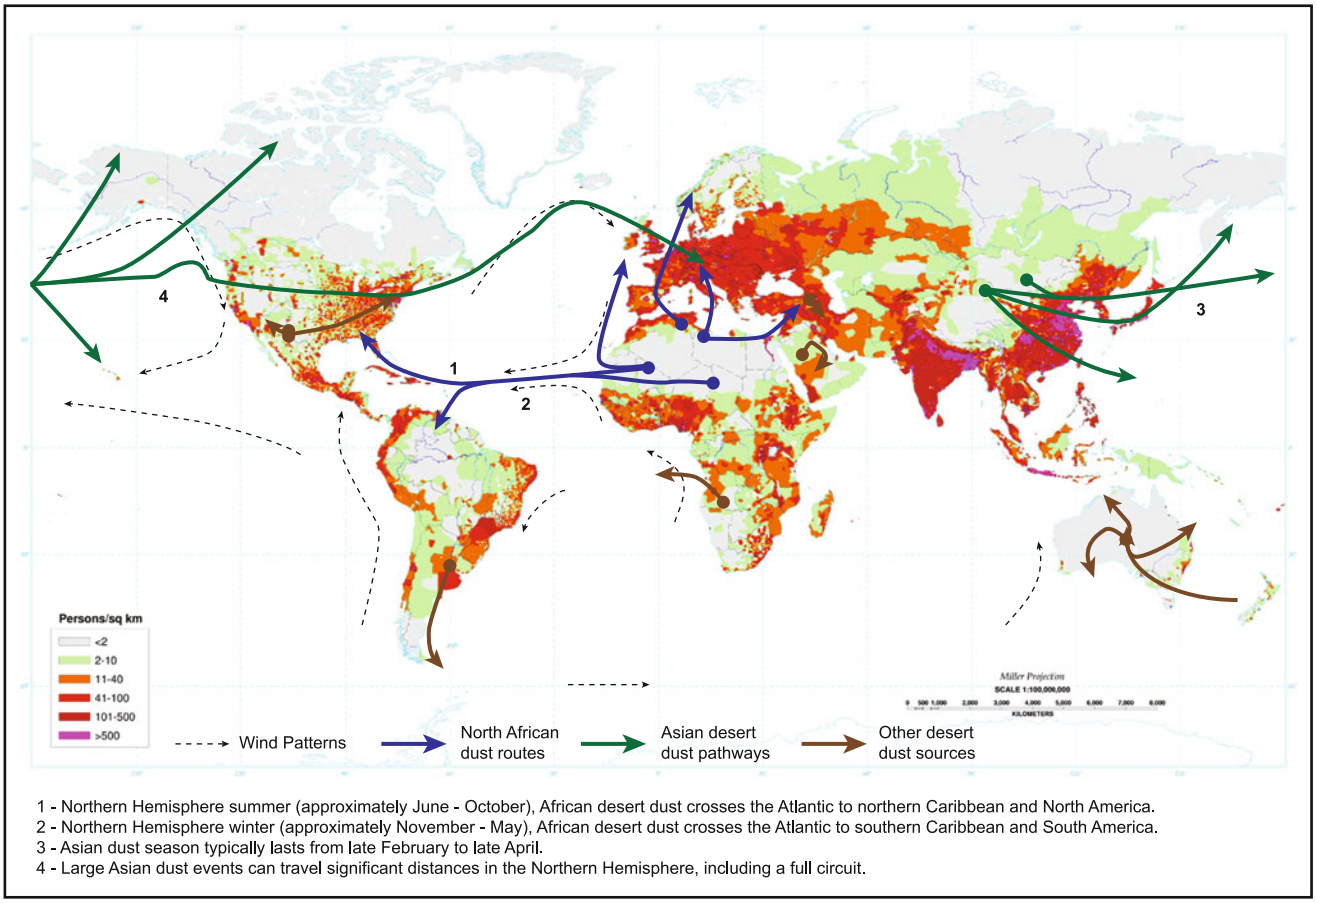
Deflation of mineral dust occurs on all continents, but the drylands of the Earth (semiarid and arid) provide the main sources, notably in rainstorm channels (*wadis*), seasonally dry alluvial fans, and ephemeral and former lake depressions (*playas*). The most prolific sources are found in a 10,000 km tract extending across the Northern Hemisphere from the North Africa/Middle East region through to central and eastern Asia, which makes up one third of Earth's land area. Dust sourced in North Africa and the Middle East constitutes up to 70 wt.% of total global dust emissions, with Central and East Asia contributing 15% (Tanaka and Chiba, 2006). Other important sources include Australia (6%), southern Africa (3%), South America (2%), and the western U.S.A. (ca. 0.1%).

Eruptions of the world's volcanoes also contribute to the global dust flux, as do natural and human-induced wildfires (bush fires). Smoke plumes from burning vegetation provide a regional contribution to global dust emissions in the form of black carbon and silica particles (Le Blond et al., 2008), a product resulting from incomplete combustion of biomass able to absorb solar radiation. While volcanic eruptions remain largely unpredictable, natural biomass burning and some human-induced wildfires, including those arising from some agricultural practices, tend to be seasonal.

Dust pathways and deposition

The atmospheric dust pathways from Earth's two dominant dust-source regions (North Africa/Middle East and central and eastern Asia) are global in distribution and seasonally variable under the influence of three global wind systems – the subtropical trade winds, the Westerlies, and the monsoons. Other transport pathways include the Middle East (including north-westerly *shamal* winds), Australia (seasonally variable owing to southern monsoon influence but including the Westerlies), southern South America (Westerlies), southern Africa (southern Trade Winds), and the Great Basin of the USA (Westerlies) (Figure 1). Modeling studies have suggested that composition of far traveled dust in the northern hemisphere is a mixture of particles derived from all three major sources (North Africa, the Middle East, and central and eastern Asia: Uno et al., 2009).

In North Africa during the northern winter (February and March), mobile anticyclonic (high) pressure cells strengthen the NE trade winds (*Harmattan*) that raise long-lasting, highly concentrated mineral dust palls into the lower troposphere, carrying dust into the Atlantic basin (Figure 1). In summer (June–August), Saharan dust outbreaks are lower in frequency and density but may persist for several weeks. Summer heating generates a thermal depression over the Sahara, which raises the regional anticyclone to altitudes above 1,500 m, causing summer dust outbreaks at higher tropospheric levels. This semipermanent Saharan Air Layer (Prospero and Carlson, 1981) sustains a westward flow of dust across the Atlantic that reaches South and Central America and southeastern North America. In the autumn-winter transition (October and November), low temperatures and increased rainfall in North Africa's Sahel zone inhibit dust release.



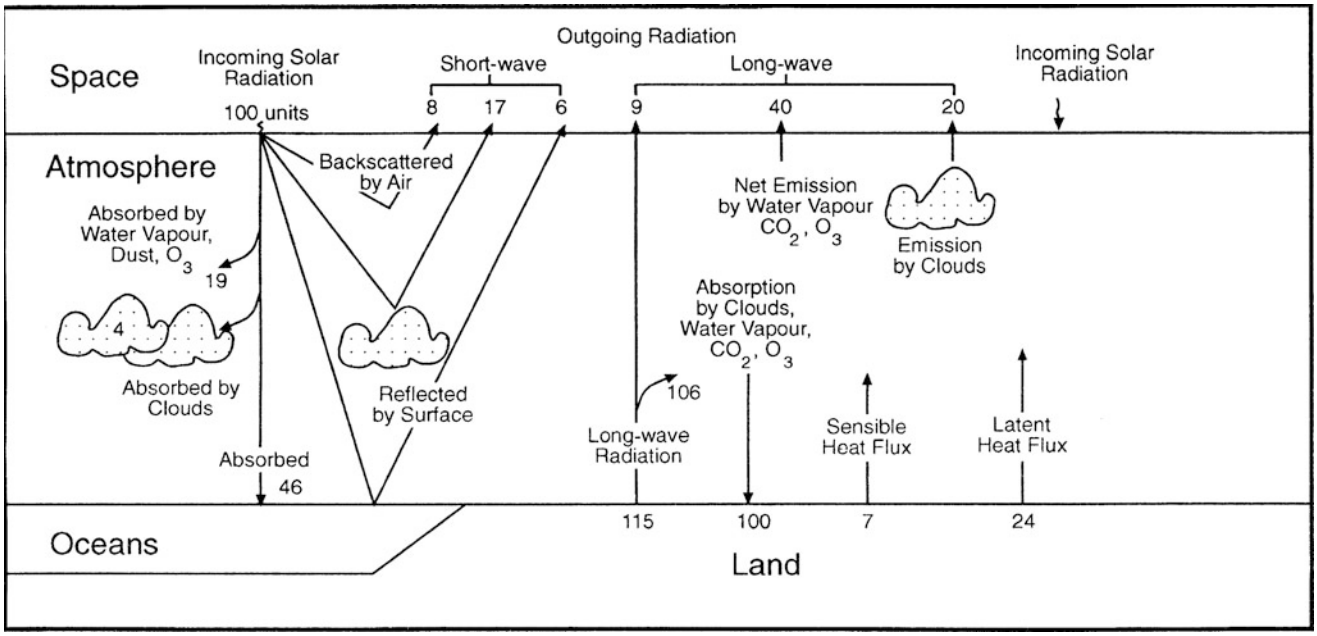
Global dust pathways from sources in central and eastern Asia are also largely driven by the Westerlies. Although more seasonal than the Saharan system, with dust storm frequency peaking between winter and late spring, dust release may occur in all seasons in north and west China. In winter, the presence of a large and stable high pressure cell (the Siberian High) maintains very cold winters, but it becomes smaller and less stable as spring approaches. Vigorous Westerly pre-frontal low pressure troughs track along the Siberian High's retreating flanks, raising dust from two main dryland sources (Mongolia/northeast China and Taklimakan Desert/northern Tibetan plateau) into the upper troposphere. These Asian pathways impact upon western, northern, and eastern China, Korea, Japan, Pacific islands, and North America. Dust from both sources traveling within both lower and upper troposphere reaches the Greenland ice sheet and the French Alps (Bory et al., 2003: Grousset et al., 2003).

Environmental effects of airborne dust

The presence of dust particles in the atmosphere affects Earth environments in several ways. These include impact on climate by changes in the radiation budget of the atmosphere, lowering of air quality, changes in the biogeochemical cycles including enrichment of soils, delivery of vital nutrition for, but also inflicting damage upon marine systems, and impacts upon human health by inhalation.

Atmospheric effects

The radiation budget is an expression of the state of balance between scattering and absorption of shortwave radiation received from the sun and long-wave (infrared) radiation emitted from Earth's surface (Figure 2). This balance is affected by the presence and characteristics of airborne dust including the load (concentration) and vertical thickness of the dust pall, and the properties of the dust particles including size, shape (and, hence, surface area), density, and mineralogical/chemical composition. Optical properties of dust, notably the ability to absorb and scatter light, are influenced by particle size, shape, and chemical composition. By reducing the solar radiation that reaches Earth's surface, dust concentration



Global Dust, Figure 1 Primary sources of mineral dust and their generalized atmospheric pathways (Modified after Griffin, 2007), and world population density 1994 (United States Department of Agriculture). Global pathways of Asian dust derived from two major sources traverse areas with population densities of over 100 to more than 500 people per km^2. Smaller regions with significantly dense populations traversed by Saharan global dust palls include the greater Caribbean (from southeast USA to northern South America), while both Asian and Saharan global dust palls traverse moderately dense populations (>41 per km^2 and locally >101 per km^2) in Europe and North America.

causes deterioration of air quality, warming of the aerosol layer, and cooling of Earth's surface.

Large atmospheric dust loads increase energy absorption levels. This is also the case with palls of coarse-grained dust commonly found close to dust sources, but the fining of mean particle size with distance along transport pathways and the increase in the proportion of small, disk- or blade-shaped mineral particles (Lawrence and Neff, 2009) increases energy scattering. The albedo of the Earth's surface (the ratio of light reflected from a surface compared to light received from the sun) beneath a dust pall and certain atmospheric dynamics can also influence the radiation balance. Surfaces with high albedo (i.e., high reflectivity), including snow and deserts, are warmed beneath a dust pall, while darker surfaces (low albedo), such as forested terrain and oceans, are cooled.

Mineral dust also affects the atmosphere's chemical composition by adsorption onto dust particles of atmospheric compounds, including those of nitrogen and sulfur. Dust particles are commonly coated with nitrates, involving heterogeneous processes in which reaction rates rise with increasing relative humidity when initially dry dust particles enter more humid air masses. Nitric acid reacts with atmospheric ammonia, forming ammonium nitrate particles, which have the potential to scatter solar radiation. Dust particles are also frequently coated with sulfur compounds which, attached as sulfur dioxide, rapidly convert to sulfuric acid. Airborne sulfate is important in scattering incoming solar radiation. At least 10% of atmospheric sulfate is associated with dust particles, the figure reaching 50% over extensive parts of the globe (Dentener et al., 1996). Reactions between acids and soluble dust particles diminish atmospheric acidity and remove aerosols with the potential to affect the radiation balance (Arimoto, 2001). The smallest dust fractions also serve as condensation nuclei in the process of cloud formation; cloud cover scatters solar radiation and thus cools the surface of land and ocean.

Global Dust, Figure 2 The radiation balance of the Earth. Numbers refer to arbitrary units of radiation (After Pickering and Owen, 1997, page 105. Re-drawn after Our future world: global environmental change (1989)).

Volcanic eruptions release mineral particles and compounds rich in sulfur and fluorine. Plume dust confined to the troposphere warms the higher altitudes and cools the Earth's surface, but the effects of many volcanic eruptions are relatively short lived. In contrast, major explosive eruptions from which ash, mineral compounds, and gaseous aerosols reach the stratosphere can prolong the "solar dimming" process and associated surface cooling effects for years. On June 15, 1991, a cataclysmic eruption of Mount Pinatubo volcano (Philippine Islands) ejected debris over 5 km^3 in volume that reached 35 km into the atmosphere (Newhall et al., 1997). The fine-grained ash cloud from this second largest eruption of the twentieth century encircled the globe.

Some wild (or bush) fires can give rise to dust and smoke plumes that are generally local to regional in scale rather than global. The environmental impact of dense pollutants arising from such fires can be intense although they are frequently short lived (Morawska and Zhang, 2002). However, the fires in the Indonesian forests in 1997–98 burned about eight million hectares of land, inflicting huge damage on the tropical ecosystem and a range of health problems across the region, as well as suffering a severe economic downturn across the whole region (Newhall et al., 1997). In the dry summer of 1998, extensive fires broke out in the boreal forest zone of both western and eastern Siberia, reaching the far east of Russia by October. The estimate of the area of forest burning is 1.1×10^7 with carbon (as CO_2, CO, CH_4, non-methane hydrocarbons, and C particles (as smoke)) entering the atmosphere (Kajii et al., 2002).

Soils and ecosystems

The transportation of dust by wind action, as well as being a degradation process involving soil erosion and nutrient loess, also plays a positive role in adding vital nutrients to ecosystems following deposition on both land and the open ocean. Actions that can have effects on the biogeochemical cycles include enrichment of soils on land and phytoplankton growth in the ocean.

It is well known that African dust reaches the SE of North America and NE South America as well as the Caribbean and other islands (Prospero and Lamb, 2003), but soils on the limestone bedrock of this region have been regarded as the result of long-term residual dissolution of the carbonate-rich bedrock. In a study of the clay-rich soils of Barbados, the Florida Keys, and the Bahamas, Muhs et al. (2007) found that certain rare earth and other trace elements are present in only very low concentrations in the local coral. Also, while tephra from the Lesser Antilles volcanic arc includes a broad range of mixed oceanic and continental crustal components, African dust and the fine-grained (<20 μm) fraction of the lower Mississippi valley loess have a narrow range of such components. Thus, it appears that North African dust is the source of the dominant parent materials in the soils of the Florida Keys and the Bahamas and an important source material in the soils of Barbados. It was also conjectured that the lower Mississippi loess may have been an important source of the regional soils for the past 700,000 years.

Wind-transported mineral dust, as a vital source of nutrition in marine ecosystems, can also influence the

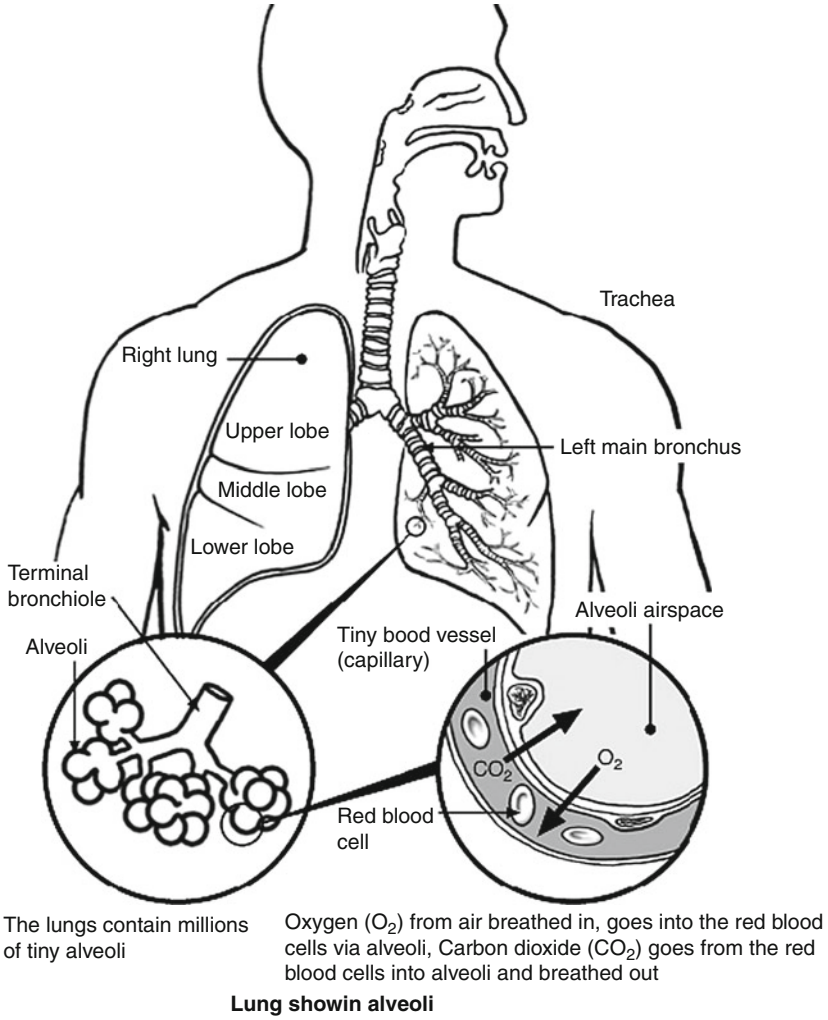
nutrient dynamics and biogeochemical cycles in the world's oceans. For example, deposition of iron in oceanic waters stimulates nitrogen fixation by plankton, thus enhancing productivity; the dominant input of iron is provided by wind-blown dust from the drylands of the world (Jickells et al., 2005). In contrast, influxes of airborne dust may have deleterious effects on ocean ecosystems. For example, in addition to transporting nutrients to the Caribbean and Gulf of Mexico region, Saharan dust also deposits harmful microorganisms, pathogens, organic pollutants, and metals (Shinn et al., 2000; Garrison et al., 2003, 2006; Griffin, 2007). Studies in the Caribbean and elsewhere have suggested that changes in the level of nutrients affect coral reef health because dust can enhance the effect of rapid growth of algae, which causes changes in marine microbial diversity (Griffin and Kellogg, 2004).

Impacts of mineral particles on human health

Many inhaled mineral particles are intrinsically toxic and/or carcinogenic and, together with the dose (dust concentration plus length of exposure), are prime causal factors in respiratory diseases. The potential of inhaled mineral particles to raise morbidity and mortality rates varies with particle properties including mineralogical and geochemical composition, degree of crystallinity, size, shape, density, solubility, and reactivity with human lung tissue and fluids; other factors affecting variability include pathogens attached to the minerals, dust concentration (the load), and the natural vulnerability of individual human subjects.

Human lung airways are susceptible to the reactivity of fine mineral dust, which is conventionally divided into the coarse (<10 μm, or PM10), fine (<2.5 μm, or PM 2.5) and ultrafine fractions (<100 nm). Dust particles with diameters < 4 μm can reach the lung's distal bronchioles and alveoli (Figure 3). Macrophage cells (mononuclear phagocytes) patrol the fluids that line the respiratory tract and engulf (i.e., phagocytise) foreign particles. Alveolar macrophages are a first line of defense in the clearing of particles from the alveoli (Plumlee et al., 2006). Acidic lysosomes and digestive enzymes within alveolar macrophages aid in the dissolution of soluble particles while, at the same time, releasing chemicals (cytokines) that attract other macrophages to assist in clearing additional foreign particles (Lehnert, 1992, cited in Plumlee et al., 2006). Macrophages, with diameters in the range 5–10 μm, are able to engulf only small particles (<2–5 μm in size (Fubini and Areán, 1999)). Particles that avoid being phagocytised and escape other clearance processes injure lung tissue. PM10 particles are usually cleared by coughing, but upper airway morbidity may result if mineral particles are sufficiently toxic and inhalation exposure is prolonged. Nanoparticles are released into the environment by natural processes and by industrial activity including manufacturing and engine exhausts, but little is known about their concentrations in global dust and their likely health impact therein.

Mineral particle toxicity



Important naturally occurring and potentially toxic particles that may be carried in global dust include crystalline silica, fibrous amphiboles, trace elements, and alkaline salts. Prolonged inhalation of silica (SiO_2: commonest form – quartz) can cause chronic (long-term) inflammation and fibrosis of the lung leading to silicosis, with potential progression to lung cancer, as known from occupational health studies. Quartz pathogenicity is influenced by the condition of particle surfaces (e.g., freshly fractured or presence of mineral coatings) and the presence on or within them of toxins. For example, aluminum salts and metallic iron can reduce the toxicity of quartz and so inhibit lung inflammation but, on the other hand, trace amounts of ferric or ferrous iron can stimulate surface oxidative stress leading to epithelium cell damage (Donaldson and Borm, 1998).

Emissions of silica, silicates, and trace metals during volcanic eruptions can have acute (short-term) effects on exposed subjects, especially those with preexisting respiratory and cardiac conditions. However, opinion remains divided as to whether exposure to volcanic ash leads to chronic diseases such as silicosis (Horwell and Baxter, 2006). The impact on lung tissue of toxic trace elements adsorbed onto mineral particles is also not fully understood, but epidemiological evidence points to an association with human airways inflammation, both acute (asthma, bronchitis, rhinitis) and chronic (fibrosis).

Dust pathways: particle size, mineral dust composition, and potential health impact

Decline in mean particle size and bulk mineral compositional changes, owing to both dry and wet deposition *in transit*, results in progressive increase in the fine silt and clay grades with distance from source (Aluko and Noll, 2006). Compositional changes can include a decline in primary mineral content, such as quartz, feldspars, and carbonates, and a proportionate increase in the phyllosilicates (e.g., clay minerals). Trace element proportions may also be raised by size fractionation during deflation and deposition. Thus, source-proximal dust (local and regional, <10 km and <1,000 km from source, respectively) may differ in composition from its distal equivalent (global dust: >1,000 km from source: Lawrence and Neff, 2009); however, this progression can be complicated by mixing of dusts derived from additional sources along the dust pathway.

The health risk to communities living close to major dust sources is likely to be higher than for more distal populations. Both acute and chronic morbidity can arise from dust inhalation close to global dust sources, as recorded in the Sahara and in western China, but information on health impacts of global-scale mineral dust is sparse and opinion is more contentious

Global Dust, Figure 3 Diagram showing lungs, alveoli, and oxygen-carbon dioxide gas exchange (From http://www.patient.co.uk/diagram/Lungs-and-alveoli.htm).

(e.g., Monteil and Antoine, 2009). Cartographic comparison of the major global dust pathways and global population density suggests that the regions of greatest potential risk from exposure to global dust may be western, northern, and eastern China, Korea, and Japan (Figure 1).

Broader agreement on causal links between distal dust loads and human morbidity rests on the presence within dust particles of microorganisms (bacteria, fungi, pollen, spores, and viruses: e.g., Griffin, 2007). Health threats include the meningitis pathogen (*Neisseria meningitidis*) (Molesworth et al., 2003), but the role of airborne pathogens in epidemics is not clearly defined. Concentrations of potentially harmful elements and compounds released by human action sometimes exceed those in natural dust palls (Holmes and Miller, 2004), but estimates of the magnitude of anthropogenic pollutant input to the global dust flux vary widely, mainly because of the sparseness of measured observational data.

Summary

Natural mineral particles, a major component of global dust, are products of rock weathering and erosion, soil-forming processes, and volcanic eruptions. Principal global dust sources are located in arid and semiarid terrains, mainly in the Northern hemisphere. Lofted into the atmosphere by strong winds, dust palls frequently travel for thousands of kilometers, sometimes circling the Earth. Dust palls impact upon the atmosphere's radiation budget and so affect the climate and biogeochemical cycles. Airborne dust can also affect human health, inhalation of toxic minerals and pathogens contributing to human morbidity and mortality. People living close to global dust sources may be subject to health risks greater than in communities located further along a dust pathway, but opinion is divided. The magnitude and impact of anthropogenically released toxins and pathogens in global dust palls are poorly known.

GLOBAL NETWORK OF CIVIL SOCIETY ORGANIZATIONS FOR DISASTER REDUCTION

Terry Gibson
Global Network of Civil Society Organisations for Disaster Reduction (GNDR), Teddington, Middlesex, UK

Definition

International network of nongovernmental organizations collaborating in the field of *Disaster Risk Reduction*.

Discussion

The Global Network of Civil Society Organizations for Disaster Reduction (GNDR) is an international network of civil society organizations working to influence and implement disaster risk reduction policies and practice around the world. It relies on the commitment, diversity of skills, knowledge, and extensive reach of its membership at all levels (particularly local) across virtually every region of the world. Members work for a broad range of organizations including large national and international NGOs, local or community-based organizations, and academic and/or research institutions. Many within the Network serve on their own national and regional networks, alliances, and associations.

The stated Goal of GNDR is to harness the potential of global civil society to engage strategically in disaster risk reduction policy and practice – placing the interests and concerns of vulnerable people at the heart of policy formation and implementation.

The need for the Global Network was identified by a number of civil society organizations at the World Conference for Disaster Reduction in 2005. It was initiated with the close support of the United Nations International Strategy for Disaster Reduction (UN-ISDR) Secretariat, in collaboration with the Special Unit for South–South Cooperation of the United Nations Development Program (UNDP). It was officially launched in Geneva during the first session of the Global Platform for Disaster Risk Reduction (GP-DRR) in June 2007.

GNDR works closely with civil society organizations, government bodies, UN agencies, and international institutions, with the intention of amplifying the voice and influence of disaster-prone communities at the national, regional, and international levels through sharing of learning and experiences, building consensus, and supporting collaborative approaches and joint actions.

A key project based on these principles is the "Views from the Frontline" (VFL) participative monitoring project (http://www.globalnetwork-dr.org/VFLreports.htm), which was undertaken by GNDR in 2009. The VFL project involved network members in a face-to-face survey of stakeholders involved in Disaster Risk Reduction at the local level, in order to establish what progress had been made in terms of the United Nations "Hyogo Framework for Action" on Disaster Risk Reduction, which had been established in 2005. The survey generated data from over 7,000 respondents at a local level, including local government officials, civil society members, and community members. There was a special focus on women and young people.

The VFL report was presented at the second session of the GP-DRR in June 2009 with the aim of promoting stronger linkages between policy established at the national level based on the HFA, and practical implementation and resourcing at the local level. The VFL program will be continued to compare results with the 2009 "baseline" survey.

GLOBAL POSITIONING SYSTEMS (GPS) AND NATURAL HAZARDS

Norman Kerle
University of Twente, Faculty of Geo-Information Science and Earth Observation (ITC), Enschede, The Netherlands

Synonyms

Global Satellite Positioning System; GPS; Sat Nav

Definition

Global Positioning Systems (GPS) are all-weather systems based on constellations of satellites that allow worldwide terrestrial, maritime, and aerial navigation and position determination, using passive receivers that

triangulate a three-dimensional position based on radio signals received from at least four satellites.

Discussion

Although Global Positioning System (GPS) is a generic term, it has become synonymous with the US-operated NAVSTAR GPS. With the first satellites launched in 1978, it became fully operational in 1995. Developed primarily for military purposes, it remains the only complete global satellite-based positioning system. It employs 24 active satellites orbiting at approximately 20,200 km altitude, ensuring that between 4 and 12 satellites are within direct line of sight of anywhere on Earth. Three-dimensional positions are determined using passive devices that receive encoded signals from at least four satellites, triangulating the position based on distances to the satellites, calculated from the message travel time (see *Electromagnetic Radiation (EMR)*). Different signals are encoded for precision military positioning and coarser civilian uses. Early handheld GPS receivers achieved positional accuracies of about 100 m. After discontinuation in 2000 of "Selective Availability," which introduced an artificial error in the civilian signal, this increased to approximately 20 m. In 2005, a signal with a different frequency was added, allowing errors due to frequency-dependent ionospheric signal delay to be calculated, improving horizontal accuracies to about 5 m. By using data from a base station with well-known coordinates, the measurements from a mobile (rover) GPS can be corrected (differential GPS), leading to mm-accuracies (see Kennedy, 2002).

GPS has become vital in disaster risk applications, since all aspects of disaster risk (see *Remote Sensing of Natural Hazards and Disasters*) have a certain location and extent that GPS allows to locate or track. Differential GPS is frequently used to collect precise ground control points needed for photogrammetric applications, but also to monitor mm-scale movements of tectonic plates or deforming volcanoes. It is also essential for airborne laser scanning as it provides precise positioning of the aircraft. GPS is the backbone of car navigation used in rapid emergency response, and reduces the hazards of air travel and maritime navigation. More recently GPS-based applications have been developed that allow multi-agent emergency response, based on knowledge of real-time positions of all response personnel. Modern GPS receivers are tiny and cheap, and increasingly common in cameras and mobile phones.

Although weather-independent, GPS requires line of sight; thus, under heavy tree cover or indoors use is limited. Development of pseudolites that broadcast GPS-like signals from fixed positions in urban areas, or linking a GPS framework with other radio networks for indoors navigation, look promising. In addition to NAVSTAR, Europe is developing the competing and more accurate Galileo system, whereas Russia has been reviving the GLONASS system (originally also commissioned in 1995), expecting to operate a global system with 24 satellites (Cojocaru et al., 2009). The Chinese Beidou system, planned as a regional service, will morph into the global Compass system with 35 satellites by 2015.

Definition

The Global Seismograph Network (GSN) is a high quality, standardized, digital, real-time seismograph network consisting of more than 150 stations distributed globally.

Discussion

The GSN provides free, open access data via the Incorporated Research Institutions for Seismology Data Management Center (IRIS DMC), which is also responsible for archiving the data from the GSN and many other seismograph stations. The data may be used for research, monitoring, or outreach purposes. The network is operated by IRIS and the United States Geological Survey (USGS) with additional funding from the National Science Foundation (NSF) and through coordination with the international seismological community. The GSN is an American contribution toward the International Federation of Digital Seismograph Networks' goal of uniform Earth coverage by broadband, three component seismographs. The GSN represents the most recent version of several global seismograph networks operated principally by the United States starting with the Worldwide Standardized Seismograph Network (WWSSN) in the 1960s. As seismograph, digital archiving, and telecommunications technology improved, the network was upgraded to the Digital Worldwide Standardized Seismograph Network (DWWSSN), then the Global Digital Seismograph Network (GDSN), and finally the GSN. The Global Telemetered Seismograph Network (GTSN) is a smaller,

also US initiated, network aimed at filling in gaps in global coverage and consists of 13 seismograph stations primarily in the southern hemisphere. A more thorough description of some of the earlier networks may be found in Engdahl et al. (1982) and the references therein.

Overview

At 4:53 PM local time (21:53 GMT) on January 12, 2010, a magnitude 7.0 earthquake devastated the Haitian capital city of Port-au-Prince and surrounding area, killing an estimated 222,570–316,000 persons (Inter Agency Standing Committee, 2010; CBC News, 2011). The Haiti 2010 earthquake is noteworthy among natural disasters that subject the affected human population to intense psychological stressors (Table 1).

Norris and colleagues (2002) posit that disasters that possess two or more of the following four characteristics are likely to create significant mental health consequences for the affected community: (1) large numbers of deaths and/or injuries, (2) widespread destruction and property damage, (3) disruption of social support and ongoing economic problems, and (4) "human" contribution to the disaster's causation. By the numbers, the Haiti 2010 earthquake possesses all of these attributes: (1) mass mortality, (2) near-total physical destruction over large areas, (3) social dislocation to a point bordering on societal collapse, and (4) ample evidence of human amplification of the earthquake's harm (preventable deaths and severe injuries attributable to dangerous and derelict standards for housing construction; uncommonly widespread and brutal interpersonal violence directed against earthquake survivors in the aftermath) (Shultz et al., 2011).

Profiling the Haiti 2010 earthquake will provide insights into the psychologically traumatizing capacity of this exceptional event (Shultz et al., 2011). The psychological consequences of the Haiti 2010 earthquake can be portrayed across five salient dimensions: (1) disaster type, (2) severity, (3) duration, (4) mortality, and (5) scope and social context of psychological impact (Table 2).

Disaster type: event description and disaster consequences

Haiti occupies the western third of the island of Hispaniola, one of the Greater Antilles islands, located between Puerto Rico and Cuba. The Haiti 2010 earthquake occurred south of the east-west trending "strike-slip" fault zone separating the massive North American tectonic plate (to the north) from the Caribbean plate (to the south). Relative to the North American plate, the Caribbean plate "slips" about 20 mm to the east each year. In Haiti, the plate boundary between these two plates presents a more complex scenario; historically, shearing pressures have created an additional fracture along the ragged juncture. The resulting tectonic shard, "the Gonave microplate," on which Haiti rides, is bracketed by two fault zones running east-west in northern and southern Haiti. The Haiti 2010 earthquake occurred along the Enriquillo-Plantain

Haiti Earthquake 2010: Psychosocial Impacts, Table 1 Haiti 2010 earthquake: disaster stressors

Impact phase stressors	Post-impact phase stressors
Exposure to severe shaking	Exposure to ongoing aftershocks
Exposure to multiple strong aftershocks	Physical injury and personal harm
Physical injury and personal harm	Pain, debility, loss of function
Entrapment in collapsed structures	Loss of limb
Perception of risk of death/extreme harm	Rampant infectious diseases
Panicked flight	Searching for missing loved ones
Loss of loved one	Caring for injured loved ones
Separation from loved ones during event	Grief for lost loved ones
Witnessing harm to others	Lack of access to emergency care
Witnessing death of others	Lack of access to primary medical care
Witnessing grotesque, troubling scenes	Lack of access to mental health care
Damage/destruction of home	Lack of survival needs (food, water)
Displacement from home	Lack of utilities and essential services
Community-wide physical destruction	Lack of sanitation, public health
	Lack of communications
	Lack of transportation
	Lack of personal security
	Rumors of additional shocks to come
	Damage/destruction of home
	Loss of personal possessions
	Displacement
	Living in temporary camps
	Witnessing dead bodies
	Witnessing severely harmed persons
	Witnessing traumatized/bereaved survivors
	Looting and gang activities
	Interpersonal and gender-based violence
	Damage to worksite
	Loss of employment
	Financial hardship
	Damage to place of worship
	Absence of government infrastructure
	Damage to schools
	Earthquake trauma reminders from aftershocks and scenes of destruction
	Family distress

Garden Fault Zone (EPGFZ) to the south. Along the EPGFZ, the plates had been "locked" in position for approximately 250 years, with escalating stress prior to the moment of release. At that moment, 4:53 PM, January 12, 2010, along 65 km of the EPGFZ, the Caribbean Plate jolted violently eastward an average distance of 1.8 m (with amplitudes as large as 4 m in some locales). As precisely described by Calis et al. (2010), the earthquake occurred on a previously unmapped steeply dipping fault that makes a high angle with the Enriquillo-Plantain fault.

With a rupture that was as close as 17 km from downtown Port-au-Prince, Haiti's capital and major population center, this near-surface earthquake shattered the city and terrified its population. At Moment Magnitude 7.0, the Haiti 2010 earthquake was very intense, but for perspective, the February 2010 earthquake in Maule, Chile, registered Moment Magnitude 8.8, generating 500 times the energy of its Haitian counterpart. Although the 2010 Chilean earthquake ranks high among the most powerful seismic events, its memory was short lived, whereas the weaker 2010 Haitian earthquake, by decimating a densely packed and structurally vulnerable population, has made its mark on human history and on the psyche of the Haitian people.

The entire nation of Haiti experienced the sensations of ground movement during the initial shock, with millions in the throes of significant shaking. The death toll, in the range of 222,570–316,000 deaths (Inter Agency Standing Committee, 2010; CBC News, 2011), places this event among the deadliest sudden-impact natural disasters on record. More than 300,000 survivors were seriously injured. Among these, an estimated 4,000 survivors sustained amputating injuries. Millions experienced excruciating pain from personal injury, or directly observed gruesome harm or brutal death as buildings toppled, or witnessed piles of decomposing bodies strewn throughout the streets. In the aftermath, with hundreds of thousands of collapsed or uninhabitable dwellings, 1.3 million persons were internally displaced, eventually finding temporary lodging in the myriad impromptu camps that were hastily erected. In the weeks following the earthquake, displaced persons, deprived of secure shelter and personal privacy, were easy prey to looting, gang violence, and gender-based violence including rape. Environmental hazards posed risks for falls, punctures, abrasions, and lacerations. Destruction of infrastructure, leading to absence of clean water, sanitation, and hygienic healthcare services, produced a cascade of untoward outcomes: infectious disease outbreaks, life-threatening wound infections, and malnutrition contributing to preventable deaths among infants and young children. Population-wide vulnerability following the earthquake exacerbated the spread and severity of a raging outbreak of cholera that caused illness in 470,000 persons and killed almost 7,000 in 1 year (CDC, 2011) (Table 3).

Disaster severity and psychological impact

The confluence of multiple physical and psychological consequences distinguishes the Haiti 2010 earthquake as singularly destructive. In a disaster, one of the strongest predictors of the severity of psychological effects is the degree of exposure to the forces of harm (Neria et al., 2008; Shultz et al., 2007, 2012a). The absolute magnitude of the forces of harm largely determines the extent of damage, destruction, displacement, death, and injury, as well as the extent of stress and trauma experienced by the disaster-affected population (Shultz et al., 2011).

At the moment of impact, exposure to the Haiti 2010 earthquake was experienced throughout the nation as ground shaking. Both the objective intensity and the subjective experience of ground shaking relate directly to the distance from the earthquake's epicenter. Persons closest to the strike zone were subjected to the kinesthetics of extreme shaking, compounded by the multisensory

Haiti Earthquake 2010: Psychosocial Impacts, Table 2 Haiti 2010 earthquake: hazard profile

Disaster type	*Definition*	Catastrophe/complex emergency
	Initial event classification	Natural disaster/geophysical/earthquake: left-lateral strike-slip faulting at angle with the Enriquillo-Plantain Garden fault system
	Ongoing event classification	Complex emergency: natural disaster followed by infrastructure collapse, massive loss of life, large-scale displacement, and interpersonal violence
	Forces of harm	Strike-slip faulting on a fault associated with a tectonic plate boundary Severe ground shaking Structural collapse of buildings
Magnitude and severity	*Moment magnitude*	Initial earthquake: M 7.0 First 4 weeks: 16 aftershocks $\geq$ M5.0 First 4 weeks: 59 aftershocks $\geq$ M4.5
	Modified Mercalli Intensity	Epicenter: X (on a 12-point scale: I–XII) MMI intensity generally diminishes as a function of distance from epicenter
Place dimension	*Epicenter*	A 40-km long rupture; shortest distance is 17 km from Haitian capital of Port-au-Prince
	Hypocenter	Rupture from near surface to 13-km depth
	Geography/geology	The region is near a tectonic plate boundary region separating the Caribbean plate and the North America plate. The main shock mostly represents faulting on an unmapped steeply dipping fault at angle with the Enriquillo-Plantain Garden fault zone (EPGFZ).
	Scale/scope	Intense shaking/destruction throughout southeastern Haiti, particularly in the capital of Port-au-Prince and surrounding areas. Shaking of varying intensity felt throughout entire nation of Haiti (27,750 km^2) and adjoining portions of Dominican Republic on island of Hispanola. Psychological impact extends to Haitian "diaspora" in United States, Canada, Caribbean, responders from many nations
	Built environment	Poorest nation in Western Hemisphere Rank 147/182 on Human Development Index 55% below extreme poverty index Widespread structural deficiencies High-density urban crowding
Time dimension	*Initial earthquake strike*	January 12, 2010, 16:53 local time (21:53 GMT)
	Duration	Initial earthquake: 15–35 s of strong shaking (estimate)
	Frequency	Strong aftershocks of gradually decreasing frequency over several months (59 aftershocks $\geq$ M4.5 in first 4 weeks)
	Duration of life/health risk	Months: cholera outbreak caused illness in 470,000 with 6,631 deaths through October 2011
	Duration of disruption	Years

experience of structural disintegration occurring in all directions around them. In some areas of particularly intense tumult, "liquefaction" occurred as the sediment lost its weight-bearing properties, causing structures to sink and crumble (Shultz et al., 2011). Punctuating the jarring, disorienting, fear-triggering sensations of tremulousness and vibration, many persons were physically injured, pinned by falling rubble, or entrapped in collapsed structures. Bodily pain, injury, immobilization, trapped confinement, and perceived life threat are psychological stressors (Shultz et al., 2011). Haitian survivors engaged in frenetic, bare-handed scramble to find and extricate family members and neighbors who had disappeared amid the heaving earth and caving debris.

Assuming an earthquake source of given orientation and rupture characteristics, it is possible to estimate the levels of shaking over an area and convert them to ratings on the Modified Mercalli Intensity Scale. The Modified Mercalli Intensity Scale (MMI) is a 12-point rating scale (I–XII). Each point on the scale is composed of an estimate of shaking intensity and a corresponding description of structural damage. The MMI estimates how strongly an earthquake is felt by people in a geographical area, and the corresponding amount of damage to buildings and dwellings.

For the Haiti 2010 earthquake, the United States Geological Survey (USGS, 2010a) has created a "shakemap" displaying the geographic areas, and estimated population numbers, for each of the MMI categories. For example, more than 1.0 million Haitians experienced violent or extreme shaking (MMI Scale IX or higher), with heavy to catastrophic damage all around. An additional 3.5 million residents experienced strong, very strong, or severe ground shaking (MMI Levels VI–VIII). Together, these data provide clear evidence that almost 4.6 million Haitians experienced ground movement at the level of

Haiti Earthquake 2010: Psychosocial Impacts, Table 3 Haiti 2010 earthquake: disaster consequences

Disaster consequence	Haiti 2010 earthquake description
Exposure to ground shaking	MMI[a] ≥ IX: violent/extreme intensity: 1.0 million persons MMI[a] VI–VII: strong/very strong/ severe intensity: 3.5 million persons
Mortality	222,570–316,000 deaths
Bereavement	Millions have lost a primary family member
Morbidity: injury	300,000 injuries requiring medical care 4,000 injuries requiring amputation
Morbidity: infectious disease	Hundreds of thousands of disease cases
Internally displaced persons (IDPs) due to earthquake	1,300,000 earthquake IDPs
Damage to homes	Destroyed homes: 97,000 Severely damaged homes: 188,000
Gender-based violence	High rate of reported rapes and assaults on women
Children without caregiver	Separation from caregiver Earthquake orphans
Lack of access to clean water	Millions of persons
Lack of access to food	Malnutrition risk: 495,000 children and 198,000 pregnant/lactating women
Lack of access to sanitation	Millions of persons

[a]MMI: Modified Mercalli Index

Haiti Earthquake 2010: Psychosocial Impacts, Table 4 Haiti 2010 earthquake: persons exposed to ground shaking by MMI level

MMI	Perceived shaking	Estimated population AT MMI level	Estimated population AT or ABOVE MMI level
X–XII	Extreme	118,000	118,000
IX	Violent	908,000	1,026,000
VIII	Severe	2,030,000	3,056,000
VII	Very strong	598,000	3,654,000
VI	Strong	926,000	4,580,000
V	Moderate	6,361,000	10,941,000
IV	Light	7,468,000	18,409,000
I–III	Weak to imperceptible	50,000	18,459,000

Source

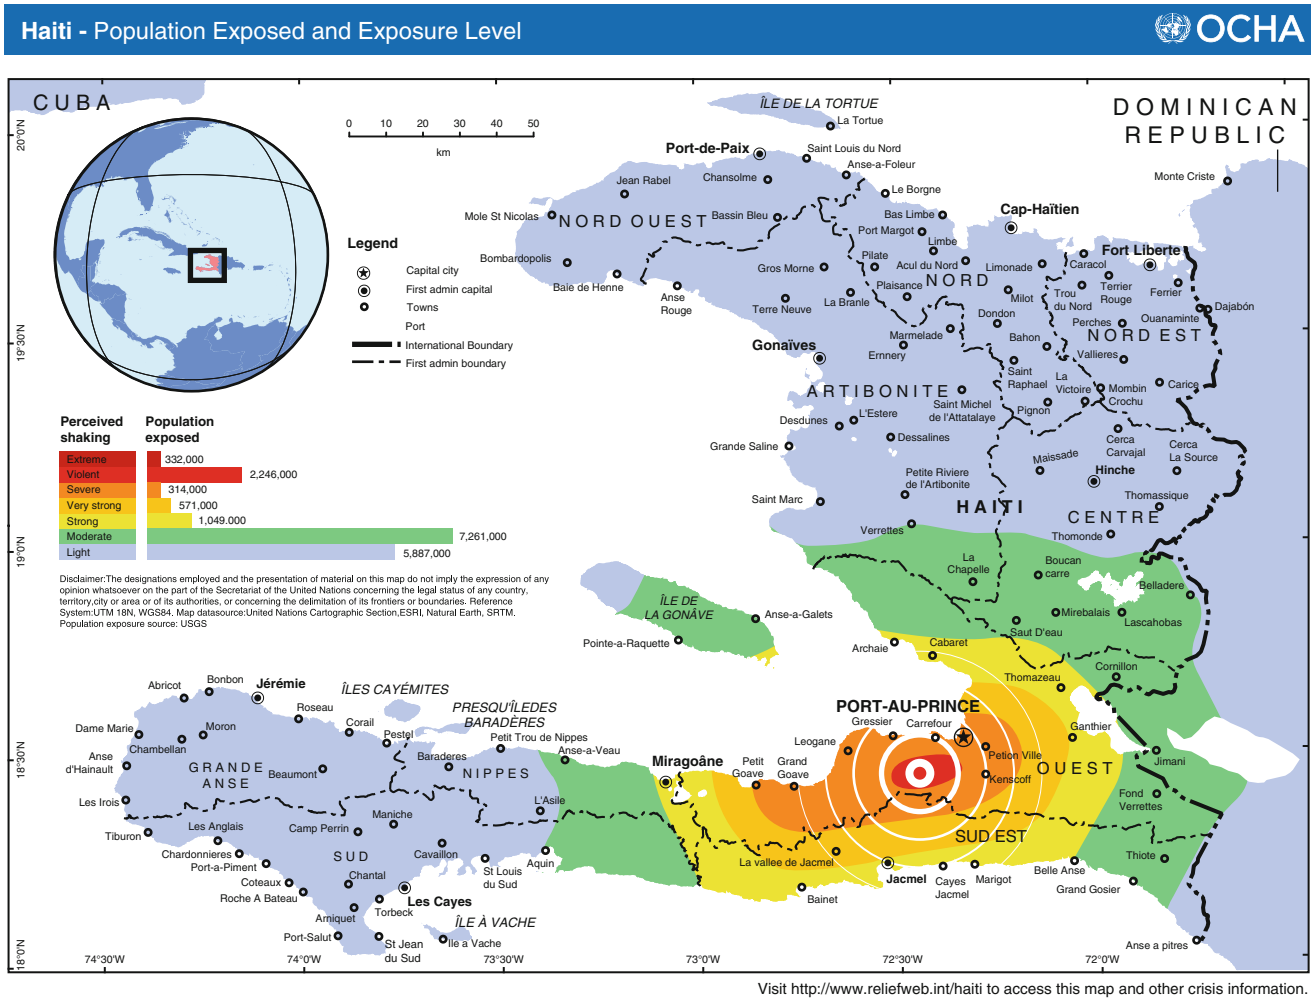
MMI VI or higher. The entire Haitian population of approximately 10 million persons experienced some degree of perceptible ground shaking, as did millions more in neighboring Dominican Republic and nearby Caribbean islands (Table 4, Figure 1).

Duration and frequency of psychological stressors

During exposure to threat or overt forces of harm, survival stress responses are activated. Moreover, the frequency of discrete disaster impacts relates to psychological trauma; a sequence of multiple strikes, and exposure to both stress and loss, tends to be more alarming than a single, discrete event (Neria and Litz, 2004). In the case of the Haiti 2010 earthquake, both duration and frequency operated in tandem to exacerbate fear and distress.

While the duration of the initial earthquake was estimated in the range of 15–35 s, repeated strong aftershocks triggered fear reactions and acted as powerful psychological reminders of the initial "mainshock" experience. Aftershocks began immediately. The first powerful aftershock (M 6.0) occurred 7 min after the "mainshock." The second aftershock (M 5.5) was experienced 12 min later. According to the United States Geological Survey (2010b), in precisely 4 weeks following the earthquake's origin, 16 aftershocks of magnitude 5.0–6.0, and 43 aftershocks of magnitude 4.5–4.9, occurred close to the original epicenter.



Disaster stress persisted long after the aftershocks tapered. Hardships in the aftermath were severe and prolonged with near-complete destruction of infrastructure, lack of survival supplies, absence of basic services, and sporadic episodes of violence on the streets and in the camps.

Mass mortality in relation to psychological impact

Sudden, concentrated, mass mortality distinguishes the Haiti 2010 earthquake from past earthquakes of similar magnitude. Most of the deaths occurred instantly or within minutes or hours of the M 7.0 mainshock. Some injured victims suffered a more protracted death over a period of days due to the circumstances of injury, entrapment, lack of access to medical care, or absence of basic survival needs.

Only one earthquake in recorded history significantly exceeded the numbers of deaths experienced in the Haiti 2010 earthquake; an estimated 830,000 persons died in the catastrophic earthquake that leveled Shaanxi, China, on January 23, 1556. Among ground-shaking seismic incidents in modern times, the Tangshan, China earthquake on July 28, 1976, with 255,000 deaths, rivaled the Haiti death toll. On December 26, 2004, a tsunami-generating seismic event killed an estimated 280,000 coastal dwellers distributed across more than one dozen nations encircling the Indian Ocean. Apart from these two earthquakes and the Indian Ocean tsunami, no other earthquake in recorded history has equaled the magnitude of mortality experienced in Haiti on January 12, 2010.

Beyond the exceptional numbers of deaths, a related feature of Haiti 2010 is the geographic concentration of mortality in a densely populated urban capital city and surrounding towns and communities. Large numbers of Haitians lost multiple family members.

Haiti Earthquake 2010: Psychosocial Impacts, Figure 1 Map of Haiti showing the epicenter of the January 12, 2010, earthquake and population affected.

The Centre for Research on the Epidemiology of Disasters (CRED) in Brussels, Belgium, is a WHO Coordinating Center and serves as the international repository for information on all reported disasters worldwide. CRED maintains an international disaster database dating from 1900 to the present. During the 110 years of tracking international disasters, a total of 1,095 damaging earthquakes have been reported including the early 2010 earthquakes in Haiti and Chile. Collectively, across these earthquakes, 2,323,000 persons were killed. The death toll in Haiti alone accounted for 10% of all earthquake deaths in 110 years of surveillance.

Loss of a loved one in a natural disaster is one of the most psychologically devastating experiences. Traumatic bereavement, leading to complicated grief, is associated with a host of psychiatric disorders including posttraumatic stress disorder (PTSD) and depression (Neria et al., 2007). Complicated (or prolonged) grief disorder (PGD) is a relatively new diagnosis, and different from normal grief in its extended duration and symptom profile (Horowitz et al., 1997). Correlates of PGD include severe functional impairment, decreased productivity, suicidality, and physical health problems (Neria et al., 2007). Yet to be explored is the interaction between disaster trauma and loss of a loved one (Neria and Litz, 2004); many survivors of the 2010 Haiti earthquake experienced both. More research is needed to fully understand the relations between PTSD and complicated grief, and whether they differ in their risk and protective factors.

Scope and social context of psychological impact

Psychosocial consequences of disasters are wide ranging and pervasive (Shultz et al., 2012a). More persons are affected psychologically than are harmed physically (Shultz et al., 2007). The Haiti 2010 earthquake has psychologically affected not only the persons within the immediate strike zone but the entire Haitian population (10 million persons), the expansive diaspora of Haitian

emigrants to the United States, Canada, and throughout the Caribbean (Shultz et al., 2012b), and large numbers of persons who have engaged in the earthquake response efforts. According to CRED data, only two earthquakes in the past 110 years affected more persons: The Haiti 2010 earthquake provides strong evidence that, in natural disasters, the "psychological footprint" of disaster is larger than the "medical footprint" (Shultz et al., 2007).

Adding to the widespread distress from physical hardships was the public perception of a complete void of national leadership to communicate with the public (INURED, 2010). In a survey conducted in Cité Soleil, Port-au-Prince, the key phrase that captured the population's sense of despair and abandonment, was, "We are on our own." This sentiment was repeatedly documented and echoed through the press and research reports. A lead researcher stated, "Failure to rally the country at a time when it is gravely wounded added to the suffering and trauma of the overall population" (INURED, 2010).

Summary

As we have previously stated, "the 2010 Haiti earthquake provides a potent example of the rare catastrophic event where all major risk factors for psychological distress and impairment are prominent and compounding," (Shultz et al., 2011). In this case example, we have illustrated the links between the descriptors of the event: (1) disaster type, (2) severity, (3) duration, (4) mortality, and (5) scope in relation to the psychological impact. We have attempted to describe how the psychological and physical consequences interplay and synergize in a seismic event of such impact severity marked by quantum loss of life, obliteration of infrastructure, and barbarous hardship in the aftermath. In fact, our detailed assessment of this event became the basis for introducing "trauma signature analysis" (TSIG) to the field (Shultz et al., 2011).

HARMONIC TREMOR*

Melanie Kelman
Natural Resources Canada, Geological Survey of Canada, Vancouver, BC, Canada

Definition

Harmonic tremor is defined as seismicity consisting of a continuous low frequency, often single frequency, sine wave with smoothly varying amplitude, and is caused by complex interactions between magma (see *Magma*), exsolved gases, and bedrock at volcanoes (McNutt, 2000).

Harmonic tremor comprises a sequence of seismic waves whose dominant frequencies typically range from 1 to 5 Hz. Harmonic tremor and spasmodic bursts (also called spasmodic tremor) are specific variants of more general volcanic tremor. However, harmonic bursts have a relatively uniform signal, whereas spasmodic bursts have a higher frequency, pulsating, irregular signal.

Volcanic tremor, including harmonic tremor, may persist for minutes to days or longer, may lack a distinct beginning or end, frequently precedes and almost always accompanies eruptions, and was the most consistent short-term indicator of impending eruptions in a study of 200 calderas worldwide (McNutt, 2000) (see also *Volcanoes and Volcanic Eruptions*). Detection of tremor is a major part of most volcano-monitoring programs (see *Monitoring Natural Hazards*). However, intrusion events can also produce similar seismicity, even though no eruption occurs.

Models for the origin of harmonic tremor involve oscillations of fluid-filled cracks (e.g., Julian, 1994; Chouet 1988), boiling of water (Leet, 1988), water or gas motions in a volcanic conduit (Hellweg, 2000; Maryanto et al., 2008), or thermoacoustic instabilities (Busse et al., 2005). Spasmodic tremor may be associated with modification of the volcanic plug or vent (Lesage et al., 2006; Jolly et al., 2010) or other brittle failure related to the movement of magma, rather than being caused by the movement of magma itself (Nishi et al., 1996). Variations in depth, duration, and amplitude of volcanic tremor suggest that multiple mechanisms may be responsible for its generation, even at a single volcano.

HAZARD

Farrokh Nadim
Norwegian Geotechnical Institute, Oslo, Norway

Synonyms

Danger; Frequency of danger; Frequency of threat; Threat

Definition

Hazard is an event, phenomenon, process, situation, or activity that may potentially be harmful to the affected population and damaging to the society and the environment. A hazard is characterized by its location, magnitude, geometry, frequency or probability of occurrence, and other characteristics.

Introduction

Hazard involves something which could potentially be harmful to a person's life, health, and property; to the society as a whole; or to the environment. There is a lack of a common ground among different disciplines and schools of thought regarding what hazard means and different disciplines apply the term in different ways (e.g., Alexander, 2002; EEA (European Environment Agency), 2006; Emergency Management, 1998; ISSMGE (International Society for Soil Mechanics and Geotechnical Engineering), 2004; TRADE (The Training Resources and Data Exchange), 1999; UNISDR (United Nations

International Strategy for Disaster Reduction), 2009). However, there is general consensus that hazard is not synonymous with risk (*risk*), but rather an important determinant of the latter.

The disaster risk community, geoscientists, and economic risk analysts often view hazard as a potentially damaging event, phenomenon, situation, or human activity that may have a negative impact on cultural, economic, environmental, institutional, physical, or social assets. Hazard may be a dormant or latent condition that represents a potential future threat such as an earthquake (*Earthquake*), or it may be an existing threat such as a creeping slope (*Slope Stability, Creep*). A hazard is characterized by its location, magnitude, geometry, mechanical, and other characteristics (*Frequency and Magnitude of Events*).

Dual meaning of hazard

One of the reasons for the ambiguity in the definition of hazard is that the term is also used to describe the temporal probability of occurrence of the event or situation in question. Whether hazard refers to the event or to its probability of occurrence within a given period of time depends on the context of its usage. As a scientific concept, this ambiguity in the meaning of hazard is not desirable. To avoid this problem, Technical Committee 32 of the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE), for instance, suggested using the term "danger" or "threat" to refer to the phenomenon that could lead to damage, and the term "hazard" to the probability that a particular danger (threat) occurs within a given period of time. In this definition, the characterization of danger or threat does not include any forecasting, whereas the characterization of hazard includes the assessment of frequency or temporal probability of occurrence. The ISSMGE definition of hazard is fine for scientific discussions. It is, however, not entirely consistent with the common usage of the term. For example, to be consistent with the ISSMGE terminology, one should refer to earthquakes (*earthquake*) and floods (*flood*) as natural threats, and not natural hazards.

Summary

Hazard is an event, phenomenon, process, situation, or activity that may potentially be harmful to the affected population and damaging to the society and the environment. The term is also used to describe the temporal probability of occurrence of the event or situation in question. The dual meaning of hazard creates ambiguity in scientific discussions and different disciplines apply the term in different ways. Considering the pros and cons of different definitions, the general definition of hazard given above is recommended.

HAZARD AND RISK MAPPING

Brian R. Marker
London, UK

Synonyms

Hazard and risk maps are sometimes included in sets of maps under names such as "Engineering geology maps," "Environmental geology maps," "Applied geological maps" or "Maps for planning, development, or conservation."

Definitions

Hazard – the probability of occurrence within a specific period of time and within a given area from a natural phenomenon of given magnitude.

Susceptibility – the extent to which a causal mechanism might affect and destabilize a potentially hazardous system (but sometimes used as a synonym for vulnerability).

Vulnerability – the sensitivity of exposure of people and assets (buildings, infrastructure, and other property) to a hazard of a given magnitude (usually expressed as a percentage loss or as a value between 0 and 1).

Risk – the likely impacts or costs of hazardous events in terms of likely deaths, injuries, damage to properties, direct financial costs, and economic disruption due to hazardous events.

Hazard mapping – the assembly of information from field and archival sources, remote sensing and, in some cases, ground investigation and sample testing on the nature, distribution, causes, magnitude, and frequency of hazardous events.
Risk mapping – the process of estimating and depicting the likely impacts or costs of hazardous events in terms of likely deaths, injuries, damage to properties, and economic disruption due to hazardous events.

Introduction

Hazard maps showing the nature and extent of actual and potential hazards have been prepared for many years, initially manually but more recently by using Geographic Information Systems (GIS). These are used for several purposes including land-use planning, insurance, environmental protection, and disaster management. Recently increasing emphasis has been placed on risk mapping which describes potential losses from hazardous events. The flexibility and ease of amending maps using GIS is valuable because many hazard and risk maps should be revised fairly often as social, economic, and environmental circumstances change and new data and methods become available. A wide range of topics are addressed including: seismic and volcanic phenomena, tsunami, landslides, rockfall, avalanche, subsidence, flooding, storm damage, dust, wildfire, and potentially harmful substances. The variety makes it difficult to generalize about the approaches to hazard and risk mapping and types of maps. Each investigation must reflect the nature of the specific hazard so the reader should refer to other entries of this encyclopedia for details of those characteristics.

Some studies consider a single hazard but that is not always appropriate because:

(a) In addition to primary damage and injuries some types of event, especially earthquakes, trigger secondary hazards such as landslides, rockfall, subsidence, and tsunami so integrated assessment can be more useful in informing decision makers of necessary actions.
(b) Many areas are subject to several potential hazards and therefore require maps for each or a multi-hazard map.

Mapping of some hazards requires consideration of ecological, meteorological, and hydrological information and risk assessment requires social and economic information. Therefore it is sometimes necessary to organize multidisciplinary teams of researchers.

The level of detail of assessments depends on the location concerned and the accessibility and amount of available data. Thus, seismic hazard maps are often more generalized than, for example, landslide hazard maps because of the uncertainty as to where a seismic event of given magnitude and depth might have impacts compared, for example, the relatively more localized effects of slope instability.

Although many studies of hazard, vulnerability and risk have been undertaken there are still many difficulties in comparing these in terms of potential damage other than in a simplified way (Carpignano et al., 2009). Also, many countries have not yet undertaken strategic hazard mapping initiatives for large areas but there are notable exceptions such as the maps for land-use planning prepared in Norway over the past 30 years (Hestnes and Lied, 1980).

Preparation of hazard maps

The initial stage in hazard mapping is the collection, collation, and interpretation of data on the nature, frequency, and magnitude of past events. Depending on the type of hazard to be considered this may include:

(a) Field mapping and/or use of air photograph and remote sensing data to establish the geology, geomorphology, topographical characteristics, vegetation cover, etc.: use of remote sensing is important where studies are of large or remote areas.
(b) Collecting samples of soils or water to determine engineering or geochemical characteristics.
(c) Examination of historical documentary data (e.g., topographical maps and air photographs of various ages, site investigation reports, media reports, historical books, and manuscripts) on hazardous events to determine the magnitudes and frequencies.
(d) For some hazards, particularly anthropogenic contamination, mapping of former or current uses of land.
(e) Assembly of information on factors that trigger or exacerbate hazards (e.g., meteorological records in relation to ground instability, or rates of erosion that might affect landslide potential).

Databases are assembled that can be drawn upon to plot a variety of maps on cadastral and topographical base maps. Topography is usually drawn from a digital elevation model (Doornkamp, 1989).

Some illustrative, but not exhaustive, examples of types of information are given in Table 1.

Caution is needed in assembling and interpreting data because:

(a) Previously mapped data may have been plotted at a number of scales and, although GIS is scale independent, these may need to be sampled and normalized to a common level of detail (see Briggs, 2000).
(b) A long historical data record is available for some hazards in certain areas (e.g., parts of Europe and China) but is sparse in other places, in which case dating techniques (e.g., radiometric, lichenometry, tree ring analysis, thermoluminescence, and cosmogenic radionuclide) must be used to establish the chronology of events (see, for instance, Smith and Petley, 1991).

Hazard and Risk Mapping, Table 1 Some factors that are taken into account in mapping of various types of hazard and risk and selected references to examples of studies

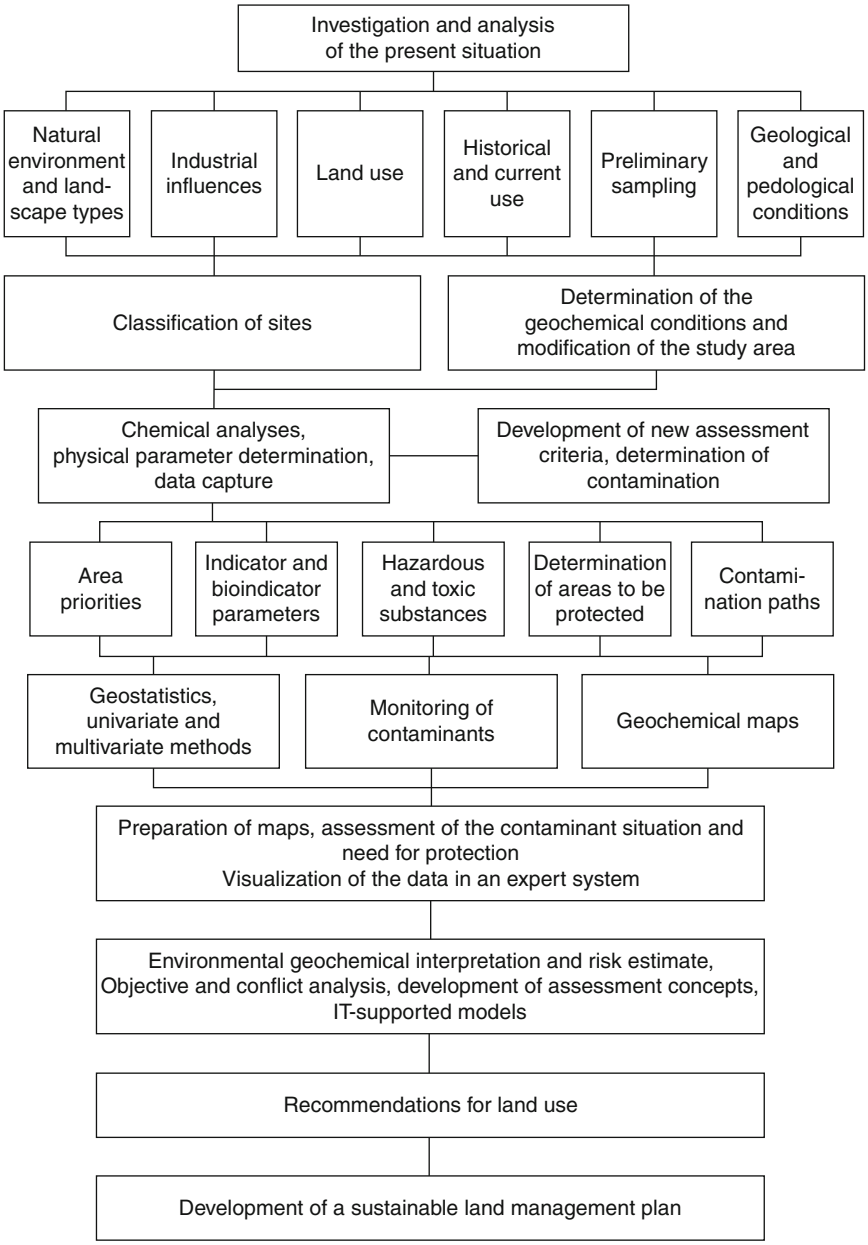
Hazard	Comments	Example references
Seismic	Identification of the maximum credible seismic event that might affect an area, likely peak particle acceleration, and likely depth ranges of events. In order to assess impacts it is also necessary to characterize the distribution of poorly consolidated overburden and bed rock, since impacts on structures are generally greater on the former, and of areas subject to liquefaction hazards. It is also prudent to assess other hazards that may be triggered by earthquakes (secondary seismic hazards) such as landslides, rockfall, and subsidence.	Adams and Atkinson (2003); Jimenez et al. (1999); Kayabali and Akin (2003); Musson and Sargeant (2007); Sanabria and Dhu (2005).
Volcanic	Identification of volcanic centers and the types of eruption that tend to occur so that the potential effects of pyroclastic gas falls and flows, lahars and lava flows, gas emissions, and the potential for large-scale cone collapse can be assessed. Many of these require assessment of directions that materials may take in leaving the volcanic center and the topography that they may flow across. Dispersal of higher level dust clouds however requires consideration of prevailing wind directions and potential for rainfall at various times of year.	Favalli et al. (2009); Hickson (2002); Hoblitt et al. (1998); Pomonis et al. (1999); Simpson and Shepherd (2001); Wadge and Isaacs (1998).
Tsunami[a]	Prediction of the likely maximum heights reached by tsunami taking account of likely directions of origin, orientations of shorelines that may be affected, sea- or lake-floor morphology, especially gradient and the occurrence of features such as reefs, locations, and orientations of constrained straits and bays, and the distribution of adjacent low lying land.	Burbidge et al. (2008); Clague et al. (2003); Study Committee on Storm Surge and Hazard Maps (2004).
Landslide	Identifying the types and extents of various types of landslides in relation to the nature of bedrock and superficial deposits, geological structures, slope angles, morphologies and aspects, slope, vegetation and groundwater behavior, as well as the potential for reactivation of earlier landslides.	Ardizzone et al. (2002); Keaton and Rinne (2002); Chacon et al. (2006); Fell et al. (2008a, b); Glade et al. (2005); Lee and Jones (2004); Malet and Macquaire (2008).
Rockfall	Angles and roughness of slopes, block sizes, strength and morphology, heights of falls and run-out distance, dip of strata, nature, spacing and infillings of joints and other discontinuities, weathering and groundwater behavior.	Abbruzzese et al. (2009); Agliardi et al. (not dated); Ayala-Carcedo et al. (2003); Irigaray et al. (2003).
Avalanche	Tracks left by past avalanches, likely extent of snow and ice cover, slope steepness, morphology and roughness, isolation, meteorological conditions, and vegetation cover.	Arnalds et al. (2004); Barbolini et al. (2011); Gruber and Bartelt (2007); Keylock et al. (1999).
Subsidence (natural cavities)	Recorded extent and nature of caves and sinkholes, bedrock characteristics including patterns of faults, joints and other discontinuities, depth to bedrock and characteristics of superficial deposits, and groundwater behavior.	Forth et al. (1999); Edmonds (2001a, b); Marker (2010); Ragozin and Yolkin (2003); Simón-Gómez and Soriano (2002).
Subsidence (mined ground)	Subsidence associated with mined ground – recorded extent, sizes, and depths of mined ground and shafts, and of associated collapses, the type of mining undertaken, the extent of mineral deposits that could contain unrecorded mined ground, the thickness and depth of overburden, patterns of faults, joints and other discontinuities, and groundwater conditions	Choi et al. (2010); Lee and Sakalas (2001); Marker (2010); Oh and Lee (2011); Statham and Treharne (1991).
Fluvial flooding	Levels, volumes, and frequencies ("return periods") of floods of specific sizes, topography of drainage basins, precipitation patterns, zones of erosion and deposition, channel morphology, surface runoff, soil characteristics, infiltration, vegetation, urbanization, defenses, and drainage.	Buchele et al. (2006); Rango and Anderson (2007); Schwab et al. (2002)
Coastal flooding	Nature, scale and frequency of recorded events, extent of coastal lowlands, coastal aspect relative to potential storm surge directions and onshore winds, coastal impediments to surges including coastal defenses	Cendrero (1989); Monirul Islam and Sado (2000); Study Committee on Storm Surge and Hazard Maps (2004).

Hazard and Risk Mapping, Table 1 (Continued)

Hazard	Comments	Example references
Storm	Consideration of the nature, scale, frequency, and impacts of significant events in relation to meteorological records of seasonal prevailing wind directions and strengths, precipitation, and potential exposure to these slopes and structures.	Heneker et al. (2006); Hofherr (2007); Watson (1995).
Dust[b]	Particle size and moisture content of soils, and vegetation cover, in areas liable to wind erosion. Prevailing wind directions and strengths. Expected patterns of rainfall (see also volcanic ash above).	Afifi and Gad (2011); McLaurin et al. (2011).
Wildfire	Vegetation cover, type, and combustibility; topography especially slope aspects; precipitation patterns; atmospheric and vegetation humidity; and prevailing wind strengths and directions.	Chuvieco and Congleton (1989); Mermoz et al. (2005); Romme et al. (2006); Sampson et al. (2008).
Potentially harmful substances	Concentrations of potentially harmful inorganic and organic elements and compounds (natural or anthropogenic) in soils, surface water or groundwater compared with concentrations that are believed to be harmful or of concern. Concentrations of substances in vegetation, bones, teeth etc. Comparison of concentrations with legal and regulatory limits.	Birke et al. (2011); Demetriades (2011); Ducci (2000); Lahr and Kooistra (2010).

[a]Tsunami are caused by earthquakes, but also by some volcanic eruptions and landslides.
[b]Dust hazards arise from soil erosion, volcanic emissions, wildfire, and many human activities.

(c) Documents may be uneven over time, or in scope, and older records are often less reliable. Also these are not necessarily comprehensive. For instance, plans of old mines and associated shafts may not show all workings, and some may have been inaccurately plotted (Freeman Fox Ltd, 1988; Marker, 2002).
(d) Some hazard phenomena cover appreciable areas (e.g., large landslides are extensive) and can be plotted accurately but others are very localized (e.g., small sinkholes and mine subsidence crown holes) and can only be shown by point symbols. In the latter case it may be necessary to represent the occurrences as, for instance, numbers occurring per unit area (Marker, 2010).



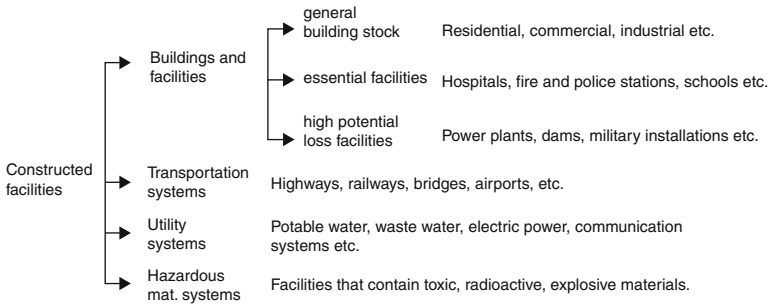
If parts of an area have more comprehensive and accurate information than others, it is necessary to extrapolate information to the latter (e.g., if, in the case of landslides, a particular geological horizon associated with slopes exceeding a particular angle is known to have a high frequency of instability, that information can be used to judge landslide potential in other parts of the outcrop). Results can be validated to some extent by developing an assessment for one part of an area and then comparing it with another part, or with a different area (see, for instance, Chung and Fabbri, 2003). A systematic and structured approach is required when considering each type of hazard. An example is given in Figure 1.

Information is usually depicted as shaded or colored zones, contours, or pixels that are classified according to presumed levels of hazard. Weightings can be allocated from quantitative scores, be expressed by relative values on a numerical scale, or indicated by general terms such as high, medium, or low. If levels of hazard are uncertain due to uneven base data gradational boundaries between zones may needed. GIS can provide auto-contouring but the defined rules are applied strictly and results can be misleading unless these are moderated using professional judgment. A further step is to attempt to predict the nature and extent of future occurrences. This requires examination of likely frequency or probability of damaging events through statistical estimation and/or modelling (Doornkamp 1989).

Modelling simulates a hazard, in many cases by expressing the physics of a process, through either of the following:

(a) Deterministic mathematical models which provide results for a chosen scenario, often the worst case, but do not provide information on uncertainty of results.
(b) Probabilistic mathematical models which use random variables to allow for uncertainties. These are now generally preferred to deterministic approaches.

There are two basic types of simulation: event based and hazard based. The event based approach calculates, for example, the damage that would be caused at each individual building by a particular type of event and is time consuming. The hazard based method is used to estimate effects from a hazard map rather than by considering specific events, but tends to overestimate consequences. Uncertainties either from the natural variability and randomness of complex phenomena, which can be estimated but not reduced, or inadequate data or



Hazard and Risk Mapping, Figure 1 Geochemical flow chart for investigating industrial influences and mining damage in urban regions (the flow of investigation is from the top to bottom (Birke et al., 2011)).

incomplete models due to limitations on understanding which can be reduced as data and understanding improve. Several models may be developed to allow for the hazardous events of various magnitudes. Alternatively a model may be used to consider several sets of originating and triggering conditions (Sanabria and Dhu, 2005). The design of models varies between types of hazard. Some illustrative examples are:

(a) Seismic hazard – Source zone characteristics can be defined and assumptions made about the origin and magnitude of a range of possible events; energy transmission and attenuation for events of specific magnitudes and distances estimated and evaluated in terms of subareas based on regolith characteristics; and building damage fragility curves used to assess impacts (Sanabria and Dhu 2005).

(b) Landslide hazard – A model can be developed by examining the proportion of rainfall that percolates down into soils and underlying bedrock, groundwater levels and flows allowing groundwater levels to be

Hazard and Risk Mapping, Figure 2 A structural inventory classification system (FEMA, 1999).

estimated for different time intervals and related to slope characteristics that determine stability thus enabling the estimation of safety factors for various slope profiles (Terlien et al., 1995).

(c) Flood hazard – Hydrological frequency analysis can be used to consider the magnitude of extreme events based on the historical record, and combined with results of hydraulic modelling taking account of channel characteristics at various points down-stream and resistance to flow to establish river channel discharges followed by sensitivity analysis to identify the key influencing factors (Mosquera-Machado and Ahmad, 2007).

(d) Wildfire – After comparing vegetation, slope characteristics, and meteorological information fuel models can be used to evaluate fire heat release, flame length, and rates of spreading for extreme but realistic circumstances (Romme et al., 2006).

In addition to mapping potential levels of hazards within an area, it is important to understand the extent to which causal mechanisms might exacerbate or destabilize a potentially hazardous system (susceptibility or sensitivity), for instance, if excavation or loading of slopes might lead to landsliding, to show where particular precautions are likely to be needed.

The reliability of hazard maps depends on the amount and accuracy of original data and the validity of prediction and modelling. While maps can provide a reasonably good understanding of what has happened in the past and an indication of where future problems might be expected, they are not necessarily an accurate guide because: some past events may have obscured effects of hazards; future events may take place where hazards have not previously occurred; and environmental change and land use may cause different patterns of hazard potential and risk in future (e.g., Ardizzone et al., 2002).

The presence of a hazard in a particular locality does not necessarily mean that it will cause significant adverse effects. A major hazardous event in a fairly sparsely populated area might have few consequences a moderately sized hazardous event in a densely populated area can lead to severe impacts on people and property. Therefore it is necessary to assess the people and assets that might be vulnerable to, and at risk from, likely levels of hazards.

Preparation of vulnerability and risk maps

Risk maps are essentially vulnerability maps enhanced to estimate the consequences in terms of lives, injuries, and/or financial impacts of events of given magnitudes. This requires the examination of the susceptibility of assets and populations and the losses. Layers of information are needed on matters such as:

- Buildings, constructions, and infrastructure, including the likelihood of damage to particular categories of structure and structural elements and the financial costs of replacing these (see Federal Emergency Management Agency (FEMA), 1999).
- Locations of key facilities such as evacuation and aid routes, hospitals, fire and police stations, and water supply facilities (see FEMA op cit).
- The distribution of people, sometimes including factors such as social circumstances, ages of potential victims or population distributions at different times of day since this influences exposure to hazards (e.g., see Ragozin and Yolkin, 2003).
- Management of responses to disasters including emergency and aid services and consequent costs (Commission of the European Communities (CEC), 2010; Morrow, 2002; Tran et al., 2008).

An illustrative example of a structural inventory classification system for constructed facilities that can be used to consider data on, and estimate financial costs of, seismic events is shown in Figure 2.

The mapping of risk has recently extended into attempts to provide multi-risk maps for substantial areas, for instance, the Risk Map Germany initiative that aims to draw on earthquake, storm, flood, and other disaster expertise (Müller et al., 2006).

Communication of results

It is important that hazards are taken properly into account when developing policies for land use and development. The extent to which that is done varies in different parts of the World, thus in some areas:

(a) There are legal and regulatory requirements to make and use maps for relevant types of hazard, for

example: Regulations are in place in Germany, Austria, Switzerland (see, for example, Aulitzky, 1994; Petrascheck and Keinholz, 2003; Bründl et al., 2009), and Iceland (Iceland Meteorological Office, 2000); in the European Union steps are being taken to develop an integrated risk management strategy (European Environment Agency (EEA), 2010); and, in the USA State, Indian Tribal and local governments are required to develop a hazard mitigation plan (FEMA, 2011).

(b) Maps are prepared as necessary and are used as guidance rather than being mandatory, for instance, most types of hazard maps in the United Kingdom (see, for instance, DTLR, 2002).

(c) Maps are prepared in response to events but are not yet formally required either legally or for guidance.

Where legal and regulatory provisions exist, planners are aware of hazard and risk maps and have professional support whereas elsewhere, some planners do not have experience in considering natural hazards. Therefore a class of simplified interpretative maps is sometimes developed for public communication purposes. These focus on the ways in which land should be considered for development using categories such as "unsuitable for built development," "areas for which full site investigation by a competent person is required with any planning application," "areas within which a walk over survey by a competent person is required to determine whether detailed site investigation is needed," and "areas where the hazard is not thought to be present" (see, for instance, Thompson et al., 1998).

Sometimes a "traffic light" approach is used (i.e., red for hazardous, amber for caution, and green for safe). This has the attraction of being simple but caution is needed because, for many types of hazard, development may still be possible in red areas if suitable precautions are taken. Also areas defined as of high relative hazard in one study are not necessarily equivalent to those defined as of high relative hazard in another. It is desirable to use similar criteria in all areas so that hazards are not exaggerated with consequent loss of confidence in investment in new development, effects of value and sales potential of existing development, or increases in costs or loss of cover of insurance. Care is needed, therefore, in developing the wording of the map legend and in disseminating the findings to politicians, administrators, financial interests, international aid organizations, and communities. While planning maps provide a basis for decision making, even where the significance of the underlying technical information is not appreciated, it is best for experts to advise alongside those maps (Marker, 1998).

Conclusion

Hazard and risk mapping are essential, steps in safe and cost-effective planning for development and for protection of people but is currently undertaken unevenly, if at all. Commonly hazard mapping is first undertaken after a damaging event takes place and causes strong public concern, but does not extend to all potential hazards and is not updated as time passes and memory of the event fades. In many cases hazard maps are prepared but are not carried through to risk and planning maps even though those are of greater assistance to practitioners in development and emergency planning. However an increasing number of countries are now incorporating hazard and risk maps into legal and regulatory processes. It is hoped that others will follow suit in future.

HAZARDOUSNESS OF A PLACE

Netra Raj Regmi[1], John Rick Giardino[2], John D. Vitek[2]
[1]Desert Research Institute, Reno, NV, USA
[2]Texas A&M University, College Station, Texas, USA

Definition

Hazard: Probability of occurrence of a certain natural or human-induced phenomenon that poses threat to life, property, and the environment within a certain period of time and within a given area (Varnes, 1984).
Hazardous place: A location with a high probability of experiencing a natural event that may be hazardous.

Introduction

Hazards broadly can be classified into three types: (a) hazards related to geophysical events, such as mass movement, land subsidence, earthquake, volcanic eruption, flood, tsunami, and fire; (b) atmospheric events, such as climate change, geomagnetic storms, winds (including hurricanes, tornadoes, and straight winds), drought, hail, freeze, and lightning; and (c) hazards created by anthropogenic activities, such as pollution, deforestation, use of herbicides and pesticides, chemical spillage, dam and reservoir failure, and fire. Every location is unique with regard to the events that can occur and those events only become hazards if people are impacted by the event; otherwise the event is simply a natural event that has occurred on Earth for eons.

In this contribution, we briefly describe geophysical and anthropogenic events and associated hazards, fundamental techniques of assessment of the hazards and associated risks, and common approaches to the mitigation of hazards.

Events and related hazards

Geophysical events

Hazards related to the geophysical events can be classified into: (1) movement of slope materials under the effect of gravity; (2) subsidence of land associated with karst terrain and the overdraft of groundwater and oil; (3) volcanic eruptions and associated movement of lahars and slope materials; (4) earthquake shaking and tsunamis; (5) floods associated with large rainstorms, snowmelt, and storm surges; (6) coastal erosion; and (7) sea level rise.

Landslides

The term landslide includes many downslope movements of soil, rock, or other Earth materials. Landslides can be activated by earthquakes, rapid snowmelt, intense rainstorms, groundwater rise, slope toe cutting by rivers, or volcanic eruptions, in conjunction with gravity and occur when driving forces, such as gravity, exceed the frictional strength of the slope materials. Landslides include: (1) rockfalls and topples, characterized by free-falling of rocks from overlying cliffs; (2) slides, slumps, and avalanches, a displacement of overburden material because of shear failure along a structural feature; (3) flows and lateral spreads of unconsolidated material associated with a shallow water table; (4) complex landslides, combination of two or more types of landslides (Varnes, 1978). In a rockfall, rocks may fall, bounce, or roll down the slope. In a topple, rocks on a steep slope break loose and rotate forward. Flows can be categorized as: (1) debris flow, (2) debris avalanche (3) earthflow, (4) mudflow, (5) lahar, and (6) creep, based on the rate of movement and the types of unconsolidated materials involved. A debris flow, characterized by a combination of water-saturated loose soil, rock, organic matter, and air, with materials varying in size from clay to large boulders, forms when loose masses of unconsolidated wet debris become unstable. A fast moving debris flow is known as a debris avalanche. Earthflows consist of saturated soil or fine-grained rock deposits and flow downhill usually on moderate slopes. A mudflow is an earthflow consisting of material that is wet enough to flow rapidly. A lahar is a special type of debris flow that originates from the slopes of a volcano. Creep is an imperceptibly slow, steady, downward movement of slope-forming soil or rock. Creep can occur seasonally, where the movement is within the depth of soil affected by seasonal changes in soil moisture and soil temperature.

The hazards and risks from landslides depend on the type of landslides. Rockfalls pose a localized threat to life and property because of limited runout distances. But slides, avalanches, flows, and lateral spreads can have great runout distance and can result in significant loss of life and property. Similarly, mudflows, associated with volcanic eruptions, can travel great distances with high speeds and may be a quite destructive phenomena. Worldwide, landslides constitute a major geophysical hazard. A most probable location for landslides is a moderate to steep slope where the soil is saturated, an area susceptible to earthquakes, volcanic activities, fluctuation in groundwater, and human-induced disturbances, or any combination of these factors. A variety of other natural causes may also result in landslides.

Some examples of recent, large and most hazardous landslides worldwide are: a volcanic eruption-induced landslide that occurred at Mount St. Helens, USA on May 18, 1980; a landslide occurred in Usoy, Tajikistan, in 1911; a landslide that caused Vaiont dam disaster in Italy on October 9, 1963; an earthquake-induced landslide occurred in Yungay, Peru in 1970; and a rain-induced landslide occurred on January 10, 2005 in La Conchita, California (Figure 1). These landslides killed many people, countless animals and destroyed great amounts of property. The landslide at Mt. St. Helens killed 50

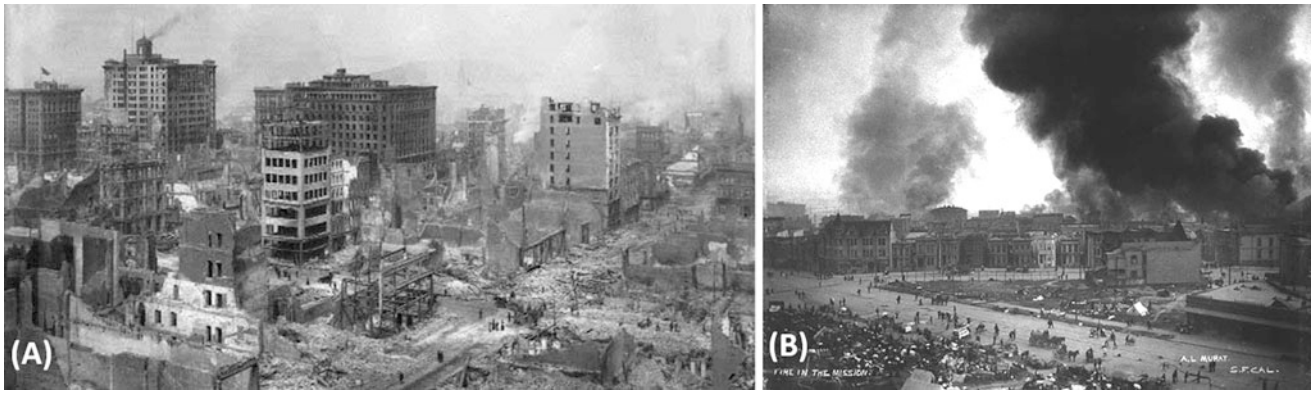
Hazardousness of a Place, Figure 1 A landslide reactivated on January 10, 2005 in La Conchita, Callifornia. The landslide killed 10 people and damaged 36 houses (Photo by Mark Reid, U.S. Geological Survey).

people and countless animals (Ylvisaker, 2003). The landslide in Usoy killed almost all people of the Usoy village. The Vaiont dam disaster killed ~1,900 people (Coch, 1995). The landslide in Yungay killed ~20,000 people. But the earthquake and landslides together in this event killed ~70,000 people. The landslide in La Conchita damaged 36 houses and killed 10 people (Jibson, 2005).

Land subsidence

Land subsidence is a gradual sinking or sudden downward settling of land with little or no horizontal motion. Subsidence can occur at or near the surface. This type of subsidence occurs mostly in areas underlain by compressible deposits, expandable clays, and organic soils. Natural and anthropogenic activities can cause land subsidence when the loss of subsurface support occurs from mining, pumping of oil or groundwater, and dissolving of carbonate rocks. Subsidence and collapse are serious hazards because they can pose significant risks to human health and safety, cracking or complete damage of structures, and interruption to transportation and other services.

Some examples of subsidence are the overdraft of groundwater and petroleum in the USA in the Houston-Galveston region of Texas; Las Vegas, Nevada; and areas in Santa Clara Basin, California (Coch, 1995). Many parts of the Japan are experiencing land subsidence because of the withdrawal of groundwater (Yamamoto, 1995).



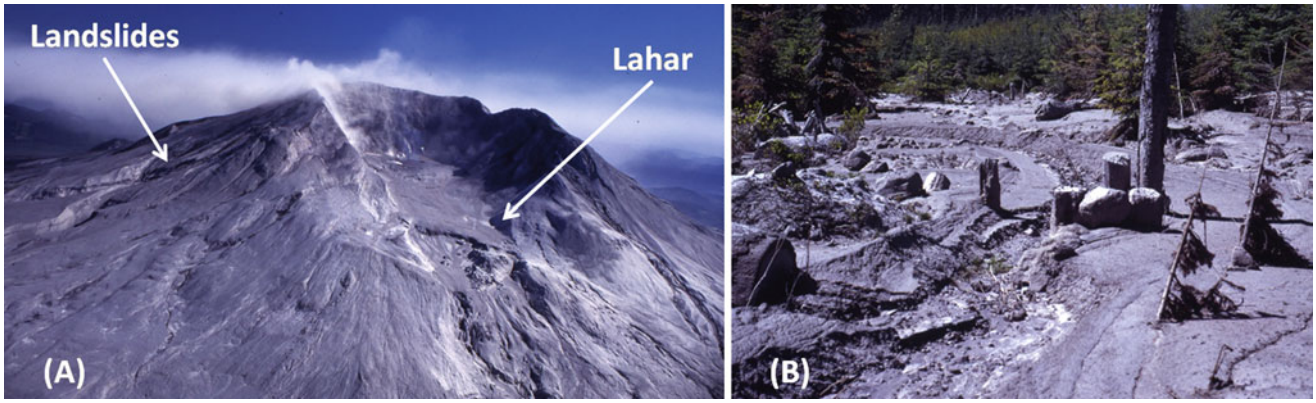
Earthquakes

Earthquakes, most common along tectonic plate boundaries, are caused by the sudden releases of strain energy stored along a fault in the bedrock. Earthquakes are perhaps the most terrifying hazards; they can destroy life and property in a very short period of time and usually occur without warning. If other hazardous events occur in conjunction with an earthquake, the severity of the hazard increases. Hazards related to an earthquake can be: (1) ground shaking and structural dislocation, (2) faulting or breaking of surface materials, (3) mass movement, (4) liquefaction of gently sloping unconsolidated materials, (5) subsidence or surface depressions resulted from the settling of loose or unconsolidated sediments, (6) tsunamis generated by seismic activities under the ocean floor, (7) flooding, and (8) fire (Figure 2).

Many metropolitan areas, such as Tokyo, San Francisco, Los Angles, and Mexico City, are in seismically active zones. These cities have been struck by earthquakes in the past, and they still have high probability for future earthquakes. Table 1 lists some of the deadliest earthquakes.

Volcanoes

Volcanoes are vents in the crust through which molten rock and associated gases escape. Volcanic eruptions, dramatic and violent events, influence large areas, can continue for a long period of time, and pose significant



Hazardousness of a Place, Figure 2 Photographs showing destruction caused by April 18, 1906 San Francisco earthquake shaking and fire; (**a**) Financial district, (**b**) Mission District (Source: Museum of the City of San Francisco).

Hazardousness of a Place, Table 1 Some of the deadliest earthquakes in history

Location	Time	M	Loss of life and property	Other hazards	Reference
Shaanxi (Shensi), China	January 23, 1556	8.0	Killed ~830,000		USGS, 2010
Lisbon, Portugal	November 1, 1755	8.7	Killed more than 60,000 people and countless animals and damaged large property	Tsunami, fire	Gutscher, 2004
San Francisco, USA	April 18, 1906	7.9	Damaged structures throughout the city, death may have exceeded 3,000 people.		Hansen and Condon, 1989
Valdivia-Puerto Montt, Chile	May 22, 1960	9.5	Killed 1,655–5,700 people	Tsunami	USGS, 2010
Prince William Sound, Alaska	March 27, 1964	9.2	Damaged many towns and cities and killed 128 people	Tsunami	USGS, 2010
Bam, Iran	December 26, 2003	6.6	Killed 26,000–40,000 people		Jackson et al., 2006
Coast of northern Sumatra	December 26, 2004	9.1–9.3	More than 283,000 people were killed and countless people were displaced in 14 countries in South Asia, and East Africa.	Tsunami	Lay et al., 2005
Port-au-Prince, Haiti	January 12, 2010	7.0	111,481 confirmed death, possibly more		CNN, January 23, 2010

hazards to people. Volcanic eruption can be very explosive or quiet. Explosive eruptions pose a risk by scattering rock blocks, fragments, and lava at varying distances from the source. Explosive eruptions can spread lava, gas, and other materials over a wide area, and may significantly modify the landscape. In quiet eruptions, materials flow rather than explode from the vent. The composition of flow varies; because it may originate from multiple sources.

Major hazards associated with volcanic eruptions are: lava flows; pyroclastic flows; tephra and ash fall; lahar, landslides, or mudflows; and emanations of toxic gases. Volcanic activity may also trigger other hazardous events including tsunamis, deformation of the landscape, floods, and tremor-provoked landslides. Lava may flow quickly or slowly, but destroys everything in its path. Lava entering the sea poses risks to life in the sea by increasing the local temperature of seawater. Lahar, a mixture of volcanic ash, rock, debris, and water, occurs when a high volume of hot or cold water mixes with ash and rock. The water may come from melting snow or ice, rainfall, or lakes. As a lahar moves downslope its size grows significantly because of the erosion and addition of water. The lahar will damage everything until the sediment load is deposited. Pyroclastic flow, a rapidly moving mixture of hot and dry rock fragments, ash, and hot gases, also destroys everything in its path by burying and burning. Other events associated with a volcanic eruption, such as earthquake and rainfall, can trigger landslides on the slope of the volcanic cone. Tephra, fragments of volcanic rock and lava blast into the air, creating hazards in a local extent as well as in a large region. Large tephra typically falls back to the ground near the volcano whereas smaller fragments are carried away by the wind. Volcanic ash can travel hundreds to thousands of miles downwind from a volcano and disrupt life and property over a wide region.

Hazardousness of a Place, Figure 3 Landslides and lahar caused by Mt. St. Helens Volcano on May 18, 1980. (**a**) The cone of the volcano showing landslides and a lahar. (**b**) Destruction caused by a lahar (Photographs were taken on June 1, 1980).

Gases and acid aerosol particles released from a volcanic eruption, fumaroles, and hydrothermal systems also create hazards. The volcanic gases, such as sulfur dioxide, carbon dioxide, and hydrogen fluoride, pose the greatest risks to human health, animals, and plants. Sulfur dioxide and hydrogen fluoride gases can lead to acid rain and air pollution downwind from a volcano. Concentrations of carbon dioxide gas can be lethal to human, animals, and vegetations.

Most volcanoes have erupted at the convergent plate boundaries that surround the Pacific Ocean. Far more unobserved eruptions occur on the ocean floor. Indonesia, Japan, and the USA experience volcanic events. Some of the deadliest volcanoes occurred at Mt. Tambora, Indonesia; Mt. Krakatau, Indonesia; Mt. Ruiz, Colombia; Mt. Pelee, Martinique; Mt. Vesuvius, Italy; Mt. St. Helens, USA; Mount Pinatubo, Philippines; and Mt Etna, Italy. Loss of life because of these volcanoes is very high, for example, the Mt. Tambora volcano killed ~88,000 people in 1815 (Stothers, 1984); Krakatau volcano along with a volcano-induced tsunami killed ~36,000 people in 1883 (Dörries, 2003); Mount Pelee volcano along with an ash flow killed at least 29,000 people in 1902 (Witham, 2005); Mt. Ruiz volcano along with volcano-induced mudflows killed more than 23,000 people in 1985 (Pierson et al., 1990); Mt. St. Helens volcano (Figure 3) along with heat and hot volcanic ash released from the volcano killed 58 people in 1980 (Witham, 2005); Mt. Pinatubo volcano along with volcano-induced avalanches of hot ash and gas, giant mudflows, and a cloud of volcanic ash killed ~ 800 people and displaced more than 100,000 people in 1991.

Flooding

Two types of flooding can be distinguished: (1) land-borne floods, or river flooding, caused runoff from large amounts of rain, and (2) sea-borne floods, or coastal flooding, caused by storm surges.

Land-borne floods occur when the capacity of stream channels to conduct water is exceeded and water overflows banks. The severity of the river flooding increases by the conditions within the drainage basin, such as excessive rainfall, low rate of infiltration, steep slopes, and lack of vegetation in conjunction with human activities, such as urbanization, improper practice in agriculture and timber production. Destruction by river flooding is attributable to: (1) residential and agricultural areas in close proximity to river,; (2) stream habitat, and (3) failure of hillslope triggered by undercutting of slope toe. The major cause of the coastal flooding is storm surge. Tsunamis are a special type of coastal flood. Most often, destruction resulted by the coastal flooding is associated with: (1) wave impact; (2) hydrostatic/dynamic forces; (3) the impact of the objects carried by the wave; (4) flooding of deltas and low-lying coastal areas by the influence of tidal action, storm waves, and frequent channel shifts; and (5) weakening of major infrastructures, such as highways and railroads. The most significant damage often results from the direct impact of waves on fixed structures.

Worldwide, the deadliest floods reported include: Yellow River floods in 1887 and 1931 (China), Mississippi River flood in 1927 (USA), and hurricane and tide-induced flood of the Netherland in 1953. The Yellow River flood of 1887 killed between 900,000 and 2,000,000 people (Kynge, 2007), countless animals and destroyed a large property. It was one of the deadliest natural disasters ever recorded. The Mississippi River flood broke out of its levee system and flooded 13 million acres of land in 1927. The flood caused over US$236 million in damage and killed more than 246 people, and left more than 700,000 people homeless (The American Institutes for Research et. al., 2005). The Yellow River flood of 1931 killed as many as four million people (Famighetti, 1995), countless animals and destroyed a large property. The Netherland flood of 1953 killed ~1,836 people and many animals and damaged 136,500 ha of land (Gerritsen, 2005).

Tsunamis

Tsunami, a series of large destructive waves that are caused by the sudden movement of a large area of the

sea floor, are mostly caused by earthquakes, volcanic activity, and landslides. As the water is displaced, it surges outward in all directions in a large wave. The wave can travel rapidly across oceans and cause destruction far from the location where they were generated. Most of the tsunamis are caused by faulting associated with earthquakes. Some tsunamis are caused by volcanic eruptions, and submarine landslides, and very rare tsunamis are caused by meteorite impact in the ocean.

Tsunami waves have exceptionally long wavelengths that measure tens of kilometers, even up to 100 km. The height of a tsunami wave is as low as 0.5 m in the open ocean with a deep water speed up to 700 km/h. As it enters shallow coastal waters, speed decreases and height dramatically increases. This water rises up offshore to form the first tsunami wave to strike the coast. Successive waves may attain several tens of meters in height, depending on local conditions. Such huge waves can dramatically alter shorelines by flooding shore and far inland areas, eroding and depositing large amounts of debris and destroying buildings and other structures.

All oceanic regions of the world experience tsunamis. Tsunamis in the Atlantic, Mediterranean, and Caribbean, however tend to be smaller and less destructive and less frequent than those in the Pacific and Indian Oceans. The Pacific Ocean is surrounded by a geologically active series of mountain chains, deep ocean trenches, and island arcs, sometimes called "the ring of fire." The earthquakes and volcanic eruptions that occur in the "ring of fire" are the source of many tsunamis. An example of the violent and largest tsunami over 40 years is the tsunami that occurred in Pacific and Indian Ocean on December 26, 2004 because of an earthquake of magnitude 9.1–9.3 near Sumatra. The tsunami killed at least 283,000 people (Lay et al., 2005). An example of volcanic eruption-induced tsunami is the tsunami induced by Krakatau volcanic eruption on August 26 and 27, 1883. The tsunami was very violent, killed thousands of people, and wiped out numerous coastal villages.

Fire

Well known causes of fire are: (1) volcanic lava; (2) earthquake tremor; (3) hot, dry, and windy days or nights; (4) electric failure, broken gas pipes, as well as lack of proper management of the fire; (5) accidental spreading of fire by people; and (6) lightning. Fire can be a severe hazard depending on the location of occurrence and the weather condition.

An example of a wind-induced fire is the one that occurred in Matheson, Canada on July 29, 1916. The fire burned an area of approximately 2,000 km^2 (490,000 acres) and killed 223 people. An example of the earthquake-induced fire is the Great San Francisco fire of April 18, 1906. The event destroyed most parts of the city and left 250,000 people homeless. An example of fire generated during an extremely hot day is the 1918 Cloquet fire. On October 12, 1918, during dry condition, sparks on the local railroads in northern Minnesota generated the fire which took 453 lives. The fire also injured 52,371 people and damaged US$73 million property (Carrol and Raiter, 1983). An example of fire induced by lightning is the Yellowstone National Park fire of 1988. Several fires burned for several months and destroyed 793,880 acres (3,213 km^2) area of the park. The fires destroyed structures, killed many animals and cost US$120 million to control the fire (National Park Service, 2008).

Coastal erosion

Areas along coastal regions are subject to erosion from actions of adjacent water bodies. Seaward sides of beaches, sand spits, and uplifted marine terraces of dunes and bluffs are the most susceptible areas. Major causes of this erosion are continuous impact of waves, currents, tides, storms, high winds, rain, runoff, increased water level, and ocean conditions caused by periodic El Niños. The impact may be gradual over a season or many years or drastic during the course of a single storm. The impact might also create landslides and floods. Coastal erosion creates special challenges for people living near the ocean and requires thoughtful planning to minimize the potential dangers to life and property. Attempts to stabilize the shoreline or beach are often futile because the forces that shape the coast are persistent and powerful.

Examples of the extensive coastal erosion occur in the coastal regions of Louisiana, California, and Shishmaref, Alaska.

Atmospheric events

Climate change

Variations in the global and regional climate have changed the size, shape, and volume of glaciers, snow, and ice sheets. Hazards associated with climate change are: (1) permafrost melting, (2) GLOF (Glacial Lake Outburst Flood) and debris flows, (3) ice avalanches from steep glaciers, (4) destabilization of frozen or unfrozen debris slopes, (5) destabilization of rock walls, and (6) freeze and drought.

Glacier and permafrost-related hazards represent a continuous threat to human life and property in mountainous regions. Related disasters can cause large damage to property and kill hundreds or even thousands of people and animals at once. Permafrost occurs on one fourth of the land in the Northern Hemisphere and is also common within continental shelves of the Arctic Ocean. Permafrost in these regions is melting because of climatic warming. This process might be a serious danger because of very large quantities of methane, a very potent greenhouse gas for global warming, stored in the permafrost. Furthermore, permafrost melting reduces the ability of the ground to support large structures.

A GLOF occurs when a lake, dammed by a glacier or moraine, fails. Main reasons for the break out of the glacial lake are: a buildup of water pressure in the lake, an avalanche of rock or heavy snow, an earthquake, intense erosion by the lake water, and breaking off a large portion

of glacier. The failure of the lake causes floods and debris flows which are very hazardous downstream. Major GLOFs have been reported from Iceland, USA, Canada, and Himalayan countries. GLOFs were frequently released from Vatnajökull Ice Cap, Iceland (Scharrer et al., 2007). Cathedral Glacier and Farrow Creek areas are known as major GLOF susceptible areas in Canada. In 1978, debris flows triggered by a GLOF from Cathedral Glacier destroyed part of the Canadian Pacific railway track, derailed a freight train, and buried parts of the Trans Canada Highway (Jackson et al., 1989). Knik River and Abyss Lake areas in Alaska and Wind River Mountains in Wyoming are major GLOF susceptible areas in the USA. Knik River had large annual outbreaks from 1918 to 1966. Almost every year, GLOF occurs in Abyss Lake in southeastern Alaska. Likewise, in early September 2003, a GLOF occurred from Grasshopper Glacier in the Wind River Mountains (Oswald and Wohl, 2007). The 12-ha lake drained an estimated 3.2 million cubic meters of water downslope into the Wind River valley.

Many GLOFs are reported from Himalayas. GLOFs regularly occur in the valleys and rivers of Bhutan. For example, in October 1994, a GLOF occurred in Pho Chhu River which caused a massive flood that destroyed many lives and property. Of the 2,674 glacial lakes in Bhutan, 24 have been identified dangerous (Srivastava et al., 2008). The higher Himalaya in Nepal is also a susceptible region for GLOF. Dig Tsho, Imja, Lower Barun, Tsho Rolpa, and Thulagi regions are potentially dangerous for GLOF. For example, Dig Tsho glacier initiated a GLOF in 1985. A recent inventory carried out by ICIMOD and UNEP/EAP-AP shows that 2,315 glacial lakes exist in Nepal and 26 are potentially dangerous (Srivastava et al., 2008). Similarly, many parts of the Chinese Himalaya are susceptible for GLOF. Longbasaba and Pida lakes of Chinese Himalaya are very dangerous. GLOF from these lakes can affect people living in 23 towns and villages downstream (Xin et al., 2008).

Geomagnetic storms

Geomagnetic storm is a rapid variation in the geomagnetic field, caused either by a gust in the solar wind or by a temporary linking of the magnetic field of the Sun with the geomagnetic field. Variation in the magnetic field does not directly impact human health, but it can disturb long-range radio communication, degrade global positioning systems, damage satellites, affect long-distance pipelines, and produce surges in electric power grid. For example, when in September 1859 the largest recorded geomagnetic storm occurred, telegraph wires in the USA and Europe experienced induced emf (Boteler, 2006). In some cases the event shocked telegraph operators and caused fires. Similarly, an electromagnetic storm disrupted power throughout most of Quebec, Canada, in 1989 (Boteler et al., 1998). The event collapsed the Hydro-Québec power grid. Geomagnetic storms can expose astronauts and high-altitude pilots to increased levels of radiation.

Winds, hurricanes, storm surge, and large rainfalls

High-speed winds can damage structures like power and communication lines, residential homes, and sometimes people. As winds exceed 45 mph, damage begins on human constructions, such as traffic signals and trees may be toppled.

A hurricane is a massive tropical storm system with rotary winds that exceed 119 km/h (74 mi/h) blowing counterclockwise around a central area of very low pressure (Coch, 1995). The formations of hurricanes begin with the disturbance in the westward-flowing air directly north of the equator. The disturbance sets up a vertical air movement that draws heat laden water vapor upward from the warm ocean. As the vapor rises, it condenses and releases great amounts of heat energy which drives the wind system into a cyclonic spiral system. When the storm intensifies, it develops hurricanes, with its spiraling arms of thunderstorms. A mature hurricane has a series of rainbands, spiral bands of high wind, and torrential rain that surround a relatively calm area of low pressure known as the eye of the hurricane. The greatest speed of winds of a hurricane is in the eyewall. Hurricane winds can extend more than 120 km (75 mi) out from the eye. Destructive tornadoes can also develop away from the storm's center during landfall. Gulf and the Atlantic coasts are the most susceptible areas to hurricanes. Similar storms in the northwestern Pacific are called typhoons, whereas cyclones occur in the Indian Ocean. Failure of coastal engineering structures increases the severity of the hurricane hazard along these coastal areas.

Hurricanes are particularly dangerous because of the large zone of influence, spontaneous generation, and erratic movement. Hazardous phenomena associated with hurricanes are: (1) winds exceeding 119 km/h (74 mi/h), (2) intense rainfall which commonly precedes and follows hurricanes for up to several days, (3) storm surge, and (4) impact on structures by wind-borne objects. The quantity of rainfall is dependent on the amount of moisture in the air, and the size and speed of hurricane. In extreme storms (stronger than category 3), the force of wind alone can cause tremendous devastation, such as toppling of trees and power lines, destruction of weak elements of homes and buildings. Likewise, intense rainfall can saturate soils and cause flooding and landslides.

Storm surge is a dome of water that moves ashore near the hurricane eyewall. As a storm makes landfall, tides can inundate most populated areas along the shore. Storm surge causes salt water flooding, which can contaminate supplies of surface and subsurface drinking water. Furthermore, storm surge floods wash out roads and leave streets filled with sand and debris.

Each year, an average of ten tropical storms, six of which become hurricanes, develop over the Atlantic Ocean, Caribbean Sea, or Gulf of Mexico. Whereas many of these remain over the ocean, about five hurricanes strike the USA coastline every 3 years (Schmidt, 2001). The loss of life and property associated with hurricanes

Hazardousness of a Place, Figure 4 Oblique aerial photographs of Bolivar Peninsula, Texas, (**a**) before (September 9, 2008) and (**b**) after (September 15, 2008) the Hurricane Ike. The Hurricane hit Bolivar hit Bolivar Peninsula on September 23, 2008 (Photo source: USGS).

and storm surges are very large. The Texas Hurricane of 1900 (Category 4) killed at least 8,000 individuals of Galveston City (Blake et al., 2007). The Okeechobee Hurricane of 1928 (Category 4) killed at least 2,500 individual (Blake et al., 2007). The Bangladesh Cyclone of 1970 killed at least 300,000 individual (Berz, 1988). Some examples of recent deadliest hurricanes are: Hurricane Andrew, Hurricane Katrina, Hurricane Rita, and Hurricane Ike. Hurricane Andrew (Category 5), Atlantic Hurricane Season of 1992 struck the Bahamas, south Florida and southwest Louisiana. The hurricane killed 40 individuals and caused US$26.5 billion in damage (Blake et al., 2007). Hurricane Katrina (Category 3) hit southern coast of the USA (south Florida, parts of Miami and Gulf of Mexico) in Atlantic season of 2005. The hurricane killed at least 1,500 individuals and damaged US$81 billion (Blake et al., 2007). Hurricane Rita (Category 3) made landfall on the US Gulf of Coast in Atlantic hurricane season of 2005, killed 120 individual (direct and indirect impact) and caused damages of US $11.3 billion (Blake et al., 2007). Hurricane Ike caused extensive destruction in Haiti, Dominican Republic, Turks and Caicos Islands, southeastern Bahamas, Cuba, and parts of southeastern Texas (Figure 4), western Louisiana, and Arkansas (USA) in 2008. The event killed 195 individuals and damages were US$29.5 billion (Blake et al., 2011).

Intense rainfall could also be very hazardous to life and property. Torrential rains associated with slow moving or stationary tropical weather systems can produce enough water to drown animals and destroy agriculture. Freshwater flooding can cause as many drowning deaths as storm surge flooding. Besides flooding, intense rain can have a disastrous effect on agriculture by drowning crops and increasing the probability of disease and pest infestations in surviving crops.

Tornadoes

Mixing warmer, humid air with cold, dry air can generate thunderstorm, tornadoes, lightning, winds, hailstorms, intense rain, and flash floods. Tornadoes are violently rotating (counterclockwise) columns of air that form a funnel shape with very low interior pressure and very high velocities in the wall. A tornado often is encircled by cloud of debris and dust. The speed of a tornado ranges from stationary to 110 km/h (68 mi/h), with average of 50 km/h (30mi/h) (Coch, 1995). Tornadoes form in the rainbands of a hurricane and cause significant damage to life and property.

Tornadoes are serious local hazards because of an extraordinarily low air pressure and very high winds. Tornadoes cause damage in various ways. The rapid, rotating winds knock down weaker structures. The wind force picks up smaller objects and can transport them to a very long distance. Tremendous amounts of debris are mobilized in a tornado and can destroy larger structures.

Many of the deadliest tornadoes were recorded with the USA, and Australia. Areas in Texas and surrounding states in the USA, known as "Tornado Alley," frequently experience tornadoes. Tornadoes hit Montana, Illinois, Indiana, and Kentucky on March 18, 1925 and killed 734 people and damaged US$16.2 million in property (Brooks and Doswell, 2000). On April 5 and 6, 1936, tornadoes hit Mississippi and Georgia, which killed about 419 people and damaged US$16 million (Brooks and Doswell, 2000). A tornado on May 11, 1953 hit Waco, Texas, and killed 114 people, and damaged US$41 million (Brooks and Doswell, 2000). On June 8 of the same year another tornado hit Flint and Beecher communities of Michigan and killed 116 people, injured hundreds and destroyed US$19 million property (Hanson et al., 1979). On April 11, 1965, one of the worst tornados outbreak in the USA history hit many areas in Michigan, Ohio, and Indiana, leaving more than 128 people dead, many people

injured, and more than US$105 million property damaged (Brooks and Doswell, 2000). A super tornado on April 3, 1974 hit many areas in Ohio, Alabama, Indiana, and Kentucky and killed 183 people, injured thousands of people, and damaged US$262 million property (Brooks and Doswell, 2000).

Many parts of Australia frequently get tornadoes, also known as Willi Willi or Dust Devil.

Lightning

Lightning is a large charge of electricity that can descend from clouds to the ground or to other clouds. Lightning initiates fires and sometimes can hurt or kill people. Worldwide, eight million lightning flashes occur every day and kill typically 300–600 people each year (Glunčič et al., 2001). The chances of being struck by lightning depend on the location. Lightning can strike a long distance from a storm, which means a wide region around a storm area can be a hazardous region of lightning. Lightning tends to travel the path of least resistance and often seeks out tall or metal objects. In the USA, lightning strikes are most prevalent in the south, southwest, and mid-western regions of the country. An average of 62 people are killed each year by lightning in the USA (Adekoya and Nolte, 2005). The deadliest lightning strike ever hit a Boeing 707 near Elkton MD on December 8, 1963. The plane crashed and killed 81 people (Uman and Rakov, 2003). Another deadly lightning strike in 1993 hit an Egyptian army fuel depot and killed 430 people.

Hail

Hail, a type of precipitation, occurs when updrafts in thunderstorms carry raindrops upward into areas of the atmosphere with temperatures below freezing. Hail is only produced by thunderclouds, usually at the front of the storm system. Hail forms on condensation nuclei, such as a dust particle or ice crystal, when supercooled water freezes in contact. The size of the hailstone ranges from very tiny (mm in diameter) to several centimeters. It can damage aircrafts, structures, and vehicles. It also can be deadly to livestock and people. For example, on April 30, 1888, hailstorms killed more than 250 people and many cattle in India (Wylie, 1936). On July 19, 1932 hailstorms killed 200 individuals in China. Similarly, hailstorms killed 56 individuals in Nebraska, USA, in 1991 and 39 individuals in Oklahoma, USA, in 1995 (Rocke et al., 2005).

Freeze

Freeze, a winter hazard, can cause substantial damage and affect facilities in the entire temperate zone (middle latitudes), and sometimes in subtropical regions where freeze is thought to be rare. In areas where freeze is common, the typical freeze incident results from lack of proper management of the structures designed to prevent freeze, for example, leaving a door or window open. In areas where freeze is infrequent and rare, the problems result from the lack of adequate insulation. Freeze directly impacts a facility by breaking or impairing the fire protection system and water system. In addition, freeze can impact instruments in industries and can interrupt production processes. Other causes of the freeze incidents are the lack of proper monitoring of forecasting system of the temperature and lack of waning system.

Drought/desertification

Drought is a prolonged, abnormally dry period, from moisture deficiency. Drought creates adverse impacts on water supply, water quality, hydropower, vegetation, soils, animals, and people. It results from large-scale disruptions of atmospheric circulation patterns that may persist for months or years. All droughts originate from too little precipitation (i.e., meteorological drought), but vulnerability increases as patterns of land and water use change. Drought occurs with the fluctuations in global weather. The most widely known recurring climatic irregularity every few years is known as the El Niño. El Niño is an extreme swing in a recurring air pressure shift across the Pacific Ocean called the Southern Oscillation. Many droughts affecting eastern and northern Australia are considered as direct result of a strong swing in the Southern Oscillation.

In last 60 years droughts affected the USA, Canada, Australia, China, and Magnolia. Although the location varies, drought occurs each year in the USA and results in serious economic, social, and environmental impacts. Based on the study of FEMA in 1995, annual losses associated with drought in the USA have been estimated to be between US$6 billion and US$8 billion (FEMA, 1995). During the 1950s, many areas of the USA, extending from the mid-west to the Great Plains and southward into New Mexico, experienced severe drought conditions. The drought subsided in most areas with the spring rains of 1957. The drought was characterized by low rainfall and excessively high temperatures. The drought devastated agricultural production and degraded the land in these regions. Again, in the 1980s (1987–1989), drought impacted many areas of the USA. The drought intensified over the northern Great Plains, spread across much of the eastern half of the USA, and affected the primary corn and soybean growing areas. The summer of 1988 is well known for the extensive forest fires that burned across western North America, including the catastrophic Yellowstone fire. In addition to dry conditions, heat waves during the summer of 1988 broke long-standing temperature records in many mid-western and northeastern metropolitan areas. Combining the losses in energy, water, ecosystems, and agriculture, the total cost of the drought was estimated at US$39 billion (Coch, 1995). Western Canada also experienced drought in 1988 and the loss in this event was estimated more than US$1.8 billion.

In the 1980s and 1990s, many parts of Australia experienced a drought. During 1979–1983, very large areas of central and eastern Australia had record of low rainfall. Although no known human deaths from starvation or disease occurred, the total impact of the event was

estimated at US$7 billion at that time. The drought affected production of cereal grain, cotton, and sugar and caused loss of livestock as well as tons of topsoil. Again, from 1991 to late 1995, a prolonged and severe drought occurred in most parts of northeastern New South Wales and Queensland. Water levels lowered in major reservoirs of the area because of the low rainfall. The deficiency in water significantly affected agriculture to a loss of US$5 billion.

Desertification, the gradual transformation of arable and habitable land into desert, is one of the most important environmental challenges in the future. Climate change and improper use of land are contributing factors. Each year, desertification and drought account for a loss of US $42 billion in food productivity worldwide (UNEP, 2004; Sivakumar, 2006). In China, nearly 20% of land area is desert. As a result of a combination of poor farming practices, drought, and increased demand for groundwater, desertification has become arguably the most important environmental challenge in China. Because of the effects of increasing desertification, farmers are abandoning their land, and the intensity of sandstorms is increasing.

Anthropogenic events

The interaction of human activities with natural geologic systems sometimes results in a hazard. Hazards created by the human activities are attributable to pollution and contamination of food, air, and water because of increase in industries, mining, and inappropriate dumping of toxic wastes; results of conflicts and wars; dam failure; deforestation; and climate change because of the excessive production of greenhouse gases.

Air and water pollution

Air pollution is becoming a serious environmental problem worldwide. The rapid rate of urbanization, industrialization, and utilization of fossil fuels are affecting air quality worldwide. Furthermore, the rise in the use of old and outdated vehicles, mostly in developing countries, is also increasing air pollution. The results of these activities are increasing the concentrations of toxic metal and dusts in air and water. Lead pollution from automobiles and cottage industries represents a major health hazard.

The sites of the disposal of the toxic waste material, such as raw sewage, sludge, incinerated ashes, contaminated soils, nuclear materials, acids, and poisonous solvents ejected by chemical, pharmaceutical, and fertilizer-producing plants, contaminate and pollute surface and subsurface water storage. The localities become a hazardous environment to the health of the local people.

Seepage of the chemicals and oils from industries and mining areas as a result of accidents, natural disaster, or human recklessness contaminate food, air, and water, sometimes in local area but occasionally over a wide region. Spills of chemicals into coastal waters can harm people, environment, and aquatic life, and can cause substantial disruption of marine transportation and economy.

Mining and gas flaring

Mining contributes to the pollution of water and air. Basic environmental impacts of intensive mining operations include: accumulation of sediments in rivers and lakes, land degradation by mining-induced deforestation, erosion and mass movement, contamination of air and water by the accumulations of dust and heavy metals (lead, arsenic, cadmium, mercury). One of the major causes of health hazards for the people is working in mines and living around mining areas. The main causes of health hazards among miners include: inhaling large amounts of siliceous dust, careless handling of mercury during gold panning, and sharing of poor quality air in the mines by large numbers of individuals.

Burning of natural gas during crude oil production is the most common gas flaring. Gas flaring also emits carbon dioxide, hydrogen sulfide, sulfur dioxide, and small quantities of toxic compounds, such as carbonyl sulfide, carbon disulphide, nitrogen oxides, and volatile organic compounds. These gases are hazardous for the health of the people living around the locations of oil productions.

Conflict-related hazards

Famine, mental and physical illness, and rapid spreading of diseases are major hazards to people created by conflict, war, and terrorism. Other hazards related to conflict, war, and terrorism include an increase in rate of mortality, morbidity and disability, degradation of land and environment, degradation of social life, and increase in crime rate. Recently, many Asian countries, such as Afghanistan, Nepal, Iraq, Sri Lanka, and African countries, such as Cote d'Ivoire, Guinea, Liberia, Nigeria, Sierra Leone, Togo, Eritrea, Ethiopia, Somalia, Sudan, Uganda, Burundi, Democratic Republic of the Congo, Rwanda, Algeria, Angola, and Zimbabwe, are experiencing these hazards because of the political conflicts, civil war, and terrorism.

Deforestation and construction

Deforestation is a process of degradation of forests resulting from various factors, such as climatic variations, and human activities. Other reasons of the deforestation are erosion, landsliding induced by road cutting, forest fire, and poor agricultural practices.

Forests, the most biologically diverse regions of the world, yield millions of species of plants and animals. Forests are also a source of medicine, money, food, shelter, recreation, and livelihood for many indigenous and nonindigenous people. Deforestation destroys this unique environment and also causes change in climate. Deforestation results in desiccation of the forest soil and leads to an increase in temperature, decrease in water storing capacity, and increase in soil erosion, which

ultimately converts a moist humid region into a desert. Furthermore, deforestation results in less of an exchange of carbon dioxide and nitrogen.

Dam failure

Dam, an artificial barrier to impound water, wastewater, or any liquid-borne material for the purpose of storage or control, can fail and damage life and property downstream. Reasons for the dam failure can be: (1) overtopping caused by floods, (2) deliberate acts of sabotage, (3) structural failure of materials used in dam construction, (4) movement and/or failure of the foundation supporting the dam, (5) settlement and cracking of concrete or embankment dams, (6) piping and internal erosion of soil in embankment dams, (7) inadequate maintenance and improper operation, and (8) vandalism or terrorism. A well-known example of dam failure is the landslide-induced Vaiont dam disaster on October 9, 1963, which killed ~1,900 people living downstream of the dam.

Assessment of hazards and risks

Identification and analysis of hazards is the first step necessary to reduce the impact of potential hazards and to remain prepared for an emergency situation. Although it is difficult to address all potential hazards of a place, assessment of hazards and risks can follow priorities so that the most likely and dangerous situations are addressed first and those least likely to occur and less likely to cause major problems can be considered later. Hazards should be prioritized based on the location and the frequency and magnitude of the events. Large magnitude events cause greater damage but fortunately they generally occur with low frequency. Events with small magnitudes typically cause smaller damage but are very frequent. Some hazards, such as landslides, usually have a local effect, others including earthquakes and hurricanes have a regional effect and some, such as volcanic dust clouds can have a global effect.

The major hazards in a place can be identified by the geological records of the historical events, survey of the recent events, current scientific knowledge, and the sensing of the environmental changes, such as change in transportation, industrial and urban development, and population densities. Then hazards can be evaluated in terms of the likelihood that a problem may occur and the damage it would cause. This information can be used to identify and prioritize major hazards. After data for all kinds of hazards are collected, a rating or weighting approach can be used to prioritize different hazards (Odeh, 2002; Li et al., 2009). Then a qualitative or quantitative approach can be used to determine the spatial distribution of a selected hazard. The result helps decision makers design and institute approaches of hazard mitigation or emergency preparedness. Hazards that are very likely to happen and would do considerable damage to people and property should be addressed first. Hazards that are less likely or that would do less damage need to be identified for attention after the more serious hazards have been addressed. Assessment requires identifying populations at risk, structures, critical facilities, and natural resources to estimate deaths and injuries, property damage, and economic losses. With such information, geographical information systems and computer models can be used to integrate hazard and vulnerability assessments to carry out the assessment of risks. Assessment of risk is necessary to make rational decisions about investments in mitigation, emergency preparedness, and warning systems.

Mitigation of hazards

Over the past few decades, science has greatly advanced the understanding of hazardous events through new theoretical approaches, experiments, computer simulations, remote sensing, and monitoring. Some events, such as volcanic eruptions, hurricanes and storms, tornadoes, and floods, are now predictable. Although prediction of some events, such as earthquakes and tsunamis, remains elusive, an early warning system based on the monitoring of the related activity can provide some time prior to the emergency situation.

Mitigation of hazards is an activity taken to reduce or eliminate the risk to life and property from hazards. An assumption of mitigation strategy is that the economy invested in mitigation will significantly reduce the economy needed for emergency recovery, repair, and reconstruction after a hazardous event. The first focus of any mitigation plan should be human settlement areas, engineering structures, and ecologically sensitive areas, such as wetlands, floodplains, lakes, and natural features which significantly reduce the impact of the hazardous events. Furthermore, natural resources and precious cultural treasure should be protected.

A mitigation approach should plan for long and short-term perspectives. Some examples of the long-term mitigation approach are adopting codes for buildings, schools, hospitals, bridges, power plants and dams; and preventing construction in areas susceptible to hazardous events, such as vulnerable seismic zones, fire-prone areas, flood plains, and low coastal areas. Another broad way of mitigating the impact of hazards is preventing and controlling the hazards by engineering methods. Events like floods, landslides, or erosion can be prevented by this method. Finally, the third approach of reducing the impact of hazards is public awareness. Expert studies are of limited value unless public officials and the public are educated about hazards, risks, and warnings of hazardous events. These approaches can produce remarkable savings of life and property.

Emergency preparedness, including evacuation before a hazardous event, is the final stage to be safe from a hazardous event. Ignoring warnings of a hazardous event could be fatal. Two examples will contrast the results of preparedness versus ignoring the warnings. Hurricane Gilbert in the Caribbean (Category 5) in 1988 was one

of the most powerful storms, but only 318 people died (Lawrence and Gross, 1989). The low death toll occurred because people and governments were well prepped for Hurricane Gilbert. Weather reports were timely and reasonably accurate. The public was educated to heed these warnings and take appropriate actions. Land use restrictions and building codes minimized loss of life and property. Governments had emergency teams waiting to provide assistance. In contrast, the 1985 eruption of Nevado del Ruiz, a volcano in Colombia, buried more than 23,000 individuals in a mudflow (Pierson et al., 1990). Scientists warned the government of Colombia about the possibility of eruption. Unfortunately, people near the volcano were not alerted and remained in their homes at the time of eruption.

Summary

The first step in the assessment of hazards is to understand major hazards associated with an area, to develop an appropriate approach of hazard mitigation, and to be prepared for emergency situations. Hazards can be evaluated in terms of the likelihood that a problem may occur and the damage it would cause. Magnitude and the frequency of the events are always necessary to understand in the analysis of severity of a potentially damaging event. Some hazards, such as landslides, have a local effect; some such as earthquakes and hurricanes, have a regional effect; and other hazards, such as volcanic dust clouds, have a hemispheric or global effect. Prioritizing hazards based on the records of the historical events, survey of the recent events, current scientific knowledge, and the sensing of the environmental changes is an appropriate way to identify the major hazards in an area.

Mitigation of hazards is an activity taken to reduce or eliminate the risk to life and property. The first choice of any mitigation plan should focus on human settlement areas, engineering structures, and ecologically sensitive areas. Any mitigation approach should be a plan with a long- and short-term perspective. Adopting codes for buildings, schools, hospitals, dams, bridges, and power plants are the long-term approach. Preventing and controlling the hazards by engineering methods can be adopted as a short-term approach.

Emergency preparedness, including evacuation before a hazardous event, is the final stage to be safe from a hazardous event. Many hazardous events are preceded by warning precursors. Educating the public about these warnings and appropriate actions needed during a hazardous event would be one of the best approaches of emergency preparedness.

HEAT WAVES

Gerd Tetzlaff
Institut für Meteorologie, Universität Leipzig, Leipzig, Germany

Definition

Heat is a feeling of discomfort. Continuous heat increases the discomfort and may cause adverse effects on health particularly combined with high levels of humidity or when exacerbated by a person's physical condition. If heat lasts for more than a couple of days it is called a heat wave. In the mid and high-latitudes, heat waves are embedded in the usual course of summer weather; in the tropics they are endemic.

Introduction

Most individuals feel comfortable with respect to thermal conditions, if little or no thermal-regulatory activities are necessary to keep the body core temperature at the level of 36.8°C. This generally is the case in conditions of slight air movement, no solar radiation, low humidity, and the air temperature in the lower to mid-20s given in °C, for indoor and outdoor conditions (Fanger, 1972). There are many additional factors involved when considering the felt heat comfort of a concrete individual, such as the general health and living conditions, the current disposition of an individual, etc. Higher air temperatures often do come together with additional effects of one or several of the mentioned parameters and then act together in causing discomfort called heat, if lasting for a period of several days, a heat wave. The feeling of discomfort increases not only with the increase of the deviation from comfortable conditions but also with time spent in such conditions.

Weather and environmental conditions are far from being constant and therefore, *almost permanently* activate the thermoregulatory system of the human body. In a wide range of environmental conditions this happens rather smoothly and unnoticed. The feeling of discomfort from exposure to heat conditions is a warning to the body to discontinue the actual exposure and/or bodily activity, otherwise adverse effects in health have to be expected. Particularly severe effects occurred in the European heat wave in August 2003 causing many thousand fatalities (e.g., Luterbacher et al., 2004; EM-DAT, 2012).

The activation of the temperature control mechanisms depends on the energy balance of the body (Jendritzky et al., 1979; US Army 2003). The temperature of the body is so warm, that in most natural environments energy is transported from the core parts of the body to the surface. The source of the energy is food transformed by the body's metabolism. There are quite different environmental conditions, climate zones, distributed over the globe. In the warmer parts of the world people do live permanently in a wide range of heat conditions and have acclimated to their endemic environmental heat. The concept of acclimation also applies for non-indigenous individuals, with several phases of the actual degree of acclimation taking time periods from days to years. The quantity and rate of the energy flux from the core to the surface depends on the structure of the thermoregulation system and available fluids, the size and the shape of the body, the quantity of the internal energy production, clothing, and the above mentioned conditions of the environment. The energy balance of the body's surface comprises the body's internal energy production as a source; and the sinks are the pulmonary energy flux, the radiation budget, the convective fluxes of sensible and latent heat, the energy conduction, and the storage. The storage is determined by the increase or decrease of the body temperature.

In heat conditions, there is a deviation from heat comfort conditions, bringing imbalances to the body's energy budget and thermoregulatory activities, going with enhanced energy transport from the core of the body to the surface enforcing increased blood circulation trying to keep thermal comfort. Additionally, often external mechanical work is performed, exercising the muscles. These then need an increased energy supply, enhancing the overall energy production in the core of the body. To keep the core temperature of the body constant when doing such external work requires the transport of the work-related extra energy to the surface. In this whole process, the muscles need increased amounts of oxygen supplied by the circulating blood, whereas on the other side the blood is responsible for the increased transport of energy from the core body to its surface.

The energy transport from the core of the body to the surface acts based upon a gradient between the core temperature and the surface temperature. The surface temperature and the surface energy fluxes, however, are largely influenced by the complex set of environmental parameters. The key parameters allowing to measure environmental conditions are air temperature, humidity, solar radiation, long wave radiation, wind speed, and air quality. Often temperature is taken as key indicator, although the energy fluxes from the body's surface depend on the combined effect of all these parameters. Certain parameter

combinations result in noticeable energy storage in the body's core, with overheating bringing adverse effects to any affected individual.

Any deviation from the felt thermal comfort conditions leads to imbalances of the body's energy budget and thermoregulatory activities. In the past, some attention was given to the development of objectively measurable indicators to characterize comfort in warm environments. The number of indices is quite large, because it proved to be difficult to quantify the whole complex cooling process of the body. This is particularly true in the absence of sufficient, or representative, empirical investigation and sampling (of select populations) from both a statistical and significance point of view. It proved to be especially difficult to quantify the individually varying properties of the body, but also the effects of bodily exercise. One of the most widely used indicators is the WBGT (Yaglou and Minard, 1957; Gaspar and Quintela, 2009), the wet-bulb global temperature. It consists of three quantities (see equation).

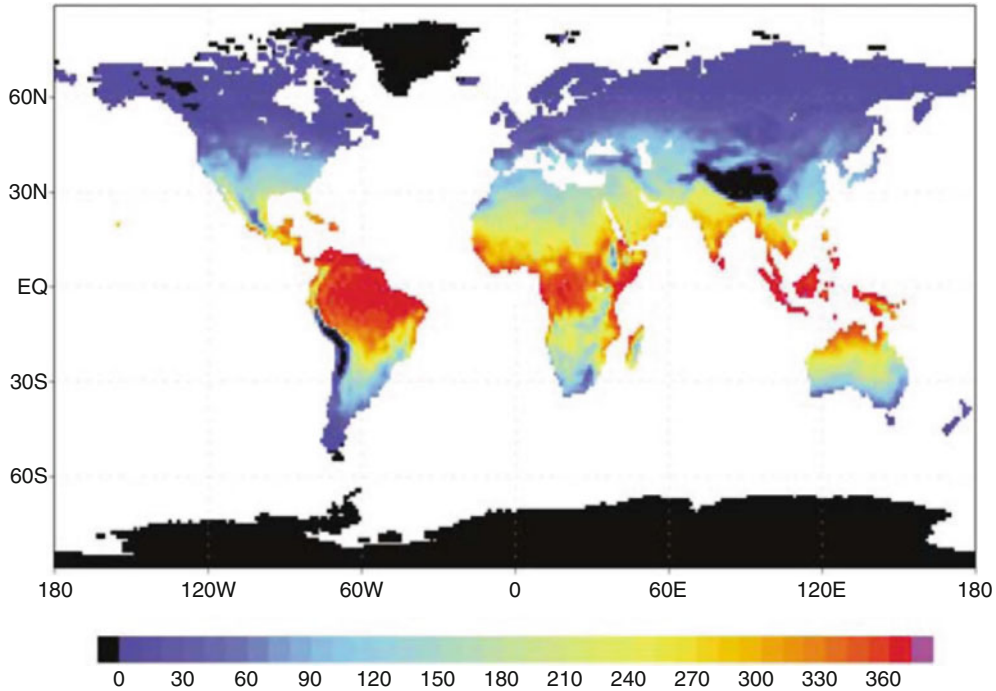
$$\mathrm{WBGT} = 0.7\ T_{nw} + 0.2\ T_g + 0.1\ T_a$$

T_{nw} is the wet-bulb temperature, T_g the globe temperature, and T_a the air temperature. The wet-bulb temperature is taken from a thermometer that is cooled by a water-soaked wick, the globe temperature from a thermometer surrounded by a black globe exposed to solar and thermal or long wave radiation, and the air temperature from a shaded thermometer. T_{nw} represents the effects of humidity, air temperature, and ventilation; T_g the effects of solar and thermal radiation, air temperature, and ventilation; and T_a the air temperature (representing a source or sink of heat with regard to the person). In addition to the definition of WBGT, some empirical thresholds were found and used to form a five-step scale for comfort and discomfort, respectively (see table below).

The WBTG concept is valid for stationary, long-term conditions. The effects of short, intermittent variations might result in differences between the measured and the individually felt comfort values, resulting in a rather general recommendation to take any heat-related discomfort feelings as a warning to prepare for action. Furthermore, comfort is to be differentiated for age, body shape and health state, and clothing. To allow for the effects of these parameters, empirically based correction factors are in use.

The reference values of WBGT heat stress index related to a body core temperature of 38°C are presented in the table. The range is from no heat stress (1) to extreme heat stress (5), valid for indoor and outdoor conditions.

Metabolic rate	According to WBGT value in W/m^2 for acclimatized persons in °C
1 (rest; ~65)	33
2 (light exercise; 65–130)	30
3 (medium; 130–200)	28
4 (heavy; 200–260)	25
5 (extreme; >260)	23 (still air), 25 (sensible air movement)



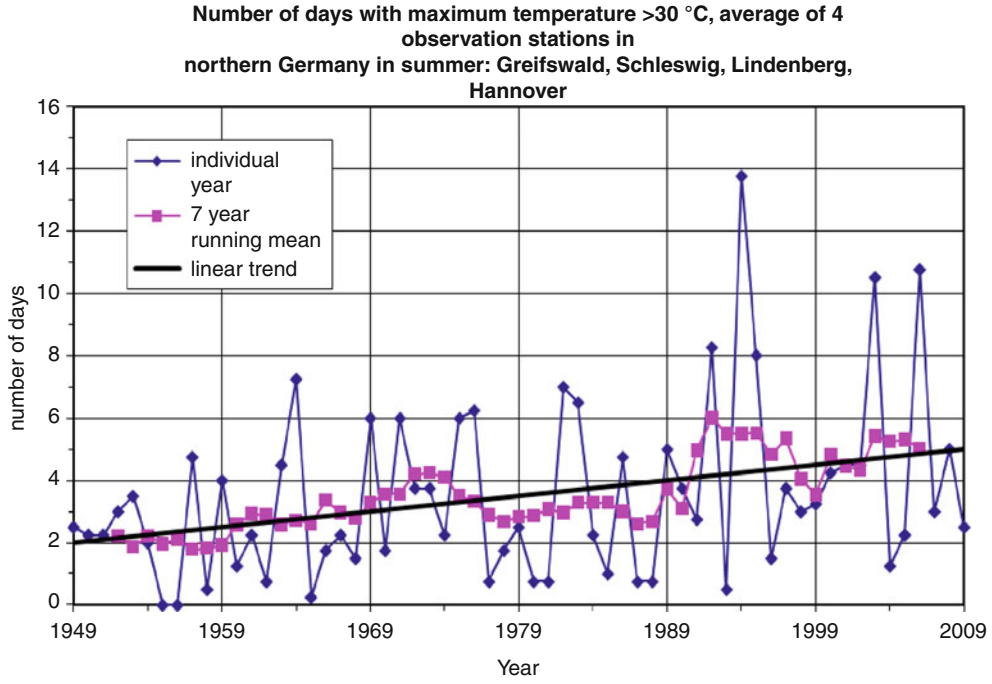
The reaction of the body to defend itself from overheating happens through three mechanisms: increase of blood flow, breathing, and perspiration (i.e., more generally transpiration). The first reaction is to increase the blood flow to bring more energy to the body's surface. Increased breathing follows as an effect. In continuing heat stress conditions sweating begins. All of these require use of the body's water and salt reserves and its ability to pump enough energy from the body's core to the surface. Sufficient water supply, thus, is a major precondition to cope with heat conditions.

If cooling mechanisms are not efficient enough to keep the core temperature at constant optimum level, or respond too slowly, a condition of heat stress arises. This can lead to problems, like heat exhaustion, heat cramps, fainting, or even heat stroke. There is abundant information available on the symptoms of these health problems and on how to respond, if they occur. In recent years, public authorities have taken efforts to also mitigate, prevent, or avoid the heat effects available to the public (Bureau of Meteorology of Australia, 2010).

Heat exhaustion is the most common heat-related ailment occurring when doing strenuous work or exercise for the environmental conditions, indicated by WBGT. The elderly or the very young may already suffer exhaustion even being at rest. This usually means that the individual sweats a lot and does not drink enough water, or does not take enough salt, or both. The symptoms are sweating, feeling weak or tired, and sometimes giddy or nauseous. The face looks pale, the skin feels clammy. In uncomplicated cases, it is sufficient to bring the individual to rest in shady and cooler place and administer some appropriate drink.

Heat cramps do occur when an individual works or exercises in a warm environment, and sweats a lot without replacing the salts lost from sweating. In cases with no further health problems, relief is achieved by drinking electrolyte solutions and resting in cool shady places. Fainting usually happens to individuals not acclimatized to a warm environment while standing still. In the majority of cases, relief is achieved if the individual lies down in a shady, cooler place.

A heat stroke is the most serious health problem caused by heat stress. It is caused by a rise of the body core temperature to about 41°C or higher. The symptoms are mental confusion, delirium, or seizures. The skin is hot and dry, often red. Such a condition requires immediate medical intervention. Rapid cooling by soaking with cold water or fanning with cool air can give relief.



Heat Waves, Figure 1 Mean annual number of days exceeding the threshold for moderate heat load at 12 mean local time taking acclimatization into account with no or light exercise (Jendritzky and Tinz, Global Health Action 2009).

As already shown in the formulation of WBGT, heat is acquired by the body by several physical properties, such as temperature, wet-bulb temperature, ventilation, solar radiation, long wave radiation, etc. For the use in weather forecasting and climatology the statistics of these parameters are mostly evaluated separately. Statistics of all parameters contributing to the formation of heat stress were merged by Jendritzky and Binz (2009). The map (Figure 1) shows the global distribution of the number of days with moderate heat load (see the aforementioned table on WBGT heat stress index). As to be expected, the humid tropical regions show an occurrence of more than 300 days per year, permanent residents mostly being acclimated and prepared to cope with the endemic heat conditions. In the mid-latitudes, the occurrence of such days ranges between about 20 and 100.

In the mid-latitudes, the days with heat stress mainly occur in the summer season and are then grouped in sequences of days, in heat waves, mostly exceeding long-term mean temperatures. Following the mid-latitude weather patterns often heat waves last 2 to about 5 days. This duration is closely connected to the basic properties of mid-latitude weather, dominated by transient, high- and low-pressure systems. The intensity of any particular heat wave depends on the temporal and local peculiarities of the pressure systems, in rare cases allowing a heat wave to last for weeks and to bring particularly hot conditions. The duration is of some relevance, because it takes a few days for the heat to penetrate the walls of most types of standard non-air-conditioned buildings and to raise the indoor temperature to heat stress conditions.

The occurrence of heat waves and their adverse effects is globally wide spread. In the last century, about 150 heat waves were documented to reach disaster level (EM-DAT, 2012). The deadliest heat waves on record globally since 1900 occurred in Europe in the years 2003 and 2010. Europe was hit almost unaware by the heat and the large number of fatalities reached more than 66,000 in the year 2003 and 55,000 in 2010 (EM-DAT, 2012). Both heat waves were accompanied by an enormous amount of material damage, mostly in forestry and agriculture. Both heat waves were caused by a long-lasting mid-latitude air flow pattern, a so-called blocking action. Such weather situations are in general well-known; however, two factors, high temperature and low precipitation, combine in a particularly unfavorable way. In both cases, the monthly average maximum temperature (July 2010 in Russia, August 2003 in France) was about 10 K higher than the long-term average. In both cases the number of days with extremely high daily maximum temeprature was unprecedented (the thresholds were 36°C in western Europe in 2003, and 30°C in Russia in 2010; Schönwiese et al., 2003; Trigo et al., 2005). In the 2003 heat wave, a large part of the victims were from the elderly (Robine et al., 2007). Several factors added to the heat stress for this population group, comprising reduced mobility, health

Heat Waves, Figure 2 Number of days with maximum temperature exceeding 30°C in northern Germany (data: Deutscher Wetterdienst).

problems, reduced ability and/or damage of the cardiovascular system, living alone, etc.

The frequency of heat waves is expected to change in the future (IPCC, 2012). Observations for Central Europe already show, that the temperature changes went with a drastic increase of the high (>30°C) and very high temperatures (Schär et al., 2004). In the last decades, the number of days with high temperature more than doubled while the increase of the average temperature was about 1 K (Figure 2).

Summary

Thermal comfort is felt individually. Heat generally means thermal discomfort activating the thermoregulatory system of the body. Heat conditions are weather-determined and if lasting for several days or longer are called heat wave. Quantification of heat needs the total energy budget of the human body. This energy budget is influenced by air temperature, humidity, ventilation, radiation, bodily activity, clothing, mass and shape of the body, health state, age, and also by individual predisposition. In the case of overheating the body's thermoregulatory system failed to keep the temperature in the tolerable range of temperature in the core parts of the body. Indicators are in use allowing a simplified description of the energy budget of the human body, so capturing effects of heat as well. These indicators classify the environmental conditions by either recommending the type of feasible bodily activity, or by requiring the cooling of the human body, both in order to avoid health damage due to overheating. The climatic conditions show a global distribution of heat stress. In some parts of the tropics, heat stress occurs on more than 300 days per year, and in the mid-latitudes, heat stress occurs on about 20–100 days. Indigenous and non-indigenous populations do acclimate to endemic or periodical heat conditions, helping to better cope with these. Heat waves can develop more frequently, when on average there are more such heat days. In recent years, the number of days with heat stress, and of days occurring in heat waves, increased in the mid-latitudes. The forecast climate change points to further increase of heat stress in many parts of the world.

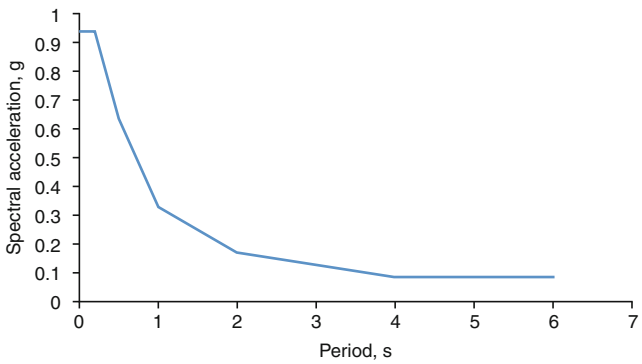
HIGH-RISE BUILDINGS IN NATURAL DISASTER



Murat Saatcioglu
University of Ottawa, Ottawa, ON, Canada

Definition

There is no precise definition of what constitutes a high-rise building. A building code definition includes buildings of over 23 m in height or approximately 6 stories high (IBC, 2009). Emporis Standards (2010) define high-rise buildings as multistory structures that are 35–100 m tall, or 12–39 stories high. Sometimes special service requirements dictate the definition. A building that is tall enough to necessitate an elevator, or as in the case of a fire code, "any structure where the height can have a serious impact on evacuation," may be classified as high-rise. In the context of natural hazards, two aspects distinguish high-rise buildings from others: (1) consequence of damage and (2) structural properties and their interactions with effects of natural hazards. High-rise buildings provide increased density of occupancy per structure, providing concentration of people in one building. Therefore, the consequence of damage tends to be more severe than that of a low-rise building. Furthermore, evacuation of upper floors of a tall building after a natural disaster may pose challenges during relief and response operations.

High-rise buildings are generally built using reinforced concrete or structural steel, and possess the required strength and stiffness against potential natural hazards. Geotechnical risk factors, including soft and compressible soils, as well as potential for landslide and liquefaction cause serious threats to high-rise buildings, which consequently require high soil-bearing capacities. Structural response of high-rise buildings gains a new dimension if the natural hazard induces dynamic forces, as in the case of wind pressures and earthquakes. The natural frequency of tall buildings tends to become lower with increased height, increasing their vulnerability to low-frequency wind and earthquake effects. High-rise buildings whose height-to-width ratios exceed approximately 4, or whose height is approximately in excess of 120 m, tend to become susceptible to vibration by extreme wind effects. These buildings may experience human perception problems, causing discomfort to the occupants, while increasing risk for potent damage to windows, external cladding elements, and other nonstructural components.

Most high-rise buildings have a fundamental period of longer than 1 s. Seismic hazard generally decreases with fundamental period. Figure 1 illustrates the Uniform Hazard Spectrum on firm ground for the city of Vancouver in Canada (NBCC, 2010). In this example, a building with a fundamental period of 1 s has approximately ½ the earthquake spectral acceleration for a low-rise building with a fundamental period of 0.5 s. Taller buildings usually attract much less seismic forces than low-rise buildings. When soil conditions are unfavorable, however, the amplification of earthquake accelerations can be multiple times higher for long-period structures. The 1985 Mexico city earthquake is a good example of the vulnerability of

High-Rise Buildings in Natural Disaster, Figure 1 Uniform hazard spectrum for Vancouver, BC, Canada.

high-rise buildings to seismic excitations when located on soft soils. In this earthquake, buildings that were 7–13 stories suffered much more damage and collapses when compared with short-period and very long-period buildings, underlining the importance of interaction between the natural frequency of buildings and the frequency of earthquake excitation.

Historical natural hazards

Definition

Natural hazards that occurred in the historical past.

Introduction

This entry deals with historical natural hazards, with some reference to the ensuing disasters (see *Hazard*, *Geohazards*, *Disasters*, *Natural Hazard*). Therefore, pollution, famines, and epidemics and natural hazards caused by humans (e.g., desertification) are not considered here. Typical fast events, such as earthquakes, and slower changes, such as climatic change that affected vast areas, and slower pervasive processes (e.g., karst dissolution) with an abrupt end (e.g., collapse of infrastructure), are included. Some of these fast and slower phenomena may have a significant geomorphological-environmental impact with long-lasting repercussions on civilizations (Trifonov and Karakhanyan, 2004; Leroy, 2012, in press).

This entry focuses on historical natural disasters which have: (1) affected the environment, resources, or material culture so much that they caused long-lasting changes in human society at a regional or global scale, (2) led to new research and involved the scientific community in scientific, and sometimes less scientific, discussions, or (3) left lasting images (Figure 1) of catastrophes that have become "imprinted" in human history (Table 1). For example, when the eruption of Mt Vesuvius is mentioned, one remembers the annihilation of the city of Pompeii.

The start of history is by definition the beginning of the written record. The appearance of the first written evidences of natural hazards and disasters varies considerably between different parts of the world. The oldest are found in Mesopotamia on clay tablets in the fourth millennium before Christ, with perhaps much earlier findings in China on turtle bones. Very early, people felt the need to commit to writing certain recurring or exceptional natural observations. The chosen period for this contribution mostly extends from 2,200 years BC to the twentieth century, with most examples from the nineteenth and twentieth centuries (Table 1). Whenever possible, the age annotation has been given in years before Christ (BC) and after Christ (Anno Domini or AD). Radiocarbon dates presented in Years BP, that is, before 1950, are given when necessary.

Techniques

Techniques to reconstruct historical natural hazard events are abundant and drawn from a very wide range of scientific fields. For the time period in this text, historical and phenological documents are supplemented by high resolution, or otherwise well-constrained, earth sciences data and archaeological records.

Historical documents and phenological indicators

In ancient history, various forms of written texts on natural catastrophes can be found. Biblical stories, such as Noah's flood or the destruction of Jericho, have a high level of uncertainty (see *Biblical Events*, *Religion and Hazards*). Chronicles usually describe events post-factum such as those in the Viking sagas, which were recorded by individuals other than direct witnesses. Contemporary detailed accounts, such as by Josephus Flavius or Pliny the Younger, are often rich in descriptions, but may be rather subjective and incomplete.

Historical observations and documents may provide valuable information about past temperatures and other features of the environment, but commonly are seasonally specific or cover a short time span. In Europe, prior to about AD 1700, the evidence weakened and often became discontinuous. China, having had written documents for much longer, has a wealth of diaries kept by individuals, many of which still remain to be deciphered.

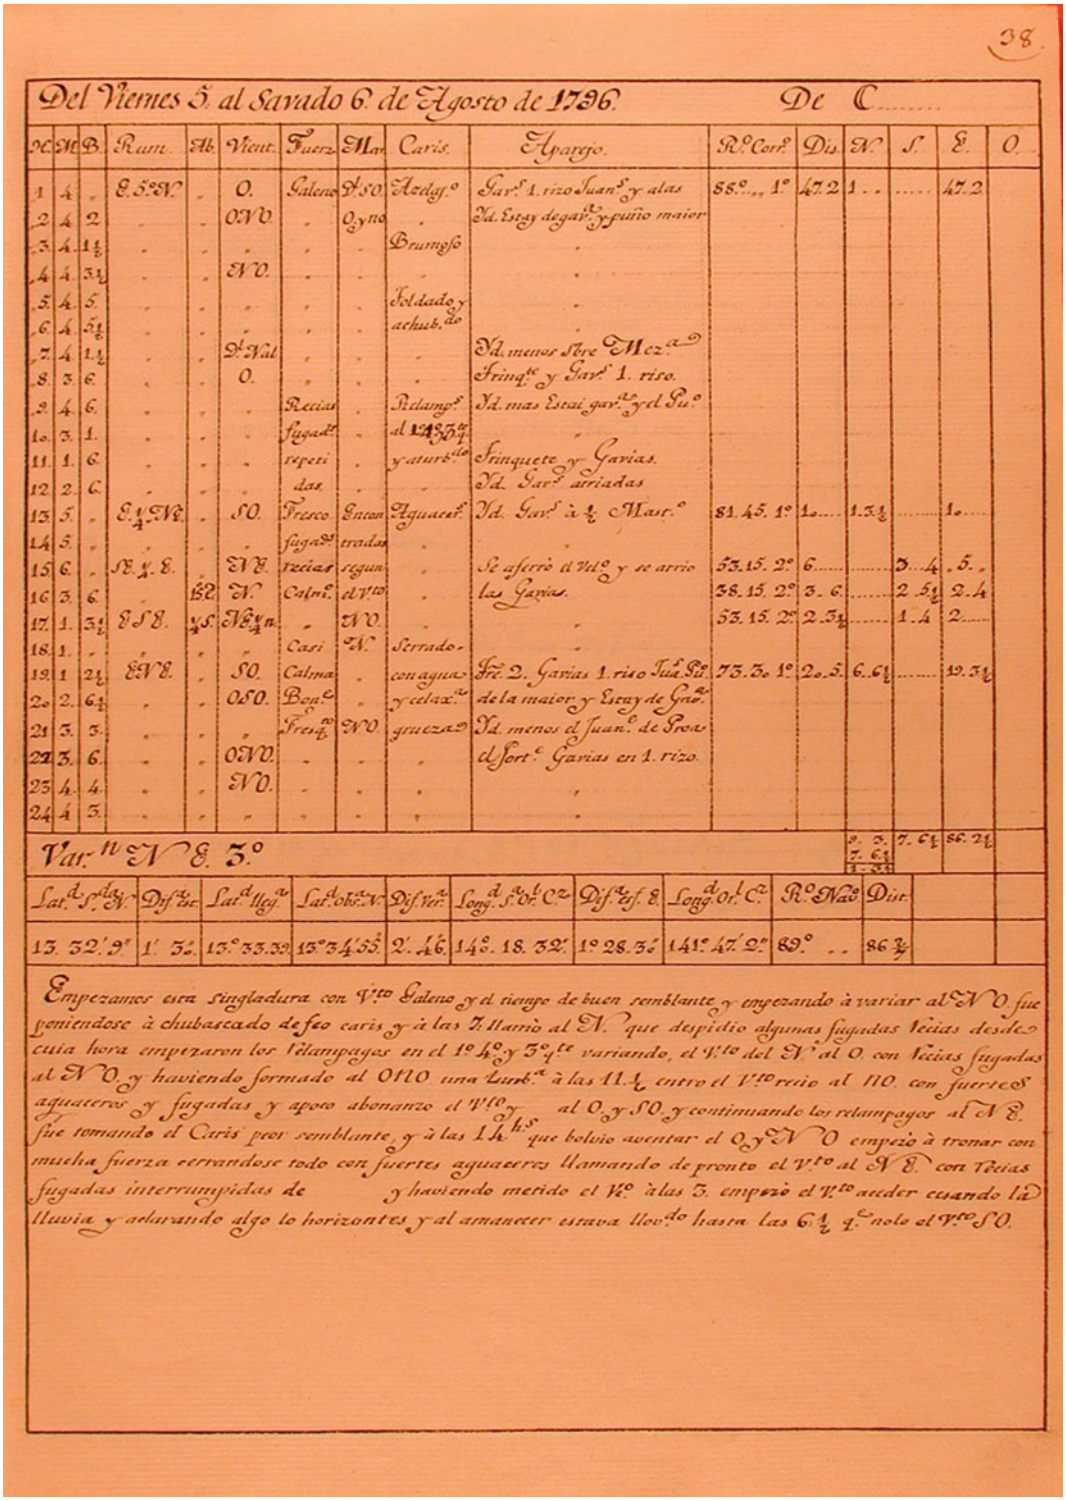
Historical Events, Figure 1 Eye-catching view of collapsed temple in a pancake pile, following the JiJi (or Chi-Chi) earthquake in Taiwan in 1999 (Photo: K. Arpe 2000).

Ship logs have been used for detecting extreme conditions at sea (Figure 2). García et al., (2000) were able, for example, to obtain a reconstruction of the North Atlantic atmospheric circulation during the sixteenth, seventeenth, and eighteenth centuries using documentary sources of the Spanish voyages to the Americas kept in the "Archivo General de Indias." Twelve possible hurricanes were identified in this way.

April to August temperature anomalies in Burgundy, France, were reconstructed from grape-harvest dates from AD 1370 to 2003, carefully registered in parish and municipal archives. Temperatures as high as those reached in the 1990s have occurred several times since AD 1370. However, the heat wave of summer AD 2003 appears to have been extraordinary, with temperatures that were probably higher than in any other year since AD 1370 (Chuine et al., 2004). The WHO has estimated that the extreme heat caused more than 15,000 excess deaths in France, Portugal, and Italy alone (Fink et al., 2004) (see *Heat Waves*).

Zerefos et al., (2007) analyzed paintings created by artists representing sunsets throughout the period AD 1500–1900 to detect the effect of volcanic eruptions on the atmosphere color.

Fluctuations of Nile flood discharge during the period from the ninth to the fifteenth century AD are documented in historical measurements of the Nile flood levels at the Roda Nilometer, opposite Old Cairo. Special attention was focused on two yearly events – one when the Nile was at its lowest point and the other when it reached its peak (Hassan, 2007). Excessively low or high Nile floods led to famines. The results indicate that there was a sharp increase in extreme low floods in the tenth century AD and a rise in the frequency of both extreme high and low Nile floods in the fourteenth century AD.



Archaeological evidence

Geohazards are recorded in many ways by archaeological evidence. New fields are emerging such as archaeo-seismology and archaeo-volcanology. Investigations focus on the geohazard effects on ancient structures, uncovered by means of archaeological excavations or pertaining to the monumental heritage (Galadini et al., 2006). Archaeological evidence records periods of abandonment and collapse of infrastructure. Building damage has been used to provide information on the location and magnitude of past earthquakes (Figure 3) (Marco 2008) (see *Earthquake Damage*, *Paleoseismology*, *Building Failure*). Houses, personal belongings, temples, citadels, and even whole towns and cities can be preserved intact beneath the volcanic ash or mud that engulfed them (Figure 4). Studies of eruptive deposits, particularly those associated with human habitation, document the nature of the event itself, including precursor activity, the eruptive sequence and the interaction of volcanic flows with human structures (Cashman and Giordano, 2008).

Paleoanthropology based on the interpretation of oral traditions and myths may also provide information on palaeohazards, such as volcanic eruption (Cashman and Giordano, 2008).

Earth sciences

The tectonic and geological structure of a region, including the occurrence of faults, rock movement, soft sediment formation-deformation, and seismic and geodynamic observations, may all provide information on past physical events and their damaging power (Marshak, 2004). Past landslides, lahars and floods, and any rapid and massive sediment or water movement can be reconstructed by studying landforms and sediment (Huggett, 2007).

Buried soils are specific archives of past environmental changes, both of slow and fast events (Yaalon, 1971; Alexandrovskiy, 1996). Preservation of microfossils within buried soils has proved to be an effective long-term recorder of a range of environmental parameters, such as moisture and temperature and have thus been widely used as proxy records of climatic change (Meunier and Colin, 2001; Golyeva and Terhorst, 2003). The stratigraphic sequence of buried soils and overlying or interstratified deposits provide evidence of interruptions of soil formation by rapid sedimentation. The radiocarbon analysis of organic matter buried in soils allows the dating of the accumulative or destructive phenomena (Alexandrovskiy et al., 2004).

Continuous proxy records

Lake sediments generally accumulate on a continuous basis, and, where obtained in outcrops or by coring/drilling, are archives for environmental changes including rapid events (Figure 5). Natural hazards are marked by anomalies, such as changes in grain size, disturbances to fine structures, and changes in sediment origin seen in, for example, geochemistry, pollen content, and charcoal concentration. Lake sediments have provided past records of floods (Arnaud et al., 2005), earthquakes (Schwab et al., 2009), hurricanes (Besonen et al., 2008), and volcanic eruptions (Bertrand et al., 2008a; Costa et al., 2012).

Deep marine sediment with a high sedimentation rate may be considered to provide comparable information to that in lake sediment; shallow marine sediment may, in addition, record phenomena such as tsunamis (see *North Anatolian Fault*) (Bertrand et al., 2011).

Corals contain annual growth bands, and therefore provide the possibility of high resolution using isotopic and geochemical analyses that may contribute to a history of flood events (Shen et al., 2005), extreme sediment flux events, changes in upwelling, sea surface temperature, and El Niño Southern Oscillation (ENSO) (Grottoli and Eakin, 2007). Ice cores may provide a fairly complete record of volcanic eruptions and comet/asteroid impacts through their chemical record, especially acid layers (Baillie, 2008) (see *Comet*). Tree-rings, in addition to the traditional dendrochronology and dendroclimatology, provide evidence for local and regional fires (Grissino-Mayer and Swetnam, 2000), hurricanes (Miller et al., 2006), and volcanic eruptions (Pearson et al., 2005).

It is worth noting the benefit of working on annually laminated sediment, tree-rings, coral annual bands, and ice core annual layers leading to strong age-depth models that allow constraining the event age, the duration of the disturbance, and their recurrence times. For example, in the annually laminated sediment of the Dead Sea, Holocene earthquakes and disturbance of lake sedimentation have been recorded by seismites. The associated palynology has been interpreted to show a decline in agriculture for 4–5 years following the two earthquakes analyzed at 31 years BC and AD 363 (Leroy et al., 2010).

Palaeoecology is a technique that is applied to the study of natural hazard reconstruction in continuous records: shells for high-energy events (Morales et al., 2008); foraminifera for seawater invasions (Mamo et al., 2009); ostracods for changes in salinity (Ruiz et al., 2010); diatoms for emergence-submergence (Sawai et al. 2004); pollen, spores, and non-pollen palynomorphs for soil wash in lakes (Leroy et al., 2009), amongst others, as these techniques record the impact of natural hazards on ecology.

Case studies

This section provides an overview of some notable natural disasters, beginning with classical geohazards, then hazards related to water and weather, followed by large-scale climatic events, and finally rarer events.

Instantaneous and destructive geohazards

This section is concerned with classical geohazards such as volcanoes, earthquakes, and landslides.

Volcanic eruptions and lahars

The AD 79 eruption of Mount Vesuvius (Italy) is one of the most famous catastrophic events in human history because of the vivid description recorded by Pliny the Younger, eyewitness of the event (see *Vesuvius*). The eruption buried the towns of Pompeii and Herculaneum (Figure 6). It was only at the end of the sixteenth century that Pompeii was rediscovered, buried below ash and rocks. Some 1,150 full casts and skeletons of people have been discovered during subsequent archaeological excavations of Pompeii (Luongo et al., 2003; Italian National Institute of Geophysics and Volcanology, 2006).

The destructive power of volcanic eruptions, strong in itself, is often exacerbated by subsequent lahars, landslides, and atmospheric emissions causing long-term consequences for humans. The AD 1815 eruption of Mount Tambora, Indonesia, is the largest and the most deadly volcanic eruption in recorded history (Oppenheimer, 2003). The mountain erupted, and ash fell 1,300 km away (Stothers, 1984). The death toll was at least 71,000 people; 11,000–12,000 were killed directly

Historical Events, Figure 6 Pompeii ruins with the Vesuvius volcano in the background (Photo: V. Targulian 2009).

Historical Events, Figure 7 Mount St Helens with trees felled in the same direction by the blast of the eruption in 1980 (Photo: K. Arpe 2002).

by the eruption, and other deaths were from starvation and disease (Oppenheimer, 2003). The eruption released sulfur into the stratosphere, causing global climate anomalies. AD 1816 became known as the "Year Without a Summer" because of the effect on North American and the European weather. Agricultural crops failed and livestock died in much of the Northern Hemisphere, resulting in the worst famine of the nineteenth century (Oppenheimer, 2003).

The relatively large scale of the May 18, 1980, eruption of Mount Saint Helens, USA, was totally unexpected despite regular monitoring (Figure 7). It claimed 57 lives and affected several hundred thousand people (Major and Scott, 1988). A large lateral blast sent a large mass failure down the mountain, sending ash up to 18 km into the atmosphere and causing a large landslide, which buried the surroundings under 45–180 m of debris. The lahars of rocks, ice, and mud rushed into river valleys and destroyed

27 bridges, 200 homes, 300 km of roadway, and 25 km of railway (Major and Scott, 1988; Major, 2003) (see *Lahar*). Spirit Lake was dammed with debris over 100 m deep, and the navigation channel of the Columbia River was reduced overnight in depth from 12 to just 4.2 m.

One of the world's largest historical explosive eruptions took place at about AD 969 from Baitoushan (Changbaishan or Paektusan) volcano, on the Chinese-North Korean border. The eruption column is estimated to have reached 25 km and thus entered the stratosphere; the eruption is thought to have had a substantial, but possibly short-lived effect on climate (Horn and Schmincke, 2000). The volcano now has a large lake in its caldera considered sacred by the Korean population living in the region: Lake Tianchi or Sky Lake.

Other extreme events not detailed here are the Santorini eruption (Greece) in the mid-second millennium BC with its tempting to link to the cultural downfall of the Minoans (see *Santorini, Eruption*), the Laki eruption (Iceland) in AD 1783 which caused a widespread dry fog and weather extremes (Leroy, 2012, in press), the Krakatau eruption (Indonesia) in AD 1883 in which more than 50,000 people perished (see *(Krakatoa) Krakatau*), many in a way similar to the Indian Ocean tsunami of 2004, and finally the Pinatubo eruption (Philippines) in AD 1991 (see Mt Pinatubo). The Smithsonian Institution has produced a catalog of world-wide volcanic eruptions, including historical ones, which can be searched by eruption date, region, and name: http://www.volcano.si.edu/world/. The Institute of Volcanology and Seismology of the Far Eastern Branch of the Russian Academy of Sciences has prepared a catalog of volcanoes and volcanic eruptions for Kamchatka and the Kuril Islands, which can be searched by name: http://www.kscnet.ru/ivs/volcanoes/holocene/ and http://www.kscnet.ru/ivs/kvert/volcanoes/.

Earthquakes and tsunamis

The strongest earthquake (see *Earthquake*) ever recorded occurred in Chile on May 22, 1960, off Valdivia. This 9.5 magnitude (M_w) earthquake killed more than 2,000 people, left two million homeless, caused heavy damage in several coastal cities, and triggered a tsunami in the Pacific Ocean that caused destruction as far as Hawaii and Japan (USGS, 2010b) (see *Tsunami*). Inland, this earthquake triggered numerous landslides in the Southern Cordillera of the Andes. It was also assumed to be responsible for the eruption of the Puyehue–Cordón de Caulle volcano (Bertrand et al., 2008b). On February 27, 2010, another very large earthquake, M_w 8.8, occurred offshore from Maule, only 273 km north of Valdivia.

The deadliest and most destructive earthquake was in AD 1556 when a M_w 8 earthquake hit the province of Shaanxi, and surrounding provinces in China, and caused 830,000 deaths (Hou et al., 1998). The death toll was especially high as many people lived in caves in loess cliffs. These easily collapsed in the shaking and created many deadly landslides.

The tectonic uplift of western Crete (Greece) of up to 9 m, a cluster of coastal uplifts in the East Mediterranean, as well as historical and archaeological data are evidence for a major seismic destruction on a nearly Mediterranean scale in AD 365 (Stiros, 2010). The earthquake affecting western Crete was associated with a reverse fault offshore of southwestern Crete, whose minimum magnitude was 8.5, hence putting it among the largest ever earthquakes. Stiros, (2010) suggested that the AD 365 destruction included at least two other major events, with epicenters close to Cyprus and Sicily and probably other areas.

Lisbon (Portugal) was destroyed in AD 1755 by earthquake shocks, a resulting tsunami, and fire (Fonseca, 2004). The M_w 8.5 earthquake and perhaps a second event occurred offshore near the Gorringe Bank and in Lisbon, respectively (Vilanova et al., 2003). Their impact extended from the Algarve to North Africa and Southeast Spain. Detailed and accurate historical accounts of the disaster have been kept by individuals who were in the city. Also, the first minister of Portugal sent a questionnaire to every parish priest requesting an exact description of what happened, leading to an exceptional scientific documentation. From these accounts, it appears that three shocks caused fires, which commonly started from stoves in the houses or from candelabra in churches, and those fires were then propagated by a northeast wind. Many people sought refuge on the banks of the Tagus River. However, many were drowned when a tsunami inundated the area 75–90 min after the earthquake (Fonseca, 2004). The Lisbon earthquake was the first disaster in which the state took on the responsibility for organizing the response to the emergency (Fonseca, 2004). This action greatly reduced hunger, spread of disease, and looting. When the time for reconstruction came, several proposals were made to reconstruct the city in a safer place; but the Portuguese king and the people insisted on occupying the lower area of Lisbon with buildings despite the engineers' advice. The King decided on razing the whole central area using rubble to make it flat. The only mitigation measures that were successfully implemented were the wider streets and the reinforcement of the house walls with a mesh to make the structures more resistant to shaking (Fonseca, 2004).

The area along the Dead Sea Fault Zone, which has been inhabited since antiquity, has a long and well-documented history of seismic activity. For example, in 31 BC, a major upheaval on the Jericho fault destroyed the town of Qumran (Karcz, 2004). A detailed description of this event appears in the writing of the historian, Josephus Flavius, who records the death from falling houses of 10,000 men. In AD 749, a major earthquake destroyed the ancient city of Jerash (Jordan) and its surroundings (Ambraseys, 2005) (Figure 8). On July 11, 1927, a M_w 6.5 earthquake hit the central, populated area of Palestine. Three hundred people were killed and about 1,000 homes were destroyed. Rock slides triggered by the earthquake stopped the flow of the Jordan River

Historical Events, Figure 8 Fallen columns at the classical Greco-Roman city of Susita, overlooking the Sea of Kinneret, collapsed during the AD 749 earthquake on the Dead Sea Fault (Photo: S. Leroy 2004).

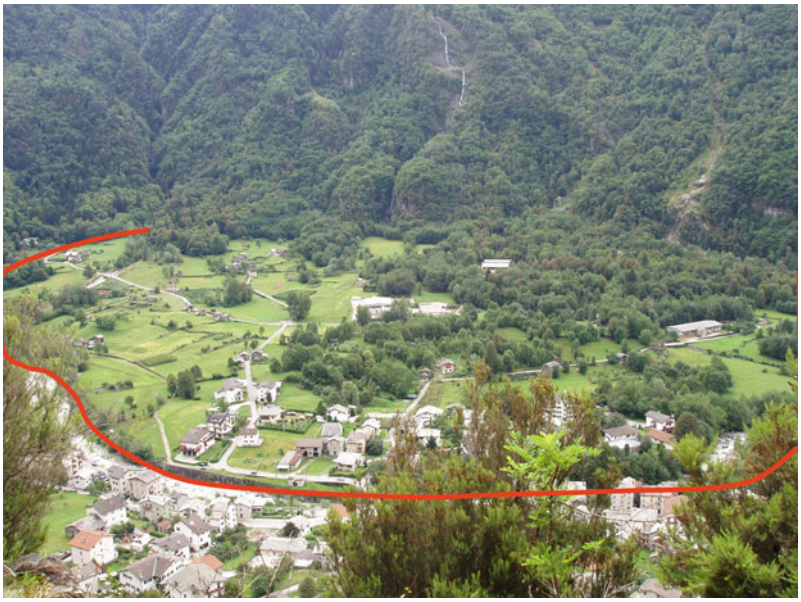
for a day. The earthquake was large enough to be recorded at seismological stations in Europe, South Africa, North America, and the USSR (Avraham et al., 2005).

In the same year, on September 11, 1927, a M_w 8 earthquake with an epicenter under the Black Sea affected the Crimean Peninsula, USSR (now Ukraine), near the city of Yalta. Seventy percent of the town buildings were destroyed (Kondorskaya and Shebalin, 1977). During this event, flares erupted from the Black Sea ranging from 20 to 500 m high and visible to a distance of 60–70 km. These flames were most likely caused by the combustion of methane gas eruptions triggered by the earthquake (Nikonov, 2009).

The AD 1908 Messina earthquake (Italy) was one of the most destructive to hit Europe. This M_w 7.5 earthquake occurred along the Strait of Messina between the island of Sicily and mainland Italy. It triggered a local tsunami, which struck within minutes of the earthquake. The cities of Messina and Reggio di Calabria were completely destroyed; the death toll was estimated between 60,000 and 120,000 (Barbano et al., 2005). The Italian government relocated many of the Messina survivors to other cities within Italy, others choose to emigrate to America.

The AD 1906 San Francisco (USA) earthquake (see *San Andreas Fault*) and the resulting fire is, as arguably, the worst natural disaster in the history of the USA. It ranks as one of the most significant earthquakes in history with M_w estimated between 7.8 and 8.5 (USGS, 2009). The death toll from the earthquake and fires was over 3,000, and at least 225,000 people were left homeless, out of a population of about 410,000 (USGS, 2009). About 90% of the city was destroyed as a result of the subsequent fires, many of them caused by ruptured gas mains.

In the Russian Far-East, tsunamis have a recurrence interval of 50–100 years (Vorobyev et al., 2006). The most destructive tsunami on record in this area took place on November 1952. This tsunami was generated by a M_w 8.5 earthquake in the Pacific Ocean. The city of Severo-Kurilsk was almost totally destroyed by three waves; the second was up to 20 m high; the cold water killed people who were swept into the sea. The death toll was estimated between 5,000 and 14,000, although the exact information was kept secret by the authorities at that time. The remaining survivors were evacuated to the interior; later Severo-Kurilsk was rebuilt in a more elevated location. After this event a tsunami warning system was established in the USSR (Piyp, 2005; Vorobyev et al., 2006).



Two other highly destructive earthquakes, the Tangshan earthquake of AD 1976 (China) and the Haiti earthquake of AD 2010, are among those having caused the highest numbers of victims. Both occurred in highly populated and poor areas (see *Tangshan, China (1976 Earthquake)*). Several catalogs of historical earthquakes have been prepared by historians, especially for the Mediterranean Region (Guidoboni and Ebel, 2009).

Landslides

Mass movements (see *Landslide*) affect people and their environment, sometimes leading to secondary disasters, such as the bursting of temporary lakes dammed by the landslide (Schuster and Highland, 2007). Heavily populated mountainous regions in particular suffer from landslides including extremely destructive events, such as the earthquake-generated landslide in AD 1556 in China, described above (Hou et al., 1998).

In the Alps, a number of landslide events were recorded in various chronicles. A historically well-documented landslide occurred on September 4, 1618 in the Chiavenna Valley, Northern Italy. About 2,420 people from villages, especially Piuro, were killed in the landslide and subsequent flooding (Guzzetti, 2000) (Figure 9). The business activity of the area, which was thriving at an international level, was totally lost and many of the surviving rich local families had to emigrate elsewhere in Europe.

The Elm landslide in Switzerland occurred on September 11, 1881, likely as a consequence of open

Historical Events, Figure 9 The Piuro landslide (N. Italy) that buried the ancient village below several debris flows (Photo: S. Leroy 2005). The *red line* shows the extent of the landslide.

slate mining undercutting a large bedding plane on the side of Plettenbergkopf Mountain. The landslide lasted 40 s and traveled about 2 km. The total volume is estimated to have been about 0.01 km^3. Some 115 fatalities were recorded and 800,000 m^2 of the village of Elm were covered with rubble reaching 3–6 m (Heim, 1882; Warburton, 2007).

Probably the greatest number of deaths from a series of landslides in recorded history occurred in Gansu (Kansu), China, on December 16, 1920. The landslides, triggered by a M_w 7.8 earthquake, occurred over an area of about 48,000 km^2, moving into valleys and covering villages, fields, and roads. An estimated 180,000 people were killed from the earthquake, landslide, and cold weather. Thousands of people living in caves carved in the high loess cliffs were buried by landslides.

A large mountain landslide disaster occurred in the Peruvian Andes following an offshore M_w 7.7 earthquake on May 31, 1970. A debris and snow avalanche slid from the summit of the Huascarán Mountain (6,654 m). By the time it reached the river, it had changed into a mudflow of over 1 km width (see *Mudflow*). Eyewitnesses describe the flow as a huge wave 80 m high (Whittow, 1980). The flow buried settlements in its path up to 10 m deep, leaving 18,000 people dead or missing (Warburton, 2007).

One of the largest landslides, or rock avalanches (see *Rock Avalanche (Sturzstrom)*), was the Saidmarreh (or Seymareh) landslide in southwest Iran, which occurred at 10,370 ± 120 ^{14}C years BP (Shoaei and Ghayoumian, 1998; Schuster and Highland, 2004). It is highly likely that this landslide was earthquake triggered. A mass of debris collapsed from a height of about 1,600 m. The landslide had an exceptionally high volume, of about 20 km^3, a depth of 300 m, a travel distance of 14 km, and a width of 5 km. It blocked two rivers, forming lakes, now drained away, and at present the lake sediment provides fertile farmland (Shoaei and Ghayoumian, 1998).

The USGS has created a list of the twentieth-century landslides that occurred in the western hemisphere on http://pubs.usgs.gov/of/2001/ofr-01-0276/.

Hazards linked to water and weather

This section includes extreme water-related and weather events which had an influence on a large area, including floods, droughts, and cyclones (see *Hydrometeorological Hazards*).

Floods

Rivers may become a serious hazard by threatening human life or property with inundation and sediment erosion or deposition (Davies, 1991) (see *Flood Hazard and Disaster*; *Paleoflood Hydrology*). China has suffered numerous floods in its history. In AD 1887, the Huang He River (Yellow River) flood damaged thousands of settlements with a combined population of seven million, of which at least one million perished (Gunn, 2007). The Yangtze (Chang Jiang), the Huang He, and the Huai rivers in AD 1931 affected more than 40 million people, with at least one million fatalities (Mingteh, 2003). This flood was preceded by a prolonged drought in China from 1928 to 1930 (Mingteh, 2003). The Yellow River is commonly called "River of Sorrow," or "China's sorrow." These Chinese floods are arguably thought to be the deadliest natural disasters ever recorded.

The Netherlands also suffered serious floods, including in AD 1953 when the North Sea flood caused one of the

worst natural disaster in northern Europe over the past two centuries. A storm surge (see *Surge*), in combination with a high tide, struck the southwest coast of the Netherlands overwhelming flood defenses. The water level locally exceeded 5.6 m above mean sea level. The damage was significant and more than 1,800 people lost their lives (Glaser and Stangl, 2003). In order to prevent future catastrophes, the coastline was protected by the construction of larger dams along the North Sea coast, one of the most massive water defense systems in the world. The event also had serious effects in eastern England (over 300 deaths) and ultimately led to building the Thames barrier in 1984.

A catastrophic flood on the Lena River at Lensk City, eastern Siberia, in May 2001 was caused by an ice jam. Lensk and adjacent villages were submerged by cold water containing large blocks of floating ice. Some 30,800 people were affected, with six fatalities; several villages and more than 3,000 houses were completely destroyed (Buzin et al., 2007). Lensk is currently being reconstructed on a more elevated site.

Glacial Lake Outburst Floods (GLOFs) occur when lakes, which have developed behind unstable ice-cored moraines, burst catastrophically because the terminal moraine dam fails. Flood triggers are ice avalanche in the lake, or breach of the dam. Within the last century, GLOFs have been recorded in Oregon, Austria, Nepal, Peru, and Argentina (Clague and Evans, 2000). Fear of glacial lake outbursts is mounting in the Himalayas for glaciers showing signs of retreat. Iturrizaga (2005) analyzed the risk in a valley of the eastern Karakoram based on recent changes and past outbursts. In the last 150 years, on average every 5 years, glacier lake floods occurred in the upper Shimshal Valley (Pakistan) with impacts sometimes as far as 150 km downstream. Traces of older and larger floods can be observed.

A jökulhlaup is a specific type of GLOF, associated with subglacial lakes (see *Jökulhlaups*). Its trigger may be, for example, subglacial volcanic activity, such as in Iceland. A large jökulhlaup occurred from the Vatnajökull glacier in Iceland, due to an eruption of the Grímsvötn volcano (Björnsson, 2002). As most of the volcano lies underneath Vatnajökull, most of its eruptions have been subglacial. Eruptions may melt enough ice to fill the Grímsvötn caldera with water, and the pressure may become sufficient to suddenly lift the glacier, allowing water to escape as an outburst flood. As a result, the Grímsvötn caldera is carefully monitored. When a large eruption occurred in AD 1996, geologists knew well in advance that a GLOF was imminent. It did not occur until several weeks after the eruption finished, but the monitoring allowed the Icelandic ring road to be closed when the burst occurred. The total volume of water released from the glacier was estimated at 3.5 km^3 (Magilligan et al., 2002). A section of road across the Skeidara plain was washed away in the ensuing flood, but no one was hurt. The Grímsvötn volcano erupted in AD 1783, that is, at the same time as the Laki volcano, and continued to erupt until AD 1785; it is likely that a jökulhlaup occurred during this time.

Drought

The archaeological record contains numerous instances of civilization collapse due to periods of drought (see *Drought*) exceeding societal resilience (Fagan, 2000; Diamond, 2005; Leroy, 2012, in press): for example, the Harappan and the Akkadian civilizations 2,200 years BC, the Moche in AD 600, the classical Maya

Historical Events, Figure 10 Medieval Jeffrey pine stumps (AD 1112 and 1350) in the West Walker River Canyon (Sierra Nevada). They grew in the valley during the droughts that contributed to the collapse of the Puebloan Indian civilization. Now the valley is a treeless place because of sudden floods (Photo: S. Leroy 2003).

period in AD 900, and the various groups of Pueblo Indians between the twelfth and the fifteenth century AD (Figure 10).

The deadliest drought in recorded history was in Northern China, called the Garden of China, between AD 1876 and 1879. Rivers were completely dry; so most crops and livestock died. Food production could not take place in a 1 million km^2 area of nine provinces, roughly equal to the size of France. The drought caused the death of an estimated nine million people in China. During these years, India also suffered a loss of eight million people, with simultaneous droughts in north Africa and Brazil, indicating a quasi-global impact. Such a large-scale phenomenon is explained by a strong El-Niño event, upwelling along the coast of Peru, with worldwide teleconnections (Aceituno et al., 2009) (see *El Niño/ Southern Oscillation*).

Several other important droughts hit China with several tens of millions of victims until as recently as AD 1959–1961. This last drought, which occurred in a non-El-Niño year, was kept secret for several decades by the communist government.

The Dust Bowl (see *Dust Bowl*) in the American Midwest in the 1930s and the Sahel drought in the 1970s and 1980s are the results of a lack of rain combined with, respectively, farming malpractice and overgrazing (Fagan, 2000).

Other meteorological events

In November 1970, the most severe cyclone in the century, with respect to storm surge height, inundation, and loss of life occurred in Bangladesh, then East Pakistan. The Bhola cyclone, a category 3 hurricane, produced a surge height of up to 10 m, which hit the coast at high spring tide, causing inundation of nearly every low-lying coastal area. The loss of life was estimated to be 500,000 (Madsen and Jakobsen, 2004). The northern Bay of Bengal has been hit by many cyclones of similar magnitudes over the years. The main factors leading to disaster are the low-lying continental shelf of the Ganges delta, the large tidal ranges, a funneling coastal configuration, frequent storms, and the densely populated coastline (Frank and Husain, 1971). The cyclone that hit the City of Coringa in the Indian section of the Bay of Bengal, in AD 1839, caused the deaths of 300,000 people. The 12 m-high storm surge caused such destruction that the harbor city, which was well known for ship building and repairing at an international level, was never completely rebuilt.

One of the well-investigated damaging cyclones was Cyclone Bola, which hit the northwest of the North Island of New Zealand in 1998. It was the largest storm event that had occurred since European settlement in the 1830s. Between March 6 and 9, 917 mm of rain fell; three people were killed due to flooding, and hundreds were evacuated when a swollen river threatened a town. Heavy rain caused massive landslides and erosion along the valley systems causing severe damage to the economy of the Gisborne Region (Page et al., 1999).

Global climatic events

The focus is here on large-scale climatic changes (see *Climate Change*), as well as relatively rapid events. Two such events concurrent with widespread cultural declines have been recorded in both palaeoecological and archaeological records at 2,200 years BC (Weiss and Bradley, 2001; Leroy, 2012, in press) and at 850 years BC (Coombes and Barber, 2005).

The latter case, which is part of the time period we examine here, corresponds to the 850 years BC shifts in settlement patterns in Western Europe (van Geel et al. 1996). It has been assigned to a change to cooler and wetter conditions at the Sub-boreal/Sub-Atlantic transition or Late Bronze Age-early Iron Age transition in Europe. A synchronous change has been found in South America (van Geel et al., 2000). This global climatic change has been attributed to altered production of ^{14}C in the atmosphere. Chambers et al., (2007) have underlined that global climatic changes at that time could be detrimental to ancient societies, for example, in the abandonment of some low-lying areas in Netherlands due to a considerable rise in ground water level (van Geel et al., 1996). At the same time, climatic changes could be beneficial to others, for example, the acceleration of the cultural development and the increase in the nomadic population of the Scythians in south-central Siberia (van Geel et al., 2004).

Rare events

This section deals with rarer events such as karst dissolution impact, bolides, limnic eruptions, lake bursts, and wildfires.

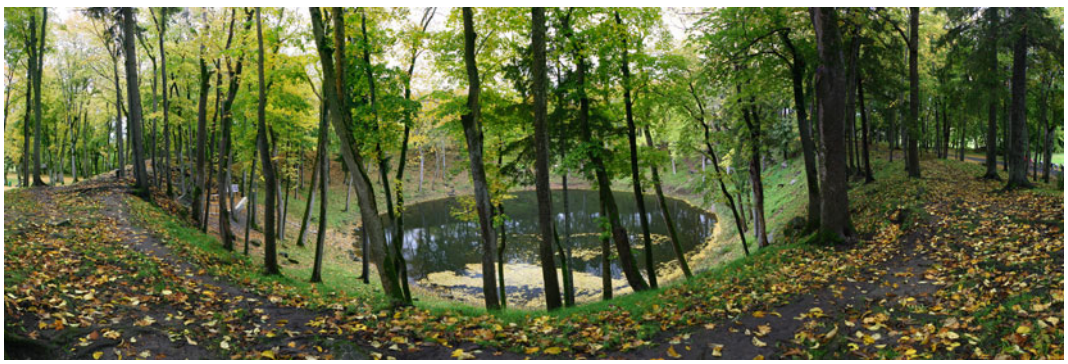
Sinkholes

Sinkholes of various origins (see *Sinkhole, Karst Hazards*) are a phenomenon occurring commonly at a local scale only. Sinkholes cause significant damages in karst areas where limestone bedrock dissolves. Sinkholes are often unexpected natural events because of their sudden and rapid occurrence in the absence of any visible external forces. Features such as sinkholes can be attributed to various myths and legends, for example, the Legend of the Invisible City of Kitezh in Russia. According to this legend, the city of Kitezh when attacked by the Mongols in AD 1237 was submerged in the waters of a bottomless lake, which suddenly appeared (Likhachev et al., 1997). It is supposed that it is Svetloyar Lake, in the Upper Volga region not far from the city of Nizhny Novgorod, where the event occurred. The origin of the lake is debatable, but carbonate and sulfate karsts are widely distributed in the area and deep lakes of karst origin are common (Bayanov, 2007).

Large sinkholes in the area of the Dead Sea, probably caused by the dissolution of underlying salt layers, pose a permanent hazard to people and the environment. Sinkholes started appearing in the Dead Sea region in the early 1980s, and the danger may only become worse

as the water level of the Dead Sea continues to fall at its current rate of 1 m per year (Abelson et al., 2006). Karst in limestone was responsible for a flash flood in AD 1988 in Nîmes (France) when the homes of 45,000 people were damaged, and 9 deaths were reported (Maréchal et al., 2008). Thousands of sinkholes are known to have formed recently in the USA. Perhaps one of the most spectacular impacts of dissolving limestone was the "Golly Hole" collapse whose surface expression appeared in a matter of hours on December 2, 1972 in Calera, Alabama, USA. It remains among the largest sinkholes in the USA with the size of a football field: 130 × 100 m in area and 50 m deep (Lamoreaux and Newton, 1986). Much of the county where Calera is located is affected by sinkhole formation, which has increased in relation to droughts and human activities, including mining and groundwater withdrawal.

Karst sinkholes associated to gypsum layers have developed extensively in Lithuania since AD 1978, damaging crop areas and communications. It is supposed that this phenomenon is correlated with climate change, which impacted local hydrological and hydrogeological regimes (Satkunas et al., 2007).



Bolides and near-earth objects

Relatively few impact craters have been discovered dating to the most recent millennia, reflecting perhaps an underestimation of their true frequency (see *Asteroid Impact, Comet*). Among them are the Wabar craters in Saudi Arabia dated at c. 290 years ago (Prescott et al., 2004), the Kaali craters in Estonia at 3,305 ± 65 ^{14}C years ago (or 1690–1510 BC) (Veski et al., 2004) (Figure 11), and the Rio Cuarto impacts at 2,300 ± 1,600 ^{14}C years ago (Schultz et al., 2004) and the Campo del Cielo craters at 3,945 ± 84 ^{14}C years ago, both in Argentina (Cassidy and Renard, 1996).

None are known to have caused a major impact on civilization. The pollen diagram from Piila peat bog, 6 km away from the Kaali impact crater, however shows a reduction of cereal pollen grains, reflecting the cessation of human activities in the region for perhaps 100 years and a dramatic drop in the concentration of arboreal taxa, reflecting the destruction of the woodland in the region (Veski et al., 2004). The mysterious dry fog of AD 536 reconstructed from various proxies, including tree-rings from both the northern and southern hemispheres, at times attributed to a possible cometary impact, at other times to a possible volcanic eruption, has been linked to several civilization downturns quasi worldwide (Baillie, 1999, 2008).

One of the largest meteorites in recorded history is the Sikhote-Alin iron meteorite, which fell in AD 1947 in the forests of the Sikhote-Alin Mountains, Far East, Russia (see *Meteorite*). The bright flash and the sound of the fall were observed by eyewitnesses for 300 km around the point of impact; a long smoke trail remained in the sky for several hours. This meteorite broke up in the atmosphere and fell as a meteoritic shower spreading fragments over an area of 48 km^2 and forming a number of craters. The initial size of the meteorite has been estimated at 900,000 kg, and the post-atmospheric mass is estimated between 70,000 and 100,000 kg (Krinov, 1966).

An object struck the sparsely populated taiga of the Podkamennaya Tunguska River basin, not far from the Siberian settlement of Vanavara, Russia on June 30, 1908. It is generally accepted that the event resulted from the catastrophic explosion of a large meteorite high above the ground. A brilliant, sun-like fireball was seen hundreds of kilometers away. A powerful explosion devastated more than 2,150 km^2 of taiga, flattening by blast several tens of millions of trees (Figure 12). At distances around 60 km, people were thrown to the ground or even knocked unconscious. The first study of the Tunguska event began with the scientist, Leonid Kulik, who carefully documented eye witnesses' descriptions in AD 1921. In AD 1927, investigating damaged taiga, he discovered that fallen trees within a huge area lay with their tops radially pointing outward from the center; in the center of this forest there were standing trunks charred and stripped of their branches; in the very center, he described a peat marsh blasted and tortured into a wavy landscape. At present

Historical Events, Figure 11 The main crater (58° 22′ 22″ N, 22° 40′ 08″ E) of the Kaali meteorite crater field that has nine identified craters located on the Island of Saaremaa, Estonia (Photo: S. Veski 2008).

Historical Events, Figure 12 Roots of trees that were pulled from the ground by the blast of the Tunguska event in AD 1908, 5 km northeast from the explosion epicenter. These trees are the only remaining witnesses of the blast. These roots can still be found 100 years after Tunguska event (Photo: V. Bidyukova, on 2 July 2008).

the "Kulik's path" has become a popular route for scientists from around the world. The Tunguska event has been reconstructed in detail (Rubtsov, 2009). This Siberian phenomenon nevertheless continues to generate scientific discussions and a number of hypotheses, including methane explosion (Kundt, 2001) or a geophysical, non-extraterrestrial origin (Ol'khovatov 2003).

Limnic eruptions and lake bursts

In Africa, a series of lakes are known to accumulate CO_2 in their lower water strata. Some of them, such as Lakes Nyos and Monoun (Cameroon), erupted in the mid-1980s and caused thousands of deaths due to carbonic acid burn and poisoning. Other volcanic lakes worldwide have dissolved CO_2 although at lower levels; but historically their water level has been known to fluctuate considerably, and at times even overflow. Lake Albano, which is the deepest (167 m) crater lake in Italy, shows frequent seismic activity and gas emissions (Anzidei et al., 2008). Historical and archaeological data were recently reassessed due to the extension of urbanization in this area close to Rome; they indicate rapid lake level changes and overflows (Funiciello et al., 2003). This reached such a dangerous situation that in 396 year BC Romans decided to dig a tunnel through the wall of the maar in order to maintain the lake at a low level.

Wildfires

Global fires and even continent-wide fires are not documented to have occurred in the recent millennia (see *Forest and Range Fires, Wildfire*). One of the largest wildfires in the US history is that of AD 1871 in the logging community of Peshtigo, Wisconsin, when a massive forest fire destroyed much of the state: nine towns and more than 1,500 people perished (Brown, 2004). This was caused by drought, high temperatures, unusual weather conditions, and by the lumbering practices of the time that left a quarter of the felled trees in the forest and large piles of sawdust near the mills.

Fires may also occur as secondary effects of other natural disasters such as in Lisbon in AD 1755, San Francisco in AD 1906, and Tokyo in AD 1923 following earthquakes.

Some periods are more favorable than others for fires. Biomass burning has broadly increased in the Northern and Southern hemispheres throughout the second half of the Holocene associated with changes in human practices and climate (Carcaillet et al., 2002). Climate, indeed, is a powerful driver of wildfire frequency. This has been especially well demonstrated in western North America (Fauria and Johnson, 2008). Moreover, the fire frequency changes in the boreal forests during the Holocene have been triggered by climate rather than by vegetation types, as demonstrated in eastern Canada (Carcaillet et al., 2001). Climatic factors, such as ENSO and insolation, have played a key role in Amazonia (Bush et al., 2008). Changes in the ENSO and the Pacific Decadal Oscillation (PDO) system affected fire frequencies all across the boreal forest of North America (Fauria and Johnson, 2008).

In summer 2010, with a major drought and prolonged high temperatures, forest and peatland fires occurred in vast areas of Russia. About 15 million hectares of forests were damaged and more than 7,000 people lost their

homes. The net effect of extreme temperature, smoke, and fires resulted in 55,800 deaths. For almost 2 months, smoke affected Moscow and its densely populated surrounding districts resulting in perhaps the most significant exposure to smoke of a major population center in recorded history. These fires as well as fires in 1972 and 2002 in Central Russia can be considered as mega-fire events with long-term consequences for atmosphere and vegetation (Chubarova et al. 2008). Data on the world fires can be found on http://www.fire.uni-freiburg.de and http://www.emdat.be.

Discussion

Why are historical events relevant to our present and future?

Many natural hazards are comprised of a series of events that are of short duration, with a long recurrence interval. Therefore, in order to have a relatively full view of the potential range of hazards in a region, a first step toward mitigation, it is essential to look back into the past using geological and historical records.

In AD 1989, as a result of the study of historical earthquakes, geodynamic and geological evidence, including radiocarbon dating of buried soils, the maximal expected earthquake intensity in the Crimean Peninsula was reestimated and raised from M_w 6.0 to 9.0. This study resulted in the cancellation of the construction plans of a Nuclear Power Plant in East Crimea (Nikonov, 2000).

The study of past wildfires is becoming increasingly relevant for our near future, as fires generate greenhouse gases (van der Werf et al., 2008), and global warming is suspected to cause droughts in some regions, which would in turn be favorable to fire increase (Torn and Fried, 1992).

Limnic eruptions are rare natural hazards, but they are interesting analogs to what could happen to geological sinks used for carbon storage, which are being put in place in order to counteract the release of CO_2 from anthropogenic activities.

Factors leading to significant influences on human environment and human society

Four factors need to combine in order to transform a natural hazard into a disaster, or even a catastrophe: time, space, type of society, and accumulation of events (Leroy, 2006; Leroy, 2012, in press) (see *Disasters*).

1. Time: An absence of warning and a spread of the hazards over several weeks or months enhance the disaster: for example, earthquakes commonly have a series of aftershocks.
2. Space: The larger the area affected, the worse the impact. Global or hemispheric events are however relatively rare. Some of them stand out, that is, global climatic changes at 2,200 and 850 years BC, tropical volcanic eruptions with an impact in the stratosphere (e.g., Tambora in AD 1815), and the ENSI event of AD 1876–79.
3. Type of society: The nature of society plays an essential role in the preparedness and response to disasters. Typically, planning is left in the hands of politicians who have short-term goals and therefore hesitate in engaging public money for long-term mitigation. Two radically different sociopolitical approaches have been recognized as efficient: either a centralized country such as the Soviet Union or the Kingdom of Portugal of AD 1755 with top-down actions to impose their authority, or bottom-up action when citizens are able to put pressure on local governments, such as in The Netherlands after the flood of AD 1953.
4. Accumulation of events: The combined effects and successive hazards can be found in the examples we have just used, such as earthquakes combined with landslides in AD 1920 in China, or subglacial eruptions with a jökulhlaup in Iceland. An analysis of historical volcanic eruptions after great earthquakes in Chile showed more volcanic eruptions than normally expected in the 12 months following the earthquakes. This was especially true for the two large earthquakes in AD 1906 and AD 1960 (Watt et al., 2009).

Are there any catastrophes in the twentieth century?

At historical and geological timescales, the twentieth century has not been subjected to many extreme events. The largest GLOFs were during the melting of the Late Pleistocene icecap and one of the largest landslides was 10,000 years ago in Iran. Few natural hazards have reached more than one million deaths in the twentieth century. The largest mega-hazards were mostly floods, for example, the China floods of AD 1931, where several million victims were counted, as these floods took place in a very densely populated region. On the scale of the number of deaths, the next largest twentieth-century hazards were cyclones and earthquakes (Wikipedia, 2010).

How different is the twentieth century from the past?

More understanding of the mechanisms behind natural hazards and more monitoring should bring us to a situation where we are better protected. However the impact of natural hazards increased dramatically during the twentieth century as shown by the trends in the frequency of natural disasters and in insured catastrophe losses (ICSU, 2005; SwissRe, 2009). Two main reasons explain this. First, more people are put at risk as the world population has increased exponentially. More people live in cities where damaged buildings may become a source of hazards. More people have been forced to settle in more marginal and risky areas. The second reason is that our modern societies increasingly depend on technology in order to function normally (Leroy, 2012, in press). Natural hazards can easily damage the infrastructure we so heavily depend on, such as

telecommunication, electricity, and transport networks. This dependency on technology may have the opposite effect than expected: it may actually make us more vulnerable.

An illustration of this in the twenty-first century is that the most recent hurricanes/cyclones have become the most expensive ones: for example, the costliest hurricane so far is Hurricane Katrina in AD 2005 (see *Hurricane Katrina*).

Historical changes and their impact: Not only negative

Despite the damage to the environment and society, many natural disasters have had long-term positive sociopolitical effects. It is clear that rapid landscape changes initiate chaos, from which, in the best cases, innovation may emerge. This surprising beneficial outcome has been recognized for many civilizations in the Holocene (Brooks, 2006). The AD 1970 Bhola cyclone in East Pakistan had a positive sociopolitical outcome, in that it led in the following year to the creation of a new country, Bangladesh. The Scythians were able to derive benefits from the 850 years BC global climatic change: they expanded the area dominated by their culture and their nomadic population density increased as more semidesert was turned into steppe (van Geel et al., 2004).

Positive scientific consequences of some twentieth- and twenty-first-century events

Extreme natural events may become a trigger for deepening of the scientific understanding of nature and may be an impetus for new ideas and technology.

A warning system for tsunami has been put in place in the Indian Ocean following the large-scale disaster caused by the earthquake and tsunami of December 2004 (see *Indian Ocean Tsunami, 2004*, *Warning Systems*). The system linking about 20 countries became active in late June 2006.

The AD 1948 Ashgabat earthquake comfortably sits in the list of the most unforgiving earthquakes in history. On the night of the October 5–6, in a matter of seconds, Ashgabat city, USSR (now Turkmenistan), with a population of 130,000, was completely devastated by a M_w 7.3 earthquake. An estimated 110,000 people perished under the ruins, and others became homeless (Nikonov, 1998). The Tashkent earthquake on April 26, 1966, USSR (now Uzbekistan) with a M_w 5.2 did not cause many human losses, but 36,000 buildings disappeared, and about 300,000 people lost their homes (Ulomov, 1971). Both towns were quickly rebuilt, taking into account the regional seismicity. These events were significant in the history of the USSR because thousands of specialists and workers from all over the USSR participated in providing aid to earthquake victims and cities' recovery.

The AD 1991 Randa rockslide, which occurred on April 18, in the tourist valley in southern Valais, Switzerland, caused disruption and devastation to the valley infrastructure and loss of livestock; 31 chalets were buried in the debris (Quanterra, 2003). On May 9, a series of slides over a period of 7 h caused a dam across the Vispa River, just below the village of Randa, resulting in 30 houses being flooded. Dust was deposited to a depth of 10–40 cm in a 1 km radius and some local housing was buried in debris up to 60 m deep (Gotz and Zimmermann 1993). The first event in April had prompted the authorities to install a seismographic and geodetic warning system. As a result, the May event was forecasted and the area was successfully evacuated (Warburton, 2007).

Finally, our society cannot stop natural hazards from happening but learning from the past may reduce the resulting disaster.

Summary

Historical natural hazards contain a wealth of information worth studying when dealing with the improvement of present mitigation plans. The instrumental record of many natural hazards is very short and it is only by looking at historical and geological events that the full range of natural forces can be estimated. Moreover, lessons may be derived from the way our ancestors have reacted to past events; we could learn from the best cases and avoid repeating the worst.

Definition

Hospital emergency management. A combination of actions, programs, processes, and capabilities that allows a hospital organization and its constituent departments to prepare for, respond to, and recover from major emergencies and disasters while maintaining critical functions.

Introduction

Hospitals are an essential community resource on a daily basis and even more so during and after a disaster (e.g., Ardagh et al., 2012). A hospital that cannot withstand the effects of a disaster not only cannot provide its critical services at the time of greatest need, it adds to the burden of the disaster (e.g., Kirsch et al., 2010): its skilled staff and vulnerable patients and visitors are likely to become victims as well. As succinctly stated by the Hospitals Safe from Disasters program (WHO and ISDR, 2008), "A safe hospital: will not collapse in disasters, killing patients and staff; can continue to function and provide its services as a critical community facility when it is most needed; and is organized, with contingency plans in place and health workforce trained to keep the network operational." This is the most basic expression of expectations of hospitals in disaster.

Standards and critical elements

There are numerous hospital preparedness standards, ranging from consensus to regulatory (e.g., Sauer et al., 2009); the latter tend to be national, the former of broader scope. Most pertain to hospitals in industrialized societies, particularly the United States. ASTM International (2009) has developed intentionally broad standards for hospital preparedness and response. The National Fire Protection Association's Standard 101 (2012), the Life Safety Code, addresses a variety of occupancies; Standard 99 (2012) covers health care facilities. The Joint Commission (2012) has long enumerated emergency preparedness standards for hospitals seeking accreditation; these standards have evolved from "disaster plans" to full-fledged emergency management programs. In terms of depth and breadth, these standards are broadly applicable, even if accreditation is not an issue. Current standards drive toward establishing preparedness as a sustainable organizational component: developing and maintaining a hazard vulnerability analysis (HVA) and an emergency operations plan (EOP). Once in place, sustainability is achieved by ongoing evaluation and update, including equipment procurement, development of procedures and training, testing through exercise and actual event, and appropriate revision (e.g., Cosgrove et al., 2008; Rubin, 2006). These criteria form the essence of effective emergency management programs in multiple disciplines and their achievement makes any organization, including a hospital, more likely to maintain function in disaster.

Hazard vulnerability analysis (HVA)

An HVA allows a hospital to prioritize preparedness and mitigation activities, including training and exercises (e.g., McLaughlin, 2001; Joint Commission, 2001; Briggs and Brinsfield, 2003; Jenkins et al., 2009). It comprises identifying hazards relevant to the area in question and

their potential impact on a hospital's ability to provide services: Ideally it combines event history, probability, and severity, so that a hospital can differentiate between likelihood and severity. As most hospitals are not stand-alone facilities, but dependent on community services, utilities, and the ability of their employees to arrive for work, a hospital HVA should consider impacts on external (community) as well as internal stakeholders. Kaiser Permanente has developed the most widely used HVA tool for hospitals (CHA, 2010); the World Health Organization's guide (2006) is applicable across a broader range of development and infrastructure status.

Emergency operations plan (EOP)

Whether called a disaster plan, emergency management plan, or emergency operations plan (EOP), the concept applies to all users. An effective EOP is not a "cookbook" or a set of instructions, but it is an important tool in all phases of disaster impact. In its essence, an EOP does the following: identifies roles, responsibilities, and authorities among the hospital staff and community partners before, during, and after an emergency; indicates incident management structures for emergency operations (e.g., Hospital Incident Command System (California EMSA, 2006) or something similar) and identifies how those structures integrate with community and larger-scale structures (e.g., Barbera and Macintyre, 2002); establishes protocols and capabilities for notifying and communicating with staff, patients, families, external agencies, media, and other stakeholders; establishes non-routine response procedures and their activation thresholds for addressing specific concerns (e.g., evacuation, safety and security, staffing, utilities, curtailing services); identifies capabilities and procedures for maintaining critical services for at least 96 h in the absence of external support (e.g., Wagner et al., 2008; CDC and AWWA, 2011), including resource management procedures for requesting, assigning, tracking, and replenishing medical and nonmedical supplies; establishes protocols for expanding staff with volunteer health care providers; and addresses post-disaster recovery and restoration. Emergency operation plans can take multiple forms, with numerous models, content guides, and checklists available (e.g., Belmont et al., 2004; GNYHA, 2006; WHO, 2006; Joint Commission, 2008; WHO and ISDR, 2010), particularly for areas of special concern or capability, but the form is less important than the quality of the underlying assumptions (e.g., Auf der Heide, 2006; Barbera et al., 2009), HVA, internal adoption, and integration with local and higher-level planning.

Surge

A major component of hospital disaster preparedness is identifying and addressing medical surge capacity and capability. Medical surge "describes the ability to provide adequate medical evaluation and care during events that exceed the limits of the normal medical infrastructure of an affected community" (CNA, 2004, 1–5). Medical surge capacity describes the ability to handle increased patient volume; surge capability describes the ability to provide unusual or specialty care (e.g., pediatric patients (Boyer et al., 2009; Kissoon et al., 2011)) or other specialized services (CNA, 2004). The concept of medical surge recognizes that disasters may compromise a hospital's ability to provide critical services not only by impact to facility and staff, but by extraordinary patient needs. Whether due to catastrophic physical impact (e.g., hurricane or earthquake) or mass illness (e.g., pandemic), medical surge needs must be assessed and incorporated into the emergency management process, identifying baseline capacity and capabilities (e.g., Rubinson et al., 2010), available (and nontraditional) resources, and an ethical process of scarce resource allocation (e.g., Christian et al., 2008; Devereaux et al., 2008a, b; Rubinson et al., 2008a, b; Hick et al., 2009; IOM, 2010).

Challenges

The most common barrier to hospital preparedness is one of economics (e.g., Barbera et al., 2009), as preparing for a future event competes with daily needs, but in many industrialized countries, such barriers may relate as much to executive prioritization as they do to actual lack of resources. The fact that most communities have not endured a catastrophe means that motivation must be driven by something other than direct experience. Inaccurate perception of risk, whether related to hazards, their physical impact, or their economic and legal impact, can lead to unrealistic planning assumptions, and in turn to insufficient preparedness (e.g., Barbera et al., 2009). Lack of sufficient resource allocation is commonly manifested in inadequate emergency equipment (particularly backup communications systems), insufficient training, and drills and exercises that are too short, too small in scope, or too optimistic (e.g., Rubin, 2006). Since the beginning of the millennium, substantial progress has been made in awareness and tangible improvements, particularly in the industrialized world, but the very scope of major disasters means that few if any regions are truly prepared for a catastrophe.

Conclusion

Hospitals are generally acknowledged as among the most critical resources for sustaining a population on a daily basis, let alone in a disaster. Although the past several years have seen greater awareness, more encompassing standards, and greater access to preparedness guidance and resources (e.g., AHRQ, 2011; CHA, 2010; ASPR, 2012a, b), preparedness is rarely considered a daily priority, resulting in chaotic disaster response and resultant increased morbidity and mortality. Even where awareness is sufficient and preparedness considered a high priority, progress is variable in industrial nations and many facilities in developing countries (and the societies in which they function) have scant resources for daily operations.

The WHO/ISDR (2008) recognition of the importance of safe hospitals is a necessary step but far from a sufficient one. Preparedness is far more a journey than a destination, and "true" preparedness more of a goal than a realistic target, but there is still ample room to expand on the progress made to date.

Definition

The human impact of hazards is the product of the interaction between hazard characteristics and the personal, community and societal factors implemented to influence people's capacity to cope, adapt, and recover from hazard effects.

Introduction

Throughout human history, people have established and developed communities and societies in locations that allowed them to take advantage of the resources and amenities (e.g., fertile soils, natural harbors, navigable rivers that serve as commercial highways, and coastal scenery) afforded by the action of natural and geological processes. However, periodically the processes that create such benefits (e.g., tectonic activity) become hazards (e.g., tectonic activity can create earthquakes, volcanic eruptions, and tsunami). For instance, the volcanic processes that contribute to creating fertile soils and scenic amenities can, during volcanic eruptions, expose those living within the surrounding area (which can have a radius of several hundred miles) to hazards such as ashfall. Similarly, the rivers that provide a resource for commerce, recreation, and tourism can channel heavy rainfall in ways that floods those living on their banks.

While natural hazards have the *potential* to create substantial loss and destruction, the nature, magnitude, and duration of hazard impacts is influenced by the choices people make regarding where and how societal development occurs (e.g., not building on flood plains), and what people do to enhance their capacity to cope with hazard impacts, adapt to their consequences, and recover from the loss and disruption experienced (Paton and Johnston, 2006; Tobin, 1999). To identify how hazards impact on human populations it is thus necessary to define the hazards that exist in a given area and the actions people and societies can take to influence the impact of hazards on people and communities.

Hazards

Most places are susceptible to experiencing multiple hazards. The term used to describe this is "hazard-scape." The hazard-scape describes not only the hazard (e.g., earthquake, wildfire) but also the characteristics and behavior of the hazards that can occur. For example, for volcanic events, hazard characteristics include ashfall (tephra), lava, ballistic material (e.g., rocks ejected by the explosive forces of the eruption), lahars, and gases. Seismic hazard characteristics include, for example, ground acceleration and liquefaction. Hazard behavior includes, for example, the return (how frequently an event occurs over time) period, speed of onset, intensity, and duration. The hazard-scape (the hazard, its characteristics and behavior) contributes to defining the risk hazards pose to the physical, social, and administrative infrastructure of human settlements (Lindell and Perry, 1992; Paton and Johnston, 2006).

For instance, hazard characteristics such as the ground shaking that accompanies an earthquake, volcanic ashfall, and tsunami inundation can cause damage to buildings, homes, roads, and other infrastructure. Hazard activity can thus injure or kill

people, leave them homeless, and limit their access to the resources normally required to sustain everyday life. Hazard impacts on infrastructure can have secondary consequences for human populations as a result of, for example, loss of utilities (e.g., water, power, and roads) and societal functions (e.g., welfare, local government, and financial services). The particular mix of hazard characteristics and behavior will differ from place to place, as will the communities they impact. These examples introduce the fact that the impact of a hazard is defined not by its hazard-scape per se, but by the consequences hazard activity has for people, the buildings that house them, the infrastructure that supports activities, and the societal functions that impose structure on everyday life. Drawing a distinction between hazard characteristics and the consequences of hazard activity is important.

How people respond to hazards

Although the causes of hazard events (e.g., earthquake) are beyond human control, people can influence the consequences (e.g., level of destruction, time to recover) that hazard events create. Thus, the impact of hazards on human populations is defined by the actions people undertake to influence the nature, severity, and duration of the consequences they experience (Lindell and Perry, 1992; Paton and Johnston, 2006). People can make choices about the consequences they may experience. If people decide not to make these choices, they increase their vulnerability to experiencing adverse impacts from hazard events. Vulnerability can also be affected by factors such as demographics (e.g., proportion of elderly people and ethnic minorities in affected populations) and socio-economic factors such as levels of poverty and quality of housing stock (Wisner et al., 2004). If people choose to, they can increase their ability to cope, adapt, and recover should a hazard event occur (Tobin, 1999). The choices that influence hazard impacts occur at several levels (person, community, societal, and environmental (natural and built)) and fall into two general categories.

The first concerns the actions that societies and their members undertake to mitigate the effects of hazards and increase their ability to cope with and adapt to hazard impacts. Since these activities are undertaken prior to hazard events occurring, they are called *preparation* or *readiness strategies*. The second relates to the procedures and resources put in place to facilitate community and societal recovery. These response and recovery strategies are undertaken during and after a period of hazard activity respectively.

The impact of hazard events is a function of the actions taken to safeguard the physical integrity of the built environment (e.g., *Land-Use Planning*, building codes, lifeline engineering, and retrofitting buildings). However, because of a public desire to use hazardous areas (e.g., adjacent to rivers or at the coast) and the relatively long return period of some damaging events, building codes, regulations and land use planning cannot provide effective mitigation for the entire risk. For hazard events that can be foreseen, an effective integrated warning system can address the residual risk (Sorensen, 2000).

Hazard impact is also influenced by the degree to which people and households prepare. Strategies must also encompass the social (including ensuring economic, business, and administrative continuity), cultural, and environmental contexts within which societal activities occur (Paton and Johnston, 2006). However, the complex nature of hazard activity makes it impossible to prepare for every eventuality. Since some level of physical and social impact is inevitable, strategies designed to facilitate physical and social recovery must be developed and be capable of implementation in a timely manner. Examples of preparation and recovery strategies are described in the next section.

Reducing the impact of hazards on infrastructure

Natural hazard activity affects specific geographical areas. As a consequence, one strategy for reducing the human impact of hazards utilizes land use planning to prevent or restrict development and population growth in areas susceptible to hazard impacts (Burby et al., 2000). While this approach can help mitigate future impacts (e.g., not developing in areas susceptible to hazard activity, ensuring post-disaster rebuilding occurs in less risky locations), it does not apply to all circumstances.

Hazard events are generally infrequent, with return periods often measured in decades or centuries. As a consequence, much economic, infrastructure, and social development has occurred in areas susceptible to experiencing hazard activity. In this context, strategies such as building design, retrofitting buildings, and strengthening essential lifelines (e.g., water, power, and roads) in ways that reduce the likelihood of their being damaged or destroyed are essential. If buildings and infrastructure remain intact and functioning, the impact of the hazard event on human populations is reduced.

While planning, regulatory, and legislative processes can facilitate the implementation of this element of a *Disaster Risk Management* strategy, the action taken to safeguard domestic housing stock and their inhabitants, requires that people take steps to reduce the impact that hazard events have on them. This level of understanding is also important from the perspective of understanding the psychological and social impacts that hazard events have on people and how they can be managed (Dass-Brailsford, 2010).

Reducing the impact of hazards on people

Hazard events expose people and communities to demands and consequences that fall outside the usual realm of human experience and increase the risk of significant loss, death, and destruction. As a result, experience of hazard activity can be accompanied by Acute Stress and, on occasion, Posttraumatic Stress Disorder (PTSD).

A comprehensive account of the psychological impact on people and its implications can be found in Norris et al. (2002a, b). People also face increased levels of stress from the temporary loss of societal functions and services. However, the impact is not the same for all people. Diversity in psychological impacts reflects demographic, psychological, and social factors.

From a demographic perspective, the psychological impacts of hazards are greater amongst children, elderly individuals, people who live alone, and those with a history of prior trauma, mental illness, and disability. Psychological impact is also a function of the distribution of event-related factors such as being injured, losing family members, loss of property and/or livelihood, and being displaced from home and losing normal support, networks, and resources. On the other side of the psychological impact coin, however, are the strengths (e.g., spiritual and cultural resources, active coping, collective efficacy, and sense of community) that enhance people's ability to cope and recover (Paton and Johnston, 2006). A critical influence on the impact of the hazard is the psychological support and recovery resources available to survivors (Dass-Brailsford, 2010).

Hazard events impact people by presenting them with demands that are atypical, challenging, and unavoidable, which creates significant change to their environment, and which overwhelms their usual coping and support resources. The demands people experience are strongly influenced by the physical impacts (e.g., ground shaking, liquefaction, wind damage, and flooding levels) that directly affect levels of damage to infrastructure and the number of casualties (Lindell et al., 2006). Not only do these physical impacts have implications for the nature of people's response to hazards, the associated loss of normal infrastructure increases the need for improvised disaster response and recovery intervention (Lindell et al., 2006). One way of doing this involves mobilizing the community response.

Effective intervention involves working *with* community members to help them regain equilibrium by recognizing and mobilizing existing strengths and capabilities in a way that facilitates their coping and adaptation (Dass-Brailsford, 2010). In the short term, the impact can be ameliorated by providing concrete help (e.g., safety, food/water, and shelter). In the medium term, intervention aims to, for example, increase peoples' understanding of the stress response, mobilizing or developing coping strategies to help them reduce their stress, and facilitating the development of social support relationships with other survivors and responders. While strategies such as these facilitate recovery in most people, some may experience more significant mental health problems. Mitigating the psychological impact of hazard experience for the latter requires the availability of mental health professionals to provide counseling and therapeutic services.

Another factor influencing the psychological impact of hazards is the degree to which people possess the resources required to respond (Hobfoll, 2001). Thus, encouraging people to develop their resources (e.g., knowledge, beliefs, coping strategies, capacity for self-reliance, household emergency plans and resources, and ability to work with others to confront local problems) will influence the nature and extent of the impact of hazards on human populations. The issue here is the generally low level of people's preparedness (Tierney et al., 2001).

Contrary to what might be expected, neither living in a high-risk area nor being informed, via public education or risk communication programs, of this risk influences people's levels of preparedness. However, public education programs that assist people to make sense of hazards and that demonstrates how and why preparing is effective in mitigating hazard consequences facilitates preparedness and, should a hazard event occur, reduce its impact on the individuals. Several models, such as the Person-Relative-to-Event-Model (Mulilis and Duval, 1995), the Protective Action Decision model (Lindell and Perry, 1992), and the Social Context model (Paton, 2008), were developed to guide the process of tailoring public education in ways that facilitate preparing. The Protective Action Decision model and the Social Context model highlight the role community processes play in facilitating both sustained hazard preparedness and the availability of support resources for recovery.

Reducing the impact of hazards on communities

Faced with uncertainty, people turn to others who share their interests and values to help them reduce uncertainty and decide how to manage their risk (Paton, 2008). Family and members of the communities (e.g., workplaces, social clubs, churches, etc.) with whom people interact regularly play a central role in helping people understand hazards and formulating and implementing their hazard management plans. The levels of collective preparedness that results from this collaboration can mitigate hazard impacts in the immediate aftermath of a disaster.

When hazard activity creates a disaster, the loss, destruction, and disruption overwhelms emergency response resources. This means that help and recovery efforts in the immediate aftermath of the hazard event come from neighbors and others within the proximal community. The level of, for example, informational and emotional social support that comes from membership of a cohesive social network of people helps reduce the psychological impact on community members. However, because it is impossible to prepare for all eventualities, communities benefit from intervention to help rebuild its support resources and networks.

The impact of a hazard event on a community is reduced and recovery facilitated by working with community members to help them regain access to and use their own resources (Dass-Brailsford, 2010). This reduces dependency on external resources, sustains community and cultural identity, and maintains social support. In so doing, it is important to accommodate community diversity (e.g., the coexistence of groups with different needs,

etc.) within an affected area. One important aspect of diversity is culture. Cultural beliefs and practices can influence the human impact of hazards in several ways.

For example, in the context of the possibility of using engineering solutions to divert lava flows from future volcanic eruptions in Hawaii, Gregg et al. (2008) found that native Hawaiians' belief that interfering with lava flows disrespects the wishes of Pele (the Goddess of volcanoes) reduced their willingness to support mitigation actions (building walls to divert lava flows, bombing lava flows) that were inconsistent with their cultural beliefs. Thus, certain cultural beliefs can increase people's vulnerability to experiencing loss should a hazard event occur. Cultural factors can also increase people's ability to cope with hazard impacts. For example, the Hakka Spirit, a cultural characteristic of the Hakka people in Taiwan, characterized by reciprocal support practices and collaborative problem solving evolved to limit the impact of typhoons and other natural hazards on people's livelihood (Paton and Jang, 2010).

Societal strategies for reducing hazard impacts

In most environments hazard events occur infrequently. This limits the opportunities people have to gain experience of hazard consequences or the effectiveness of mitigation measures for themselves. To identify what they may have to contend with and what they might do to manage their risk, people rely on information from expert scientific and emergency management sources through public education programs. Societal-level factors influence the impact of hazards in other ways.

Government plays a role by influencing the policies and resourcing that contributes to readiness and recovery efforts. They provide direction for planning, land use strategies and structural and engineering mitigation measures. Factors such as disaster business continuity planning play an important role in minimizing economic impacts of hazard impacts and ensure that continued availability of employment that makes an important contribution to recovery (Paton and Johnston, 2006).

Summary

The impact of hazards on people is a function of the interaction between the hazard and the characteristics of the people, communities, and society that lives in harm's way. From a social perspective, hazard impacts are influenced by several factors. Community members, businesses, and societal institutions that are prepared (e.g., household emergency plans and business continuity plans) in ways that enhance their safety and facilitate their continued functioning even when experiencing disruptive hazards consequences (e.g., ground shaking, volcanic ashfall, and flood inundation) will experience less severe impacts and will recover more quickly. Since people cannot prepare for all eventualities, the severity and duration of hazard impacts will be influenced by the availability of strategies that facilitate social and physical recovery and that accommodate the community diversity (e.g., demographics, ethnicity, and culture) that affects the distribution of hazard impacts within affected communities. Finally, strategies must accommodate the fact that the hazards that communities may face will change over time. For example, changes in land use patterns (e.g., land clearance, industrial development, and pressure for affordable housing) and factors such as climate change are changing the hazard-scape people will have to contend with. Understanding and managing the human impacts of hazards is thus a dynamic and iterative process.

HUMANITY AS AN AGENT OF NATURAL DISASTERS

Thomas Glade[1], Andreas Dix[2]
[1]University of Vienna, Vienna, Austria
[2]Otto-Friedrich-University Bamberg, Bamberg, Germany

Definition and introduction: humans and natural disasters

Humans have relied on the Earth's landscapes for thousands of years. Only in the last few centuries have people become more independent from the natural environment. With the advent of specialized tools and technology, they have become the primary contributors to change in the environment. For example, people applied fire for widespread forest clearance, they have developed unique methods to modify the soil for agricultural use, they routinely construct water reservoirs and divert rivers, they actively modify landscapes directly through excavation, and other land modifications or indirectly through groundwater extraction. Such advanced change and development in human capacity has led to an interesting phenomenon. On the one hand, people have become better and more efficient in their use of the environment, but on the other hand they have become much more reliant on the Earth as a whole. Within the vulnerability debate, this is referred to as the "vulnerability paradox" (e.g., Burton and Cutter, 2008), which suggests that the more efficient humans become, the more vulnerable they are toward disturbances such as natural hazards.

In terms of natural hazards and disasters, societies' exposure to the vulnerability paradox has important consequences. Numerous studies are available which try to prove that natural processes have changed dramatically over the several last decades. Indeed, it is correct that some process have actually changed in their magnitude and frequency. However, what is the driver of these changes? We have to ask: are these still considered natural processes, ones which act independent of human influence or society? What do we actually have to measure when we want to better understand and manage natural hazards? In short, this leads to the final question: what actually causes the disaster?

There are a number of arguments that support the premise of independency that humanity can influence natural processes. This is in fact true for geophysical hazards including earthquakes, volcanic eruptions, or tsunamis. However, the consequent disaster is more dependent on many more factors than just the natural elements (Kennedy, 2006; Wisner et al., 2004).

It is clear that humans are heavily dependent on nature. Although some authors claim that humanity is independent from nature and actually influenced by the human actions, this strong position is clearly questioned within sociology (e.g., Lidskog, 1998). It is possible that society considers itself independent and self-determined, but it is evident from many recent natural disasters, such as the December 2004 tsunami or the earthquakes in Pakistan 2005, in China 2007, or in Chile and Haiti 2010, that humans do rely heavily on nature and the natural processes affecting the Earth.

There is indeed a large need to cope with a suite of natural processes, in terms of management or, as often discussed, as risk governance. Besides the assessment of the social system, ranging from personal matters to national interests and global involvements over a wide variety of institutions, it is most important to effectively assess the natural processes. One of the main problems currently facing the natural science-based analyses and assessments are the limited availability of data. Continuous and comparable measurements of environmental parameters are available for some decades (e.g., water levels, volcanic activities, earthquakes, etc.) or centuries (e.g., single climate parameters, water stages, ocean tides, etc.). Unfortunately to allow the application of sustainable land use and secure developments, there is a need to extract information to longer time periods in order to recognize extreme events with returning periods of hundreds or thousands of years. Since we are now reaching the maximum limit of recording periods we should consider and assess other sources of information on such data – besides historical archives. Such information is relevant as it includes the knowledge gained on former natural physical processes as well as of the coping response of prior societies. Both types of information (society and nature) is only available through historical archives.

Historical perspectives

After an event there is a wide range of sources and methods for collecting available information. In the case of historical events the information is limited to written records. These records were commonly and intentionally produced for purposes other than reporting on the disasters. Consequently, one of the major methodological hurdles is to locate relevant and informative files. The respective archives and files have to be analyzed in

the appropriate context (e.g., socioeconomic, political). This is even more important for earlier periods such as the fourteenth or fifteenth century where only a few written records survived or the social and historical context is unclear.

Nevertheless, historical events involving disasters can be reconstructed, if the historian is able to carefully reconstruct the available and often sparse information. For example, Scanlon (2002) successfully reconstructed one catastrophe, the explosion in the harbor of Halifax, Canada (December 6, 1917), where two vessels collided, one of them transporting ammunition. This was one of the largest nonnuclear explosions in human history where more than 1,600 people died, and much of the city was destroyed. Scanlon (2002) shows how poor and inaccurate the contemporary reports are and then shows how it is possible to successfully reconstruct the explosion and aftermath differently and much more precisely (Scanlon, 2002). In this example, additional historical information included pictures and maps. The use of many different information sources is really the only way of collecting data to ensue a successful study (Dix, 2008). A clear advantage is that we are able to learn more about distinct events as well as the societal reactions, specifically how societies deal with a given. With this knowledge base, it is possible to learn from previous experiences of human societies that cope with natural risks.

Interestingly, it is also possible to study how such societies calculated natural risks and how they perceived vulnerability in the past. Bankoff (2003, 2004), for instance, successfully shows how the historical perspective can be used within the analysis of vulnerability issues in a non-Western society, in this case the Philippines (Bankoff, 2003, 2004).

A major problem is the extensive time required to adequately collect sufficient and accurate information to reconstruct a good (quality, reliability, quantity) data and time series of an event or events (Dix, 2012). In the case of climate history research based on historical archives, it is apparent that there are good quality data (Glaser, 2001). Unfortunately, this is not the case in regard to the quality of data for other topics. To emphasize this point, it is clear that prior to the Indian Ocean tsunami of 2004, the global level of knowledge concerning tsunami threats was generally poor in this region but the level of awareness increased dramatically thereafter. Unfortunately, the situation regarding detailed knowledge on the frequency and magnitude of paleo-tsunamis remains poor over many parts of the world (e.g., Mediterranean).

Humanity as a major force for disasters

Results of analysis of some historical archives demonstrates that, indeed in the case of some past societies which have experienced major disasters, human intervention of the natural processes was not a factor (all geophysical hazards). Major historic examples include volcanic eruptions, such as Vesuvius on April 12, AD 79, which buried Pompeii (Luongo et al., 2003) or the three major volcanic eruptions of the nineteenth and twentieth century; Tambora 1815 (Oppenheimer, 2003), Krakatau 1883 (Simkin and Fiske, 1984), and Mount Pelée on Martinique 1902 (Scarth, 2002). Similarly, many earthquakes have caused severe damage without the influence of human societies including the 1348 earthquake in Southern Germany and Switzerland (Borst 1981) or the Lisbon earthquake on November 1, 1755, which caused more than 10,000 fatalities (Chester, 2001).

Non-geophysical hazards such as storm surges are different. As with most hazards, the spatial exposition to the natural environment is the main factor affecting damages. But in the case of events such as storm surges, issues surrounding the quality of adjustments toward natural hazards are relevant, for example, dykes in case of storm surges, as realized as early as the late medieval period (Allemeyer, 2012). The recent case of the flooding of New Orleans and wide parts of the coastal areas of Louisiana in the aftermath of Hurricane Katrina demonstrates that existing institutions and measures of security like storm warning, hurricane shelters, and dykes may fail (Brinkley, 2006). In comparison, the indirect human influence resulting from extensive peat mining and the leveling of marshland surfaces contributed to the tremendous loss of life and cultivated areas especially in the case of the so-called "Grote Mandränken" (directly translated: "large drowning of population") storm surges on the coast of the North Sea in 1362 and 1634 which totaled several thousand victims (Glaser, 2001).

Another case of indirect influence is the wide range of excessive erosion events. Bork (1988) discusses the major influence of severe heavy rainfalls in 1342 in parts of Central Europe and the consequent gully erosion and appearance of deserted villages in the 1340s (Bork, 1998). He also collected a number of examples of the interference of land use and excessive erosion from all the continents (Bork, 2006).

There are also historic disasters which resulted from a direct interference by humans to the landscape, such as the Elm rockfall in the Canton Glarus, Switzerland on September 11, 1881 which was triggered by mining excavations of the slope toe (Hauer, 2001). Another example is the Vaiont landslide on October 9, 1963, a tragic case of reactivation of unstable slopes and old landslide areas following the construction of a dam (Kiersch, 1980; Genevois and Ghirotti, 2005). This latter disaster shows clearly that a historical survey in advance of human construction would have had indicated old landslide events in this area.

In all cases, intensified land use of any type (e.g., agriculture, built-up area) contributes to the major adverse forces related to disasters. These are, in most cases, unintentional responses. In the "industrial period," most people did not consider the potential consequences of large magnitude events. There is often a general belief that people can adequately manage their environment. Society commonly believes that to be aware of potential nature hazards is sufficient and that their limited past experience

with potential natural hazards will suffice. Most societies are not aware that the Earth surface was also formed by very large events, generally considered as catastrophic. When focusing on long-term landform development, numerous landforms only exist because of these large-scale events. Hence, societies tend to manage natural processes and make decisions based on their limited knowledge of temporal and spatial patterns for potential hazardous processes. In this context, historical information can significantly contribute to this knowledge because it can demonstrate the possible effects of previous larger events on humanity.

Summary

It is evident, that natural processes will always occur and that disasters are simply a result of the inappropriate adaptation of society to live with such processes. However, it is also evident that occasionally the anthropogenic actions or inactions enhance the disaster potential. Extensive use of natural resources changes the environment as we know it, for example, extensive groundwater extraction caused land subsidence of up to 3.9 m in some Chinese cities (Xu et al., 2008) and geothermal fluid extraction in New Zealand led to a subsidence of about 15 m since 1970 (Allis et al., 2009). Inappropriate agricultural practices can result in extensive soil erosion (Uri, 2000), and artificial water reservoirs may destabilize slopes and trigger possible failures that could produce disasters (Kiersch, 1980; Genevois and Ghirotti, 2005). As early as 1999, Hooke showed that for the USA, more sediment had been moved by humans than under natural conditions.

The key issue for the future is not to assign responsibility or blame to specific groups or individuals in the discussion on the impact of humanity on the environment. It is most important that we better understand the environment, but is also important to understand the social systems and in particular the interaction between society and environment. In order to make sustainable decisions, we have to be fully aware of potential consequences, to weigh the negative and positive responses of development based not only on short-term considerations, but also reflecting upon long-term environmental changes. It is essential to find a consensus within all affected parties, that is, by applying risk governance principles. Herein, the monitoring of our current environment, the modeling of acting processes, and the definition of scenarios helps society to live with the risk. Our current knowledge on previous disasters is very limited, but largely important to determine the actual role of humanity as an agent of natural disaster. Historical information on former natural disasters will help us to understand the processes involved and the related consequences.

Risk Governance

HURRICANE (TYPHOON, CYCLONE)

Robert Korty
Texas A&M University, College Station, TX, USA

Definition

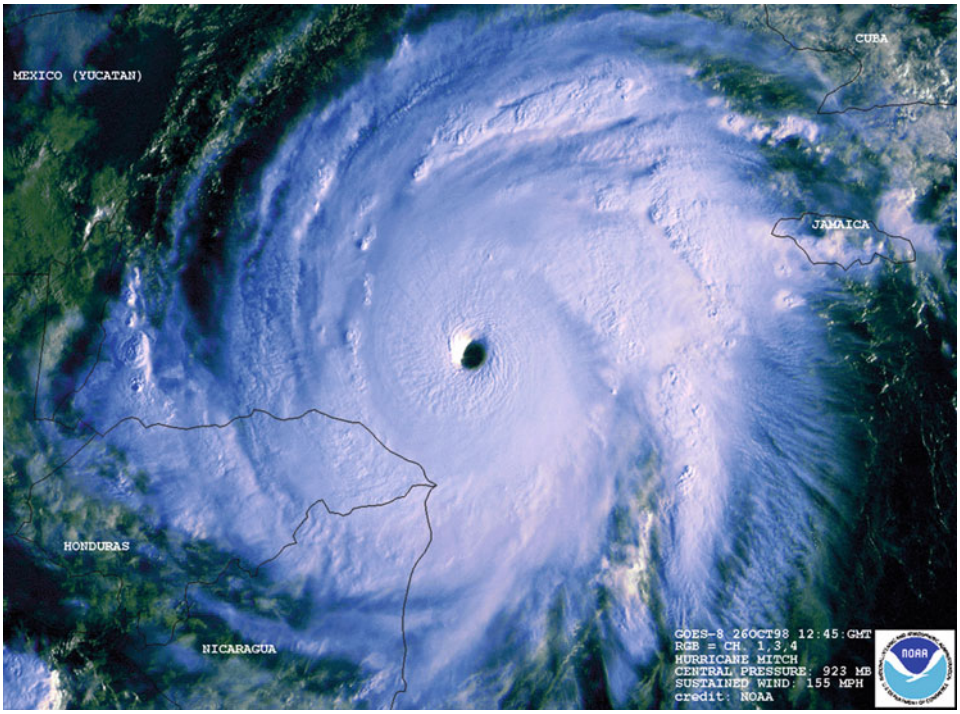
Tropical cyclone. An organized, cyclonically rotating system of convection driven by fluxes of heat derived from the ocean. Tropical cyclones are classified by their intensities using nomenclature that varies regionally. Tropical storms are tropical cyclones that have maximum sustained winds between 17 and 32 m/s (34–63 kts); intense tropical cyclones – those with winds of at least 33 m/s (64 kts) – are called *hurricanes* in the Atlantic and eastern North Pacific basins and *typhoons* in the western North Pacific. Typhoons whose maximum sustained 1-minute surface winds exceed 65 m/s (130 kts) are called *super typhoons*, and the strongest hurricanes (Category 3 or higher on the Saffir-Simpson Hurricane Wind Scale; see Tables 1 and 2) are classified as major hurricanes in the Western Hemisphere. In the Indian Ocean and South Pacific, tropical cyclones are referred to as *cyclones*.

Hurricanes

Introduction

Tropical cyclones are low-pressure systems driven by fluxes of enthalpy, a thermodynamic variable that consists of sensible and latent heat components, from the ocean to the atmosphere. In a tropical cyclone, air-sea fluxes of enthalpy principally arise in the form of evaporation from the ocean. These cyclones are characterized by deep convection near their center and 1-min sustained surface speeds of at least 17 m/s. Figure 1 shows a satellite image of Hurricane Mitch (1998) in the Caribbean Sea near the time of its peak intensity. The storm exhibits the classic hallmarks of intense hurricanes: a ring of deep convection surrounding a comparatively calm eye in which clouds are mostly absent. Outer bands of convection spiral into the core of the storm, but the most violent winds are confined to a tight radius around the center. Upper level outflow carries moist air away from the center at the top of the storm, which fans high-level clouds out to radii several hundred kilometers away from the eye.

Hurricane (Typhoon, Cyclone), Table 1 Original Saffir-Simpson scale of hurricane intensity (Simpson and Riehl, 1981). Classification is determined by wind speed alone, and slight modifications to the scales have been made in 2012; see Table 2 for current definitions. The minimum central pressure and storm surge in the original scale are estimates of common values associated with storms of that strength



Category	Wind (m/s)	Pressure (hPa)	Storm surge (m)	Damage
1	33–42	>980	1.0–1.7	Minimal
2	43–49	965–979	1.8–2.6	Moderate
3	50–58	945–964	2.7–3.8	Extensive
4	59–69	920–944	3.9–5.6	Extreme
5	≥70	<920	≥5.7	Catastrophic

Hurricane (Typhoon, Cyclone), Table 2 Saffir-Simpson Hurricane Wind Scale. This scale underwent a minor alteration in 2012 to alleviate awkwardness associated with conversions between various wind units. Hurricane intensities are estimated in 5 kt intervals, and the more commonly used units of mph or km/h had been previously rounded in the tables

Category	Wind (mph)	Wind (kts)	Wind (km/h)
1	74–95	64–82	119–153
2	96–110	83–95	154–177
3	111–129	96–112	178–208
4	130–156	113–136	209–251
5	≥157	≥137	≥252

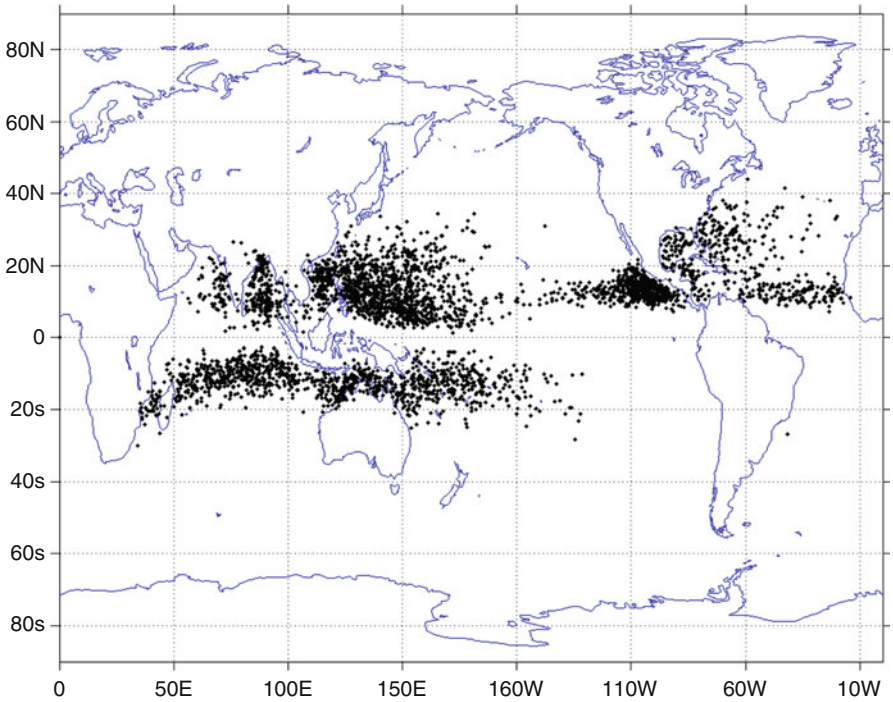
To aid warnings and communication, intense tropical cyclones – those with wind speeds of at least 33 m/s – are further classified in the Western Hemisphere using the Saffir-Simpson Hurricane Wind Scale, which is based on the damage they are capable of causing (Table 1 reports the original scale from Simpson and Riehl (1981) whereas Table 2 shows the current definitions). This scale bins hurricanes by strength into categories numbered from 1 (weakest) to 5 (most severe). Cyclones in the Southern Hemisphere affecting Australia are rated using a similar but slightly different scale (Table 3). Whereas the Saffir-Simpson scale uses the highest sustained wind to establish categorization, the Australian scale rates storms by their highest wind gust. Note that in any event the damage potential does not increase linearly with the wind speed – the kinetic energy of the wind increases as the square of the wind speed, and the damage that can result is also a nonlinear function of wind speed.

Tropical cyclones form principally in low latitudes around the globe. Figure 2 shows the points of origin of

Hurricane (Typhoon, Cyclone), Figure 1 Satellite image of Hurricane Mitch taken at 12:45 UTC on October 26, 1998. At the time this image was taken, the storm was bordering on Category 5 intensity with maximum sustained winds estimated to be 155 mph and a minimum central pressure of 923 mb. (Image courtesy of NOAA Operational Significant Event Imagery: http://www.osei.noaa.gov/Events/Tropical/Atlantic/1998/Mitch_10/TRCmitch299B_G8.jpg).

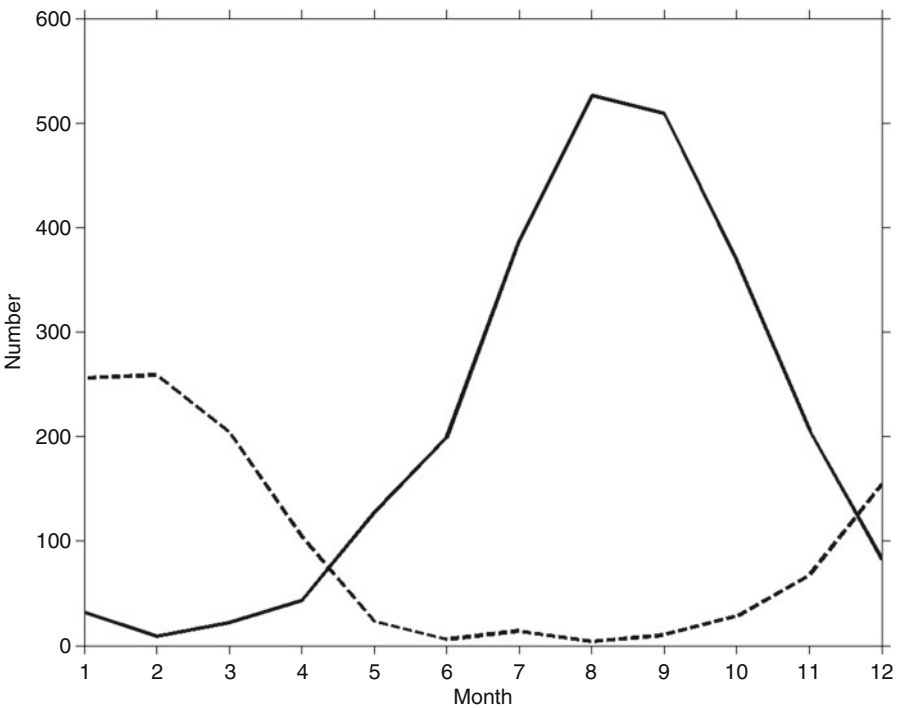
Hurricane (Typhoon, Cyclone), Table 3 Australian classification of tropical cyclone severity

Category	Strongest wind gust
1	<125 km/h (< 34.7 m/s)
2	125–170 km/h (34.7–47.2 m/s)
3	170–225 km/h (47.2–62.5 m/s)
4	225–280 km/h (62.5–77.8 m/s)
5	>280 km/h (>77.8 m/s)



all tropical cyclones between 1979 and 2008. They are common in the tropical North Atlantic, Caribbean Sea, Gulf of Mexico, tropical North Pacific, tropical Indian Ocean, and the central and western tropical South Pacific. They are rare in the South Atlantic, where only one hurricane was observed during this time period, and none has been observed in the eastern South Pacific. Storms do not form on the equator, where the vertical component of Earth's planetary vorticity (measured by the Coriolis parameter) vanishes. Storms most commonly form during the summer and autumn months in each hemisphere (June to November in the Northern Hemisphere; December to May in the Southern), but can form outside of this window, particularly in the western North Pacific, where some tropical storm activity is common throughout the year. The distribution as a function of month is plotted in Figure 3, which shows the late summer/early autumn peaks in each hemisphere.

Approximately 90 storms form around the world each year. This entry reviews the features common to these storms around the world: their structure and factors that influence formation and govern their intensity. More recent studies have probed a relationship between tropical cyclone climatology and climate, and a discussion of these ongoing efforts is included in the "Summary" section.



Structure and size

In mature storms, the axisymmetric part of the circulation is so much stronger than the asymmetric motions that it is often helpful to view these separately. The primary circulation is very nearly in gradient balance, a balance between pressure gradient, Coriolis, and centripetal accelerations, although winds in the surface boundary layer often exceed the balanced value (see Bui et al., 2009 for further discussion). The primary circulation evolves when heat and momentum sources drive a secondary circulation, which in turn change the distribution of heat and momentum.

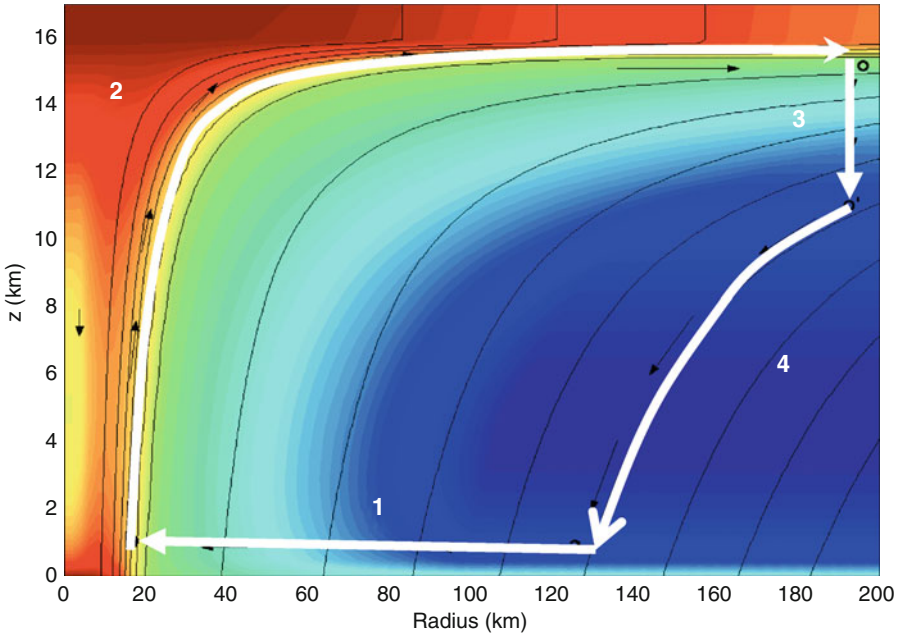


Figure 4 shows a modeled cross section in the radial-height plane of a mature, axisymmetric storm. Air flowing

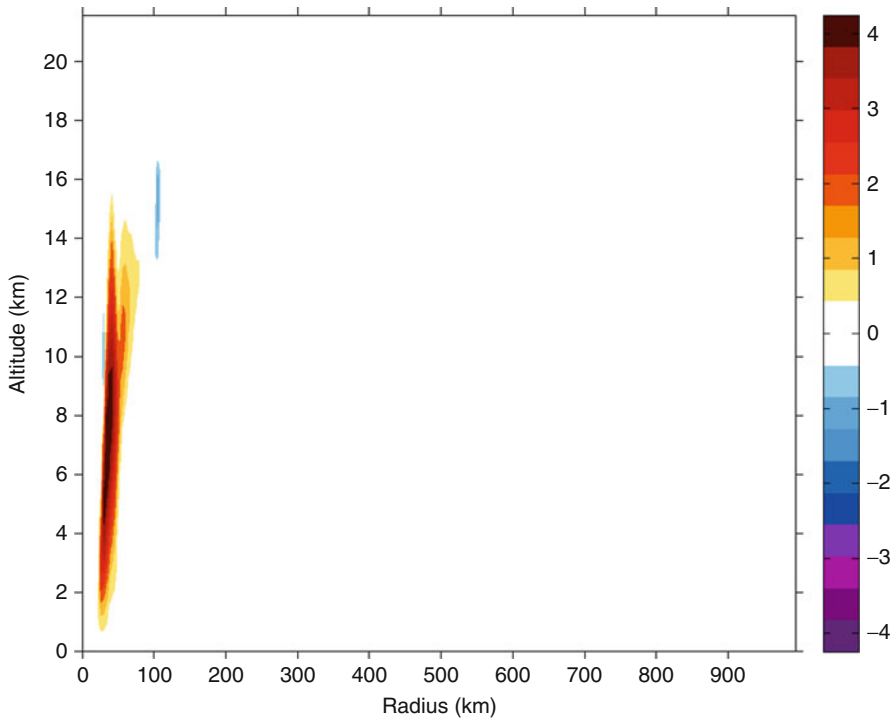
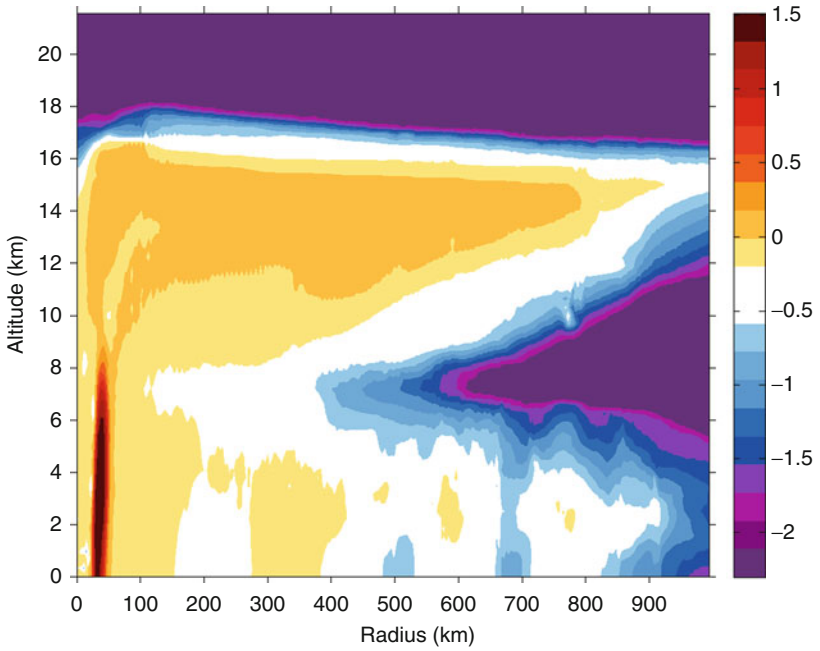
into the circulation in the boundary layer spirals in, rotating around the vortex center while migrating toward the center via a radially inward component of the surface wind field. In the eyewall, saturated air rises along angular momentum surfaces that are tilted away from the center with height. Thus, the eye of a hurricane is shaped like a football stadium: deep convection that usually towers through the full depth of the troposphere (∼15 km high) that tilts at an angle of up to 45°.



Surface winds are highest in this narrow region, and radial pressure gradients are correspondingly tight. As one moves outward from the eyewall, surface winds decrease at a rate roughly inversely proportional to the square root of the distance from the eyewall (see, e.g., Kossin et al., 2000; Mallen et al., 2005). Figure 5 shows this profile is captured in models of idealized hurricanes, such as those described by Rotunno and Emanuel (1987); note the rapid drop in the azimuthal component of the surface wind with radius moving away from the eyewall.

Figures 6–9 show the modeled radial-height cross sections of several meteorological variables from an updated version of the Rotunno and Emanuel (1987) model. Figure 6 shows the concentration of strongest azimuthal winds close to the center, with values tapering off at greater radii. Figure 7 shows the radial component of the wind, which is inward in the boundary layer and outward aloft. Figure 8 completes the mass circulation with strong upward velocities in the eyewall and gradual descent occupying a much area outside of the eyewall (including in the eye itself). Liquid water content (Figure 9) is highest in the boundary layer, but it is elevated at great heights in the eyewall and generally high in the upper-level outflow between 12 and 15 km. These model cross sections are consistent with measurements taken directly in the field. Figure 10 shows radar images taken during an Air Force Reconnaissance mission into a mature Hurricane Floyd in 1999. The convection is deep and tilted in the eyewall, and generally shallower at greater radii, as can be seen in Figure 11, which shows a radar image on a vertical cross section through the center of Floyd. The actual three-dimensional structure can have important azimuthal asymmetries, even in the most mature storms, which feature organized convective rainbands; see Houze (2010) for a good review of their structure.



The size of a tropical cyclone varies considerably from one storm to another, and considerably less research has been devoted to studying the factors that characterize the size distribution of storms. Dean et al. (2009) found that the size distribution in Atlantic hurricanes follows a roughly log-normal distribution, which would suggest that the size of a given storm may be primarily a function of the geometry of the initial disturbance, but Hill and Lackmann (2009) hypothesize that environmental relative humidity may play a role. Typical eye diameters are O(10 km), though some reach O(100 km). Typical radii for tropical storm force winds are a few

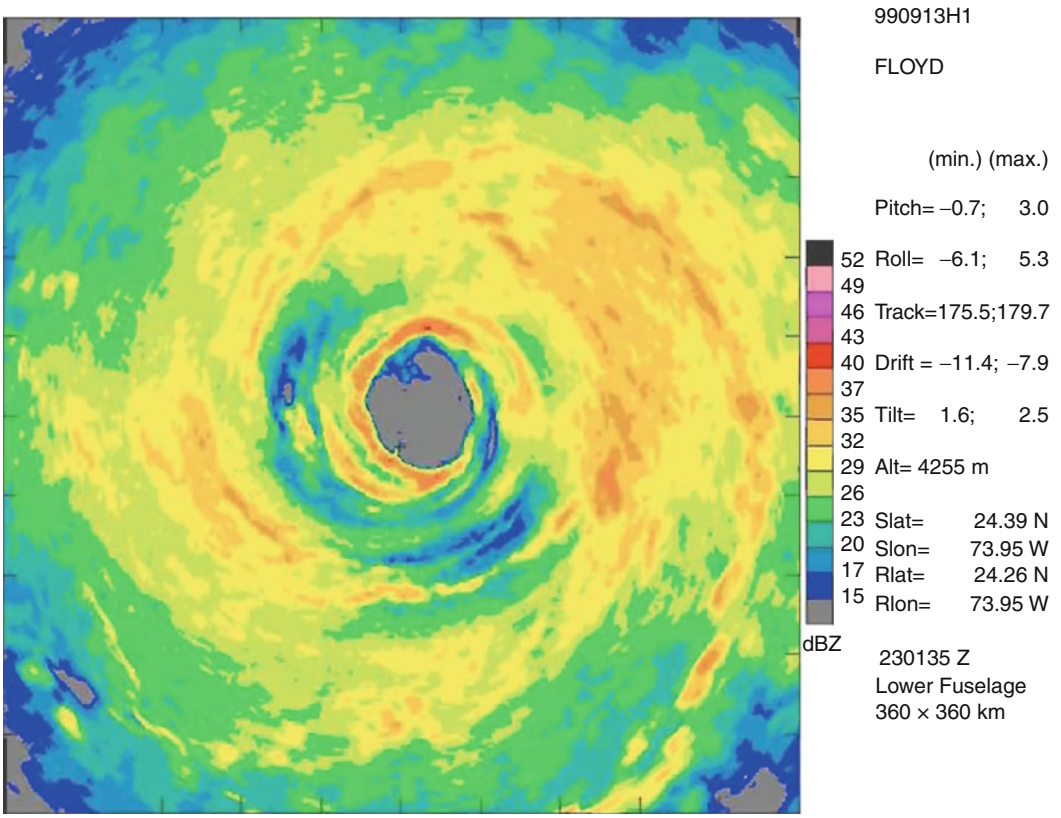
Hurricane (Typhoon, Cyclone), Figure 9 As in Figure 6, but for the natural logarithm of the liquid water content (g/kg).

hundred kilometers, though some storms – particularly those transitioning into extratropical cyclones – are considerably larger in size.

Genesis and climatology



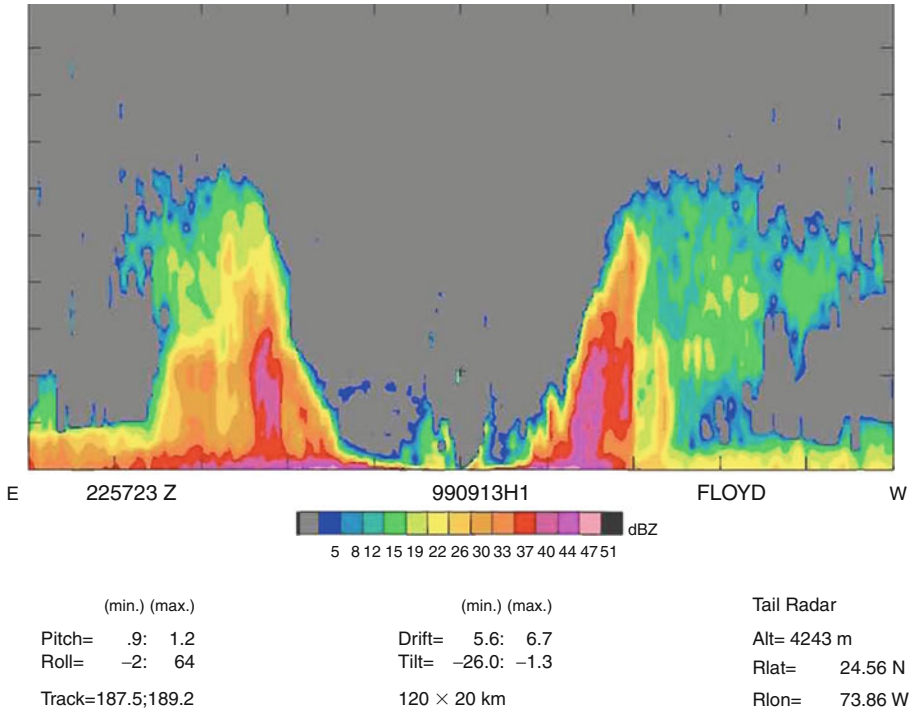
As seen in Figure 2, tropical cyclones form over a wide swath of the world's tropical and subtropical oceans, and are principally born in one of three belts. One lies in low latitudes of the Northern Hemisphere and stretches from the coast of Africa across the Atlantic Ocean, Caribbean Sea, and Gulf of Mexico into the eastern Pacific Ocean. A second Northern Hemisphere cluster begins in the central and western Pacific and extends westward to the northern Indian Ocean, the Bay of Bengal, and the Arabian Sea. In the Southern Hemisphere, genesis is concentrated in the Indian and Pacific Oceans from Madagascar eastward to the central South Pacific. Tropical cyclones in the South Atlantic are rare. Storms form most often during late summer and early autumn in their respective hemispheres (the peak is August–October in the Northern Hemisphere and January–March in the Southern Hemisphere).

William Gray indentified a number of environmental conditions common to genesis in regions around the world in pioneering work (Gray, 1968, 1979). These include a propensity to form over oceans with surface layers that are warm and deep. The structure of the upper tropical ocean includes a well-mixed surface layer that occupies the topmost 25–200 m in which temperatures vary little; below this is the thermocline, a region in which temperatures begin a sharp decline toward a cold abyss. Surface water temperatures at the point of tropical cyclone genesis are usually >26°C, although each year a small number of storms form over water colder than this. This isotherm is not a required threshold for genesis, but rather a coincident indicator of regions in which genesis is common.

Gray (1968) also identified the importance of temperature and moisture profiles in the lower atmosphere to developing tropical cyclones. The role has been clarified by the subsequent theoretical development of potential intensity theory by Emanuel (1986, 1988) and Holland (1997). Tropical cyclones are driven by positive fluxes of enthalpy from the ocean to the atmosphere, but this heat must be transported vertically by deep convection. If the atmosphere's thermodynamic profiles contain stable layers that inhibit convection, then a tropical cyclone will be unable to generate the deep layer structure characteristic of intense systems.

Other factors that are common at points of tropical cyclone genesis include low vertical wind shear (usually defined as the vector difference between the 850 and 200 mb winds), and some incipient cyclonic vorticity from which an initial disturbance can grow. Tropical cyclones do not form on the equator, where the vertical component of the planetary vorticity vanishes.

These criteria, first catalogued by Gray (1968, 1979), are the basis for a genesis potential index used in more recent studies by Camargo et al. (2007). The presence of a warm, deep layer of surface water, convectively neutral (or unstable) profiles, vorticity, and the absence of wind shear are clearly conducive to genesis, but this collection of conditions is common in the tropics, while genesis remains sporadic and rare. Thus, while these factors are



Hurricane (Typhoon, Cyclone), Figure 10 Radar image in Hurricane Floyd taken at 23:01 UTC on September 13, 1999.

important and appear to be necessary, their presence never guarantees formation of a tropical cyclone.

Part of the difficulty in forming tropical cyclones is that they are unable to spontaneously generate when the large-scale conditions are conducive; they require a trigger to develop. The trade wind regions of the tropics are most often characterized by a moist marine boundary layer topped by an inversion in temperature that arises from a gradual subsidence in the free troposphere. Thus the moisture content of a column of atmosphere in this region is confined to very near the surface, and it falls off sharply with height across the inversion. Deep convection that has enough buoyancy to punctuate through the inversion layer and tap unstable air aloft occurs in regular but isolated bursts, but these convective cells are unable in our present climate to spawn tropical cyclones on their own. The convective towers quickly consume the supply of moist enthalpy stored in the boundary layer, which leaves in their wake cool, dry air that is brought down to the surface by downdrafts generated by the convection, choking off a continued supply of fuel. Evaporation from the ocean resumes, but under normal wind speeds this process occurs slowly: the timescale to restore the moisture levels to their normal boundary layer values is a day or so. If winds are stronger (owing to an incipient vortex, for example), the evaporative process is accelerated.

Thus tropical cyclogenesis can occur only where evaporation is augmented by stronger surface winds; they require a trigger to start. Nascent clusters of convection are inhibited from growing into tropical cyclones because downdrafts bring down drier air from the middle troposphere, which is usually quite dry in the tropical atmosphere. As air parcels ascend in convective updrafts, excess water content is removed by precipitation. When air sinks back to the surface, it is dry, although mixing from shallow convection and evaporation of falling precipitation partially rehydrates parcels. Thus cyclogenesis will be favored when the middle troposphere is more humid than average, as it appears that nascent disturbances must first saturate the troposphere before genesis can occur (Bister and Emanuel, 1997).

Tropical cyclones also require vorticity. As shown in Figure 2, while cyclogenesis is common throughout the tropics, these storms do not form on the equator itself, where the vertical component of planetary vorticity goes to zero. Genesis is also preferred in regions where the atmosphere develops cyclonic spin with respect to the earth (cyclonic relative vorticity). These factors that favor genesis have been known for several decades (Gray, 1979;

Hurricane (Typhoon, Cyclone), Figure 11 Radar image taken along a vertical cross section inside the center of Hurricane Floyd taken at 22:57 UTC on September 13, 1999.

McBride and Zehr, 1981), but their presence is insufficient to guarantee development. Undoubtedly, there are several routes by which genesis can occur, and these details remain the subject of active research studies.

Tracks and motion

Once formed, tropical cyclones follow a path guided by both external, environmental factors and internal dynamics. Steering by the background wind patterns are often of primary importance in advecting a storm downstream, and the vertically averaged lower-tropospheric flow is most often a principal driver. Absent any strong steering, storms tend to move poleward and westward owing to some internal dynamical constraints.

Earth's planetary vorticity f increases with the sine of the latitude heading northward. Consider a storm in the Northern Hemisphere that is being advected to the west by a background flow of easterly winds. Because the storm has cyclonic vorticity (relative vorticity ζ and f have the same sign), air circulates around its center in a counterclockwise fashion in the Northern Hemisphere. As air rotates northward up the eastern side of the storm, it moves into an area where the planetary vorticity is higher than it was where it originated. Thus it decreases in relative vorticity to compensate, and it acquires an anomalous clockwise spin. Conversely, air rotating southward along the western side of the storm moves to an area where planetary vorticity is lower than it was where it originated, and thus the air acquires additional counterclockwise spin to compensate. The net effect of both of these anomalous spins is to induce a poleward push to the trajectory of the storm, which is embedded in an otherwise east-to-west flow. This is known as the β-effect, after the rate at which Earth's planetary vorticity changes with latitude (Smith, 1993).

Tracks generally follow a slightly poleward off due west trajectory in the deep tropics, but as a storm ventures toward the subtropics, interactions with middle latitude weather systems being advected from west-to-east can turn the trajectories in a more pronounced poleward direction before recurving them in the westerly middle latitude flow.

Intensity

Tropical cyclones have their strongest winds near the surface, a consequence of being warm-cored systems. As noted previously, wind speeds are highest in the eyewall of a hurricane and decrease inversely with distance from the eyewall (see Figure 5). Thus the most violent part of a storm is confined to a smaller fraction of the storm near its center, although as noted earlier, the size of both the eye and the storm itself can vary substantially from one hurricane to another. In the strongest hurricanes, the maximum winds can reach 85 m/s, making these among the fiercest weather phenomena.

As high as the surface wind speeds are, they are not unbounded by nature. In fact, there is a thermodynamic limit on how strong storms can be. The factors generally needed for genesis outlined in the last section show the

importance of both warm surface waters and a favorable atmospheric temperature and moisture profile. The relationship between these imposes a constraint on a cyclone's maximum wind speed, analogous to a Carnot heat engine's constraint on the thermodynamic efficiency of an engine.

Early researchers recognized that hurricanes derive their energy from fluxes of heat from the ocean (Riehl, 1950; Kleinschmidt, 1951). Most of this comes in the form of evaporation of ocean water into the boundary layer of the hurricane, and these surface fluxes become stronger as the wind speed increases. Emanuel (1986) showed that a mature tropical cyclone can be viewed as a steady, axisymmetric flow with an energy cycle that resembles that of an ideal Carnot heat engine, which is diagrammed in Figure 4. On the first leg, as a parcel of air spirals toward the center of a hurricane in the atmospheric boundary layer, fluxes of enthalpy from the ocean and dissipative heating (Bister and Emanuel, 1998) add heat to the hurricane while surface temperatures remain nearly constant. This causes pressures to fall as entropy rises and angular momentum decreases as a result of the loss of kinetic energy through frictional dissipation with the sea surface. As temperatures are nearly constant along this journey, the pressure drop is analogous to the first leg in a Carnot cycle: one of isothermal expansion. Once the parcel reaches the eyewall, it turns upward as it rises along a surface of constant angular momentum under slantwise convective ascent (leg 2 of Figure 4); this ascent is one in which entropy remains nearly constant, and so this is analogous to adiabatic expansion to the lower pressures in the upper troposphere.

In nature, where actual storms are not bounded to recirculate every parcel of air, the outflow from a hurricane is mixed with its environment far removed from a hurricane's core, which results in an open energy cycle. Numerical models, however, can be enclosed with artificial walls, which allow the cycle to be closed conceptually (Emanuel, 2003). In the third leg of Figure 4, where temperatures in the lower stratosphere or upper troposphere are around 200 K, a parcel of air loses heat to space by radiation as it sinks to higher pressures; this is isothermal expansion. In the final leg, although air continues to lose heat to space just as in leg 3, this amount is very nearly equal to the amount that would have been gained if all of the rainwater had remained suspended in the air and evaporated as the parcel descends rather than fall out of the system. So while entropy is lost and gained in this leg, little or none is available for kinetic energy production (see Emanuel, 2003 for a full discussion). Thus, this final leg is nearly one of adiabatic compression.

Heat input and dissipation of kinetic energy occur through heat and momentum fluxes in the boundary layer. These are usually quantified using bulk aerodynamic formulae:

$$F_p = -C_D \rho \left|\vec{V}\right| \vec{V} \tag{1}$$

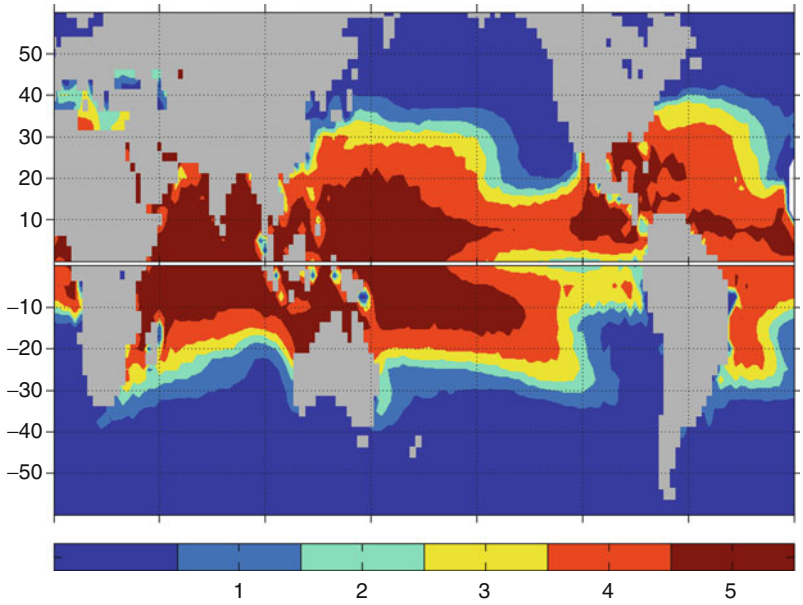
and

$$F_k = C_k \rho \left|\vec{V}\right| \left(k_0^* - k\right). \tag{2}$$

Here F_p and F_k are the fluxes of momentum and heat, respectively, V is the near-surface vector wind (usually taken to be at 10 m), ρ is air density, k is the specific enthalpy of air near the surface, ${k_0}^*$ is the saturation enthalpy of air that is saturated with water at the ocean temperature (i.e., a parcel of air in contact with the ocean), and C_D and C_k are nondimensional drag and enthalpy exchange coefficients. Both C_D and C_k depend on sea state, but their precise values are uncertain in the complex sea states and high wind environments characteristic of a hurricane.

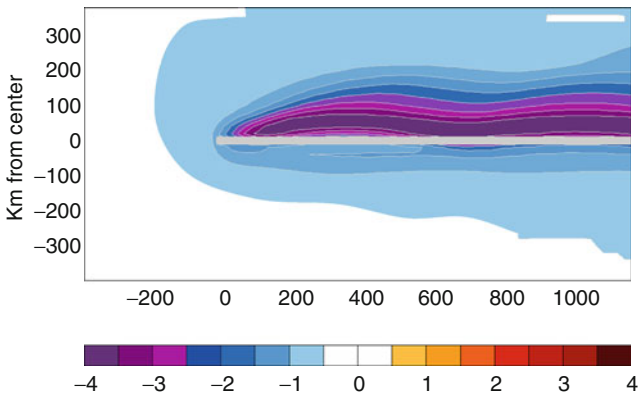
The ocean to atmosphere enthalpy flux that feeds a hurricane is augmented through dissipative heating in the atmospheric boundary layer by an amount

$$D = C_D \rho \left|\vec{V}\right|^3 \tag{3}$$



(see Bister and Emanuel, 1998). Thus the total heat put into a hurricane, integrated over all radii and azimuthal angle θ along leg 1 of Figure 4, is

$$Q = \int_0^{2\pi} \int_0^{r_o} \left[C_k \rho \left|\vec{V}\right| \left(k_0^* - k\right) + C_D \rho \left|\vec{V}\right|^3 \right] r dr d\theta. \tag{4}$$

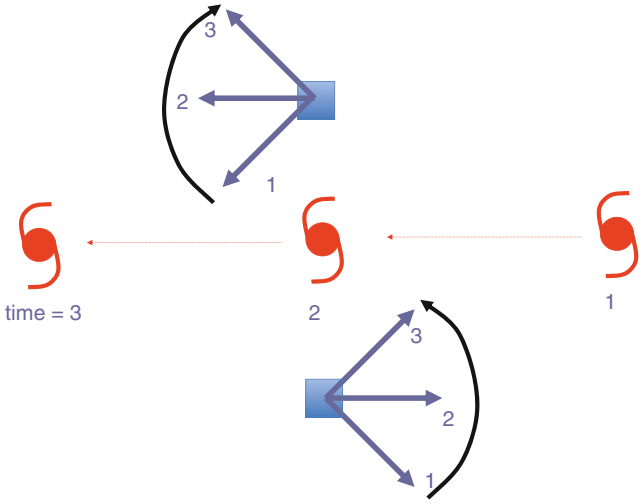


The work done by the hurricane's Carnot cycle is simply the total heat input given by Eq. 4 multiplied by the thermodynamic efficiency, which is the ratio of the difference between the hot input (SST, T_s) and cold output (T_o, the temperature at the top of the convection) divided by T_s. This work must balance the dissipation of momentum given by Eq. 3 integrated over all radii and azimuthal angles. Combining these, and assuming that the integrals are dominated by the values near the radius of maximum wind where these quantities spike, the maximum wind speed possible in a hurricane is given by

$$\left|V_{\max}\right|^2 = \frac{C_k}{C_D} \frac{T_s - T_o}{T_o} \left(k_0^* - k\right). \tag{5}$$

This derivation parallels Emanuel (2003); an alternate, more technical derivation is presented in Bister and Emanuel (1998), but yields the same result. This equation shows that the maximum possible wind speed in a hurricane is a function not merely of the SST (T_s), but rather a more complex function that couples it to the temperature at which convection outflows in the atmosphere (T_o) – that value will be established by the temperature and moisture profiles in the atmosphere that dictate how high a parcel of air will rise before it is no longer buoyant. Thus assessing how intensities could change in other climates requires not just knowing how SST changes, but rather how it changes in relation to the atmosphere that is in equilibrium with it.

Hurricane (Typhoon, Cyclone), Figure 12 Peak value of the maximum potential intensity at any point during the annual cycle (Values were computed using the Bister and Emanuel, 1998) algorithm from data in the NCEP/NCAR reanalysis fields between 1979 and 2008. These were then averaged over each of the 30 years to form a single mean-annual cycle. The highest values from this cycle are shown here.).



Hurricane (Typhoon, Cyclone), Figure 13 SST change in the wake of a westward-moving storm in a coupled hurricane-ocean model. The track of the storm is shown by the solid gray line, and its current location is centered at (0, 0). Cooling of several degrees Celsius is pronounced along and to the right of the track in its wake.

As seen in Figure 12, potential intensities equal to the strength of a Category 4 or 5 hurricane are common over a wide part of the globe, yet very few of the storms that form reach their upper bound (Emanuel, 2000). An individual storm will be subjected to specific conditions that often limit its ability to reach its full potential. These include wind shears, dynamic interactions with neighboring meteorological features, and interactions with the underlying ocean itself.

Price (1981) described the mechanism by which tropical cyclones cool the surface of the ocean. Figure 13 shows the deviation from initial sea surface temperature (SST) in the wake of a westward moving hurricane output from a simple coupled model. Water temperatures are cooler by several degrees along and north of the track (the right hand side of this hurricane). While some heat is lost to the atmosphere during the passage of a storm through air-sea fluxes, the amount is quite negligible compared to heat content of the upper ocean; if these were the only cause of cooling, SSTs would be only a fraction of a degree lower behind a hurricane. The principal reason why water temperatures are lower by several degrees Celsius after the passage of a hurricane is that cooler water from the thermocline has been mixed into the surface layer by turbulent processes instigated by the hurricane itself.

The strong surface winds in a hurricane act as a stress on the upper ocean, and this stress imparts momentum to the ocean currents in the mixed layer. As currents here build in strength under a hurricane, shear increases at the interface between the surface layer and thermocline. When this shear becomes sufficiently strong, turbulent mixing ensues, and colder, denser water from the upper thermocline is entrained into the surface layer, resulting in a drop in temperature.

As can be seen in Figure 13, there exists a pronounced bias in the location of maximum cooling: it is much larger to the north of the track, while SSTs are nearly unchanged to the south. This is a result of the action of the Coriolis force on a temporally varying wind stress. When the winds blow on the ocean, water is initially pushed in the direction of the wind, but the Coriolis force turns currents to the

Hurricane (Typhoon, Cyclone), Figure 14 The wind vectors at two points north and south of a westward-moving Northern Hemisphere hurricane are shown for three times in *gray*. As a hurricane moves west, the winds at a fixed point turn as the cyclonic wind field moves by. The direction the wind vector turns is different on the right and left sides of the track: to the right, the wind vector turns clockwise or to its right with time, while it turns counterclockwise or to its left on the left side of the track. The temporal turning of the wind vector augments the torque exerted by the Coriolis force on parcels of water to the right of the track, while it opposes it on the left. As a result, currents in the upper ocean will be stronger in magnitude on the right than on the left of a track.

right in the Northern Hemisphere, so that transport is ultimately at a right angle to the wind. In the case of a moving hurricane, the wind stress itself is turning with time, and as diagrammed in Figure 14, the wind stress vector rotates clockwise on the right side of a track, and counterclockwise on the left. This means that on the right side of the track, the wind stress vector will rotate in the same direction that the Coriolis force is turning the currents, augmenting the strength of the currents here. To the left of the track, the reverse is true, and currents are weaker. As noted above, the strength of the currents determines the strength of the shear that builds on the base on the mixed layer; thermocline water is much more readily entrained on the right side of the track where currents have the largest velocities (Price, 1981, 1983).

While much of the cooling occurs in the wake of a storm, this process develops quickly enough to influence the air-sea fluxes that feed the hurricane itself. Thus a hurricane induces cooling of the surface water, which acts as a negative feedback on hurricane intensity by reducing the strength of the very fluxes on which a storm relies. Storms that move rapidly, travel over deep layers of warm water, and those that pass over parts of the ocean with a weaker thermocline stratification will be less affected by this interaction than those that do not (Schade and Emanuel, 1999).

One factor that is often responsible for inhibiting intensification well short of the thermodynamic limit is vertical wind shear (DeMaria and Kaplan, 1994; Emanuel, 2000). While a direct, negative link between vertical wind shear and tropical cyclone intensification exists, the physical mechanisms that cause a reduction in intensity remain under investigation. Several mechanisms have been proposed; shear may reduce intensity by ventilating the vortex core, increasing tropospheric stability, and eddy momentum fluxes, which decelerate tangential and radial winds (Simpson and Riehl, 1958; DeMaria, 1996; Frank and Ritchie, 2001; Wu and Braun, 2004; Tang and Emanuel, 2010).

Summary and open questions

Tropical cyclones rank among the most intense weather events in the world, although most fail to reach the full limits set by thermodynamics. They are sporadic events by nature, with only about 90 storms forming worldwide each year: they require a trigger to form, as even when conditions are supportive they do not spontaneously generate. While they form mostly in low latitudes of the world, they can affect subtropical and higher latitudes as well; tracks are biased to turn poleward owing to variations in Earth's planetary vorticity.

Recently, there has been renewed interest in the question of whether or not tropical cyclones are responding to changes in climate. Some work has focused on the Atlantic basin, which contains only about 15% of the storms that form worldwide, but has one of the longest and most reliable records of observations owing to regular aircraft reconnaissance. How the climatology and intensity of tropical cyclones changes with climate remains an area of active research. Historical records of tropical cyclones provide the most obvious avenue for investigation, but they are in many respects ill suited for analyzing how characteristics respond to climate because they are relatively short and have varying quality over their length (Landsea et al., 2004). Global satellite coverage was unavailable before the 1970s, meaning that records in remote parts of the world are likely incomplete before then. Another avenue is to use global climate models (e.g., Bengtsson et al., 2007), but even as resolution improves, these remain unable to resolve the inner core of tropical cyclones given the fine scales of the physics involved (Rotunno et al., 2009). Downscaling – where output from global climate models is then used to run a full physics hurricane model – offers a way to study these questions with models without succumbing to the computational costs of running global-scale models at very high resolutions (Emanuel, 2010).

One other avenue of research comes from the nascent field of paleotempestology. Liu and Fern (1993) showed that overwash from intense tropical cyclones is recorded in the sediment record on the inland side of barrier islands, and some of these records cover thousands of years. Each of these cores might be viewed as a single paleoweather

station, but as the number of cores grows around the world, it may be possible to get some important information about how the climatology of landfalling, intense tropical cyclones varied over the Holocene.

CASE STUDY

HURRICANE KATRINA

Joann Mossa
University of Florida, Gainesville, FL, USA

Background

Hurricane Katrina of the Atlantic Ocean in August 2005 is an important natural hazard case study because it was the costliest hurricane as well as one of the five deadliest in the history of the United States (http://www.katrina.noaa.gov/; Beven et al., 2008). Although it affected several states, the most severe damages occurred in southeastern Louisiana and along the Mississippi coast, the former receiving the most media attention. The Gulf Coast of Mississippi experienced the most severe quadrant of the storm and suffered near total devastation on August 28–29 with a maximum 9 m (27.8-ft) storm surge along the shore but an overall surge that reached up to 19 km (12 miles) inland and wiped out towns and forests, leaving 238 people dead (Knabb et al., 2006). There were an estimated 1,577 deaths in Louisiana directly or indirectly related to Katrina because the heavily populated Greater New Orleans area was affected (Knabb et al., 2006). Many citizens, politicians, and scientists considered the preparation, flooding, and response to the storm in New Orleans a debacle, and as a result, it spurred many investigations, reports, documentaries, and books (e.g., Horne, 2006; van Heerden and Bryan, 2006; U.S. House of Representatives, 2006).

Environmental vulnerability and engineering problems

The vulnerability and risk of living in southeastern Louisiana and the other Gulf areas impacted by Hurricane Katrina has been long recognized by many (e.g., Kelley et al., 1984; Colten, 2006). Located in a deltaic setting, on a natural levee and backswamp between the Mississippi River and several large lakes, elevations in New Orleans are low and large portions of the city are below sea level (McCullough et al., 2006). Engineering structures and modifications are widespread; the metropolitan area is surrounded by artificial levees and floodwalls, plus numerous canals and other waterways creating multiple inroads of vulnerability. The area surrounded by levees requires a system of pumps to remove rainfall from lowlands following rainstorms because there is nowhere else for water to drain. During the past century, wetlands throughout southeastern Louisiana have been disappearing at an accelerated rate. One reason is the maintenance of the Mississippi River in its present course by multiple control structures near the juncture with the Atchafalaya, a site of potential avulsion, which results in sediment resources going off the continental shelf. Land loss is also due to the lack of wetland deposition from Mississippi River floodwaters due to presence of artificial levees and creation of numerous canals through wetlands to support extraction of petroleum, other resources, and navigation. The region is also experiencing subsidence related to compaction and settling of recently deposited sediments and movement of growth faults (Dixon et al., 2006). Subsidence has been accelerated by oxidation and shrinkage of organic-rich drained soils, associated mostly with development of areas surrounded by artificial levees; the loading of sediments with structures, buildings, and levees; and pumping of groundwater.

Flooding preparation, impacts, and response

The challenges associated with protecting this type of terrain are numerous, as the region has become more vulnerable with time; yet, ultimately, engineering failures caused the flooding associated with Hurricane Katrina. Portions of levees and floodwalls were overtopped or bent by the incoming storm surge. Other sections developed leaks and breaches or collapsed due to problems with the materials or foundation. Ultimately, about 80% of New Orleans was flooded, with low areas inundated with waters 6 m (20 ft) and higher for several days to weeks (http://www.katrina.noaa.gov/maps/maps.html). Levee problems prompted external reviews of levee design and construction, which is the responsibility of the U.S. Army Corps of Engineers, and maintenance, which is the purview of local Levee boards. It was concluded that both system design flaws and lack of adequate maintenance were problematic (Andersen et al., 2007).

Coupled with the environmental and engineering problems were historical, behavioral, and socioeconomic factors. There had not been a storm of this severity for decades; thus, officials lacked experience in planning for and recovering from major storms, and some residents did not take this potential threat seriously. The social vulnerability of poor and older residents with limited access to information and transportation was also a major problem. Although the National Hurricane Center and National Weather Service provided accurate forecasts and abundant lead time, many inhabitants could not or did not evacuate. After the flooding, many were without basic provisions, some were rescued by helicopter off rooftops, and others found shelter in places like the Superdome or Morial Convention Center, which were not staged to handle a problem of this scope and magnitude. These places were not adequately stocked with water and food and had insufficient personnel for emergency assistance. Dissemination of information and emergency response coordination of local, state, and federal agencies were made difficult by confusion regarding the chain of command, disruption of communications infrastructure, and other information flow impediments (Day et al., 2009). The U.S. Coast Guard seemed best prepared of the agencies involved in the emergency response and rescued most of the roughly 60,000 people stranded in New Orleans (U.S. Government

Accountability Office, 2006). Until transported to shelters in other states for assistance, people suffered for days in difficult conditions. About 50–70% of the housing experienced severe flooding; financial aspects of this debacle were magnified by the fact that many homeowners lacked federal flood insurance (U.S. Department of Housing and Urban Development, 2006). There were many problems with efforts by individuals and city, state, and federal authorities to evacuate, plan, communicate, provide relief, and assist in recovery. Ultimately, investigations resulted in the resignations of the Federal Emergency Management Agency director Michael D. Brown and the New Orleans Police Department Superintendent Eddie Compass and widespread criticisms of President George W. Bush, Governor Kathleen Blanco, and Mayor Ray Nagin.

Aftermath

Southeastern Louisiana and the Gulf Coast of Mississippi will likely be forever changed from this event. Years after the storm, the population of New Orleans is much lower than prior to Hurricane Katrina. People of different backgrounds have different levels of place attachment and reasons for returning (Li et al., 2010). The levees were repaired prior to the subsequent storm season, but the city is still vulnerable to storms of this magnitude or larger. Redevelopment is being planned more carefully than in the past; some areas will not be rebuilt, and in other areas, buildings will need to be elevated (U.S. Army Corps of Engineers, New Orleans District, 2009). Conflicts are continuing over levee improvements and who should be responsible for funding them. The U.S. Government, (2006) identified 125 specific recommendations from studying what went wrong with Hurricane Katrina. Legal battles of citizen plaintiffs against the United States Army Corps of Engineers have been fought and won (U.S. District Court, Eastern District of Louisiana, 2009). It remains unknown how much learning has occurred but it is now better understood that the city and its people and others in low-lying areas of the Gulf Coast are vulnerable and that the numerous engineering structures built to protect them are not infallible.

HYDROCOMPACTION SUBSIDENCE

Andrew J. Stumpf
Prairie Research Institute, University of Illinois at Urbana-Champaign, Champaign, IL, USA

Synonyms

Hydroconsolidation; Near-surface subsidence; Sagging; Shallow subsidence

Definition

A process of collapse and compaction that occurs in silty to sandy sediment (soil) having a low bulk density, is saturated for sustained periods, but the water is subsequently removed (Krynine and Judd, 1957; Dudley, 1970). Infiltrating water enters the porous structure of the sediments weakening interparticle bonds of clay if present and reducing capillary tension between coarser soil particles that provided strength when unsaturated. Removal of these structural bonds causes overall consolidation and is manifested by settlement under loads and subsidence at the ground surface (Inter-Agency Committee on Land Subsidence in the San Joaquin Valley, 1958; Lofgren, 1960; Sajgalik, 1990).

Soil characteristics

Soils susceptible to hydrocompaction are geologically immature deposits or reclaimed soils that are uncompacted or unconsolidated predominantly composed of silt and sand grains with a small amount of clay, usually less than 12% (Bull, 1964). Likely soils typically have a water content below 10% (Waltham, 1989), loose, bulk density <1.3 g/cm^3, and a high void ratio or porosity ranging from 38% to 60% (Feda, 1966; Dudley, 1970). The soils also have sufficient dry strength because of interparticle bonds that resist compacting and readily absorb large load stresses (Waltham, 1989). Hydrocompaction is common in soils containing montmorillonite clay (Rogers et al., 1994) and other swelling clay minerals.

Process

Hydrocompaction occurs after saturating and drying, silty to sandy soils that contain weak structural bonds formed between particles by capillary tension, clay, or soluble precipitants (Prokopovich, 1963, 1986; Lofgren, 1969). As the soil becomes saturated, the structural support provided by both capillary action and clay bonds are weakened. The soil then undergoes deformation or a change in volume to a denser structure under its own weight or the weight of an overlying structure. The areal subsidence or settlement underlying a structure has been triggered by large-scale irrigation projects, canal leakage, waste water disposal, and other modifications to drainage and evaporation (Lofgren, 1969).

Distribution

Collapsible soils qv "*Collapsing Soil Hazards*" prone to hydrocompaction are present in wind-blown silt (loess qv "*Loess*") found in the United States, Europe, Russia, Ukraine, Afghanistan, Thailand, and China, and alluvial silt on fans and mudflows in the southwestern United States (Lofgren, 1969; Waltham, 1989). Hydrocompaction may also occur in volcanic ashes, colluvial deposits, and organic-rich sediment (Stephens et al., 1984; Waltham, 1989).

Hazards

Hydrocompaction may cause rapid subsidence of the ground surface causing significant damage to property. Subsidence as large as 5 m can occur over a wide area (Waltham, 1989) and can promote further collapse by sapping and piping (see entry *Piping Hazard*) in the subsurface.

Summary

Hydrocompaction is a serious land subsidence issue where unsaturated, fine-grained soils are modified by human interactions. The extent over which this collapse process has been identified indicates its importance as a natural hazard. Rogers et al., (1994) provides a thorough review of the problem in a global perspective and encourage discussion between the scientists and engineers to overcome their misunderstandings about the process that have resulted from differences in terminology used by the varied disciplines involved with the process and consequence.

HYDROGRAPH, FLOOD

Fernando Nardi
University of Tuscia, Viterbo (VT), Italy
Hydraulics Applied Research & Engineering Consulting S.r.l, Rome, Italy

Synonyms

Flood time–discharge relationship; Flood wave; Storm hydrograph

Hydrograph, Flood, Figure 1 Schematic representation of the flood hydrograph.

Definition

The hydrograph is the plot of water-flow discharge (run-off) versus time at a given river station (where a flow gauge might be located). The storm hydrograph represents the discharge record of river flow during extreme events, as the flood volume exceeds the maximum conveyance capacity of the river channels (see also *Flood Stage*) and the floodwaters – overtopping the banks – propagate through the floodplain (see entry *Floodplain*).

Discussion

The flood hydrograph is indirectly linked to a wide range of heterogeneous, spatially distributed factors pertaining to the upstream areas of the watershed. Those factors include the climatic, hydrologic, geomorphologic, geologic, hydraulic, and ecological conditions that, together with artificial features (e.g., levees, reservoirs, bridges, etc.), characterize the flood generation, propagation, and inundation phenomena, and range from the hydrologic forcing (precipitation regime, represented by the rainfall hyetograph) to the hillslope and river network morphology, the land use, soil, vegetation, and surface roughness properties up to the human-made interventions by means of civil infrastructures and structural *flood protection* systems.

Figure 1 shows a schematic representation of the flood hydrograph and its main features: the rising and falling limb (recession curve), the base flow and time, the lag time (time interval between the rainfall and discharge peaks), the peak discharge, and the total volume (estimated as the area under the curve that is the integral of the hydrograph function for the given time period). The shape of the flood hydrograph curve provides direct information for understanding the dynamics of the flood hydraulics and its evolution in time with specific regard to the volume and the maximum (peak) discharge.

HYDROMETEOROLOGICAL HAZARDS

Gordon McBean
The University of Western Ontario, London, ON, Canada

Synonyms

Climate and related hazards; Flood; Water; Weather

Definition

Process or phenomenon of atmospheric, hydrological or oceanographic nature that may cause loss of life, injury

or other health impacts, property damage, loss of livelihoods and services, social and economic disruption, or environmental damage. (United Nations International Strategy for Disaster Reduction, UNISDR, 2009a).

Introduction

Throughout the history of this planet, hydrometeorological hazards have had great impact. From the prehistoric to biblical floods to the tragic events of recent times, humanity has been afflicted by floods, storms and droughts. In 2008, Cyclone Nargis swept through the Bay of Bengal and caused over 130,000 deaths in Myanmar (Center for the Research on the Epidemiology of Disasters, CRED, 2010); 17 years earlier Cyclone Gorky had resulted in a similar death toll in Bangladesh. Drought in sub-Saharan Africa has been a frequent occurrence and in 1983 the death tolls in Ethiopia and Sudan totaled close to half a million people. About 30,000 people died in the floods in Venezuela in 1999. The European death toll due to the summer of 2003 heat wave is now estimated at 70,000 people (Robine et al., 2008).

The exact direct and indirect economic costs (lives, infrastructure, etc.) associated with hydrometeorological hazards is not readily quantifiable. An estimated total loss of $125 Billion (CRED, 2010) (all values in $US) was attributed to Hurricane Katrina in 2005 whereas Hurricanes Charley and Wilma, before and after Katrina, added another $30B in losses. The losses due to the Yangtze flood of 1998 in China and Hurricane Andrew of 1992 in the USA were also close to $30B. The wild fires in Indonesia in 1997 had estimated losses of $17B.

This entry will address different types of hydrometeorological hazards with respect to their past and projected changes with a changing climate. This will be followed with a more in-depth discussion of the impacts of hydrometeorological hazards. Reducing impacts due to these events is very important; one of the ways of reducing impacts is to advise people in advance, the role of scientific predictions, so they can prepare and take appropriate actions. A description of the current research investigations related to gaps in current knowledge will follow and then a summary.

Types of hydrometeorological hazards

Hydrometeorological hazards include a wide range of phenomena and can be generally thought to include storms, floods, droughts, and temperature extremes and their associate phenomena. Hydrometeorological hazards are a major part of what is called the climate. Climate is a broad term but in the minds of most people it is the major hydrometeorological events that play a critical part in defining the climate. The category of storms includes tropical cyclones, which are known in some regions as typhoons and in others as hurricanes; and higher-latitude, extra-tropical cyclones, including blizzards and heavy snowfalls which sometimes cause avalanches. In coastal regions, storms can result in storm surges resulting in high waves and temporarily high sea level leading to coastal flooding. Other storm examples are smaller-scale events such as tornadoes, thunderstorms, and heavy precipitation, sometimes causing flash floods. Warming events leading to rapidly melting snow or the breakup of ice jams on rivers can also result in flooding. Hazards can also result from significant temperature variations. Heat waves, together with reduced precipitation, can lead to droughts and wildfires. Cold spells create havoc for human health and some ecosystems, for example icing, black ice, frost damaged plants, wet snow and downed trees. Hydrometeorological conditions also can be a factor in other hazards such as air pollution, landslides, locust plagues, epidemics, and in the transport and dispersal of food, water, vector and rodent-borne diseases, toxic substances, and material from volcanic eruptions. Hydrometeorological hazards directly and indirectly impact human health.

The Center for the Research on the Epidemiology of Disasters (CRED) (Rodriguez et al., 2009) defines: meteorological disasters as "events caused by short-lived/small to mesoscale atmospheric processes (in the spectrum from minutes to days) (such as a storm)"; climatological disasters as "events caused by long-lived/meso to macroscale processes (in the spectrum from intra-seasonal to multi-decadal climate variability) (such as extreme temperature, drought and wildfire)"; and hydrological disasters as "events caused by deviations in the normal water cycle and/or overflow of bodies of water caused by wind set-up (such as flood and mass movement (wet)." Hydrometeorological hazards, as defined above (from UNISDR), include meteorological, climatological and hydrological hazards and disasters as defined by CRED.

Observed and projected changes in hydrometeorological hazards

The Intergovernmental Panel on Climate Change (IPCC) 2007 Fourth Assessment Report has concluded that the "warming of the climate system is unequivocal" (IPCC, 2007, p. 5). With a warming climate, unprecedented hydrometeorological extreme events can occur as the trend in the mean variable, such as temperature, leads to a situation beyond the previous range. For some variables there may be critical thresholds that cause hazardous conditions and these thresholds may be breached more frequently with the shift in the mean. Changes can also be caused by changes in the variability. With the observed warming there have been increases in the frequency and/or intensity of hydrometeorological hazards as tabulated in Table 1. The IPCC used the following terms to indicate the assessed likelihood, using expert judgment, of an outcome or a result: *Virtually certain* > 99% probability of occurrence, *Extremely likely* > 95%, *Very likely* > 90%, *Likely* > 66%, *More likely than not* > 50%, *Unlikely* < 33%, *Very unlikely* < 10%, *Extremely unlikely* < 5% (IPCC, 2007, Box TS.1, p. 3). With respect to the risks of extreme weather events, the IPCC, in 2007, found that responses to some recent extreme events reveal higher

Hydrometeorological Hazards, Table 1 Recent trends, assessment of human influence on the trend and projections for extreme weather events for which there is an observed late-twentieth century trend. (IPCC, 2007 – Table SPM.2. p. 8)

Phenomenon and direction of trend	Likelihood that trend occurred in late twentieth century (typically post 1960)	Likelihood of a human contribution to observed trend	Likelihood of future trends based on projections for twenty-first century using SRES scenarios
Warmer and fewer cold days and nights over most land areas	Very likely	Likely	Virtually certain
Warmer and more frequent hot days and nights over most land areas	Very likely	Likely (nights)	Virtually certain
Warm spells/heat waves. Frequency increases over most land areas	Likely	More likely than not	Very likely
Heavy precipitation events. Frequency (or proportion of total rainfall from heavy falls) increases over most areas	Likely	More likely than not	Very likely
Area affected by droughts increases	Likely in many regions since 1970s	More likely than not	Likely
Intense tropical cyclone activity increases	Likely in many regions since 1970s	More likely than not	Likely
Increased incidence of extreme high sea level (excludes tsunamis)	Likely	More likely than not	Likely

levels of vulnerability than found earlier. It is important to examine decadal statistics as it is difficult, if not impossible, to attribute a specific, single extreme event due to a changing climate. The impacts of an extreme event may also depend on antecedent conditions. For example, a heavy rainfall event that occurs after a long period of drought may create more of a hazard than situations without these antecedent conditions.

The IPCC projections, also in Table 1, are that there will be very likely more heat waves and heavy precipitation events and likely increases in intense tropical cyclone activity. The IPCC (2007) report notes higher confidence than in earlier assessments with respect to projected increases in droughts, heat waves, and floods, as well as their adverse impacts. They comment that the "altered frequencies and intensities of extreme weather, together with sea level rise, are expected to have mostly adverse effects on natural and human systems" (IPCC, 2007, Sect. (3.3.5).

The IPCC (2007) assessment was largely based on 2006 and earlier scientific publications. A new IPCC report "Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation" has been published IPCC (2012). This report is primarily focused on hydrometeorological hazards, their changes with climate and disaster risk reduction – climate change adaptation strategies, and will provide an authoritative update. Newer research has confirmed the role of human activities in the global hydrological and atmospheric moisture cycles (Stott et al., 2009; Willett et al., 2007) and short-duration extreme precipitation (Zhang et al., 2010). Extreme precipitation would be expected to increase at a rate higher than changes in mean precipitation due to the nonlinear relationship between moisture content and temperature (Pall et al., 2007; Kharin et al., 2007) but the relationships are complicated for both mid to higher-latitudes (Meehl et al., 2005) and the tropics (Emori and Brown, 2005).

As the ocean surface temperature increases, it is likely that there will be an increase in intense tropical cyclone activity (CCSP, 2008; Gillett et al., 2008; Wing et al., 2007; Elsner et al., 2008) with the strongest tropical cyclones becoming stronger. Associated rainfall is also expected to increase (Nolan et al., 2007; Knutson et al., 2008). Due to the large amount of the interannual variability, detectable increases in tropical cyclone intensities may not be clearly manifest for decades to come (Bender et al., 2010). Storms at mid to higher latitudes will also be influenced by changes in climate but average cyclone activity may not be expected to change much (Bengtsson et al., 2009).

The general definition of drought is "a period of abnormally dry weather sufficiently prolonged for the lack of precipitation to cause a serious hydrological imbalance" (Heim, 2002). Drought also has several alternative definitions depending on the perspective. A meteorological drought is defined in terms of the magnitude of precipitation deficit. An agricultural drought depends on root zone soil water balance and a hydrological drought is related to stream flow, lake and groundwater levels (Heim, 2002). The duration of the precipitation deficit is also important from the point of view of impacts (Nicholls and Alexander, 2007). Drought indices such as the Palmer Drought Severity Index (PDSI) (Palmer, 1965) or the Standard Precipitation Index (Lloyd-Hughes and Saunders, 2002) are often used due to the lack of direct measurements (Trenberth et al., 2007; Seneviratne et al., 2010). Extreme droughts have had extensive impacts (Kallis, 2008; Beniston, 2009; Burke et al., 2006; Alexander and Arblaster, 2009; Easterling et al., 2008; Wang et al., 2009). Heat waves, such as that in Europe in 2003,

are often related to drought (Fischer et al., 2007a, 2007b). In some regions, the changes in drought frequency have been difficult to document since one climate-induced change, the increase in precipitation, may be countering the tendency for more droughts (Easterling et al., 2007). There has also been more interannual variability in the Sahel drought in recent years and more spatial variations (Greene et al., 2009; Ali and Lebel, 2009). Projections on a regional basis are summarized in Christensen et al. (2007).

Global average sea level is now rising faster than earlier predictions (Copenhagen Diagnosis, 2009; Rahmstorf et al., 2007) such that by 2100, global sea level rise in a world of unmitigated greenhouse emissions may well exceed 1 m with the upper limit ~2 m (Note these quoted estimates exceed the 0.6 m given in the IPCC report). Sea level will also continue to rise for centuries after global temperatures have been stabilized, and several meters of sea level rise must be expected over the next few centuries. With increases in storm intensity, there will likely be higher precipitation and winds, leading to higher storm surges flooding coastal regions and risks of river flooding as well. Many low-lying coastal, river-delta megacities, already stressed by rapid population growth and economic, social, health, and cultural difficulties, are now increasingly vulnerable due to hydrometeorological hazards associated with climate change leading to increased risk of disasters that will affect not only the cities but the regions. An OECD report has ranked cities (Nichols et al., 2008) in terms of population and other exposures. The projected increases in hydrometeorological hazards with sea level rise will impact coastal megacities (Nichols et al., 2007).

Impacts of hydrometeorological hazards

A hazard, be it hydrometeorological or otherwise, is defined as a "potentially damaging physical event, phenomenon or human activity that may cause the loss of life or injury, property damage, social and economic disruption or environmental degradation." (UNISDR, 2009a) Hazards by themselves do not create disasters which are defined as a "serious disruption of the functioning of a community or a society involving widespread human, material, economic or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources" or alternatively the characteristic of a disaster is the sense of overwhelming the capacity of communities to respond, and cause "extensive loss or disruption to the physical, social and administrative infrastructure" of a nation (Paton and Johnston, 2006). Disasters actually are the result of the situation when a hazard impacts a vulnerable community, ecosystem, or other region, where a vulnerability is defined as the "conditions determined by physical, social, economic, and environmental factors or processes, which increase the susceptibility of a community to the impact of hazards." This leads to the formal definition of disasters as social phenomena which stem from interaction between two key elements: hazards–triggering agents stemming from nature, as well as from human activity–and vulnerabilities–susceptibility to injury or loss influenced by physical, social, economic and cultural factors (Alexander, 1997; Mileti, 1999; McEntire, 2001; Paton et al., 2001).

The impacts of hydrometeorological hazards are immense (McBean and Ajibade, 2009). The number of disasters impacting global society has been increasing rapidly from about 150 per year in the 1980s, to over 200 per year in the 1990s to almost 1 per day for the period 2000–2008 (Table 2) (Rodriguez et al., 2009). In 2008 the two most disastrous events were Cyclone Nargis with major impacts in Myanmar, and the Sichuan earthquake in China. During the period 2000–2008, 356 were hydrometeorological disasters compared to 36 geophysical disasters (Table 3) (Rodriguez et al., 2009). Annually, these hydrometeorological disasters affected 220 million people as victims (deaths plus people affected) and caused about $82B in damages. The hydrometeorological disasters were predominantly hydrological (54% of which 44% were floods) and meteorological (30% of which 27% were storms). Although these figures are staggering, both insurers and scientists expect that climate change will bring more frequent and intense extreme hydrometeorological hazards, potentially resulting in more costly disasters in years to come. "In view of continued global warming, we anticipate a long-term increase in severe, weather-related natural catastrophes." (Topics Geo, 2006).

One of the challenges for analyzing trends in disaster statistics is that organizations use different methodologies for tabulating the information (Sapir and Vos, 2009). For 2008, the Centre for Research on the Epidemiology of Disasters (CRED) recorded 354 natural disasters of which 322 were hydrometeorological with about 166 million

Hydrometeorological Hazards, Table 2 Number of hydrometeorologicaly related disasters by decade and per year (with number of geophysical for comparison) (Rodriguez et al., 2009)

	1900–1909	1910–1919	1920–1929	1930–1939	1940–1949	1950–1959	1960–1969	1970–1979	1980–1989	1990–1999	2000–2008

Per year (unit)	3	7	6	7	12	23	46	78	150	203	356
Geophysical	40	28	33	37	52	60	88	124	232	325	328

Hydrometeorological Hazards, Table 3 Average number of occurrences, victims and damages per year for period 2000–2008 for climatological, hydrological and meteorological and their total – of hydrometeorological origin, with statistics for geophysical events for comparison (Rodriguez et al., 2009)

	Occurrences (per year)	Number of Victims (Million per year)	Damages ($Billion per year)
Climatological	54	82	9
Hydrological	194	99	20
Meteorological	108	39	53
Total hydrometeorological	356	220	82
Geophysical	36	9	20

victims (people killed or affected) and economic costs exceeding US$ 104B. In contrast, Munich Re Data Service (Topics Geo, 2008) recorded a total of 750 disasters with the total cost of hydrometeorologicaly related events being US$ 134B. Although CRED and the MunichRe Data Service (NatCatService, 2010) recorded different disaster occurrences and economic losses, their ratios of hydrometeorological events to the total were about the same. Also, analyses of their data show similar rising trends (Gall et al., 2009; Rodriguez et al., 2009). With the upward trend with regard to the scope and magnitude of disaster impacts, it is important to note that the losses are highly influenced by the occurrence of "mega-disasters" affecting tens of millions of people and/or causing billion of dollars worth of economic damage. Topics Geo (2006) categorizes disasters on a scale of 1–6, with Category 5 events, called devastating catastrophes, causing more than 500 deaths and/or overall losses of more than $US 500 million, The number of these Category 5 events has increased from 5 to 15 events per year in the 1980s to 15–25 events per year in the period 1990–2005 to 28–41 events per year in the 2006–2008 period (2008 had 41 devastating catastrophes, the largest number ever). Between 1950 and 2009, 41% of disasters were due to meteorological hazards; 28% due to geophysical hazards; 25% due to hydrological hazards; and 6% due to climatological hazards such as droughts and heavy rains affected by El Nino. Overall losses (US$ 2,000B) are distributed similarly to the number of events but insured losses (about US$ 415B) are predominantly (80%) due to meteorological hazards (storms). This reflects the impacts of storms more on developed countries where there is extensive insurance compared to earthquakes that often happen with greater impact on people and uninsured property in the developing world. Although geophysical events are less frequent, they cause more of fatalities (53% of the two million fatalities) compared to 36% for the meteorological events.

Although all countries have been impacted by natural disasters, the relative impacts usually are larger in human lives in developing countries and larger in economic costs in developed countries (Mileti, 1999; Mizra, 2003). In highly developed countries, the average number of deaths per disaster is 23, whereas the number increases dramatically to about 150 deaths per disasters in medium and to over 1,000 deaths per disaster in less developed countries (Mutter, 2005). While the absolute dollar costs of disasters in highly-developed countries are large, the damage as a percentage of Gross Domestic Production (GDP) is much larger in the developing country (Handmer, 2003). Among the key findings and recommendations of the UN ISDR Global Assessment Report on Disaster Risk Reduction (2009b) were the following:

- Global disaster risk is highly concentrated in poorer countries with weaker governance.
- Weather-related disaster risk is expanding rapidly both in terms of the territories affected, the losses reported and the frequency of events.
- Climate change is already changing the geographic distribution, frequency, and intensity of weather-related hazards and threatens to undermine the resilience of poorer countries and their citizens to absorb and recover from disaster impacts.
- The governance arrangements for disaster risk reduction in many countries do not facilitate the integration of risk considerations in development.

The highest number of hydrometeorological disastrous events is most often recorded in Asia. Of the four category 6 catastrophes of 2008, for example, two were in Asia, one in the USA and one in the Caribbean. This trend is especially important due to the population density of the most vulnerable nations. An event in India or China is likely to affect more people than in one of the smaller, less densely populated nations since there is likely to be fewer inhabitants in any given site. However, the number of victims per 100,000 inhabitants list was led by Djibouti, Tajikistan, Somalia and Eritrea. This demonstrates that, in addition to population density and area of vulnerability, the economic ability of a nation to respond is an important factor in assessing the potential impact of any natural hazard. Developing nations often have minimal preventative measures and are unable to respond adequately in the immediate aftermath. Additionally, the attempt to recover from such events may be economically debilitating as well. For instance, the events in Myanmar and Tajikistan resulted in damages exceeding 20% of their Gross Domestic Production (GDP).

Disaster risk reduction

Historically, public policy in disaster risk reduction has been heavily concentrated on responding to the disasters after they have happened, reflecting a belief that disasters are unfortunate but random calamities beyond our control (Henstra and McBean, 2005). The present approaches used to address hazards and disasters are built around the key themes of traditional disaster management: mitigation (lessening or limitation of adverse impacts), preparedness (capacities to effectively anticipate, respond to, and recover from the impacts), response (services and public assistance during or immediately after a disaster), and recovery (restoration, and improvement where appropriate, of communities) (Paton and Johnston, 2006; Godschalk, 1991; Godschalk and Brower, 1985). While all four themes are necessary, most national disaster management plans focus on response and recovery. Primarily, governments are often more willing to put funding into response instead of prevention and preparedness because, while they must be seen to be responding to tragic events that have occurred, investments to prevent future events that may not occur are more politically risky. Further, developing countries are often limited to these strategies since while aid for response efforts is often available, funding for prevention measures is more difficult to obtain (UNISDR, 2005; Mileti, 1999). There will, unfortunately, always be need for response and recovery but the focus on disaster management is and should be shifting toward the inclusion of mitigation and preparedness efforts. Mitigation and preparedness both rely in substantial part on knowledge of what is or may happen – seeing the future.

Seeing the future: the role of scientific predictions

Prediction is used across the natural, environmental, social and economic sciences. "Prediction is a statement or claim that a particular event will occur in the future. Narrowing the sense of prediction it may be added that the place and time of event are known as well (Mesjasz, 2005)." The Oxford Dictionary defines the verb to predict as to "foretell, prophesy." The noun *forecast* is defined as: "conjectural estimate of something future, especially, of coming weather." *Conjecture* is the "formation of opinion on incomplete grounds." The sense of estimate, future and incomplete information is certainly consistent with the sense of prediction of natural and human systems. Prediction is the process of looking ahead on the basis of incomplete knowledge of the present and with incomplete understanding of how the system works.

Prediction can play a role in better planning for the future to reduce the impacts of hydrometeorological hazards (McBean, 2007). For natural physical systems including hydrometeorological systems, there are sets of physical "laws" such as those of Newton that are well tested and provide a basis for prediction. For weather forecasting, "progress in understanding and predicting weather is one of the great success stories of twentieth century science" (National Research Council, 1998). The skill of weather forecasts on all scales has been improving (Jolliffe and Stephenson, 2003; Nichols, 2001). Simonovic (2009) has recently reviewed flood modeling approaches. Predictions of the occurrence of other geophysical hazards, such as earthquakes, show increasing skill but due to the complexities of the relationships and the difficulties in observing the details of the present state, it is not yet possible to make predictions of the timing and magnitude of an event with high skill (Nigg, 2000, pp. 135–156).

Since disasters result from the intersection of hydrometeorological events and vulnerable communities, there is also need for predictions of human actions which is often more difficult. The World Summit on Sustainable Development (WSSD, 2002) recommended that an integrated, multi-hazard, inclusive approach be taken to address vulnerability, risk assessment and disaster management, and that among the necessary actions was to strengthen early warning systems. The World Conference on Disaster Reduction (UNISDR, 2005) called for "people-centred early warning systems" to be a key part of the response to the tragedies of natural hazards. The international community has clearly identified early-warning systems, which must be based on predictions, as a key response to global concerns.

Hydrometeorological events can occur on time scales from minutes to days to seasons to decades to centuries. There is a general relationship between physical and temporal scales of the events. Small physical-scale events generally have short lifetimes and larger events last longer. Thus a tornado, very small-scale event, is formed, travels over a short distance, and then disappears in less than a few hours. Storms that generate high winds and precipitation amounts typically cover a 100 km area and track over half a continent or more and last for days. The accuracy of prediction of hydrometeorological hazards will be dependent on the cumulative uncertainties in each component of the prediction system; this has been referred to as the "cascade of uncertainty" (IPCC, 2004). For floods, the skill depends on first the skill of the weather forecast and then of the hydrological prediction system (McBean, 2002). The skill of predictions (Murphy, 1997) depends on the characteristics of the phenomenon. There are several types of predictions of hazardous natural events.

Deterministic prediction uses information on the observed state of the system at an initial time to predict future successive states to some future time. The sequence events are "determined," to the extent the predictive model has skill. The coupled atmosphere-water-ocean system is what mathematicians call a dynamic, non-linear, chaotic system in which small differences in the initial state, time t_o, amplify with time (Lorenz, 1993, pp. 102–110) and this sets the limit of system predictability since the initial state cannot be known exactly. For small-scale, short-lived phenomena like tornadoes and thunderstorms, skilful deterministic predictions are only for minutes to hours. However, for major weather systems, there is skill for several days although it decreases as the length of the forecast increases. Lorenz (1993) has demonstrated that the theoretical limit for deterministic weather predictions is about 2 weeks.

Beyond the deterministic limit, predictions of statistical quantities or probabilities are possible using statistical

approaches based on the longer deterministic prediction timescales of the components of the coupled atmosphere-ocean system that naturally change more slowly than others. Ensemble prediction technique is now being widely used in weather predictions, for days through seasons, to improve skill and also to provide the user with information on the probable skill of the prediction. Since tornadoes are embedded in and largely determined by the large-scale weather system, a probabilistic forecast can be made that gives an increased risk of a tornado for the next day, then clarifies and refines the forecast as the risk becomes clearer and eventually a deterministic forecast can be made. Prediction of these small-scale phenomena and their possible changing characteristics with climate must be approached by risk management techniques (McBean, 2005). The large-scale features of the atmosphere adjust more slowly than the smaller-scale cloud-weather systems, and the oceans, due to their large thermal capacity, adjust much more slowly than the atmosphere. Thus, one can use this information to extend beyond the atmospheric deterministic limit to provide predictions of the statistical occurrence of events. The ensemble approach is now widely used in seasonal predictions. These could be that a region will be warmer or colder than "normal" or wetter with risk of floods, or drier with risk of drought. This provides useful information but does not predict the sequence of events over the prediction period just that more warm days will occur, for example. Some skill in predictions for several seasons is possible for some events. This approach of cascading forecasts and increasing clarity of the risk of a hazardous event needs to be part of the prediction system for reducing the impacts of natural hazards. The concepts of a seamless prediction system are outlined in Shapiro et al. (2010).

One of the important challenges for national meteorological-hydrological services (NMHS) is to develop better their prediction skills and their approaches to risk management, recognizing there will always be some uncertainty in their predictions. Understanding risk communications and the relationship between warnings of risk, risk communication and society's response to risk is essential when dealing with hydrometeorological hazards (Leiss, 2001). Scientific assessment of risk and the public perception of risk are probably different, unless a good job is done of risk communication, connecting the two. Predictions need to better translated, including the statements of probabilities and risk assessment, into understandable terms. There is need to understand better how the public sees a risk, especially its qualitative dimensions (Descurieux, 2010).

Building capacity for knowledge-based disaster risk reduction

Of particular concern is the fact that capacity building for disasters has not been implemented in all nations. There are many barriers that account for this trend. First, as the Global Assessment Report on Disaster Reduction- 2009 asserts, disaster risk is "highly concentrated in poorer countries with weaker governance." (UNISDR, 2009b). Other barriers in the design and implementation of strategies for capacity development include how priorities should be set, what role each level of government should play, how strategies should be coordinated and how outcomes should be evaluated. Finally, the substantial amount of uncertainty surrounding hazards, vulnerability and the prediction of future events, proves to be a significant barrier to global capacity building (McBean, 2009b; Burton et al., 1993). The impacts of a changing climate or disaster events are largely determined by a society's or community's vulnerability; a function of its exposure to climate and other hazards, its sensitivity to the stresses they impose, and its capacity to adapt to these stresses. Vulnerability can be reduced through actions to minimize exposure, reduce the sensitivity of people and systems, and strengthen the community's adaptive capacity (McBean and Rodgers, 2010). Each of these actions requires an integrated approach and their implementation will necessitate surmounting barriers and constraints.

Research investigations to support disaster risk reduction

On December 22, 1989, the United Nations General Assembly (1989) declared the decade of the 1990s as the International Decade for Natural Disaster Reduction. The objective of the International Decade for Natural Disaster Reduction was to "reduce through concerted international action, especially in developing countries, the loss of life, property damage and social and economic disruption caused by natural disasters such as earthquakes, windstorms, tsunamis, floods, landslides, volcanic eruptions, wildfires, grasshopper and locust infestations, drought and desertification and other calamities of natural origin." Among the goals were: "(c) To foster scientific and engineering endeavours aimed at closing critical gaps in knowledge in order to reduce loss of life and property;" and "(e) To develop measures for the assessment, prediction, prevention and mitigation of natural disasters through programmes of technical assistance and technology transfer, demonstration projects, and education and training, tailored to specific disasters and locations, and to evaluate the effectiveness of those programmes." This was the first major international research program focussing on disaster risk reduction, including that due to hydrometeorological hazards. At the World Conference on Natural Disaster Reduction, Yokohama, 1994 (UNISDR, 1994), hydrometeorological hazards and the need for research were a focus of the resulting Yokohama Strategy and Plan of Action for a Safer World.

The World Climate Research Programme was originated in 1980 and is now co-sponsored by the International Council for Science (ICSU), the World Meteorological Organization (WMO) and the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO). The two overarching objectives of the WCRP are: *to determine the*

predictability of climate; and *to determine the effect of human activities on climate*. To achieve its objectives, the WCRP adopts a multidisciplinary approach, organizes large-scale observational and modeling projects, and facilitates focus on aspects of climate too large and complex to be addressed by any one nation or single scientific discipline. One of the challenges in climate prediction is in improving forecasts of climate extreme events with time-scales from several weeks, to seasons, years and even decades. Statistics of extreme events such as their probability of occurrence, duration, and intensity are very important for assessing the risks of hydrometeorological hazards. Linking the ongoing research on global energy and water cycles, the cryosphere and climate variability, the WRCP has identified and is now focusing on these extreme events.

Whereas the World Climate Research Program has focussed on hydrometeorological hazards within the climate time–scale context, the new World Weather Research Programme of the World Meteorological Organization is addressing these events on the weather time–scale. The Program is working to advance society's ability to cope with high impact weather through research focused on improving the accuracy, lead time and utilization of weather prediction. A major component of WWRP is the THORPEX (THe Observing Research and Predictability Experiment) program which is a global international research program focusing on high-impact weather with the research priorities of addressing: Global-to-regional influences on the evolution and predictability of weather systems; Global observing system design and demonstration; Targeting and assimilation of observations; and societal, economic, and environmental benefits of improved forecasts. The scope of the research includes mesoscale weather forecasting; nowcasting; weather modification assessment; tropical meteorology; and verification research. The primary research strategy is to promote, initiate, coordinate or manage: field campaigns, long-term research projects, and programs that are well suited for international collaboration and are designed to advance the underlying science of weather forecasting, to use research to advance forecasting techniques and to enhance the utilization of weather information; the establishment of archive centers that bring together international data sets that would not be easily accessible through other means and to set up reference datasets that form the basis for testing, comparing, and improving modeling and data assimilation strategies; end-to-end Research and Development Projects (RDPs) to advance understanding of weather processes, improve forecasting techniques and increase the utility of forecast information with an emphasis on high-impact weather; and Forecast Demonstration Projects (FDPs) to evaluate research techniques, tools, and concepts in an operational setting to facilitate the transfer of research results into operational practice.

When the International Council for Science (2003) undertook a Priority Area Assessment on Environment and its Relation to Sustainable Development and reviewed strategic options for future ICSU activities related to environmental research, it was concluded that research on "Natural and human-induced hazards" was one of four possible new fields of work. The resulting ICSU Planning Group concluded that, "despite all the existing or already planned activities on natural hazards, an integrated research programme on disaster risk reduction, sustained for a decade or more and integrated across the hazards, disciplines and geographical regions, is an imperative. The value-added nature of such a programme would rest with the close coupling of the natural, socio-economic, health and engineering sciences."

As a result a new research program Integrated Research on Disaster Risk – addressing the challenge of natural and human-induced environmental hazards (IRDR) was created (McBean, 2009a; ICSU, 2008) with the co-sponsorship of ICSU, the International Social Sciences Council and the United Nations International Strategy for Disaster Reduction (ISDR). The Science Plan of the proposed IRDR Programme would focus on hazards related to geophysical, oceanographic, and hydrometeorological trigger events; earthquakes; volcanoes; flooding; storms (hurricanes, typhoons, etc.); heat waves; droughts and fires; tsunamis; coastal erosion; landslides; aspects of climate change; space weather; and impact by near-Earth objects. The effects of human activities on creating or enhancing hazards, including land-use practices, would be included. The IRDR Programme would deal with epidemics and other health-related situations only where they were consequences of one or more of the aforementioned events. Technical and industrial hazards and warfare and associated activities would not be included per se. The focus on risk reduction and the understanding of risk patterns and risk-management decisions and their promotion would require consideration of scales from the local through to the international level.

Focusing on disaster risk reduction, the research will be aimed at integrated risk analysis, including consideration of relevant human behavior and decision-making processes in the face of risk. The IRDR is guided by three broad research objectives:

1. Characterization of hazards, vulnerability, and risk; with sub-objectives: identifying hazards and vulnerabilities leading to risks; forecasting hazards and assessing risks; and dynamic modeling of risk.
2. Understanding decision making in complex and changing risk contexts with sub-objectives: identifying relevant decision-making systems and their interactions; understanding decision-making in the context of environmental hazards; improving the quality of decision making practice.

Reducing risk and curbing losses through knowledge-based actions. The IRDR research program fulfills the need for an international, multidisciplinary, and an all hazard research program emphasized in the Hyogo Framework for Action. The added value of such a research program lies in its coupling of natural sciences' examination of hazards with socio-economic analysis of vulnerability and mechanisms for engaging the policy decision-making process. The IRDR will draw upon the expertise and scientific outputs of many

partners in research. Specifically, it is hoped that IRDR will be able to catalog and analyze successful capacity building systems and strategies for resilient communities in order to benefit those threatened by climate-related hazards.

Summary

Hydrometeorological hazards, mainly floods, storms, and droughts, are the trigger mechanism for most of the "natural" disasters around the world. These events affect hundreds of millions of people and create major economic and social hardships. Scientific research has led to much improved knowledge of these events so they can, with some confidence, be predicted in the short term. With a changing climate, the characteristics of these hazards are changing, mostly in ways to cause more impacts, and these changes raise major scientific challenges that, while being addressed, still need more emphasis. Further, since the disasters result from the impact of a hazard on vulnerable communities and systems, there is a strong need for an integrated approach to understanding and addressing these hazards, vulnerabilities and resultant disasters to reduce the impacts in the future.

HYOGO FRAMEWORK FOR ACTION 2005–2015

Pedro Basabe
United Nations Complex, Nairobi, Kenya

Definition

Resilience: "The ability of a system, community, or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions." UNISDR. Geneva 2009.

Introduction

Every year, millions of people, their livelihood, and assets are affected by droughts, floods, cyclones, earthquakes, volcanic eruptions, wildland fires, and other hazards. In early 2010, the earthquakes in Haiti, Chile, China, caused more than 300,000 casualties, and the volcanic eruption of Iceland's Eyjafjallajökull volcano paralyzed the air traffic and trade in Europe for almost 1 week. This reminds all how vulnerable people are to natural hazards and related disasters, and the respect that society needs to give to nature and its related hazardous phenomena.

Increased population densities, environmental degradation, and global warming adding to poverty will make the impacts of natural hazards even worse.

Whereas many know the human misery and crippling economic losses resulting from disasters, what few realize is that this devastation can be prevented through comprehensive disaster risk reduction (DRR) policies, mechanisms, programs, and measures on the ground.

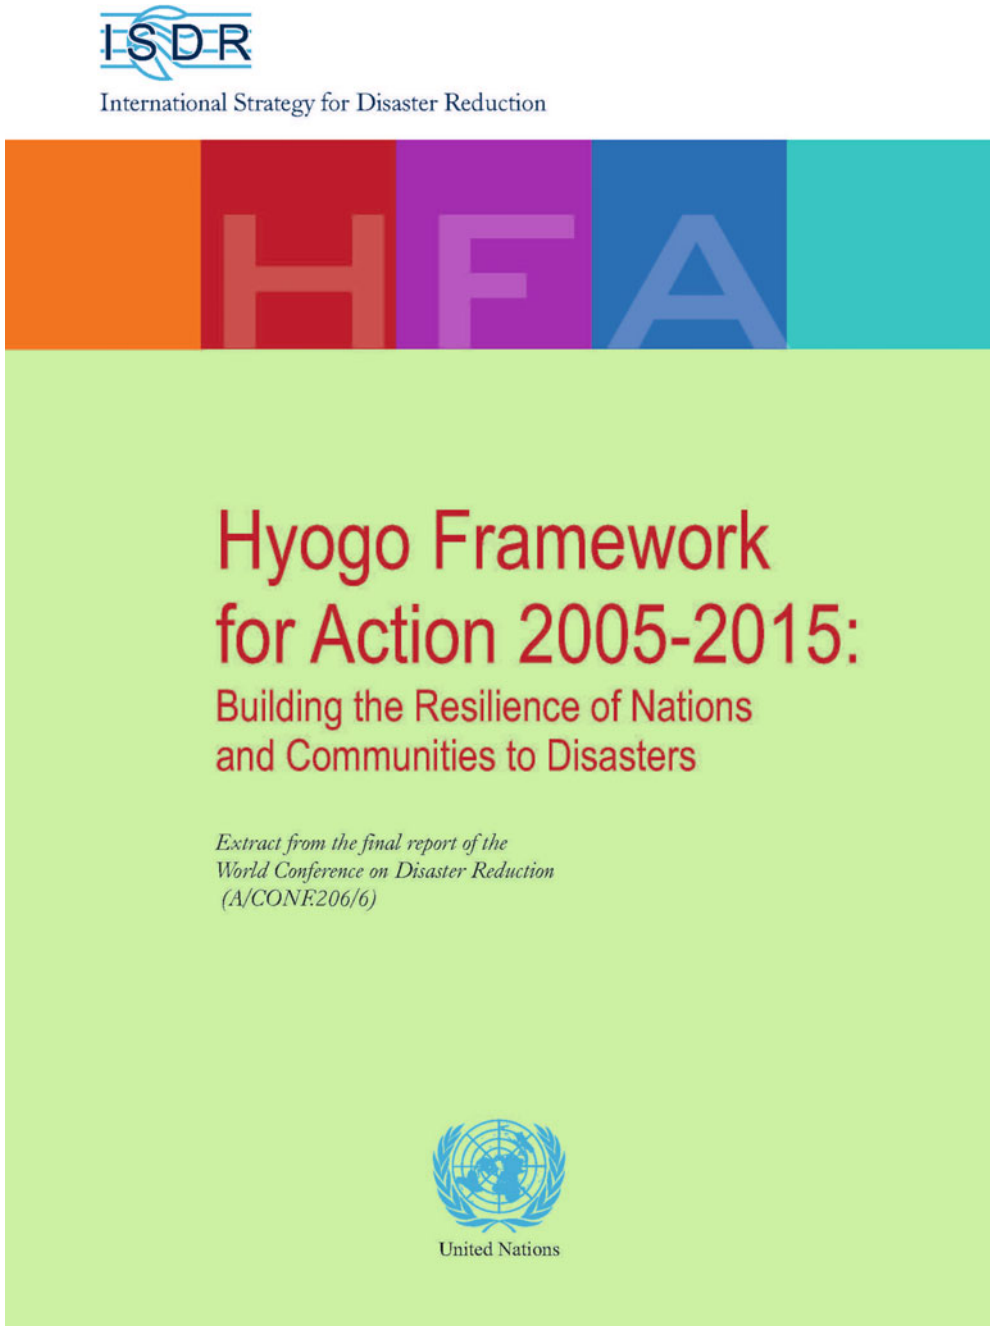
This contribution summarizes the agreed framework to build the resilience of nations and communities to disasters as well as existing strategy and program for DRR in Africa which includes strategic areas of intervention, major areas of activities, expected results, and indicators to monitor progress.

Framework for disaster risk reduction

Governments around the world have committed to take action to reduce disaster risk, and adopted, in January 2005 at the World Conference on Disaster Reduction held in Kobe Japan, a guideline to reduce vulnerabilities associated with natural hazards, called the Hyogo Framework for Action (HFA). This was accomplished under the auspices of the United Nations International Strategy for Disaster Reduction (UNISDR).

The Hyogo Framework is the key instrument for implementing disaster risk reduction, it assists the efforts of nations and communities to become more resilient to, and cope better with, the hazards that threaten their development gains.

Its overarching goal is to build resilience of nations and communities to disasters, by achieving substantial reduction of disaster losses by 2015 – in lives, and in the social, economic, and environmental assets of communities and countries.

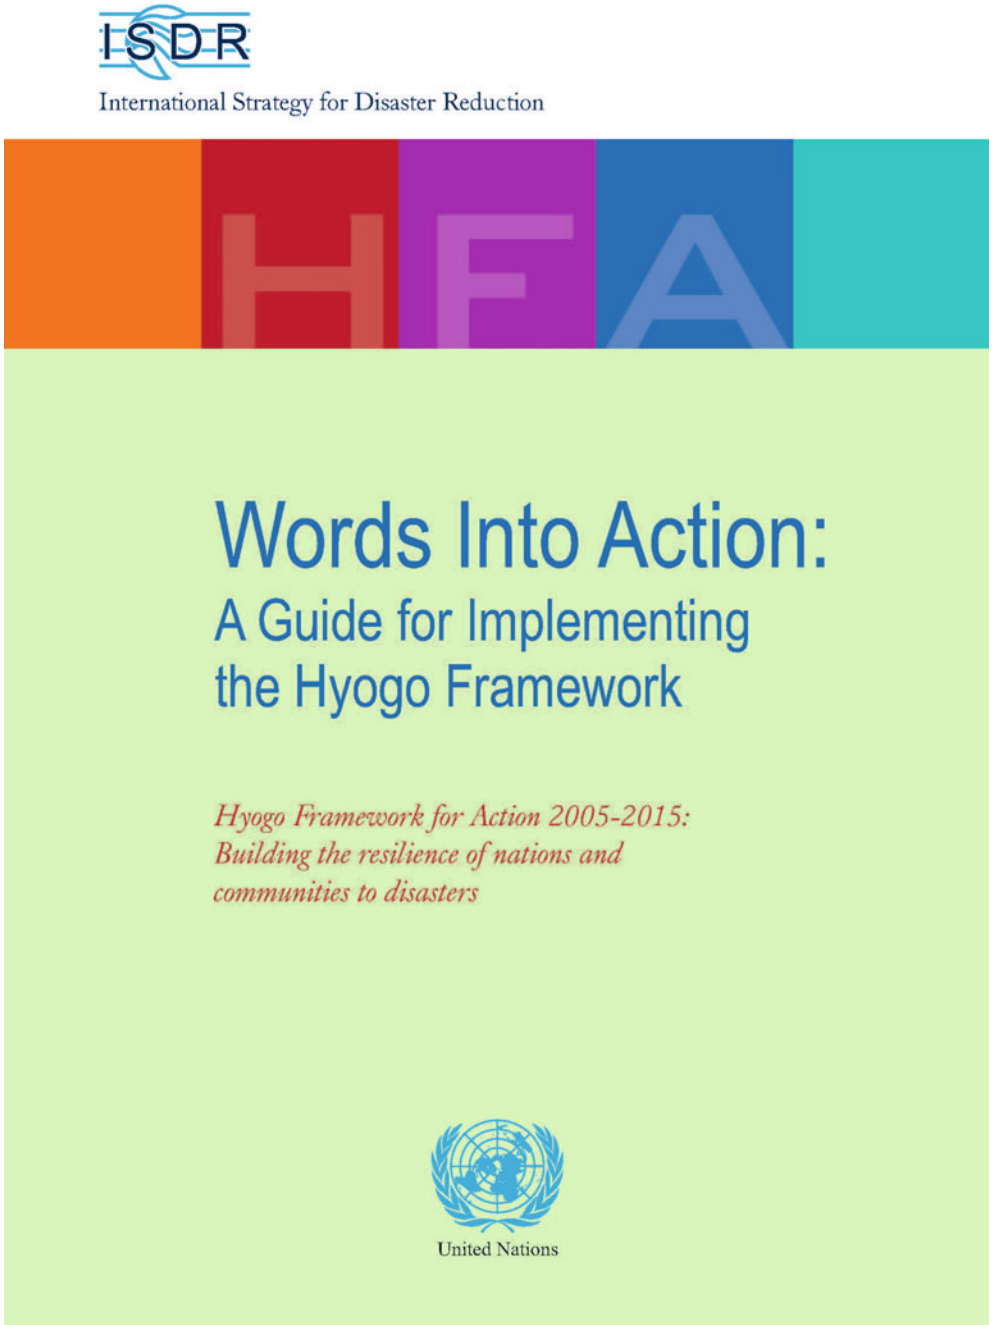


To attain this expected outcome, the HFA has three strategic objectives (Figure 1):

1. The more effective integration of disaster risk considerations into sustainable development policies, planning, and programming at all levels, with a special emphasis on disaster prevention, mitigation, preparedness and vulnerability reduction.
2. The development and strengthening of institutions, mechanisms, and capacities at all levels, in particular at the community level that can systematically contribute to building resilience to hazards.
3. The systematic incorporation of risk reduction approaches into the design and implementation of emergency preparedness, response, and recovery programs in the reconstruction of affected communities.

The HFA offers the following five areas of priorities for action, guiding principles, and practical means for achieving disaster resilience for vulnerable communities in the context of sustainable development.

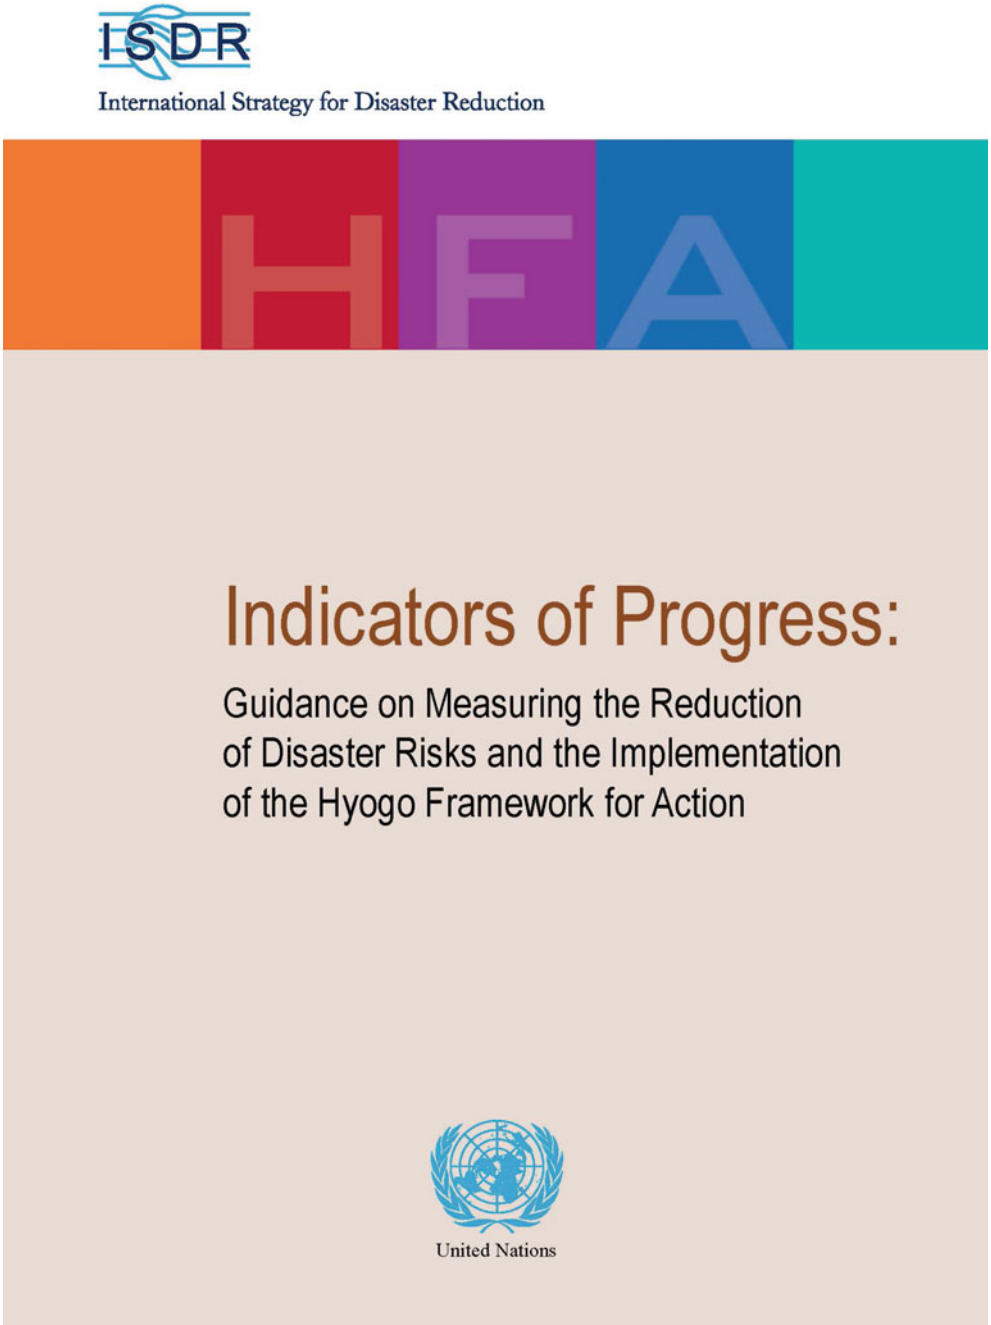
1. Ensure that disaster risk reduction is a national and a local priority with a strong institutional basis for implementation.
2. Identify, assess, and monitor disaster risks and enhance early warning.
3. Use knowledge, innovation, and education to build a culture of safety and resilience at all levels.
4. Reduce the underlying risk factors.
5. Strengthen disaster preparedness for effective response at all levels.



In their approach to disaster risk reduction, States, regional and international organizations, and other actors concerned should take into consideration the key activities listed under each of these five priorities and should implement them, as appropriate, to their own circumstances and capacities.

Hyogo Framework for Action 2005–2015, Figure 1 Hyogo framework for action 2005–2015: building the resilience of nations and communities.

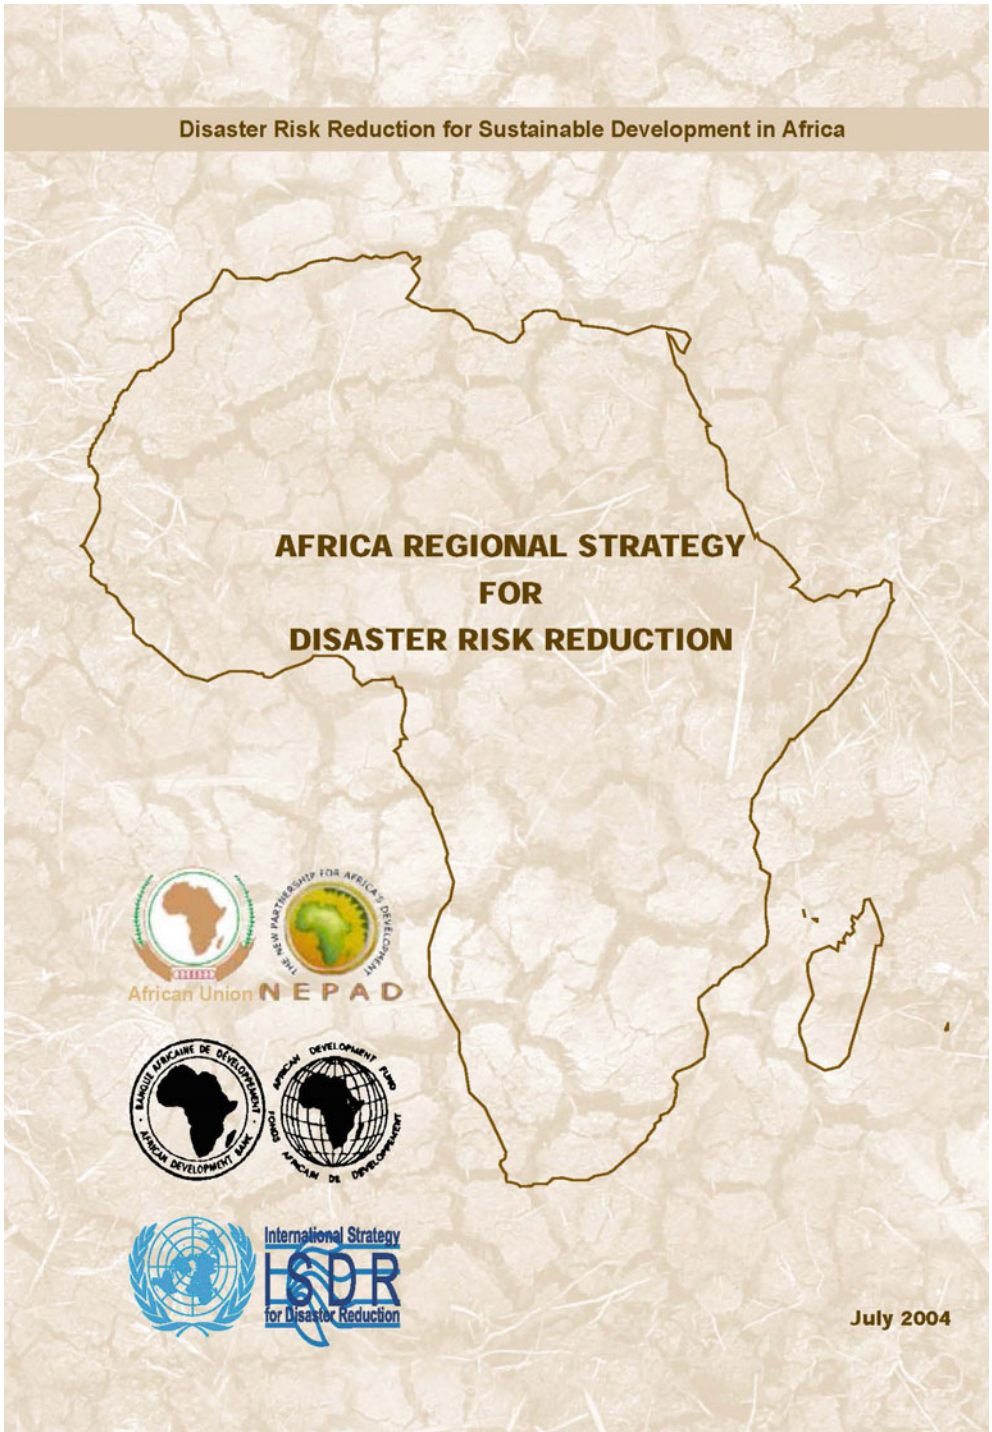
Since the adoption of the HFA, many global, regional, national, and local efforts have addressed disaster risk reduction more systematically. The UNISDR has facilitated guidelines, indicators, and a number of good practices, and promote implementation at all levels (Figure 2). Nevertheless much remains to be done.



One of the key achievements has been the establishment by Member States of multisectoral national platforms to coordinate disaster risk reduction programs and activities in countries. Many regional and subregional intergovernmental organizations have adopted strategies and programs for disaster risk management (Figure 3).

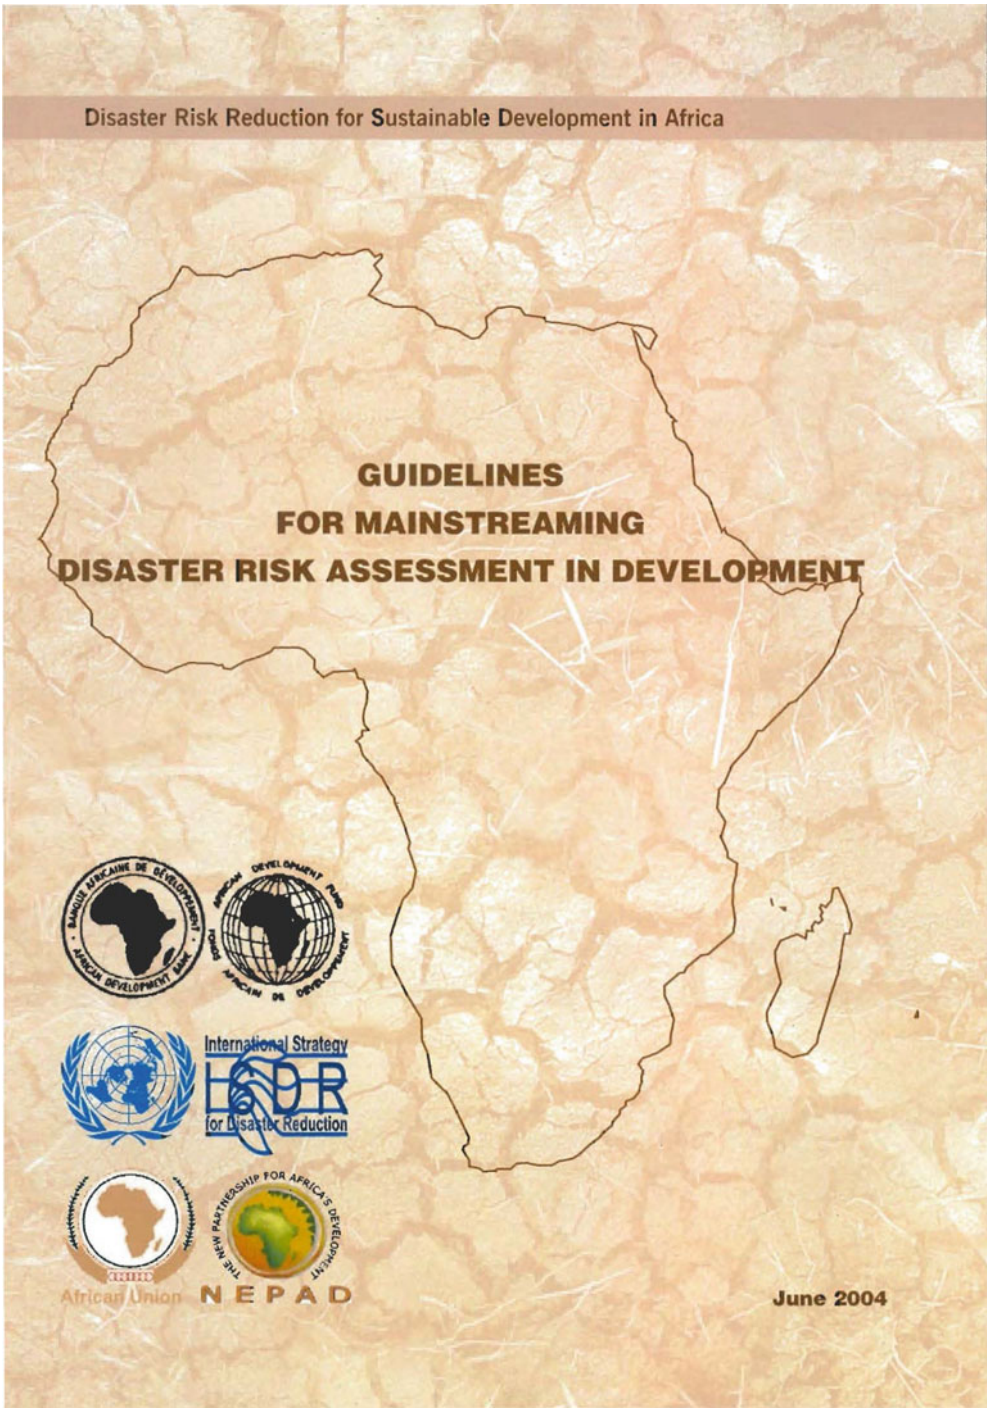
Hyogo Framework for Action 2005–2015, Figure 2 Words into action: a guide for implementing the hyogo framework.

The Africa strategy and program of action for disaster risk reduction (DRR)



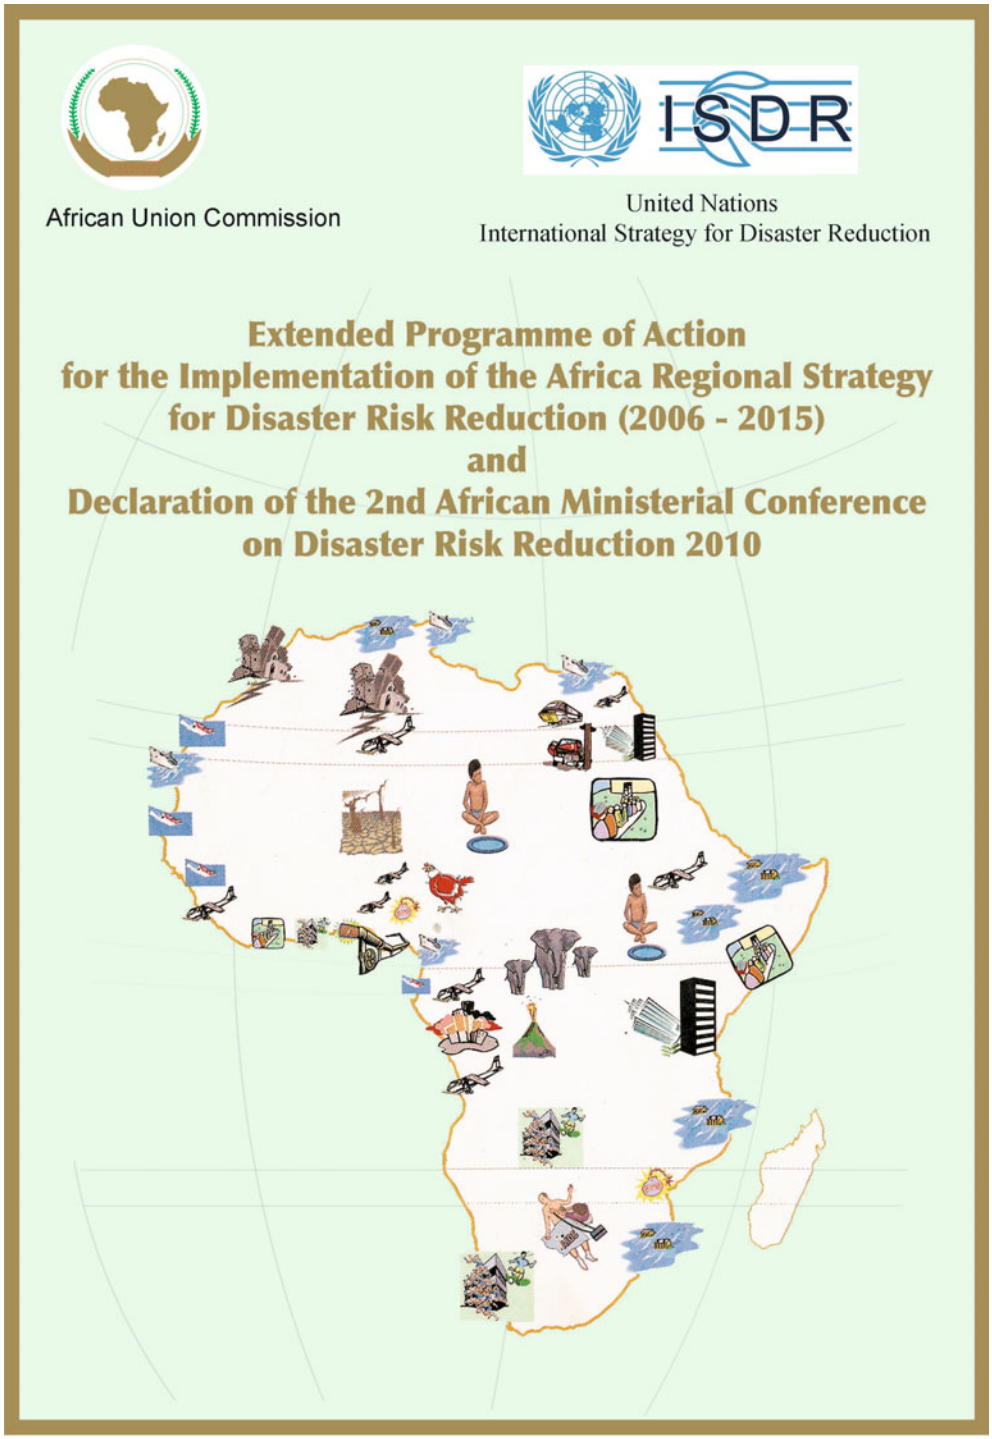
Africa was the first continent that showed political commitment to disaster risk reduction by formulating in 2004 the "Africa Regional Strategy for Disaster Risk Reduction," "Programme of Action 2005–2010" for its implementation and "Guidelines for Mainstreaming Disaster Risk Assessment in Development," under the aegis of the African Union Commission, the NEPAD Secretariat, African Development Bank, and with support of the UNISDR and UN partners (Figures 4, 5, and 6). These documents were officially adopted at the First African Ministerial Conference on DRR in Addis Ababa in 2005.

Hyogo Framework for Action 2005–2015, Figure 3 Indicators of progress: guidance on measuring the reduction of disaster risks and the implementation of the hyogo framework for action.



Africa has also advanced the implementation of the HFA and the Africa Strategy and Programme of Action at the subregional level. Several Regional Economic Communities (RECs) have engaged with DRR issues.

The Intergovernmental Authority on Development (IGAD), the Southern African Development Community (SADC), The Economic Community of Central African States (ECCAS), the Economic Community of West African States (ECOWAS), and the East African Community (EAC) and the Indian Ocean Commission (IOC) have developed strategies, policies, or programs for disaster risk reduction based on the priorities for action of the HFA and the Africa Regional Strategy for DRR. There have also been initiatives for South-South cooperation to build on successful experiences from across the region.



Hyogo Framework for Action 2005–2015, Figure 4 Africa regional strategy for disaster risk reduction.

In addition, specialized subregional institutions such as the IGAD Climate Prediction and Applications Centre (ICPAC), the Southern African Development Community's Climate Services Centre (SADC CSC), the AGRHYMET Regional Centre (ARC), and the African Centre of Meteorological Application for Development (ACMAD) are responding to a major regional and global challenge through enhanced services for DRR and climate change adaptation.

Hyogo Framework for Action 2005–2015, Figure 5 Guidelines for mainstreaming disaster risk assessment in development.

At the national level, governments in Africa have moved forward with the implementation of the HFA priorities for action and related regional objectives. Until the end of 2011, 35 countries have established or strengthened National Platforms for DRR or similar coordinating mechanisms. Several of them are working to develop legal frameworks and national plans or have included DRR topics in National Poverty Reduction Strategic Papers (PRSPs) and considered linkages between Climate change and DRR in the National Adaptation Programmes of Action

Hyogo Framework for Action 2005–2015, Figure 6 Extended program of action for the implementation of the Africa regional strategy for disaster risk reduction (2006–2015).

(NAPAs). More specifically, six African countries are working in multiyear strategic planning with UN assistance, including disaster risk management (Figures 7 and 8).

At the Second Africa Ministerial Conference held in April 2010 in Nairobi, Kenya, it was agreed to revise and extend the "Africa Programme of Action for the Implementation of the Africa Strategy for Disaster Risk Reduction till 2015 and better align with the HFA.

The extended Africa Programme of Action considers emerging challenges and the most frequent natural

hazards in Africa, such as drought and floods currently more frequent due to climate change factors and growing vulnerability. The program defined concrete activities, expected results and indicators to monitor progress.

Ministers also agreed to accelerate the implementation of the African Strategy and Programme of Action, including the officialization of mechanisms at national, subregional, and regional level to support implementation and concrete recommendations to invest in DRR and carry out systematic activities (Figure 9).

Extracts of the Africa ministerial declaration on DRR, 2010

Recommendation 7:

To strongly urge Member States to increase their investments in disaster risk reduction through the allocation of a certain percentage of their national budgets and other revenue dedicated to disaster risk reduction and report to the next Ministerial Conference, considering other related African Ministerial resolutions;

Recommendation 8:

To call upon development and humanitarian partners to ensure that disbursement of one percent (1%) of development assistance and ten percent (10%) of humanitarian assistance, in line with the Chair's Summary of the Second Session of the Global Platform, supports disaster risk reduction, preparedness and recovery, including from violent conflicts and/or severe economic difficulties;

Recommendation 12:

To call upon Member States to undertake vulnerability assessments of schools, health facilities and urban centres, and develop and implement plans to ensure their safety and resilience;

Hyogo Framework for Action 2005–2015, Figure 9 A man carts a precious drum of water through a sandstorm in Tillaberi region in southwestern Niger © Jaspreet Kindra/IRIN.

Under priority one:

4. *Compared with 2005 baseline, an increased number of countries have DRR in their PRSPs, NAPAs, and other relevant development plans*.

Under priority two:

3. *At least 2 RECs have sub-regional hazard risk early warning systems and protocols for sharing such early warning information with countries*.
4. *Number of cities with policies and/or strategies on Safer Cities and multi-dimensional vulnerability reduction*, etc., etc.

Under priority four:

8. *Compared with the 2005 baseline, an increased number of countries with plans to ensure the safety of schools and hospitals*.

HYPOCENTER

Maurice Lamontagne
Natural Resources Canada, Ottawa, ON, Canada

Synonyms

Earthquake focus; Focal point

Definition

A point beneath the Earth's surface where the vibrations of an earthquake originates and which corresponds to the location where the motion on a fault surface starts. The focal depth of earthquake hypocenters may vary from the surface down to nearly 700 km in subduction zones.

Discussion

Earthquake magnitude, and more precisely the Moment Magnitude, is function of the amount of slip and area of

the fault surface that ruptures during an earthquake. For small earthquakes, such as magnitude 4 or less, or for earthquakes displayed on maps and cross-sections at a regional scale, the hypocenter is essentially a point with three coordinates (latitude, longitude, and focal depth). As the magnitude increases, the earthquake rupture is no longer a point but is rather a surface. In this latter case, the hypocenter is defined as the point where the rupture started.

The traditional method used to calculate the earthquake hypocenter is similar to that used for determining the epicenter, that is, by triangulation of epi- or hypo-central distances from recording stations. These distances are derived from arrival times of seismic phases assuming a velocity model for the seismic phases. The simplest method to calculate these distances relies on the difference between the arrival times of the S-wave and the P-wave at each station. The philosophy behind calculating an epicenter versus hypocenter is similar, the main exception being that the third dimension (i.e., the focal depth) is also considered in the triangulation.

To calculate the location of an earthquake, one has to determine the optimum values of four earthquake parameters: the latitude, the longitude, the depth of the hypocenter, and the time of occurrence of the event. The best estimates of these parameters are those that minimize the differences between the observed and the calculated arrival times (i.e., the residuals) for each phase recorded at seismograph stations (Kissling, 1988). The focal depth, essential to the calculation of a hypocenter, can also be calculated or estimated by other methods. A traditional one is to recognize reflected phases in teleseismic records of an earthquake, such as the pP phase (P phase reflected off the surface in the region of the epicenter) (Kulhánek, 2002). This can also be done for local earthquakes recorded at regional distances if intracrustal phases can be recognized or their arrival times measured. For local earthquakes, it is advisable to use near-field recordings of P and S phases and find the solution that minimizes the residuals (time difference between the recorded phase and the estimated phase assuming a given hypocenter and origin time). Crustal phases and the modeling of surface waves can also provide estimates of focal depths (Kulhánek, 2002). The presence of Rayleigh waves can indicate a near surface (less than 15 km depth) for a small earthquake (Kulhánek, 2002). Finally, macroseismic data can be used to infer focal depths (Musson and Cecić, 2002).

ICE AND ICEBERGS

Norm Catto
Memorial University of Newfoundland, St. John's, NL, Canada

Definition

An iceberg is a floating mass of ice.

Discussion

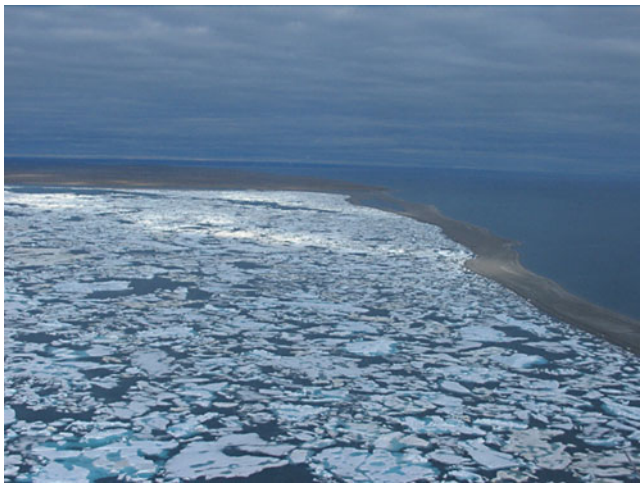
Ice poses hazards to mariners in three ways: as floating sea ice, icebergs, and riming. Floating ice and icebergs continue to pose hazards, despite advances in meteorological and ice forecasting, radar, and communication. Since the sinking of *Titanic* in 1912, more than 500 ice–ship collisions have occurred in the North Atlantic. Worldwide, 5–10 collisions occur annually.

Sea ice

Floating sea ice poses a hazard to ship traffic in several shipping lanes, including the North Atlantic, Arctic, and Southern Oceans. Sea ice is composed of freshwater, formed from surface freezing in coastal areas and embayments, ice lifted by waves and tides from beaches, and pieces which break off (calve) from glaciers and ice shelves that reach tidewater. Sea ice gradually accumulates throughout the winter. Although some areas of the Arctic and Antarctic support multiyear ice, which have survived the previous summer, ice which poses a hazard to mariners is dominantly single-year. The hazard is thus at its greatest from midwinter towards the end of winter and early spring, where the maximum amount of ice has accumulated and has moved toward the shipping lanes. Sea ice transported by currents flowing toward the Equator, notably the Labrador Current off eastern Canada, may extend more than 1,000 km seaward. In this area, the maximum southern extent typically is reached in early March, with ice extending to 44°N. Sea ice in this area may require the services of icebreakers to keep shipping lanes clear. Sea ice typically recedes from the northern tip of Labrador, Cape Chidley, in early July, opening Hudson Strait for navigation by vessels plying the Churchill (Manitoba, Canada)–Europe grain shipping route. The autumn sea ice expands southward to close off Hudson Strait to navigation in September.

For northern and Arctic coastal communities, the development of sea ice is critical for winter transportation and subsistence hunting. Unexpected variations in ice thickness, or breakup due to strong wave action, can pose hazards for travelers. Climate warming has resulted in inconsistencies in the timing, persistence, and thickness of sea ice in many Arctic areas. Open leads (*polyna*; *ashkui*) present in coastal areas can also pose hazards for travelers, although they are also suitable areas for harvesting fish and marine mammals.

Icebergs



Icebergs are composed of freshwater generated from calving of glaciers, which reach tidewater in the Arctic and Antarctic, in addition to isolated glaciers in mountainous coastal areas.

Icebergs are concentrated by the major ocean surface currents. In southernmost Davis Strait, one of the major areas of iceberg concentration, iceberg numbers have varied between 1,800 and 2,000 annually since 1990. Traveling with velocities of 1–4 km/h, icebergs can persist for several years from the point of calving, and reach latitudes of 40°N or S. However, icebergs melt rapidly in water warmer than 2°C. An iceberg 40 m high above the water line and 100 m long (approximate volume 2,000,000 m^3 and mass approximately 10 million ton) will completely ablate in 24 days in 2°C water, and requires only 15 days in 4°C water. Such large icebergs make up approximately

Ice and Icebergs, Figure 1 This iceberg drifted south to St. John's, NL, Canada.

Ice and Icebergs, Figure 2 Floating Sea Ice, Cape Kellett, Banks Island, Arctic Canada.

20% of the iceberg population in the southern Davis Strait, and about 5–6% at the mouth of the Strait of Belle Isle. Smaller fragments ("growlers") increase in proportion southwards as the larger icebergs disintegrate, but an average "growler" will endure for less than 5 days in 4°C water. Less than 10% of the icebergs that enter Labrador waters from the southern Davis Strait survive to 52°N; less than 1 in 10,000 potentially would reach the latitudes of the northernmost trans-Atlantic shipping routes.

Riming

Riming occurs where super-cooled spray from waves freezes on contact with objects. The process is analogous to the occurrence of freezing rain over land, but the proximity of the waves can result in much more rapid riming, causing vessels to become top-heavy and capsize. Ships and oil platforms operating in northern waters are vulnerable to sea-spray riming. Crews on vessels encountering freezing sea spray need to work rapidly to remove the ice in any way possible to prevent riming. Riming can also occur along the coastline, causing damage to property.

ICE STORMS

Ronald E. Stewart
University of Manitoba, Winnipeg, MB, Canada

Synonyms

Freezing precipitation storms; Freezing rain storms; Icing events

Background

Winter storms in which the temperature falls below 0°C commonly occur over many regions of the world. The form of precipitation within such storms is often variable and may include snow (dry or wet), freezing rain, ice pellets, and rain (Stewart, 1992). These various forms of precipitation can occur simultaneously in a storm.

Winter precipitation that contains some liquid may freeze when it strikes a cold surface; such an event is referred to as an ice storm. The result of this

icing is hazardous and sometimes catastrophic (Henson et al., 2007).

Definitions

There are several types of winter precipitation (<0°C) that contain or are composed entirely of liquid. Terms to describe some of these are defined formally by the World Meteorological Organization, and are used in all countries, including Canada; however, some are not defined formally. For example, terms such as slush and liquid core pellets were only coined by researchers in the last few years. The precipitation types containing liquid that can occur below 0°C are summarized below. Freezing Rain – Rain that falls in liquid form but freezes upon impact to form a coating of glaze upon the ground and on exposed objects (Environment Canada, 1992). Ice Pellets – A type of precipitation consisting of transparent or translucent pellets of ice, 5 mm or less in diameter (Environment Canada, 1992). Wet Snow – Snow that contains a great deal of liquid water (Environment Canada, 1992). Slush – Precipitation composed of a mixture of liquid and ice in which the original snowflake's shape is not discernible. (Theriault et al., 2006). Liquid Core Pellets: Partially refrozen drop with an ice shell and liquid water within it (Theriault and Stewart, 2007).

Formation

Winter precipitation is formed through several different processes. A particular type of temperature profile, consisting of a warm layer of air (>0°C) aloft and a cold layer below (<0°C), is required to form some of the hazardous types of freezing precipitation (e.g., Zerr 1997). These two atmospheric layers are called the melting and the refreezing layers, respectively. Snowflakes falling through a melting layer either melt or partially melt, depending on their size and atmospheric conditions of the layer. Depending on the degree of melting, these particles may or may not refreeze completely when falling through the refreezing layer before reaching the surface. In addition, freezing drizzle (small supercooled drops) can be formed by all-liquid processes within an atmosphere completely below 0°C.

Several types of precipitation containing liquid can occur at temperatures below 0°C and/or coexist because of the varying precipitation size distribution aloft. For example, when falling through a given melting layer, smaller particles will be more likely to melt completely, whereas larger ones will only partially melt. The completely melted particles will reach the surface as liquid (freezing rain) if the refreezing region is not cold enough (approximately >−5°C) to initiate freezing through ice nucleation. Larger particles may melt only partially and these will at least begin to freeze in the refreezing layer; if freezing is complete they would normally fall as ice pellets and if incomplete, as liquid core pellets. It may also be that the largest particles only melt a small amount in the melting layer, resulting in wet snow falling into the refreezing layer. These particles may not refreeze entirely prior to reaching the ground, where they do finally freeze. Such explanations highlight how icing at the surface can be due to the freezing of several types of particles. Freezing precipitation is a catch-all phrase to describe such particles.

Collisions between the different types of precipitation can alter their relative amounts. For instance, Hogan (1985) states that the freezing of a falling supercooled drop can be initiated by a collision with an ice crystal. In this case, it will decrease the amount of supercooled rain and ice crystals and ice pellets tend to be formed. As well, Stewart et al. (1990) showed that collisions between supercooled liquid drops and ice pellets could significantly decrease the amount of freezing rain at the surface.

Freezing precipitation is normally associated with a surface warm front, although under some conditions it may also be associated with a cold front. The warm frontal circulation with warm air rising above cold air is conducive to generating the necessary temperature profile for freezing precipitation. The ensuing band of freezing precipitation generally varies from about 10 to100 km in width and can extend hundreds of kilometers along a front. More intense storms with stronger warm and cold air circulations generally lead to more favorable conditions for more intense and/or wider bands of freezing precipitation.

There is often a well-defined organization to the evolution of the forms of precipitation in the transition region. Stewart and King (1987) showed that a five-step evolution from snow to ice pellets and then to freezing rain is expected under simple conditions and one of these steps actually includes all three precipitation types occurring simultaneously (freezing rain, ice pellets or liquid core pellets, and wet snow). This progression arises because of the systematic warming aloft and cooling below as a warm front passes.

The actual form of precipitation also depends upon local features. Ascending and descending air induced by local features leads to adiabatic cooling and heating, respectively, and this can alter the form of precipitation through changes in the vertical temperature profile. The presence of valleys and surface topographic effects can, for example, channel low-level air into particular locations and subsequently alter the forms of precipitation. This process contributed to the 1998 ice storm over Montreal and surrounding areas, one of Canada's largest disasters (Henson et al., 2007).

Summary

Freezing precipitation is a hazardous form of precipitation that causes major impacts whenever and wherever it occurs. It is a natural feature of winter weather and there is also growing concern as to how it may change in occurrence within a future climate. If winter storms become more intense, this may well lead to more ice storms.

IMPACT AIRBLAST

Natalia Artemieva
Planetary Science Institute, Tucson, AZ, USA

Definition

Impact airblast is a shock wave in the atmosphere caused either by a cosmic body entering the Earth with hypersonic velocity or by an expanding impact plume.

Discussion

Damage effects of an airblast depend on the peak overpressure (the maximum pressure in excess of the ambient atmospheric pressure) and the gas velocity behind the shock (commonly known as the wind speed). The effects of impact-generated airblasts are based on data from US nuclear explosion tests (Glasstone and Dolan, 1977). Some objects are sensitive to overpressure: 0.03–0.07 bar is enough to shatter a glass window, 0.2–0.7 bar – to destroy a brick wall panel; other objects are sensitive to the wind speed: ~30% of trees are blown down at 40 m/s and 90% at 60 m/s (a *tornado* wind speed is usually lower than 30 m/s). The user-friendly Web site: www.lpl.arizona.edu/impacteffects provides estimates of impact airblast effects (Collins et al., 2005).

Although any hypervelocity cosmic body hitting Earth produces shock waves, the amount of damage on the surface depends on body size. Small bodies (diameters <50 m) are efficiently decelerated in the upper atmosphere; shock waves decay quickly and reach the surface as a package of acoustic waves. These waves may be used to estimate the meteoroid's parameters. Larger bodies (50–300 m) are decelerated at lower altitudes and strong shock waves may reach the surface. A classic example of such an airblast is the Tunguska explosion in 1908 (Vasilyev, 1998). The ground effect of this event is a butterfly-shaped region of devastated forest extending over 2,000 km^2. Numerical models (Artemieva and Shuvalov, 2007; Boslough and Crawford, 2008) show that the Tunguska airblast was caused by a 50–100 m diameter *asteroid* or *comet* releasing an energy of 5–20 Mton TNT (1 ton TNT is equivalent to the energy of $4.18 \cdot 10^9$ J) at altitudes of 5–15 km. No crater or projectile material has been confirmed at the impact site so far. The largest objects (>300 m) reach the surface and excavate an impact crater (*asteroid impact*). The hypervelocity expansion of an impact plume and *impact ejecta* also creates shock waves in the atmosphere. The damage effects are combined with other environmental consequences of impacts – *impact wildfires, earthquakes, tsunami, and impact ejecta.*

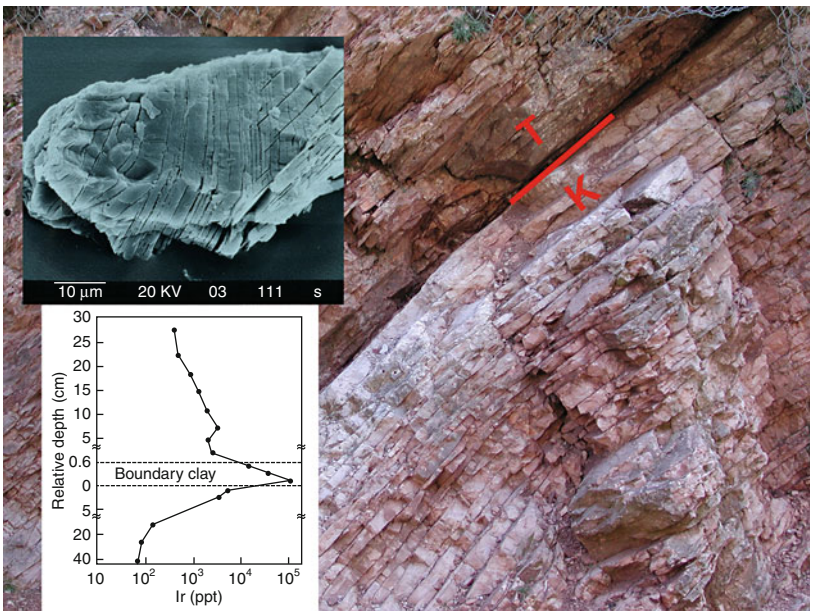
IMPACT EJECTA

Christian Koeberl
University of Vienna, Vienna, Austria
Natural History Museum, Vienna, Austria

Definition



Impact ejecta are sediments comprising material that was thrown out from an impact crater during its formation and deposited around it. Impact ejecta are in general rather heterogeneous due to variations in target composition, and often include glassy materials (impact glasses) and shocked minerals, and, in some cases, a minor meteoritic component.

Discussion

In contrast to many other planets (and moons) in the solar system, the recognition of impact craters on the Earth is difficult, because active geological and atmospheric processes on our planet may obscure or erase the impact record in geologically short times. Impact craters are recognized from the study of actual rocks – remote sensing can only provide supporting information. Petrographic studies of rocks at impact craters can lead to the discovery of impact-characteristic, shock metamorphic effects, whereas geochemical studies may yield information on the presence of meteoritic components in these rocks. Apart from studying meteorite impact craters, significant information can also be gained from the study of impact ejecta. Such ejecta are found within the normal stratigraphic record, where they can provide excellent time markers, and allow one to relate an impact event directly to possible biological effects. Impact ejecta are commonly divided into two groups – proximal ejecta (those that are deposited closer than 5 crater radii from the crater rim) and distal ejecta. In some cases, impact events have been identified solely from the discovery and study of regionally extensive or globally distributed impact ejecta.

A well-known case in point is the Cretaceous–Tertiary (K-T, now usually called the K-Pg = Cretaceous-Paleogene boundary), where the discovery of an extraterrestrial signature, together with the presence of shocked minerals, led not only to the identification of an impact event as the cause of the end-Cretaceous mass extinction, but also to the discovery of a large buried impact structure about 200 km in diameter, the Chicxulub structure (Yucatan peninsula, Mexico).

The first physical evidence pointing to a contribution of extraterrestrial material that was discovered was the presence of anomalously high PGE abundances in K-T boundary clay in Italy and other locations around the world. The contents of Ir and other PGEs were found to be enriched in these K-T boundary clay layers by up

Impact Ejecta, Figure 1 The figure shows the famous K-T boundary location at Gubbio, Italy, where the initial evidence was discovered that a large-scale impact event occurred at the end of the Cretaceous. Within a succession of layered limestone a thin (1–2 cm) clay layer was found, which contains shocked minerals (such as shocked quartz, similar to the upper inset, which shows a secondary electron microphotograph of an etched quartz grain with shock lamellae or planar deformation features), as well as distinct enrichments in the element iridium and other platinum group elements of extraterrestrial origin (*lower inset*).

to four orders of magnitude compared to average terrestrial crustal abundances; inter-element ratios of the PGEs in K-T boundary clay samples are very similar to the values observed in chondritic meteorites, and osmium and chromium isotopic studies of the K-T boundary provided further evidence of an extraterrestrial component. Further evidence for impact are: shocked minerals (including shocked quartz and shocked zircon), impact glass (some fresh, some devitrified), impact-derived diamonds, and spinel. The source crater of the K-T boundary ejecta, the ca. 200 km-diameter Chicxulub structure in Mexico (also subject of ICDP drilling projects) was only discovered in the early 1990s and is now firmly linked to the K-T ejecta by geochemical evidence.

Another well-known ejecta layer occurs in late Eocene marine sediments around the world that contain evidence for at least two closely spaced impactoclastic layers, which are linked to the Popigai and Chesapeake Bay impact craters (100 and 85 km diameter, respectively).

Tektites are another form of distal impact ejecta, the source craters of which have long remained elusive. To date only three of the four known Cenozoic tektite-strewn fields have been connected to source craters. Distal ejecta ("impactoclastic layers") can be used as markers for impact events in the stratigraphic record. "Impact markers" are a variety of chemical, isotopic, and mineralogical species derived from the encounter of cosmic bodies (such as cometary nuclei or asteroids) with the Earth. Distal ejecta layers can be used to study a possible relationship between biotic changes and impact events, because it is possible to study such a relationship in the same outcrops, whereas correlation with radiometric ages of a distant impact structure is always associated with larger errors. The discovery and detailed study of distal ejecta layers have led to the discovery of previously unknown large impact structures (e.g., Chicxulub and Acraman).

IMPACT FIREBALL

Peter Brown
Centre for Planetary Science and Exploration (CPSX), University of Western Ontario, London, ON, Canada

Definition

Impact fireball is the collective light, heat, and shock phenomena created when a relatively large solid object ("meteoroid") encounters the atmosphere at high speed (>11 km/s).

Discussion

Surface damage from fireballs surviving atmospheric passage to the ground with a substantial portion of their original kinetic energy is usually confined to larger stony objects (the precise cutoff is poorly known, but believed to be in the range of >100 m) or small (down to a few meters in size) iron meteoroids (which comprise about 3% of the impacting population (Ceplecha et al., 1998)). Damage at ground level may also result from smaller fireballs that are stopped higher in the atmosphere due to airblast effects of the shock propagating to the ground.

The direct danger from fireballs increases with size – a 100 m diameter object (producing a very large fireball) is believed to impact the Earth roughly once per 7,000 years whereas a 2 m iron object collides with the Earth about once every 5 years (Brown et al., 2002).

In addition to the danger at ground level caused by direct impact effects, it has been proposed that impact fireballs of sufficiently large energy may produce ionospheric and magnetospheric disturbances, which could affect radio propagation. The debris trail left by very large fireballs consists of significant amounts of micron-sized meteoric dust that may cause short-lived localized cooling at the Earth's surface while production of NO at the impact site for very large fireballs may affect ozone on regional scales (Adushkin and Nemchinov, 1994). Finally, impact fireballs may be misinterpreted as nuclear airbursts and could accidentally trigger hostile responses from nation states unable to distinguish between impact fireballs of natural origin and nuclear detonations (Tagliaferri et al., 1994).

IMPACT FIRESTORMS

Tamara Goldin
Center for Earth Sciences, University of Vienna, Vienna, Austria

Synonyms

Impact wildfires

Definition

Impact firestorms are a possible environmental effect of large meteorite impacts and a consequence of the large amount of heat released by an impact event, which may ignite wildfires. Locally, impact firestorms can result due to heat radiated near the impact site by the ablating impactor and the rising fireball (Toon et al., 1997). On a larger scale, impact firestorms can result from heat radiated by high-speed distal ejecta as they reenter, decelerate, and heat up in the Earth's atmosphere.

Discussion

The discovery of soot in distal ejecta deposits (Wolbach et al., 1985) from the Chicxulub impact at the end of the Cretaceous (65 Ma) first suggested that global wildfires raged on the continents immediately following the impact event. Calculations suggested that the ejecta, transported around the globe at hypersonic speeds (5–10 km/s in distal localities), radiated enough thermal energy to ignite the world's forests (Melosh et al., 1990) and thus would have been a major contributor to the environmental catastrophe following Chicxulub or any impact of this magnitude. However, the impact firestorm hypothesis for Chicxulub has faced recent criticism. New soot analyses support an origin from fossil hydrocarbons in the target rocks at Chicxulub (Harvey et al., 2008), not woody biomass. Furthermore, numerical modeling of the atmospheric reentry of ejecta suggests that ejecta particles settling through the atmosphere shield the Earth's surface from much of the downward thermal radiation emitted from later-entering ejecta and reduce the thermal pulse at the Earth's surface below the limits for wood ignition (Goldin and Melosh, 2009). Although the heat pulse would still cause significant environmental damage, global impact firestorms may not result from a Chicxulub-sized impact. However, wildfires in the vicinity of the impact will still occur, as was observed following the 1908 Tunguska airburst in Siberia.

IMPACT TSUNAMIS

Galen Gisler
University of Oslo, Oslo, Norway

Synonyms

Meteor impact wave; Water crater

Definitions

Impact tsunami. A water wave produced by the impact of a large meteor (asteroid or comet) into a large body of water, the ocean, for example. Impact tsunamis may prove destructive to persons or property on coastlines near the impact site.

Introduction

Collisions between bodies in the Solar System occur very frequently. When an asteroid or comet collides with a rocky planet (e.g., Mercury, Venus, the Earth, the Moon, and Mars), it can produce an impact crater. On the Moon,

craters have been recognized since the beginnings of the telescopic age. Mars and Mercury were found to have craters early in the space age, and craters on Venus have been seen using high-resolution radar observations through its dense cloud cover. There are now roughly 200 impact craters recognized on Earth, all on dry land or on continental shelves. For reviews, see Holsapple (1994) and Melosh (1989). A list of terrestrial impact craters is maintained on the website http://www.lpi.usra.edu/science/kring/epo_web/impact_cratering/World_Craters_web/intromap.html.

Because the Earth's surface is covered 70% by ocean, most asteroid or comet impacts have occurred in the ocean, and will do so in the future. Unfortunately, up to now, no definite crater sites on the abyssal plains of deep oceans have been identified and confirmed. Tentative identifications in the literature have been accompanied by intense debate (Masse et al., 2006; Pinter and Ishman, 2008). It is much more difficult to survey the seafloor to the same extent as dry land, of course. But because water absorbs so much of a projectile's energy by moving out of the way and vaporizing, very little energy is left to penetrate the seafloor unless the projectile's size is a substantial fraction of the water depth. In contrast, a few underwater craters are known to exist on the continental shelf. One is the Mjølnir crater, off the northern coast of Norway (Tsikalas et al., 2002) and another is the Montagnais crater, off Nova Scotia (Jansa et al., 1989).

When an impact occurs in the deep ocean, a transient crater is produced as the water is pushed out of the way. Some water is vaporized, and some water is lifted into a "crown splash" high up into the atmosphere immediately around the transient crater, much like the splash made when a rock is thrown into a pond. Because a water crater is unstable, it soon closes in on itself and produces a vertical jet from its center, which can also be seen in the pond's rock splash.

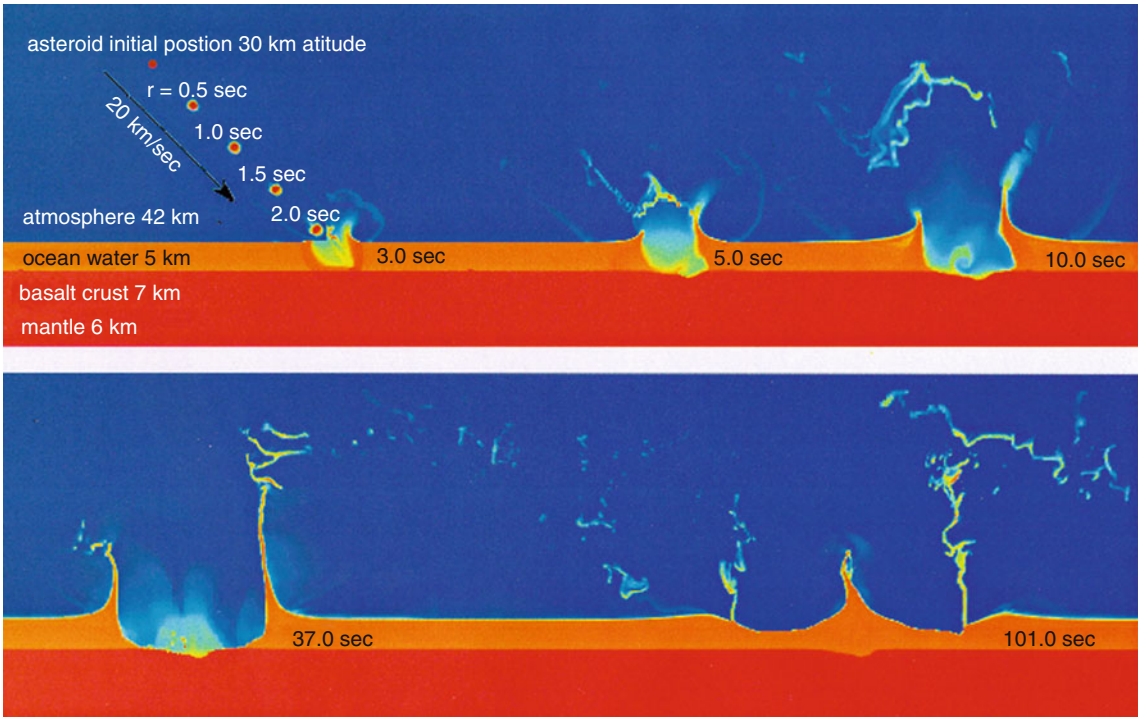
The collapse of the crown splash and the subsequent collapse of the central vertical jet both produce waves that emanate from the impact site. These are often referred to as *impact tsunamis*, but they are very different in many important respects from classical tsunamis caused by earthquakes or underwater landslides.

Probability of impact

In the 4.6 billion year history of the Earth and Moon, these bodies have been struck by asteroids or comets many thousands of times. Most impacts are small ones, and the big ones are very rare. The rate of impact has decreased dramatically over time. Early on, the solar system was cluttered with millions of multi-kilometer-sized bodies. Collisions between the major planets and smaller bodies gradually cleaned out the vast majority of the latter. The probability of an Earth impact by a body of a particular size in the future can be estimated from the present number of bodies of that size in the asteroid population. According to Morrison et al. (2002), Earth impacts of kilometer-sized bodies occur once in a million years on average, whereas bodies of a hundred meter diameter strike the Earth every few centuries. Bodies smaller than a hundred meters in size enter the Earth's atmosphere more frequently, but most of these burn up as meteors or explode high in the atmosphere, occasionally leaving fragments on the ground as meteorites.

Physics of water impacts

The physics of impact cratering in general is covered extensively in the book *Impact Cratering* by Melosh (1989). Cratering in rock differs from cratering in water only in the late stages, when the reduced mobility of rock results in a permanent change to the landscape. A high-speed impact into water initiates a shock wave that compresses and heats the water in an expanding hemispherical region around the projectile. In the rarefaction wave behind the shock, a significant amount of water is vaporized, as is much of the projectile itself. Water expands explosively when suddenly vaporized, to a volume a thousand times greater than it occupied when still liquid, and the pressure of this expansion drives the development of the water crater. The transient crater expands to a diameter twenty or more times the diameter of the asteroid within a few seconds. This crater is very symmetrical even for fairly high-angle impacts, though the crown splash may not be (see Figure 1).



The pressure of the water surrounding the transient crater forces a refilling of the crater. Water rushes into the center from all directions and collides with itself at high speed, producing a jet that can rise upward many kilometers, even into the stratosphere. Meanwhile, the collapse of the crown splash develops into a rim wave that moves outward in all directions. The central jet falls back into the center and produces a second, smaller, transient crater, which in turn rebounds into a second jet. This may go on for several cycles for a very large impact. Each rebound produces a new wave.

Wave production in impacts

The waves that are produced in impacts result from the collapse of the crown splash and the collapse, possibly multiple times, of the central jet. These waves can be of very high amplitude near the impact point, but they decay rapidly away from the impact site. These waves feel the ocean bottom because of their amplitude, much as near-shore waves do. They therefore *break* in deep water, and lose a great deal of their energy to surf, local turbulence in air and water, and interference. The remaining weaker waves propagate out in all directions, spreading out energy as they go.

Differences from classical tsunamis

Classical tsunamis are produced when large earthquakes or landslides happen under water. In both of these cases, the *source region* is much larger than an impact crater. The source region for the 2004-12-26 Sumatran tsunami

Impact Tsunamis, Figure 1 Montage of frames from a three-dimensional simulation of an impact of a 1 km diameter asteroid into an ocean of 5 km depth. The asteroid is assumed to come in at a 45-degree angle at a speed of 20 km/s. As it penetrates the water, it is vaporized, along with a comparable quantity of the ocean water, and an asymmetric transient crater is produced. The explosive expansion of the vaporized water leads to the cavity's becoming more symmetric, and large amounts of water are lofted tens of kilometers up into the atmosphere in the crown splash and central jet. The subsequent collapse of these two features leads to the setup of impact waves.

(a 300-year event) was roughly 1200-km long by 50-km wide, whereas a 1 km asteroid impact (a million-year event) will produce a transient crater of only 20-km diameter. The much larger source region for a classical tsunami means that the wavelength is considerably longer, roughly 100 km for the Sumatran tsunami. Calculations indicate a wavelength of about 40 km for a 1 km asteroid impact (Gisler et al., 2010).

Because the wavelength of the Sumatran tsunami, like other classical tsunamis, is so much greater than the water depth in mid-ocean (about 5 km), it propagates as a *shallow-water wave*, with high speed and low amplitude in mid-ocean but piling up as it moves into shallower water. The wave speed for a shallow-water wave is proportional to the square root of the water depth, so the front of the wave slows down while the rest catches up as the depth decreases. The asteroid impact tsunami is not a shallow-water wave, but an intermediate wave, whose speed is less strongly dependent on the water depth. It therefore experiences less pileup on entering shallower water. Since the wavelength is considerably shorter, a smaller volume of water is delivered to the shoreline.

The Sumatran tsunami was a *line source*, so it propagated perpendicular to that line with little angular dispersion, whereas an asteroid impact is a *point source*, so it will propagate in all directions with considerable dispersion. Other geological sources of tsunamis like underwater landslides have different directionality, some being quite highly focused.

All of these considerations indicate that the amount of water delivered per meter of affected shoreline is much less for an asteroid impact than for an earthquake tsunami of comparable energy. The total earthquake energy released by the Sumatran event at the Earth's surface has been estimated at 26 Mt TNT equivalent (USGS, http://neic.usgs.gov/neis/eq_depot/2004/eq_041226/neic_slav_e.html). The same energy would be released by a stony asteroid of 75-m diameter entering Earth's atmosphere at 20 km/s. Such an event would occur on average once in 300 years, coincidentally similar to the estimated return time of the Sumatran earthquake.

Recent calculations (Gisler et al., 2010) show that ocean impacts of less than about 300-m diameter would have dangerous effects near the impact site, but negligible ocean-wide effects.

For these most probable impacts, the effects on distant shores would be similar to the effects of severe storm surges rather than tsunamis. Asteroids larger than about

700 m in diameter could indeed produce dangerous waves at great distances, but even for these cases, the near-field and atmospheric effects would be of greater severity.

Summary: dangers from oceanic impacts

The real dangers from likely asteroid impacts in the ocean are, just as for land impacts, the atmospheric effects. A 100-m asteroid striking the earth at 20 km/s has a kinetic energy of 66 Mt TNT equivalent, similar to 3,000 Hiroshima bombs. Such an event would produce a severe atmospheric blast wave that would shatter any structures over thousands of square kilometers on land. On water, but within a few tens of kilometers of a populated shoreline, this could result in tens of thousands of deaths. Hurricane force winds, high atmospheric temperatures, and the fallout of large quantities of water from the crown splash and the central jet will also produce dangers for coasts within range. Larger impacts will inject significant amounts of water vapor into the stratosphere, and could thereby produce a significant change in Earth's climate.

But long distance tsunamis – impact tsunamis – are not a significant danger from impacts that might come upon us unexpectedly.

IMPACT WINTER

Owen Brian Toon
University of Colorado, Boulder, CO, USA

Synonyms

Nuclear winter

Definition

Impact winter, named after "nuclear winter," has prolonged subfreezing temperatures and reduced precipitation caused by stratospheric dust, smoke, and sulfates resulting from an impact.

Discussion

Following a large impact the vaporized impactor, containing iridium, as well as melted target material rises in a hot fireball and reenters globally like an immense swarm of shooting stars, heating the upper atmosphere. The hot upper atmosphere radiates light to the surface, broiling many creatures living at the time and setting vegetation on fire as was postulated to have occurred after the impact at Chicxulub in Mexico some 65 million years ago.

The fires generate sooty smoke, which joins dust recondensed from the vapor, and sulfate from the impactor in the atmosphere. Each of these materials has a separate origin, and evolution, and each is capable of causing an impact winter (Toon et al., 1997). The particles absorb sunlight, and reflect sunlight back to space, so less light reaches the surface. Hence, surface temperatures begin to drop and, with a cooled ocean, precipitation also begins to decrease. Low temperatures, precipitation, and sunlight eventually kill many of the animals that escaped that original broiling to death and can cause mass extinctions of many species in the oceans. Even modest smoke injections, such as would follow a nuclear conflict, may cause a "nuclear winter" under which mid-latitudes would remain below freezing for several years, and global precipitation could decline by 90% (Robock et al., 2007). Similar "anti-greenhouse effects" have been observed on Saturn's moon Titan and on Mars after global dust storms.

INCLINOMETERS

Erik Eberhardt
University of British Columbia, Vancouver, BC, Canada

Synonyms

Slope indicators; Transverse deformation gauges

Definition

Inclinometers are devices used to monitor subsurface landslide movements through a probe or fixed transducer designed to measure inclination with respect to vertical (see Dunnicliff, 1993 for a detailed description).

Discussion

Operation using a probe inclinometer involves lowering the probe down a borehole and measuring its inclination at a number of fixed points as it is pulled back to surface (Figure 1). Comparison of repeated periodic surveys provides an indication of active shear surfaces at depth as a function of time. Operation can also be carried out by fixing a probe, or series of in-place inclinometer probes, at desired depths to monitor continuous movements across known active shear surfaces.

below or near the ocean floor. Volcanic eruptions, landslides, and asteroids can also generate tsunamis.

Introduction

The December 26, 2004, tsunami was the most deadly tsunami and which led to one of the greatest disasters in historical times. Some 280,000 people were killed in South Asia, Southeast Asia, and East Africa. The Aceh province in the Sumatra Indonesian Island was the most affected area with about 167,000 killed. The December 26, 2004, tsunami was unusually violent, but deadly tsunamis are frequent in Indonesia. This country may have faced more than 250 tsunamis during the last four centuries, with over one third being deadly. This contribution focuses on the December 26, 2004, tsunami impacts in the Aceh province, in Indonesia, which was the most damaged area.

Tsunami sources and offshore tsunami propagation

The 2004 Indian Ocean tsunami was triggered by a 9.15 magnitude earthquake (Meltzner et al., 2006; Chlieh et al., 2007) that occurred at 0:58:53 GMT, 7:58:53 LT (t_{EQ}). The epicenter was located at 3.3 N, 95.8 E with a focal depth of approximately 30 km. The earthquake was responsible for a sudden fault slip estimated on average from 12 to 15 m (Synolakis et al., 2005; Lay et al., 2005) to 20 m (Fu and Sun, 2006). In the model suggested by Chlieh et al. (2007), the latitudinal distribution of released moment has three distinct peaks at about 4°N, 7°N, and 9°N, which compares well to the latitudinal variations evident in the seismic inversion and of the analysis of radiated T waves.

The tsunami waves propagated across the Indian Ocean (Figure 1) at an average velocity of 800 km/h (Lay et al., 2005), impacting the Sumatran coast between 20 and 40 min after the main shock of the earthquake (Lavigne et al., 2009).

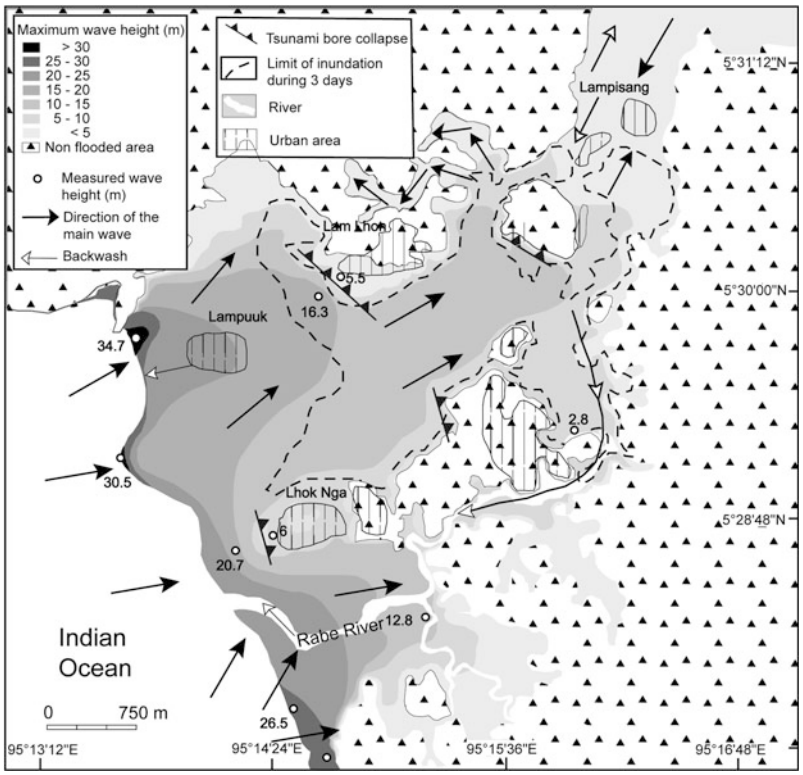
Precursory signs of the tsunami

In the Banda Aceh area, the great earthquake generated ground subsidence (Meltzner et al., 2006), with amplitudes ranging from a few centimeters to about 2 m. Such large subsidence along the coast could have suggested to an informed observer the occurrence of a vertical displacement of the seafloor as a result of the earthquake, which was one natural warning signal of the incoming tsunami.

Local people reported hearing three detonations similar to bomb explosions that sounded between the main tectonic shock and the tsunami arrival. These bangs are probably peculiar to earthquakes caused by the breaking of a sinking plate (Kato and Tsuji, 1995). However, Shuto (1997) suggested that “thunder-like” sounds are

generated and heard at distant places when tsunamis higher than 5 m hit coastal cliffs.

Another preliminary sign of the impending tsunami was a withdrawal of the ocean waters near the shore after the first shock of the earthquake (Yalciner et al., 2005). The extent of the withdrawal exceeded 1 km off Banda Aceh and Lhok Nga. The corresponding lowering of the sea level has been estimated at 5 m +/− 1 m by local fishermen (Lavigne et al., 2009).



The last warning sign of the tsunami arrival was the massive migration of bird colonies flying landward from the open sea. Numerous eyewitnesses reported – after the disaster – to hear birdcalls, which were interpreted by some villagers as a warning for people threatened by the tsunami (Lavigne et al., 2009).

Overland tsunami propagation and its geomorphological effects

Based on eyewitness accounts, about ten separate waves affected the region; this indicates a high-frequency component of the tsunami wave energy in the extreme near field. The largest tsunami wave heights were on the order of 35 m (Figure 2) with a maximum run-up height of 51 m (Lavigne et al., 2009). This run-up related to earthquake-induced tsunami has been exceeded at least four times previously: Indonesia in 1674 (80 m), Kamchatka in 1737 (63 m), Japan in 1771 (85 m), and Krakatoa in 1883. Evidence of a significant discontinuity in the tsunami wave heights and flow depths was noticed along a line approximately 3 km inland (Figure 2), which is interpreted to be the location of the collapse of the main tsunami bore caused by sudden energy dissipation (Lavigne et al., 2009).

The geomorphologic impacts of the tsunami waves include (Paris et al., 2009) beach erosion; destruction of the sand barriers; numerous erosion escarpments up to 2 m in the dunes; bank erosion in the river beds, with local retreats exceeding 30 m; and plurimetric scars typically 20–50 cm deep on the slopes. The upper limit of erosion appears as a continuous trimline at 20–30 m a.s.l. The erosional imprints of the tsunami extend to 500 m from the shoreline and exceed 2 km along riverbeds. The fringing reefs were not efficient in reducing the erosional impact of the tsunami.

The recognition and analysis of tsunami deposits provide clues to better understand the sedimentary signature, sediment transport, and deposition of past tsunamis and to better assess tsunami hazard. Normally, graded couplets or triplets of layers were used to identify the run-up of the three main waves (Paris et al., 2007). The local effects of the topography could be identified: thickest deposits in the topographic lows (50–80 cm), great spatial variations in thickness, landward coarsening, and very poor sorting at the wave breaking point, bimodal

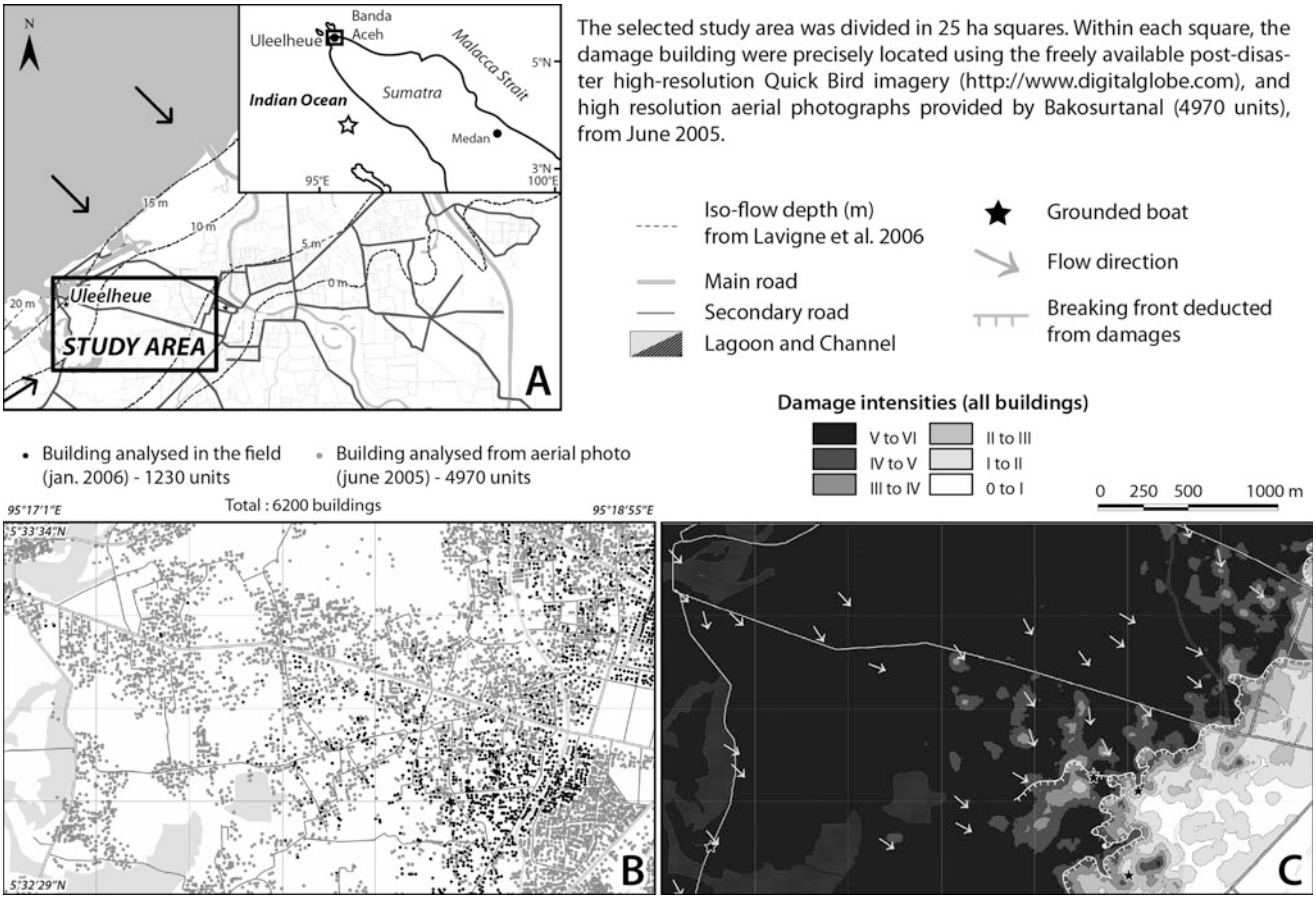
Indian Ocean Tsunami, 2004, Figure 2 Tsunami propagation across the West Coast of Banda Aceh (Lhok Nga subdistrict) (Source: Lavigne et al., 2009).

grain-size distributions reflecting different sources of sediments.

Although the deposition by the tsunami is mainly represented by extensive sheets of sand up to 5 km inland (Paris et al., 2007), megaclasts of soil, road, boulders of coral, and beach rock were also deposited onshore. The tsunami was able to detach and transport coral boulders in excess of 10 t over 500–700 m and megaclasts of the platform in excess of 85 t over a few meters. The fraction of boulders transported from offshore and deposited inland represent only 7% of the total number of boulders moved during the tsunami. Almost 1,800 boulders were identified offshore (Paris et al., 2010). However, the boulder deposits do not appear, at present, as powerful indicators to reconstitute palaeo-tsunami magnitudes.

Tsunami-induced damages

In Indonesia, 654 villages and 63,977 families were affected by the tsunami (Republic of Indonesia, 2005). As a whole, the December 26, 2004, disaster in Aceh and North Sumatra is estimated to have resulted in a loss of about US$4.5 billion (Leitmann, 2007), representing 2.7% of the national GDP or more than 97% of the Aceh province's GRDP. In addition to casualties, the tsunami also caused damage to various sectors. For example, it is estimated that 1,168 schools experienced the impact, or 16% of the schools existing before the disaster. Six hospitals and 6 polyclinic units were damaged (Figure 3). Damaged places of worship in Aceh comprised 1,069 mosques and musholla praying rooms. In the industrial sector, the extent of damage to small and medium industries was estimated at an average of 65%, and large industry at 60%. The impact of the disaster on the infrastructure sector includes the damage suffered by the sectors of housing (about 252,000 houses totally or partially damaged), transportation, energy and electricity, postal and telecommunications service, drinking water and sanitation, water resources, as well as other facilities.



Indian Ocean Tsunami, 2004, Figure 3 Destruction of the Uleelheue hospital, northwest suburb of Banda Aceh (Photo: F. Lavigne).

A spatial analysis of tsunami-induced damages in the northwestern suburbs of Banda Aceh city (Leone et al., 2011) pointed out that nearly all of the buildings suffered grade 5 damage (i.e., destruction/collapse), and only a few reinforced concrete buildings (e.g., big mosque, hospital, and school) suffered from very heavy damage to structures (grade 4). No substantial to heavy damage (grade 3) has been observed. The tsunami also damaged port breakwaters, destroyed or washed away small vessels, and violently moved large vessels ashore. Figure 4 underlines a steep drop in the damage gradient around 2.7 km from the coast. Patterns of building damage are related to the location of the propagating bore with overall less damage to buildings beyond the line where the bore collapsed (Leone et al., 2011; Lavigne et al., 2009). The final shape of the line outlines digitations that can be associated with different wave heights or roughness variations of the topography.

The root causes of the disaster: People's vulnerability in the face of the hazard

During the last decade, several deadly tsunamis occurred in Indonesia. One thousand nine hundred sixty people perished in Flores in 1992 (Imamura et al., 1995), 238 in East Java in 1994 (Maramai and Tinti, 1997), 110 in Irian Jaya in 1996 (Matsutomi et al., 2001), and 733 in South Java in 2006 (Lavigne et al., 2007). The recurrence of tsunami-related disasters increased the awareness of scientists and authorities and emphasized the need for improved tsunami disaster risk reduction policies. In response, the TREMORS seismic network was created in 1996. The Meteorological and Geophysical Agency of Indonesia (BMG) has been managing this network which is operating 24/7. On December 26, 2004, an earthquake warning was issued and transmitted to Indonesian authorities. It was further broadcast on Metro TV national channel but only five minutes before the tsunami struck the city of Banda Aceh in Northern Sumatra. The time lead was, however, insufficient to prevent a major disaster.

The tsunami further hit mostly unprepared local communities who were not covered by tsunami disaster risk reduction programs unlike other communities throughout the country (Morin et al., 2008). Indeed, only a few people spontaneously ran to higher ground following the withdrawal of the sea. In some instances, many locals actually rushed to the beaches to gather fish grounded on the beaches before being swept away by the tsunami. Significant differences were, however, observed among the different ethnic groups who live in the area (Gaillard et al., 2008a). About 170,000 Acehnese and Minangkabau people died in the Northern tip of Sumatra whereas only 44 people passed away in the neighboring Simeulue Island located near the earthquake epicenter. Such a difference in the death toll does not lie in the nature of the hazard but in different human

Indian Ocean Tsunami, 2004, Figure 4 Investigation of tsunami-induced damage on buildings after the December 26, 2004 tsunami. (**a**) Studied area between Uleelheue and downtown Banda Aceh. behaviors, which were deeply influenced by the cultural, social, economic, and political context. Seeing the sea's withdrawal, Simeulue Island inhabitants immediately escaped toward surrounding mountains. The accounts passed from generation to generation of the deadly 1907 tsunami enabled them to understand what was happening. Simeulue inhabitants even have their own word to name the phenomenon: *smong*. Conversely to Simeulue communities, Acehnese and Minangkabau people, respectively, in the cities of Banda Aceh and Meulaboh, did not anticipate the phenomenon and were thus caught by the waves. Eventually, the Indonesian government fostered the use of the word *smong* through its integration into the official Indonesian language. This helped in increasing national awareness of tsunami hazards, all the more so as *smong* creates a very helpful acronym: SeMua Orang Naik Gunung ("Everybody moves up on the hills") (Morin et al., 2008). Another similar account of indigenous knowledge in the face of the 2004 tsunami was reported by Arunotai (2008) in Surin Island in Thailand where Moken fishing communities, attentive to nature forewarnings, avoided the tsunami.

The Simeulue and Surin islands stories suggest that loss of life is easily avoidable in the face of tsunami hazard. However, in the event of a warning signal, whether based on local or scientific knowledge, people's behaviors and the capacity to protect oneself may be further hindered by a deep tangle of structural factors. Among these factors, political and economic constraints played a great role in explaining why Acehnese people were unable to face the tsunami. At the time of the disaster, an armed conflict had been affecting the province for more than 30 years (Gaillard et al., 2008b). This led to the impoverishment of the region and the fear of the people to evacuate inland where violence was raging. The armed conflict also contributed to the progressive deconstruction of the social and political organization of the villages, including the lingering erosion of local knowledge, by the Java-based Indonesian government (Gaillard et al., 2008a).

What can we henceforth expect if a tsunami hit again regions which are now covered by the Indian Ocean Warning System? This system was actually already working when a tsunami hit Pangandaran, Java, in July 2006, but hundreds of people were still killed. Although warning

was issued on time, it was not transmitted down to local authorities for political reasons, allegedly connected to avoid panic movements among locals. Moreover, people did not systematically recognize natural forewarning signs. Both the December 26, 2004, catastrophe and the July 2006 disaster revealed the pressing need for implementing an efficient warning system and empowering local communities and authorities with adequate resources to face the threat of tsunami hazard. Tsunami preparedness is a key component of disaster risk reduction policies. It should be included in multi-hazard risk reduction programs which emphasize local knowledge and socially and economically acceptable actions to mitigate people's vulnerability. It should further involve a large range of stakeholders which span from local communities, local and national authorities, NGOs, international organizations, scientists, and the media.

Summary

The December 26, 2004, tsunami was the most deadly tsunami (280,000 people killed) in recent history which led to one of the greatest disasters in historical times. This entry explores a broad range of scientific investigations in the Aceh province, Indonesia, from geophysical aspects (tsunami sources, offshore and overland tsunami propagation, and its geomorphological effects) to social aspects (damages, people's vulnerability, interpretations of precursory signs, etc.).

INDUCED SEISMICITY

Maurice Lamontagne
Natural Resources Canada, Ottawa, ON, Canada

Synonyms

Anthropogenic seismicity; Stimulated seismicity; Triggered seismicity

Definition

Induced seismicity is a general expression that includes all earthquake activity brought about by man-made perturbations of the effective shear stress existing on faults and fractures. This can arise by changing the acting stresses or the pore-fluid pressure. These perturbations can be caused by the impounding of water reservoirs, mining activity either underground or at the surface, high pressure injection of fluids for hydrothermal power generation or oil production, removal of underground fluids such as oil, gas, and water, and underground explosions (Simpson, 1986).

Induced seismicity

Strictly speaking, the expression "induced seismicity" is correctly used if the seismic activity causes a stress change comparable in magnitude to the ambient shear stress acting on a fault to cause slip (McGarr et al., 2002). These authors define "triggered seismicity" if the stress change is only a small fraction of the ambient level. In other words "induced seismicity" applies if the stress changes brought about by the change in conditions are causing the seismicity whereas the other definition implies that it is the perturbation that "advanced the clock" of a seismic event that would have eventually occurred. It should be noted that this distinction in terms is not followed by all.

Water reservoir impounding

Notwithstanding the distinction above, the most famous types of "induced seismicity" are related to the impounding of large reservoirs (more correctly referred to as "reservoir-triggered seismicity"; RTS). At least 70 cases of RTS are recognized worldwide (Gupta, 1992) but more cases may have escaped detection depending on the magnitude detection threshold of the local seismograph networks. Damaging RTS has occurred at Hsinfengkiang (China), Kariba (Zaire), Kremasta (Greece), Koyna (India), Oroville (USA), and Aswan (Egypt) (Gupta, 1992). This phenomenon is well documented and it is recommended that reservoir impounding be monitored by an array of local seismographs a few years prior to impounding (ICOLD, 2008).

Mining and quarrying activity

Mining-induced seismicity, sometimes called rockbursts, because of the mining safety aspects is probably the best studied type of induced activity. Because the activity is taking place very close to areas subject to direct observation and measurement, mining-induced activity offers the best opportunity to examine the relative importance of depth, scale, state of stress, pore-fluid pressure, and mining technique (McGarr et al., 2002). The safety considerations of mining-induced activity have also led to advanced monitoring of the activity itself as well as to the potential causative factors. Surface mining is also reported to have caused induced activity (McGarr et al., 2002).

Injection of fluids

There are a number of cases of seismicity caused by the injection of fluids. In 1960s, the injection of fluids in the Rocky Mountain Arsenal well near Denver Colorado was the first time when a clear relationship was established between the fluid injection and the triggered seismicity. One of the best studied case is the KTB well of Germany where fluids under pressure were injected at a depth of 9.1 km (Zoback and Harjes, 1997). Through relatively modest increase in pore pressure, hundreds of microearthquakes were triggered. In 2006, injection of fluids near Basel, Switzerland, has triggered seismic activity with a magnitude 3.4 earthquake that has caused some three million dollars of damage to houses. This is a reminder that the physical processes and parameters that control injection-induced seismicity are still poorly understood (Kraft et al., 2009).

Summary

Due to the increase in exploration and exploitation of deep wells, the phenomenon of induced seismicity may well become subject to increased interest by scientists and, if this seismicity is felt at the surface, by the public. The possibility of induced seismicity should be considered in the design phase of large-scale projects such as large reservoirs (ICOLD, 2008).

INFORMATION AND COMMUNICATION TECHNOLOGY

Peter S. Anderson
Simon Fraser University, Burnaby, BC, Canada

Definition

Information and communication technology (ICT) refers to the advancement and use of contemporary electronic information systems, brought about by the convergence of computer and telecommunications technology. ICT is also concerned with improving human and organizational problem solving through use of technologically based processes and systems that enhance the efficacy of information in a variety of tactical and strategic operational situations. ICT provides a common intellectual framework to interconnect all of the stages of hazard phenomena and resultant human and environmental interaction.

Introduction

The healthy functioning of modern societies is effectively based on the high-quality and expeditious circulation of information. This is even more germane in the case of societies vulnerable to natural hazards. There, accurate information and its reliable and timely communication are of importance, as people's lives, assets, and environments are at stake. However, with the increasing complexity of modern society, no single organization involved in disaster risk reduction practices has the requisite knowledge to understand and address all of the consequences of hazards.

A fundamental problem in dealing with natural hazards, especially atmospheric and oceanographic hazards, is that they respect no boundaries. Their effects can cut across social, cultural, economic, geopolitical, and ecological domains and the adequacy of countermeasures is greatly influenced by the degree to which actions can be coordinated and integrated among the relevant disciplines, professions, and jurisdictions within all phases of hazard phenomena (Anderson, 1991). The systematic organization of these activities forms the basis for an emerging discipline, often referred to as "emergency management," "disaster management" or, more recently, "disaster risk reduction." In general, it aims to foster a continuous process by which individuals, groups, and communities of interest share responsibility for helping to avoid or ameliorate the impacts of disasters resulting from hazards. This more comprehensive and collaborative approach marks a paradigm shift from a traditional fixation on relief and recovery to incorporate a broader focus on risk and vulnerability management to help make communities more resilient to disasters.

Information creation and exchange underpin these activities and form crucial interdependent links in the chain of sound natural disaster risk reduction measures to bring together those who have knowledge about hazards and their characteristics with those who must deal with their consequences from local to global scales (NRC, 1998). This chain of measures includes hazard, vulnerability, and risk analysis (HVRA), prevention and mitigation, preparedness, response, recovery, and rehabilitation.

"HVRA" is a three-stage process that enables communities to: (1) collect and analyze information on the probable location and severity of dangerous natural phenomena and likelihood of their occurrence within a specific period in a given area (OAS, 1991); (2) as determined by physical, social, economic, and environmental factors or processes, estimate the vulnerability – the degree of loss or harm that would result from the occurrence of a natural phenomena of given severity, and (3) for a given hazard event, determine the nature and extent of risk or exposure by analyzing potential hazards and evaluating existing conditions of vulnerability (UNISDR, 2004). The results of the HVRA process establish the social and operational contexts for all subsequent measures. "Prevention and mitigation" involve longer term and sustainable structural (technological) and nonstructural (social) measures to prevent hazards from developing into disasters altogether, or to reduce the effects of disasters when they occur. They include activities such as hazard and risk mapping, risk communication and education, land-use planning and zoning, regulation, structural fortification, and insurance. "Preparedness" is aimed at minimizing the loss of life and property during an actual hazard event, and includes developing and adopting strategic and tactical plans to identify and effectively mobilize human and material resources in case of a disaster. Early warning is a key component that facilitates delivery of timely information through authorized institutions and available communication channels, to

enable individuals and organizations, about to be exposed to a hazard, to take steps to avoid or reduce their risk and to initiate follow-on response actions. "Response" includes actions employed during or immediately after a hazard event to meet the urgent life preservation and basic subsistence needs of those affected. "Recovery and Rehabilitation" is concerned with immediate and long-term decisions and actions taken after a disaster to restore or improve the pre-disaster conditions of the stricken society and environment, while encouraging and facilitating necessary adjustments within the other risk reduction measures to reduce future disaster risk (UNISDR, 2004).

Each measure requires information drawn from multiple sources to support decision making at many different levels and scales (NRC, 1998). Local authorities need information that is sufficiently detailed to be useful in planning all aspects of disaster risk reduction – information such as hazard and risk maps; land-use planning; locations of vulnerable populations; community hazard awareness; critical infrastructure; transportation routes and emergency resources. Senior level authorities need aggregated regional and national level information to support policymaking, program development, multijurisdictional disaster response coordination, and recovery financial and other assistance. International bodies require national and regional level information to formulate and stimulate global disaster reduction strategies and partnership programs. Utilities and essential service providers need information to develop and implement business continuity and restoration plans. Individuals and community organizations need information to support personal and neighborhood preparedness and risk reduction initiatives. Sometimes, the same information, such as real-time atmospheric and flood hazard information, is required at all levels.

Role of information systems

A major challenge to adopting an effective and comprehensive disaster risk reduction approach is that crucial information is gathered and held by a range of individuals, organizations, and disciplines through complex and varied processes (NRC, 1998). However, information systems can assist collective planning and decision making by providing a standardized means to systemically gather, organize, and present data from a wide assortment of sources. The advancement and use of contemporary electronic information systems, brought about by the convergence of computer and telecommunications technology, commonly referred to as Information and Communication Technology (ICT), is unparalleled for gathering, storing, retrieving, processing, analyzing, and transmitting information. ICT is also concerned with improving human and organizational problem solving through use of technologically based processes and systems that enhance the efficacy of information in a variety of tactical and strategic operational situations. ICT provides a common framework to interconnect all of the stages of hazard phenomena and human and environmental interaction. However, to be effective, countries need to develop the necessary human resources and strengthen the capacities of institutions and communities to use and integrate ICT applications (UNESCAP, 2009).

Today, hazard data and derived information is readily available across all types of ICT networks and user devices. This trend is evident in the expanded use of: space and terrestrially based remote sensing to detect and monitor hazards; global positioning systems (GPS) and geographical information systems (GIS) to locate and map hazards, associated risk, vulnerable populations, and critical infrastructures; complex computer modeling to predict and forecast extreme hazard events; and an explosive growth in interconnected communication channels that enable millions of people to share data and information concurrently and to collaborate and problem solve in ways not previously possible (NRC, 1998). Using Internet and data warehousing techniques, ICT tools are also being widely used to build knowledge warehouses to support planning and policy decisions for mitigation, preparedness, response, and recovery at all levels.

ICT assists scientists to systematically collect, manage, analyze, and interpret baseline data. For example, field data can be remotely collected through broad sensor arrays and measurement devices and instantaneously relayed over networks. Using a multitude of interoperable space and terrestrial communication methods, the data can be simultaneously gathered from numerous locations and quickly processed by high capacity computers to construct predictive models to improve forecasting and help users interpret and understand the hazard's physical processes. Increasingly, through specialized national and international networks linked to the Internet, derived hazard occurrence information can be viewed almost immediately after its data collection, enabling notification of seismic events around the world, the tracking of hurricanes and tsunamis waves, monitoring of stream flows and water levels, forecasting of extreme weather, etc. The derived information can be communicated to planners, managers, responders, and other stakeholders to enhance and improve their understanding of extreme hazard events and to trigger appropriate warnings and response.

Some information systems integrate current with archived information to enable dynamic prediction modeling of hazard behavior. For example, regional tsunami warning centers use forecast modeling to generate estimates of wave arrival time, wave height, and likely coastal inundation areas immediately following large coastal or submarine earthquakes. Given time constraints of running very complex tsunami forecast models in real time, wave generation, propagation, and inundation computation can now be expedited by accessing a database of precomputed scenarios containing information about tsunami propagation from a multitude of sources. As the actual waves propagate across the ocean and successively reach preinstalled sea level gauges and sophisticated pressure gauges set on the ocean floor, the detected and recorded sea changes are transmitted back to the warning center

which, in turn, processes the information and produces new and refined estimates of the tsunami characteristics. The result is a progressively more accurate forecast of the tsunami that can be used to help identify threatened coastal areas, calculate estimated times of wave arrival, and formulate and issue targeted watches, warnings, and/or recommended evacuation instructions (IOC, 2008).

Remote and in situ sensing and data acquisition

One of the most important tools available to the risk reduction community is remote sensing of the environment. Remote sensing is commonly referred to as the science of obtaining and interpreting information about area, object, or phenomena from a distance, using sensors that are not in physical contact with the object or phenomena being observed. In its broadest sense, remote sensing includes aerial, satellite, and spacecraft observations of the Earth's surfaces. Remote sensors measure different wavelengths, from optical to radar, of electromagnetic radiation that have interacted with the Earth's surface. Different sensors aboard airplane or satellites are used extensively in providing imaging, ortho-photographic, and mapping information to support both detailed micro- and regional level studies of land surface, marine, and atmospheric hazard interactions. It is particularly valuable in detecting and mapping many types of natural hazards that were previously undetected or recorded such as landslides, volcanoes, tornados, and earthquake-induced fault lines.

Earth observation is also useful in viewing the same area over long periods of time and, as a result, make it possible to monitor natural processes, environmental change, and human interaction and impacts to model and simulate past, present, and future trends and projections. If susceptibility to natural hazards can be identified in the early stages, measures can be introduced to reduce the social and economic impacts of potential disasters through better mitigation, preparedness, and adaptation strategies (Wattegama, 2007). Examples include using remote sensing to observe and monitor: coastal shores, snow cover regimes, glaciers, and sea ice surface features for climate change prediction; precipitation, soil water, and crop lands for food production and famine prediction, and land transformation before and after earthquakes for infrastructure design and engineering.

Remote sensing has become a valuable resource during and after hazard events to support early warning, response, and rescue and post-event recovery. Meteorological satellites enable officials to observe atmospheric patterns and visualize the formation and intensity of cyclones and other extreme weather events, track their progress across regions and predict impact of locations at-risk in time to warn residents and deploy vital resources. Other systems enable similar observation of flooding and tracking of major wildfires. Post-event observation has permitted rapid damage assessment mapping of tsunami (Bonda Ache 2004, Japan 2011), flood (Nepal 2008) and earthquake (Haiti 2010, Japan 2011) hazard impacts.

Remote sensing is often supplemented by the integration and networking of surface-based in situ sensing in which measuring devices are either immersed in, or at least touch, the object(s) of observation. These devices when connected to satellite or terrestrial telecommunications networks permit real-time observation. For example, sensors can record and transmit remote watershed snow pack data to enable hydrologists to predict annual flood and drought conditions and, when supplemented by real-time stream flow gauges, support flood warning and response. Wireless networks incorporating seismometers, temperature probes and cameras are now routinely used to remotely monitor high-risk volcanoes. Both remote and in situ sensing systems have become critically important in the monitoring of locations where the hazards pose extreme physical risk to observers, such as volcanoes and landslides.

Geographic information systems

With the availability of large volumes of remotely sensed data, computing systems and specialized applications, such as Geographic Information Systems (GIS), permit geo-referenced data to be stored, retrieved, manipulated, mapped, and visualized in combination with data collected from other sources such as human settlement, critical infrastructure, evacuation routes, and public assembly locations. By utilizing online GIS, planners, responders, and the public can pool and share information through computer-generated databases and maps. GIS provides the mechanism to standardize, integrate, centralize, and visually display both static and dynamic critical information before, during, and after hazard occurrences. In recent years, the explosion of Internet mapping applications, such as Google Earth, Google Maps, and Bing Maps, has given the public access to ever-expanding amounts of geographic data and allowed users to annotate and share maps with others. GPS enabled mobile smartphones and personal data assistants (PDAs) incorporating GIS can display their locations in relation to fixed facilities (nearest hotel, gas station, fire hall), mobile assets (vehicle, people), or communicate their coordinates back to central servers and Web sites for display or other processing.

Decision support and incident management systems

ICT provides a framework for integrating database management systems with analytical models, GIS, statistical databases, and tabular reporting capabilities into decision support and incident management systems (DSIMS) that can be used to reduce the time needed to make crucial decisions regarding task assignment and resource mobilization during response phases. Among other features, these systems can also incorporate event reporting, resource and critical assets management, interagency situation reporting, duty logging, call center tracking, contact databases, infrastructure status reporting, action planning, impact sighting and damage assessment, and public and interagency notification. Through secure wide-area

network connections, system information can be shared on an interagency basis to enhance situational awareness and provide a common operational perspective. DSIMS also provides a stored memory of events to assist in recovery and longer-term mitigation efforts.

Early warning systems

For many natural hazards, the knowledge about their current and forecasted states often resides beyond the geographical locations of those who could be affected. ICT provides a unique means to ensure the timely and accurate delivery of this information in the form of routine bulletins, special notifications, or warnings. A warning can be defined as the timely communication of information about a hazard or threat to people at risk in order for them to take necessary actions to mitigate any potentially negative impacts on themselves, those in their care and their property (Samarajiva et al., 2005). Warning, therefore, must be viewed not simply as a technology, but rather as a unified system made up of five critical and interrelated elements: (1) HVRA; (2) detection and monitoring; (3) emergency management structure; (4) local notification and dissemination, and (5) public education and community capacity (Anderson, 2006). No single technology is sufficient to warn everyone, and ICT must encompass both traditional media (radio, television, loud speakers, sirens, amateur radio) as well as new media (text messaging, cell broadcasting, Internet, satellite radio, automated telephone notification) in order to reach all segments of the public, day, or night.

Internet and new social media

Since the early 1990s, the Internet has become one of the world's most important social networking tools for stimulating and enhancing virtually all aspects of risk reduction across disciplines, jurisdictions, genders, and cultures. More recently, an even newer generation of interworking has begun to take shape that allows increasingly larger portions of the population to play a more self-determinist role in these activities. The emergence of Web 2.0 – SMS, blogs, social networks (YouTube, Facebook, Twitter), Flickr, RSS feeds, Voice-over-IP, and Open Source Software represents a culture shift from the Internet being largely shaped by storage and retrieval applications toward a real-time interactive environment that cultivates users becoming active participants rather than passive viewers. The Internet now offers rich user experiences including Web video and audio streaming, interactive maps, timely content, and virtual worlds that can be used not only for online entertainment, but also for practical risk reduction purposes both for the public-at-large and risk managers (NRC, 2009).

Even in the absence of official warning and communication, people affected by natural hazards now communicate directly with each other and the world-at-large. The first reported impacts of the 2004 Indian Ocean Tsunami were sent via Short Message Service (SMS) and posted on blogs in Sri Lanka. During the 2005 Hurricane Katrina disaster, many New Orleans residents of affected coastal areas were able to communicate with friends and relatives via SMS when traditional landlines were unavailable. Similarly, Haitians buried under debris from the 2010 earthquake were able to text for help and be located through their mobile phones. Crowdsourcing, crisismapping and resource management tools such as Ushahidi and Sahana enable citizens to report incidents, self-organize and collectively respond to local relief and recovery needs.

These same applications allow risk managers to shift focus from what needs to be done for the community, to what can be done with the community (NRC, 2009). Electronic social networks enable emergency responders and support agencies to assess continuously social impacts of extreme hazard events and observe self-organized community responses. They can also supplement scientific observation and analysis of the same events. For example, while seismic detection systems help to generate numeric models to identify the source and estimated magnitude of the earthquakes, social feedback systems such as email, Twitter, and Facebook, enable rapid subjective assessment of how and where they were felt. In the near future, smart phones and other PDAs will serve as sensor platforms to instantly record and relay hazard-related data from millions of user locations globally, enabling more precise modeling of natural hazards and effects. This data tied into GIS systems and land type and land-use databases will enable rapid impact and damage predictions to enable emergency teams to plan initial response.

Summary

In summary, ICT can assist collective planning and decision making by providing a standardized means to systemically gather, organize, and present data from a variety of sources. Today, hazard data is readily available across all types of ICT networks and user devices to enable millions of people to share data and information concurrently and to collaborate and problem solve in ways not previously possible. The derived information can be communicated to planners, managers, responders, and other stakeholders to enhance and improve their understanding of extreme hazard events and to trigger appropriate mitigation, warning, response, and recovery actions. Newer social media versions enable emergency responders and support agencies to assess continuously social impacts of extreme hazard events and observe self-organized community responses. However, to be effective, countries need to continuously foster and support the development of human, institution, and community capacities to use and integrate ICT applications.

INSECT HAZARDS

Philip Weinstein
University of South Australia, Adelaide, SA, Australia

Definition

Insects have been an integral part of human culture since the beginning of recorded history, and most likely much earlier. The world's few remaining hunter-gatherer societies eat insects as well as their products, suggesting that insects have formed part of human ecology throughout our evolutionary history. Then as now, insects posed a hazard to people impinging on their domain, for example, in harvesting honey from bees – the latter being the biggest insect killer of humans in the developed world. The relationship between humans and insects is thus a complex one, and they have been revered (sacred dung beetles of Egypt) and feared (insect phobias) with equal passion. This contribution focuses on insect hazards that can be defined in the same way as insect pests – that is, insects that are "judged by man to cause harm to himself, his crops, animals, or his property" (Dent, 1993, p. 1). Such harm can be readily discussed in the following categories: stings and allergies, bites and disease, and physical and imagined hazards.

Stings and allergies

The Hymenoptera (bees, ants, and wasps) arguably present the greatest direct hazard to humans of any insects, because their stings are both venomous and allergenic – meaning that people are at risk not only of the acute pain of the venom injected with a bee sting, but also of anaphylactic shock (and potentially death) if they have developed an allergy to the same venom. The Hymenoptera possess a highly modified ovipositor, which, instead of serving the original function of egg laying, has developed an associated venom gland and thus, can be used defensively. It is important to appreciate that with the exception of hematophagous (blood-feeding) insects discussed elsewhere, no insect actively pursues humans. Thus, bites and stings are largely administered in self-defense, sometimes to victims who accidentally disturb insects in the course of other duties (stepping on a foraging bee), and other times in response to deliberate provocation (removing honey from a hive), but never proactively in the way that a predator seeks prey. Having said that, swarms of bees protecting their hive can rarely cause death in humans, by the sheer number of stings (even in the absence of allergy); particularly worrisome are aggressive varieties commonly called "killer bees." In Australia, where underground nests of the imported European wasp can grow to over a meter, an unusual hazard is caused for people who step on and fall into such nests. Some ant venoms can be as potent as bee or wasp venom, but again the major threat is also from allergic reactions (Goddard, 1996). Many insects cause or exacerbate respiratory allergies in humans, hence fly and cockroach antigens (often in feces) are likely to be as potent in asthma etiology as are the better recognized house dust mite allergens. Occupational exposure to particular species of insects can lead to any number of unexpected allergic reactions, from skin irritation to anaphylaxis. By far the majority of morbidity (disease) and mortality (death) cases from insect stings is a result of allergic reactions – only insect relatives (spiders, scorpions) possess venom potent enough for a single animal to cause death by envenomation.

Bites and disease

By analogy with stings and allergies, it is generally not the bite of an insect that poses a hazard to humans, but more so the diseases that can be transmitted by biting insects. It is true that larger individuals of many species (beetles, soldier ants) are capable of breaking human skin to cause severe pain to a probing finger – but again this behavior is purely defensive and does not constitute a significant hazard from a public health perspective. By contrast, disease transmission by biting insects does constitute a public health problem, with more people dying annually of mosquito-borne disease than of any other disease. For the continued existence of their species, blood-feeding insects are dependent on at least the female finding a blood meal: egg maturation, and therefore the next generation, is dependent on the availability of protein from such a meal. By the early Cretaceous, mosquitoes and other biting flies were "on the lookout for the fresh blood of every [vertebrate] from small frogs to gigantic dinosaurs" (Poinar and Poinar, 2008, p. 33). As mammals evolved, the feeding preferences of many hematophagous insects changed to capitalize on the increasing availability of mammalian blood – culminating in the ready and regular availability of human blood once agricultural communities appeared. The latter were often situated near water bodies where mosquitoes breed, and hungry swarms can potentially make life outdoors a veritable misery in such situations.

Every year, close to 300 million people catch mosquito-transmitted malaria, and about a million people – mostly children – die (WHO, 2009). Malaria parasites (protozoa of the genus *Plasmodium*) are transmitted to a new host from the mosquito's saliva when an infected mosquito takes a blood meal. The parasites go on to multiply in the host, causing the symptoms of infection and sometimes death. Add to that problem a dozen other diseases transmitted by mosquitoes (including dengue fever and West Nile virus), and it is clear that mosquitoes are, globally, by far the most hazardous insects to humans. Some other insects (tsetse flies, sand flies, reduviid bugs, fleas) and insect relatives (ticks) have a similar ecology, actively pursuing hosts to obtain blood meals, and incidentally infecting the latter with pathogens that include the causative organisms of sleeping sickness, viral encephalitis, plague, and other potentially lethal diseases. Hematophagous insects can, therefore, be legitimately feared in areas that harbor such diseases, and precautions should be taken against being bitten. Generally the risk can be dramatically reduced by simple measures: avoiding peak biting times (dawn and dusk); wearing light colored, loose, long-sleeved clothing; using personal insect repellents outdoors and knockdown sprays indoors; and sleeping under insecticide-impregnated bed nets.

Finally, insect parasites rate a mention in this category – insects that spend their lives on humans, feeding on blood. Lice are virtually the only insects that have adapted to the relatively hairless state of humans, and not surprisingly, the ones that do infest us have species specifically adapted to heads, pubic hair, and clothing. Only the latter, body lice, pose a significant threat, and again it is because of their potential to transmit disease. During the First World War, more soldiers died from louse-borne typhus than died in battle.

Physical impacts

Insects are at their most spectacular when in large numbers in outbreaks and swarms, and can pose direct hazards that result from the sheer mass of their bodies, as well as indirect hazards that result from losses in human productivity. An outbreak can generally be conceived of as any situation where insect numbers reach unacceptable levels (as judged by economic, medical, or aesthetic criteria), and outbreaks are driven by both abiotic (nonliving environment) and biotic (living environment) triggers.

The interaction between climate and locusts provides a classic example of an abiotically driven insect hazard. Locusts, like all insects, are cold blooded, and the rate of development is, therefore, temperature-dependent. In many cases, it is also humidity or rainfall dependent and female locusts require soft wet soil in order to successfully lay their eggs underground. When these conditions are perfect (from the insect's perspective!), nymphs (young locusts) hatch in such large numbers that a physiological change is triggered: The high frequency of contact with their fellow nymphs causes these locusts to grow into swarming, migratory adults. Swarms can contain millions of individuals, and have plagued man since our earliest recorded history: "[The locusts] covered the face of the whole earth, so that the land was darkened; and they did eat every herb of the land, and all of the fruit of the trees. . ." (Exodus 10: 14). Swarms have been recorded that are tens of kilometers long and traveling at over 100 km per day, stripping the ground of all vegetation when landing to feed. Food security is obviously threatened by such large masses of herbivorous insects, and historical famines have led to the entrenchment of such events in our culture and language (as reflected in everyday expressions of overconsumption such as "like a plague of locusts"). In the modern era, plagues are arguably less frequent as a result of monitoring and control efforts, and famines can sometimes be avoided by the remedial redistribution of international food reserves. Locusts, nevertheless, also continue to affect human well-being indirectly, for example by interfering with modern means of transport such as cars, trains, and aeroplanes by overwhelming the mechanical operation with masses of (crushed) bodies.

Turning to biotic triggers of outbreaks, it is fair to say that many of these are anthropogenic. Natural predators of insects may be inadvertently removed by changing land use, as when bat habitats are destroyed. The elimination of such useful creatures removes their nightly mosquito-control service, thereby producing an increased risk of disease transmission as discussed elsewhere. Other common

examples include the spraying of agricultural insecticides, when predatory spiders are often also killed, and their prey can then "rebound" to create worse pest problems: The indirect hazard created is then one of threatening food security or other industries such as timber production. Importation of potential pest species into new environments can also pose a hazard, particularly when these environments are devoid of the insects' usual predators (as with the American cockroach, now a globally distributed threat to hygiene in urban kitchens). In anthropogenically simplified ecosystems, there is generally a lack of biodiversity, and insect pests are, therefore, more likely to escape from the biological control normally provided not only by predation, but by interspecific competition (other species competing effectively for the same resources, such as food or nesting areas). Abiotic (climatic) variables often enhance the effect of such biological mechanisms because pest species are generally the best adapted to exploiting environments with rapidly changing conditions – and it is, therefore, likely that the number and extent of insect hazards will increase with global climate change.

Imagined hazards

Insects have profoundly influenced Western culture through time, permeating our language, arts, history, philosophy, and religion. However, as human society has become progressively more urbanized, insects have become progressively more estranged: There is now generally an aversion to insects, with much misplaced fear resulting from inadequate information and lack of more regular contact. The range of such aversions spans the full spectrum of appropriate apprehension when faced with the possibility of a bee sting, through subclinical and clinical insect phobias, to full-blown psychotic delusions of insect attacks and infestations. Phobias involve an irrational fear of insects without the insect bites or infestation actually being experienced, and phobic objects are often totally harmless insects (e.g., dragonflies, moths, and crickets); delusions involve the patient believing that the bites or infestations are actually occurring (Weinstein and Slaney, 2004).

Outlook

It is worth concluding here with consideration of the paradoxical nature of attributing a hazardous nature to insects, both real and imagined. On the one hand, we have seen that mosquito-borne disease kills over a million people every year: In countries with these diseases, people generally do not fear insects, but accept them as part of everyday life (and in some places even depend on them as food). On the other hand, in most developed countries, there are few or no diseases transmitted by insects, and the risk of dying from a sting is less than one in a million (in the same order as being struck by lightning and much less likely than being murdered). Yet in these developed countries, insects are feared to the point of featuring in psychiatric disorders alongside devils and alien abductions. As increasingly intangible elements of urbanized Western culture, it seems likely that insects will continue to be over-rated as a hazard to our health and wealth.

Definition

Insurance is a risk management tool that redistributes a disaster risk among a high number of insured individuals or businesses, and enables one to cover large and accidental losses incurred by them.

Overview

Insurance is a key element of a disaster management cycle, especially as part of the last stage of recovery and reconstruction. It allows each individual to transfer the risks they face to an intermediary that mutualizes these risks among a large number of the insured. When a disaster occurs in one area, they obtain a premium to cover their losses. However, insurance systems in different countries face a number of difficulties related to low insurability rates and the growth of insured damages.

According to the German reinsurance company Munich Re, between 2000 and 2008 natural catastrophe losses reached USD 898 billion, of which USD

287.6 billion (32%) were insured. In 2008, an earthquake in Sichuan, China, the largest natural disaster that year, caused USD 85 billion in economic losses, but only USD 300 million were actually insured. The same year, hurricane Ike destroyed parts of the Caribbean and southern United States, with overall estimated losses of USD 38 billion, but in this case almost half of the losses (USD 15 billion) were insured. Munich Re notices a continuous increase of extreme weather-related events likely linked to climate change (Natural catastrophes, 2009). This growth in claims puts a serious strain on insurance systems and, in consequence, some of the largest disasters in the United States have led to the bankruptcy of a number of small insurers and cessation of disaster insurance offers in hazard-prone areas (Godschalk et al., 1999).

Policyholders, even in the developed countries, are concerned about a low level of insurability (Paklina, 2003). This reluctance is in many cases the result of the human perception of the risk that neglects events with very low probabilities of occurrence, like natural hazards. People do not perceive insurance in the manner that economists assume, but treat it rather as a form of investment. They rather prefer to insure against high-probability, low-consequence events to those with low probability, but with high consequences (Slovic et al., 2005). Cognitive dissonance reduction, on the other hand, may lead to denying the risk and renouncing of mitigation actions (Facing Hazards and Disaster, 2006). Another explanation is that individuals expect to obtain governmental and private aid when a disaster happens. In that case, they perceive insurance as an unnecessary expense (Raschky and Weck-Hannemann, 2007). In Japan, where the national government does not generally authorize financial aid to individuals, the insurability rate is considerably higher (Japan Large-Scale Floods and Earthquakes, 2009).

Imperfections of the insurance market lead some governments to the introduction of new schemes, increasing market penetration, for example, compulsory insurance or government-backed reinsurance mechanisms (France Policies for Preventing and Compensating Flood Related Damage, 2006). In hazard-prone areas, two types of insurance exist: optional and a package system (Paklina, 2003). The first leads to very low penetration rates (in case of flood insurance between 5% and 10% in countries like Austria, Belgium, Germany, Italy, Mexico, or the Netherlands) as the demand for insurance coverage is high in flood-prone areas. Insurance rates are then expensive due to repeated damages. In the package system, the insurance covers the combination of such risks as floods, fires, hurricanes, storm surges, and earthquakes. The risk is spread over a higher number of the insured, across a number of areas with different levels of various disaster risks.

In 1968, the United States adopted the National Flood Insurance Program (NFIP), a unique system providing federally backed basic flood insurance for residential and commercial areas. Its main aim was to reduce the risk of flood losses, reduce demand for federal assistance, and to preserve and restore natural functions of floodplains (Wetmore et al., 2006). Its characteristic feature is linking of the insurance system with other flood mitigation measures. The Community Rating System (CRS) provides discounts on flood insurance for individuals in the communities that establish floodplain management programs, including public information, mapping and regulatory activities, flood damage reduction, and flood preparedness (Burby, 2001). Still, NFIP effectiveness is described as limited with a penetration rate growth from 13% in 1990 to an estimated 22–25% in 2002 (Paklina, 2003).

IEMS

Definition

The Integrated Emergency Management System (IEMS) refers to an all-hazard approach to the coordination, direction and control of disasters independent of their type, origin, size, and complexity. In the early 1980s, this term was coined by the Federal Emergency Management Agency, FEMA, of the United States.

Today the term Integrated Emergency Management System is sometimes also used for computer-based emergency management systems that allow managing all scales of incidents by fostering collaboration and information sharing. These systems are discussed elsewhere (see section Cross-references).

Elements of the integrated emergency management system

FEMA's Integrated Emergency Management System is a framework for effective emergency management that integrates partnerships on local, state, and federal level, including the collaboration of government agencies, private sector, and media. IEMS covers all phases of emergency management, namely mitigation, preparedness, response, and recovery. The IEMS framework describes different elements, processes, and principles for these emergency management phases. Important key elements of the IEMS are:

- **Hazard analysis**: An all-hazard analysis provides the basis for the other IEMS processes since it leads to a better understanding of the consequences and needs of different types of disasters.
- **Capability assessment**: All currently available response capabilities for different emergency response functions, like resource management, mass care, or communication need to be documented and assessed in order to identify shortfalls.
- **Emergency planning**: Emergency plans are based on the hazard analysis and capability assessment. They include a capability inventory, discuss possible consequences for different events, and list the required actions. Plans are important for training and response.
- **Capability maintenance and development**: Even if the current response capabilities are considered to be adequate the available capabilities have to be maintained by regular plan updates, resource maintenance, and training. In case of insufficient capabilities, short-, medium-, and long-term capability development plans have to be created.
- **Emergency response**: Emergency response activities should be based on the emergency plans and modified as necessary. Evaluations of after-action reviews need to be integrated into the existing plans.
- **Recovery and mitigation efforts**: The goal of the recovery efforts is to restore the community function to normal as soon as possible. Recovery itself can be viewed as an opportunity to create a more resilient community. Therefore mitigation efforts, like for example, strengthening infrastructures, can either be an integral part of the recovery phase or they can be initiated prior to a disaster.

Definition

Intensity Scales. A scale to measure the effects and degree of damage caused by an earthquake to the local environment and buildings affected by the seismic event using descriptive evidence to categorize the severity of the damage caused.

Introduction

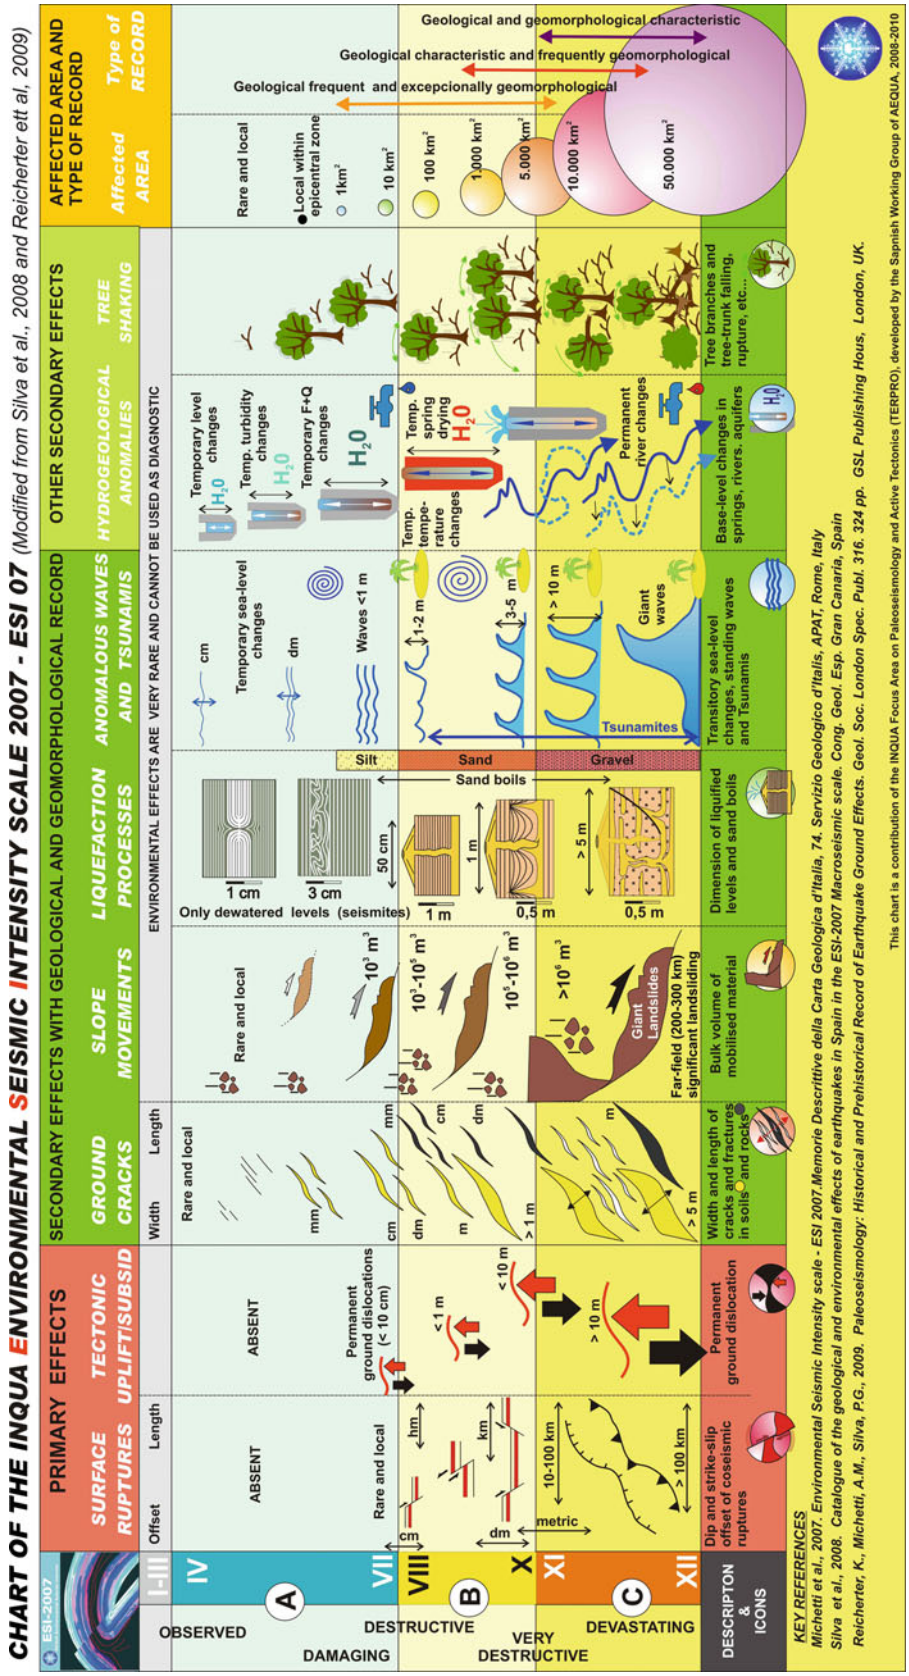
The size and damaging effects or severity of an earthquake are described by measurements of both magnitude and intensity. In seismology (the study of earthquakes), scales of seismic intensity are used to measure or categorize the effects of the earthquake at different sites around its epicenter. Various seismic scales can be used to measure and compare the severity of the seismic event. The amount of elastic energy released by an earthquake is measured on a magnitude scale (see *Magnitude Measures*) whereas the effects of intensity of ground motion or "shaking" occurring at a given surface point are measured on an *intensity scale*.

Seismologists use earthquake intensity as their most widely applicable measure of the size of an earthquake. Intensity is measured by means of the degree of damage to structures of human origin, the amount of disturbance to the surface of the ground and the extent of human and animal reaction to the shaking (Bolt, 2006).

Intensity can therefore be defined as a classification of the strength of shaking at any place during an earthquake, in terms of its observed effects (Musson, 2002).

A series of *intensity scales* have been developed to semi-quantify this degree of damage and disturbance. These scales use descriptive evidence in order to establish the probable size of the earthquake causing the damage. This assessment of earthquake intensity depends on the macroseismic observations (observations of the actual effects of the earthquake), in what is termed the "meizoseismal zone" (the area of maximum disturbance during an earthquake where there is observable damage to buildings). It is not based on measuring the ground motion with instruments (microseismic observations). The descriptive scales have important uses, firstly in determining earthquake size in areas where there are limited seismographs to measure strong ground motion and secondly to retrospectively determine the size of historical earthquakes from contemporary accounts taken at the time of the seismic event. This method can be subjective and is very much dependent on the underlying geological ground conditions which may dampen or exaggerate the effects of the earthquake, but it does provide some limited data on the distribution of ground shaking during a particular event and gives an approximate estimate of the epicenter of the earthquake. It is therefore important that correlations can be made between the various scales used over historical time (Musson et al., 2009). The intensity at a point not only depends on the strength of the earthquake (magnitude) but also on the distance from the earthquake to that point and on the local geology at that point.

Intensity studies enable the macroseismic field of historical and contemporary earthquakes to be reconstructed and through this reconstruction it is often possible to identify the seismogenic source (Panza et al., 1991; Gasperini et al., 1999). The intensity parameter allows for a comparison to be made between more recent earthquakes and historical ones. This is based on the destructive effects described and detailed in the intensity scale used.



Macroseismic scales

A considerable number of macroseismic scales have been developed over the last 200 years in order to try and semi-quantify and describe the effects of an earthquake via a measure of intensity (Musson, 2002; Musson et al., 2009). The first such scale was considered to have been developed by the Italian Jacopo Gastaldi in 1564 (Hao et al., 2005; Xie, 1958). About 8 or so such scales have been more widely adopted, evolving over time and usage. The first widely adopted scales were developed by de Rossi (1874) and Forel (1881) leading to the Rossi-Forel Scale (de Rossi, 1883). The inadequacies of these early scales led to the development of more modern versions together with entirely new scales, an evolving

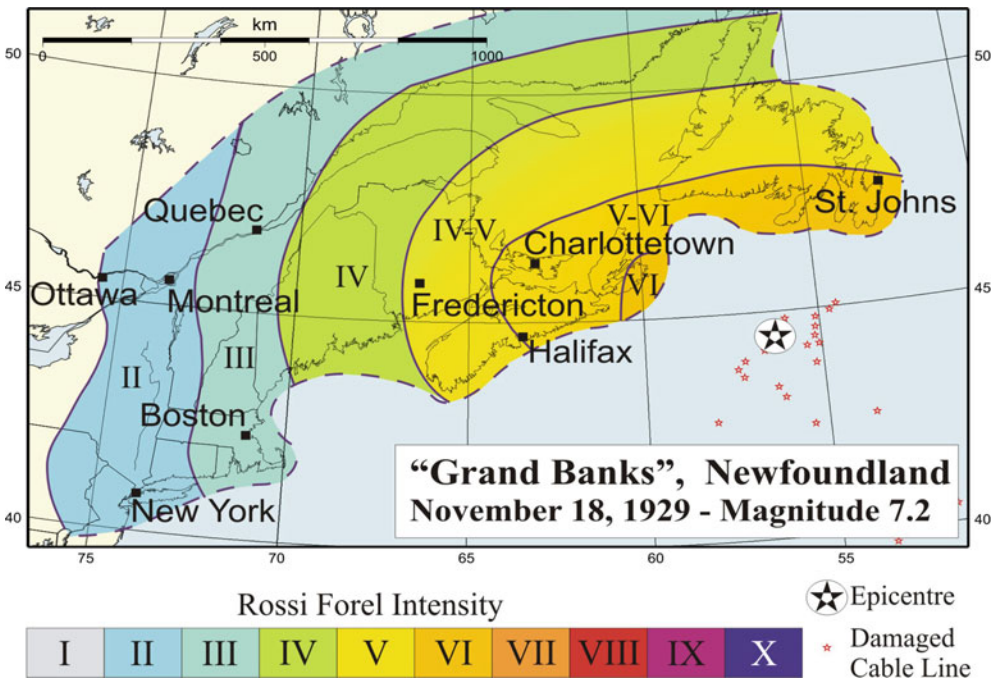
Intensity Scales, Table 2 Modified Mercalli Scale after Richter (Richter, 1958)

Intensity level	Description
I	Not felt. Marginal and long period effects of large earthquakes
II	Felt by persons at rest, on upper floors, or favorably placed
III	Felt indoors. Hanging objects swing. Vibration like passing light trucks. Duration estimated. May not be recognized as an earthquake
IV	Hanging objects swing. Vibration like passing of heavy trucks; or sensation of a jolt like a heavy ball striking the walls. Standing motor cars rock. Windows, dishes, doors rattle. Glasses clink. Crockery clashes. In the upper range of IV, wooden walls and frame creak
V	Felt outdoors; direction estimated. Sleepers wakened. Liquids disturbed, some spilled. Small unstable objects displaced or upset. Doors swing, close, open. Shutters, pictures move. Pendulum clocks stop, start, change rate
VI	Felt by all. Many frightened and run outdoors. Persons walk unsteadily. Windows, dishes, glassware broken. Knickknacks, books, etc., off shelves. Pictures off walls. Furniture moved or overturned. Weak plaster and masonry D cracked. Small bells ring (church, school). Trees, bushes shaken (visibly, or heard to rustle)
VII	Difficult to stand. Noticed by drivers of motor cars. Hanging objects quiver. Furniture broken. Damage to masonry D, including cracks. Weak chimneys broken at roof line. Fall of plaster, loose bricks, stones, tiles, cornices (also unbraced parapets and architectural ornaments). Some cracks in masonry C. Waves on ponds; water turbid with mud. Small slides and caving in along sand or gravel banks. Large bells ring. Concrete irrigation ditches damaged
VIII	Steering of motor cars affected. Damage to masonry C; partial collapse. Some damage to masonry B; none to masonry A. Fall of stucco and some masonry walls. Twisting, fall of chimneys, factory stacks, monuments, towers, elevated tanks. Frame houses moved on foundations if not bolted down; loose panel walls thrown out. Decayed piling broken off. Branches broken from trees. Changes in flow or temperature of springs and wells. Cracks in wet ground and on steep slopes
IX	General panic. Masonry D destroyed; masonry C heavily damaged, sometimes with complete collapse; masonry B seriously damaged. (General damage to foundations.) Frame structures, if not bolted, shifted off foundations. Frames racked. Serious damage to reservoirs. Underground pipes broken. Conspicuous cracks in ground. In alluvial areas sand and mud ejected, earthquake fountains, sand craters
X	Most masonry and frame structures destroyed with their foundations. Some well-built wooden structures and bridges destroyed. Serious damage to dams, dikes, embankments. Large landslides. Water thrown on banks of canals, rivers, lakes, etc. Sand and mud shifted horizontally on beaches and flat land. Rails bent slightly
XI	Rails bent greatly. Underground pipelines completely out of service
XII	Damage nearly total. Large rock masses displaced. Lines of sight and level distorted. Objects thrown into the air
Masonry A	Good workmanship, mortar, and design; reinforced, especially laterally, and bound together by using steel, concrete, etc.; designed to resist lateral forces
Masonry B	Good workmanship and mortar; reinforced, but not designed in detail to resist lateral forces
Masonry C	Ordinary workmanship and mortar; no extreme weaknesses like failing to tie in at corners, but neither reinforced nor designed against horizontal forces
Masonry D	Weak materials, such as adobe; poor mortar; low standards of workmanship; weak horizontally

process that continues to this day (Musson et al., 2009). The comparison of different intensity scales is thus an important issue when trying to understand and cross-correlate historical seismic events (Table 1).

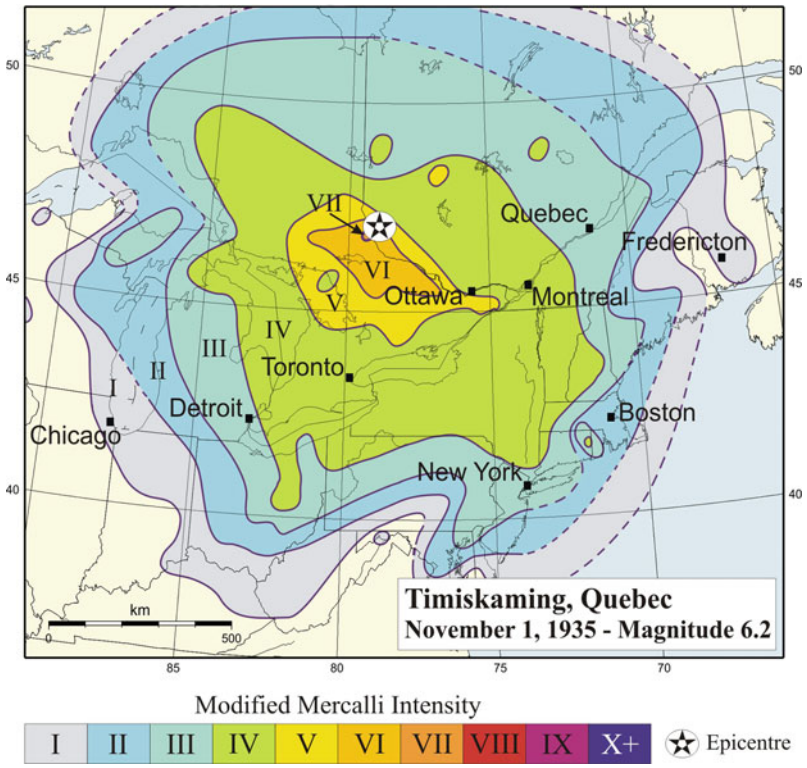
One of the first intensity scales describing earthquake effects on the environment is given in Annex C to the European Macroseismic Scale (EMS-98) by Grünthal (Grünthal, 1998). One of the first proposals of an intensity scale based on effects on rocks and considering terrain vulnerability, thus complementing the EMS-98 environmental scale, is presented by Vidrih (Vidrih et al., 2001). In 2007, another scale was constructed resulting from a series of international meetings (Michetti et al., 2004, 2007) (Figure 1). INQUA (International Union for Quaternary Research) ratified the Environmental Seismic Intensity Scale (ESI-2007) which is now being widely adopted (Reicherter et al., 2009).

All of these *intensity scales* use 10, or more commonly 12, degrees or classes of earthquake effects to describe and define the intensity of the earthquake and the consequent severity of its effects.



Historical development of macroseismic scales

The first widely accepted *intensity scale* was developed by P N C Egen in 1828 (Egen, 1828) followed by the work of de Rossi and Forel (Musson et al., 2009). In 1921 Charles Davison (Davison, 1921) identified 27 different *intensity scales* which increased to 39 in 1933 (Davison, 1933). Giuseppe Mercalli, born in Italy, was the principal developer of two key scales: the Mercalli, 1883 Scale and a second scale published in 1902 (Mercalli, 1883, 1902). These were principally modifications to the Rossi-Forel Scale. In 1904 another Italian Adolfo Cancani proposed a 12-point scale (Cancani, 1904) which added two extra degrees of intensity to deal with the reporting of very strong earthquakes. In 1912, August Sieberg, a German geophysicist, revised the scale definitions which involved a considerable expansion of the description entries (Sieberg, 1912). He continued to develop this scale and published the Mercalli-Cancani-Sieberg Scale in 1923 (Sieberg, 1923). This scale was further modified in 1931 by two American seismologists, Wood and Neumann,



Intensity Scales, Table 3 Ground effects in the MCS-1930, MM-1931, MSK-1964, and Japanese (JMA) intensity scales (After Esposito et al., 1997; Serva, 1994)

Intensity Scales, Figure 3 Isoseismal map of the Timiskaming earthquake 1935, Modified Mercalli Intensity Scale (Halchuk, S., Geological Survey of Canada).

where the original work was translated into English with some changes and published as the Modified Mercalli Scale (Wood and Neumann, 1931). This was completely reworked in 1956 by Charles Richter (Richter, 1958) to become the Modified Mercalli Scale of 1956 (Musson, 2002) (Table 2).

In Europe initial work by Sergei Medvedev, a Russian, together with a Czechoslovak Vit Kárník and an East German Wilhelm Sponheuer led to another 12-point scale being published in 1964 known as the Medvedev-Sponheuer-Kárník or MSK-64 Scale (Medvedev et al., 1964). In 1988, the European system was again further developed to include aspects of more modern building types and designs which resulted in the European Macroseismic Scale, EMS-98 (Grünthal, 1998).

The Japanese Meteorological Agency published a very detailed *intensity scale* which was idiosyncratic to aspects of Japanese buildings and environment (JMA, 1996). This *intensity scale* is measured in units of *shindo* which literally means "degree of shaking." The present use of the JMA scale converts instrumental ground motion readings into these intensity values (Musson et al., 2009). Cross-correlation with previous versions of the scale and other scales is difficult.

In China, the China Seismic Intensity Scale (CSIS) is a 12-degree system created in 1954 by Prof. Li Shan-Bang (Li, 1954) and rewritten by Prof. Xie Yu-sou in 1957 (Xie, 1957). The China Seismic Intensity Scale was supplemented and simplified by Prof. Liu Hui-Xian in 1978 (Liu, 1978), taking account of new kinds of modern buildings, which had been destroyed by strong earthquakes in recent years both in China and elsewhere in the world (Wang, 2004). The scale is sometimes referred to as the Lièdù Scale, literally "degrees of violence."

Environmental seismic intensity scale (ESI-2007)

The INQUA Environmental Seismic Intensity Scale is a 12-degree macroseismic scale which follows the same basic structure of the other historical 12-point scales (Michetti et al., 2007; Reicherter et al., 2009). The main advantage of the ESI 2007 scale is the classification, quantification, and measurement of several known geological, hydrological, botanical, and geomorphological features for different intensity degrees (Reicherter et al., 2009). The scale differentiates two main categories of earthquake effects on the environment:

Primary
Fault surface ruptures
Tectonic uplift/subsidence

Intensity Scales, Table 4 Summary of significant macroseismic scales

Scale name	Acronym	Date	Intensity levels	Original usage	Comments	Reference
Egen		1828		Southern Europe		Egen (1828)
de Rossi		1874		Southern Europe		de Rossi (1874)
Forel		1881		Southern Europe		Forel (1881)
Rossi-Forel	RF	1883	10	Southern Europe	Used for about two decades until the introduction of the Mercalli intensity scale in 1902. Still used in the Philippines	de Rossi (1883)
Mercalli		1883	6	Southern Europe	An adaptation of the de Rossi scale.	Mercalli (1883)
Mercalli		1902	10	Southern Europe	Modification of the de Rossi scale.	Mercalli (1902)
Cancani		1904	12	Southern Europe	Modifications to deal with very strong earthquakes.	Cancani (1904)
Sieberg		1912	6	Southern Europe	Definitions considerably expanded.	Sieberg (1912)
Mercalli-Cancani-Sieberg	MCS	1923	12	Southern Europe Global	Still used today in Southern Europe.	Sieberg (1923, 1930)
Modified Mercalli	MM-31	1931	12	Southern Europe USA	MCS translated into English with some additions.	Wood and Neumann (1931)
Modified Mercalli of 1956	MM-56	1956	12	Southern Europe USA	Complete overhaul of the 1931 version.	Richter (1958)
Medvedev		1953	12	Russia	Also known as the GEOFIAN scale.	Medvedev (1953)
Medvedev-Sponheuer-Karnik	MSK-64	1964	12	USSR Europe, India, Russia, CIS		Medvedev et al. (1964)
	MSK-81	1981	12		Minor modifications made. Became EMS-92	Grünthal (1993)
European Macroseismic Scale	EMS-98	1998	12	Europe, Global	Employs vulnerability classes and involve construction type.	Grünthal (1998)
China Seismic Intensity	CSIS	1954	12	China	Lièdù Scale	Li (1954)
		1957	12	Hong Kong		Xie (1957)
		1980	12			Liu (1978)
Japan Meteorological Agency Seismic Intensity	JMA	1884	4	Japan, Taiwan	Shindo scale	Japanese Meteorological (1996)
		1898	8		Changed to a numerical system	
		1908	8		Levels given descriptions	
	JMA-96	1996	10		Following the Great Hanshin earthquake in 1995, Shindo was further expanded to a total of 10 levels	
Environmental seismic intensity	ESI-2007	2007	12	Europe, Global	Ratified following the 17th INQUA Congress.	Michetti et al. (2004)

Secondary
Ground cracks
Slope movements
Liquefaction processes
Anomalous waves and tsunamis
Hydrogeological anomalies
Tree shaking

Primary effects triggered by surface faulting can be further sub categorized:

Almost absent for intensity degrees below VIII
Characteristic but moderate for intensities between VIII and X
Diagnostic for stronger intensities of XI and XII

Table 3 highlights the ground effects and the associated intensity degree from the various macroseismic scales. Figure 1 summarizes the ESI-2007 scheme and highlights the main diagnostic characteristics of the different effects resulting from a seismic event. The chart provides a qualitative framework to assess affected areas, the geological and geomorphological setting of the area and their respective degree of presentation through time. Reicherter et al. (2009) provides a detailed appendix, which outlines the definitions of the intensity degrees used in the ESI-2007 scale. Various case studies are available (Mosquera-Machado et al., 2009; Papanikolaou et al., 2009; Tatevossian et al., 2009; Ota et al., 2009) which have been used to benchmark this *intensity scale*.

Intensity and isoseismal maps

The presentation of intensity data is usually done in the form of a map (Musson, 2002). By drawing lines on a map between places of equal damage (hence equal intensity) a series of isoseismal (term coined by Robert Mallet in 1862) contours can be created. This isoseismal line can be defined as a line bounding the area within which the intensity is predominantly equal to, or greater than, a given value. Figures 2 and 3 show examples of isoseismal maps for two different *intensity scales*.

Arias intensity

In 1970, Arturo Arias, a Chilean engineer, proposed a way to determine objectively the intensity of shaking during an earthquake by measuring the acceleration of transient seismic waves (Arias, 1970). It is an important measure of the strength of ground motion. The time-integral of the square of the ground acceleration became known as the Arias Intensity (Equation 1), which represents the square root of the energy per mass thus having units of "m/s." This intensity must not be confused with the macroseismic intensity scales, which describe the subjective intensity of shaking as reported by people and building damage.

$$\textbf{Arias Intensity } I_A = \frac{\pi}{2g}\int_0^{T_d} a(t)^2 dt(\mathrm{m/s}) \qquad (1)$$

Where g is the acceleration due to gravity and T_d is the duration of signal above the threshold level.

Summary

A variety of *Intensity Scales* have been developed to measure the degree of damage caused by an earthquake to the local environment and buildings affected during a seismic event. A variety of descriptive evidence is used to categorize the severity of the damage caused. Many scales have been developed and modified for local site conditions (Table 4).

INTERNATIONAL STRATEGIES FOR DISASTER REDUCTION (IDNDR AND ISDR)

Karl-Otto Zentel[1], Thomas Glade[2]
[1]Deutsches Komitee Katastrophenvorsorge, Bonn, Germany
[2]University of Vienna, Vienna, Austria

Terminology

Disaster Risk Reduction: The concept and practice of reducing disaster risks through systematic efforts to analyze and

manage the causal factors of disasters, including through reduced exposure to hazards, lessened vulnerability of people and property, wise management of land and the environment, and improved preparedness for adverse events.

Early Warning: The set of capacities needed to generate and disseminate timely and meaningful warning information to enable individuals, communities, and organizations threatened by a hazard to prepare and to act appropriately and in sufficient time to reduce the possibility of harm or loss.

ENSO-El Nino Southern Oscillation Phenomenon: A complex interaction of the tropical Pacific Ocean and the global atmosphere that results in irregularly occurring episodes of changed ocean and weather patterns in many parts of the world, often with significant impacts over many months, such as altered marine habitats, rainfall changes, floods, droughts, and changes in storm patterns.

National Platform for Disaster Risk Reduction: A generic term for national mechanisms for coordination and policy guidance on disaster risk reduction that are multi-sectoral and interdisciplinary in nature, with public, private, and civil society participation involving all concerned entities within a country (UNISDR, 2009, Terminology of Disaster Risk Reduction).

Background

During the 1970s and 1980s more than 800 million people were affected by natural disasters. More than 23 billion US$ damage were caused and 3 million people killed (General Assembly A/RES/43/202). The worst disasters were the droughts in sub-Saharan Africa region and floods in Southeast Asia, each of which claimed several hundred thousand victims.

These developments led to an increasing attention to the subject of disaster reduction. The President of the American Society of Science, Frank Press, started an initiative to declare the 1990s a Decade for Disaster Reduction. The aim of this initiative was to integrate already existing scientific knowledge in the field of disaster reduction into development decisions and projects.

The increasing losses caused by natural disasters led to a number of developments in the humanitarian sector. The tragic events of the 1980s led to the decisions in 1992 at the European Commission to establish the European Commission Humanitarian Office (ECHO) and at the United Nations to improve coordination of the work of the UN Agencies by a central coordinating organization with a humanitarian mandate (today), the Office for the Coordination of Humanitarian Affairs (OCHA).

In its Report "Our Common Future," the World Commission on Environment and Development (so-called Brundtland Commission) made a clear link between the need for implementation of disaster reduction measures and sustainable development (Report of the World Commission on Environment and Development "Our Common Future").

> The Commission has sought ways in which global development can be put on a sustainable path into the 21st century.
>
> During the 1970s, twice as many people suffered each year from "natural" disasters as during the 1960s. The disasters most directly associated with environment/development mismanagement – droughts and floods – affected the most people and increased most sharply in terms of numbers affected. Some 18.5 million people were affected by drought annually in the 1960s. 24.4 million in the 1970s. There were 5.2 million flood victims yearly in the 1960s. 15.4 million in the 1970s. Numbers of victims of cyclones and earthquakes also shot up as growing numbers of poor people built unsafe houses on dangerous grounds.
>
> The results are not in for the 1980s. But we have seen 35 million affected by drought in Africa alone and tens of millions affected by the better managed and thus less- publicized Indian drought. Floods have poured off the deforested Andes and Himalayas with increasing force. The 1980s seem destined to sweep this dire trend on into a crisis-filled 1990s (Report of the World Commission on Environment and Development "Our Common Future". p 23).

The Commission identified the link between the negative effects of natural disasters and poverty: "*Such disasters claim most of their victims among the impoverished in poor nations*, . . ." (Report of the World Commission on Environment and Development "Our Common Future"., p 42).

Reasons for the increasing negative effects of natural disasters were seen in unsolved development problems: "*All major disaster problems in the Third World are essentially unsolved development problems. Disaster prevention is thus primarily an aspect of development, and this must be a development that takes place within sustainable limits*." (Grann et al., 1985, p 43)

The start

In its 42nd General Assembly in 1987 the United Nations – based on the Report of the World Commission on Environment and Development – already made important and guiding decisions to establish an International Decade on natural disaster reduction in the 1990s. It was expected that special attention should be given to less developed countries as those are the most affected by natural disasters. Goals for the Decade were identified and member states were asked to establish national committees in order to support the goals. The main emphasis was given towards the transfer of technology and scientific knowledge in the field of disaster reduction. Resolutions (refer to Box 1).

An Ad Hoc Expert Group, chaired by Frank Press, was established to further define the role and structure of the Decade. On April 11, 1989, this expert group provided a joined declaration the "Tokyo Declaration" in which the experts clearly identified the root causes of the increasing losses, identified the important role of the international system, and underlined the need for national activities to support the decade.

Within the Tokyo Declaration it was stated:

> Vulnerability to natural disasters is rising due to population growth, urbanization, and the concentration of industry and infrastructure in disaster-prone areas. . . .
>
> We believe that the Decade is a moral imperative. It is the first coordinated effort to prevent the unnecessary loss of life from natural hazards. . . .

> The Group calls for all countries to form national committees to plan for and coordinate national efforts (Tokyo Declaration, 1989, p.1).

In its letter to the Secretary General dated June 1, 1989, Frank Press gave a strong statement toward the need for action, for integrated approaches combining different constituencies as well as a continuum approach throughout the disaster management cycle.

> Fatalism is not longer acceptable; it is time to bring the full force of scientific and technological advancement to reduce the human tragedy and economic loss from natural disaster. We must take an integrated approach to disaster reduction, bringing new emphasis to pre disaster planning, preparedness, and prevention, while sustaining our post disaster relief capabilities. Our humanitarian efforts must be broadened to encompass disaster- resistant instrument as well as timely warnings in which people at risk receive, understand and act upon the information conveyed (ref. June 1, 1989 p iii).

At the 44th session the General Assembly of the United Nations the members proclaimed IDNDR.

> para1"Proclaims the International Decade for Natural Disaster Reduction, beginning on 1 January 1990"; (GA 44/236; 85th Plenary meeting; 22 December 1989)

The goals defined in the Resolution of 1987 were kept as objectives for the Decade. The member states agreed:

> The objective of the International Decade for Natural Disaster Reduction is to reduce through concerted international action, especially in developing countries, the loss of life, property damage and social and economic disruptions caused by natural disasters such as earthquakes, windstorms, tsunamis, floods, landslides, volcanic eruptions, wildfires, grasshopper and locust infestations, drought and desertification and other calamities of natural origin (ref. GA/RES/44/236 Annex A).

Member states were asked to establish National Committees and inform the Secretary General about their initiatives. IDNDR became through this request one of the very few United Nations organizations/structures linked to corresponding national structures. UNESCO and WMO are examples of similar protocols. A special high-level council should be established to provide advice to the Secretary General. A Scientific and Technical Committee (STC) to develop overall programs, identify gaps in technical knowledge, and to assess and evaluate activities carried out was foreseen.

A secretariat was established – attached to the United Nations Disaster Relief Coordinator - to manage and coordinate the day-to-day work. The United Nations Development Programme (UNDP) became the focal point to oversee the programs. The resident coordinators were asked to integrate the goals of the Decade into their work. The World Meteorological Organisation (WMO) and the United Nations Education and Scientific Organisation (UNESCO) became major contributors to the Decade. In order to fund the secretariat and programs, member states were asked for voluntary contributions to a trust fund. Already in this declaration a review of the Decade was foreseen for 1994.

Based on the broadly defined goals, the STC identified a number of specific areas of activities which would mark progress to be achieved at the end of the Decade period (ref. Plate/Merz Naturkatastrophen p. 33). Herein it was claimed that by the year 2000, all countries should have in place:

1. Comprehensive national assessments of risks from natural hazards, with these assessments taken into account in development plans
2. Mitigation plans at national and/or local levels, involving long-term prevention and preparedness and community awareness
3. Ready access to global, regional, national, and local warning systems and broad dissemination of warnings

Box 1

"The General Assembly . . .

Recognizing the responsibility of the United Nations system for promoting international cooperation in the study of natural disasters of geophysical origin and in the development of techniques to mitigate risks arising there from, as well as for co-ordinating disaster relief, preparedness and prevention, including prediction and early warning.

para 3. Decides to designate the 1990s as a decade in which the international community, under the auspices of the Unites Nations, will pay special attention to fostering international co-operation in the field of natural disaster reduction.

para 4. Goals

(a) To improve the capacity of each country to mitigate the effects of natural disasters expeditiously and effectively, paying special attention to assisting developing countries in the establishment, when needed, of early warning systems;
(b) To devise appropriate guidelines and strategies for applying existing knowledge, taking into account the cultural and economic diversity among nations;
(c) To foster scientific and engineering endeavours aimed at closing critical gaps in knowledge in order to reduce loss of life and property;
(d) To disseminate existing and new information related to measures for the assessment, prediction, prevention and mitigation of natural disasters;
(e) To develop measures for the assessment, prediction, prevention and mitigation of natural disasters through programmes of technical assistance and technology transfer, demonstration projects, and education and training, tailored to specific hazards and locations, and to evaluate the effectiveness of those programmes;

para 7. Calls upon all governments to participate during the decade in concerted international action for the reduction of natural disasters and, appropriate, to establish national committees, in co-operation with the relevant scientific and technological communities with a view to surveying available mechanisms and facilities for the reduction of natural hazards, . . ." (42/169, 1987 96th plenary meeting, 11. December 1987)

The midterm review "World Conference on Natural Disaster Reduction, Yokohama, Japan, 23–27 May 1994"

In the beginning years of the Decade, the efforts made were very scientifically oriented, giving special emphasis on technical possibilities in the sectors of prevention and mitigation. The Yokohama conference 2004 clearly recognized the still existing gaps between the vision – as formulated at the beginning of the Decade – and reality. This reality was that the goals and targets were far from being achieved as one would have expected after half of the Decade had passed by: Many of the delegates of the 147 nations represented at the conference commented that 95% of the Decade's work needs to be done in its second half. In the "Assessment of the status of disaster reduction midway into the Decade/Yokohama Strategy" it was concluded that "*Awareness of the potential benefits of disaster reduction is still limited to specialized circles and has not been successfully communicated to all sectors of society, in particular policy makers and the general public*" (Yokohama Strategy and Plan of Action, 1994, p 7).

The conference came to the conclusion that the intended impact of the technical solutions could only achieve the given goals if they were integrated in an appropriate socioeconomic and political framework. This can be evaluated as a major turnover for problem-oriented thinking and management. Suddenly, the involved parties realized that structural measurements indeed help to address the problems; however, they were far from solving the issues.

The conference unanimously accepted the declaration of the "Yokohama Strategy." The 18-page document gives clear outlines and a plan of action although no specific disaster or action is mentioned in detail. The targets of IDNDR were broadened in the "Yokohama Strategy" to integrate cultural, socioeconomic, and political aspects into disaster reduction programs of the Decade.

End of the IDNDR decade

The international community was increasingly aware that natural disasters are a major threat to social and economic stability and that disaster prevention is the main long-term solution to this threat. The largest challenge of the Decade laid, therefore, in the creation of a global culture of prevention as the Secretary General Kofi Annan stressed: "*We must, above all, shift from a culture of reaction to a culture of prevention. Prevention is not only more human cure; it is also much cheaper . . . Above all, let us not forget that disaster prevention is a moral imperative, no less than reducing risks of war.*" (International Decade for Natural Disaster Reduction, Programme Forum, 1999, Proceedings p 13) The IDNDR Secretariat in the United Nations organized the "IDNDR International Programme Forum – Towards Partnerships for Disaster Reduction in the 21st Century" as the closing event of the Decade.

The Geneva Programme Forum ended with the "Geneva Mandate", a joint statement of the participants of the Forum. Furthermore, the strategy "A Safer World in the 21st Century: Disaster and Risk Reduction" was developed. In this strategy the following goals were formulated:

(a) To increase public awareness of the risks that natural, technological, and environmental hazards pose to modern societies.
(b) To obtain commitment by public authorities to reduce risks to people, their livelihoods, social and economic infrastructure, and environmental resources.
(c) To engage public participation at all levels of implementation so as to create disaster-resistant communities through increased partnerships and expanded risk reduction networks at all levels.
(d) To reduce economic and social losses caused by disasters as measured, for example, by gross domestic product. (A Safer World in the 21st Century: Disaster and Risk Reduction, http://www.unisdr.org/eng/about_isdr/bd-safer-world-eng.htm)

These goals were the basis for the successor arrangement "International Strategy for Disaster Reduction (ISDR)".

During the Decade tragically the number of major natural disasters rose by nearly a third, compared to the 1980s, more than two and a half times as many people died, and economic damage tripled, according to statistics provided by Munich Reinsurance Company. Some suggested that this showed the failure of the IDNDR Decade. However, it has to be emphasized that first of all any action taken on the political level needs time to be implemented and therefore, visible also in decreasing consequences. Additionally one could also argue: If the IDNDR had not been in place, the losses would have been even greater. In any case, these developments made it evident how necessary further efforts in the area of disaster reduction were and how important it was that the findings from the Decade become implemented. The need for a continuation was obvious. However the discussion about if and how to organize a follow-up to the IDNDR was very much dominated by diverting interests of agencies and member states on structural and administrative aspects.

The Decade contributed very much to an increased understanding for the need of disaster reduction in order to achieve sustainable development. One of the major achievements of the Decade was the clear recognition that hazards are only one factor which may cause disasters and that human activities are at least equally important. Thus, the humanity is not the victim of environmental conditions, it is also responsible and even partly the driver of this adverse development. However, the focus of the Decade on natural disasters was based on several reasons:

(a) Larger losses and more negative effects by natural disasters in developing countries
(b) The traditional point of view by developed countries with regard to vulnerabilities, different levels of

development, coping capacities, and the need for a transfer of technology
(c) Avoiding diverting discussions about real causes of susceptibility to disasters
(d) Developing a program which could be acceptable to the majority of member states

From the political point of view, the shift of real causes from poverty and underdevelopment to natural hazards proved to be successful in order to reach an agreement for the IDNDR.

Continuation and the International Strategy for Disaster Reduction (ISDR)

The negative trends in disasters throughout the 1990s clearly underlined the need to continue with international coordinated efforts to reduce the impacts of natural disasters. The Secretary General of the United Nations, Kofi Annan, proposed to the member states to continue the successful work of IDNDR in form of an International Strategy for Disaster Reduction. The objectives and goals are based on the outcomes of the Geneva Forum of IDNDR. They show a shift from protection to the management of disasters. Emphasis is placed on the resilience of societies.

> para 6 The main objectives of the Strategy are: (a) to enable communities to become resilient to the effects of natural, technological and environmental hazards . . . (b) to proceed from protection against hazards to the management of risk, by integrating risk prevention strategies into sustainable development activities. (International Decade for Natural Disaster Reduction: successor arrangements (Report of the SG) A/54/497, 1 November 1999)

The strategy is based on four main goals derived from the above objectives taken from the Geneva Mandate.

In its resolution 1999/63, the Economic and Social Council requested the Secretary-General to:

> *(a) Establish, as at January 2000, an inter-agency task force, with representation from all relevant United Nations bodies and members of the scientific and technical community, including regional representation, to serve as the main forum within the United Nations for continued and concerted emphasis on natural disaster reduction, in particular for defining strategies for international cooperation at all levels in this field, while ensuring complementarity of action with other agencies; (b) Maintain the existing inter-agency secretariat function for natural disaster reduction as a distinct focal point for the coordination of the work of the task force, to place the inter-agency task force and inter-agency secretariat under the direct authority of the Under-Secretary-General for Humanitarian Affairs and to finance it from extrabudgetary resources through a specific trust fund.* (International Decade for Natural Disaster Reduction: successor arrangement, A/54/497)

At the same time member states were asked to maintain their IDNDR Committees in the form of National Platforms for disaster reduction. This change from Committees to Platforms was based on the recognition of disaster reduction being a cross-cutting issue which needs to involve many stakeholders. The term "Platform" was seen as being the appropriate one to express the model of a place where all stakeholders – despite their background – could meet at the same level.

The General Assembly agreed to this proposal and by Resolution A/RES/54/219 the International Strategy for Disaster Reduction became established.

By accepting the by ECOSOC proposed structure the secretariat kept its status equal to OCHA. The structure was chosen in order to ensure the universal, interdisciplinary, and intersectoral nature of the secretariat instead of integrating disaster reduction into the structures of the United Nations Development Programme (UNDP) or the Office for the Coordination of Humanitarian Affairs.

However, with the structures of an Inter-Agency-Secretariat and an Inter-Agency Task Force the contact to structures outside the United Nations like the scientific community and member states was weakened.

World Summit on Sustainable Development, South Africa, 2002

The first important World Conference following the establishment of ISDR was the World Summit for Sustainable Development (WSSD) in Johannesburg, 2002, which provided the floor for the follow-up to the decisions taken at the United Nations Conference on Environment and Development (UNCED), Rio de Janeiro, 1992. In the outcomes of the WSSD member states of the United Nations recognized disaster reduction as a prerequisite to achieve sustainable development. In Chapter IV member states agreed on:

> "An integrated, multi-hazard, inclusive approach to address vulnerability, risk assessment and disaster management, including prevention, mitigation, preparedness, response and recovery, is an essential element of a safer world in the twenty-first century. Actions are required at all levels to:
>
> (a) Strengthen the role of the International Strategy for Disaster Reduction and encourage the international community to provide the necessary financial resources to its Trust Fund;
> (b) Support the establishment of effective regional, subregional and national strategies and scientific and institutional support for disaster management;
> . . .
> (f) Encourage the dissemination and use of traditional and indigenous knowledge to mitigate the impact of disasters and promote community-based disaster management planning by local authorities, including through training activities and raising public awareness; (Report of the World Summit on Sustainable Development, Annex, Plan of Implementation of the World Summit on Sustainable Development. (Document A/CONF.199/20). Chapter IV: Protecting and managing the natural resource base of economic and social development, No. 37, pp. 27–28.)

These references were clear improvements with regard to the recognition of disaster reduction compared to the Outcomes of United Nations Conference on Environment and Development (UNCED), Rio de Janeiro 1992.

The Outcomes of the WSSD led to a number of resolutions on ISDR with the title "Natural Disasters and

Vulnerability." The first of this resolutions A/RES/58/215 (2003) referred to the Johannesburg Declaration on Sustainable Development and:

> . . .*urges* the international community to continue to address ways and means, including through cooperation and technical assistance, to reduce the adverse effects of natural disasters, including those caused by extreme weather events, in particular in vulnerable developing countries, through the implementation of the International Strategy for Disaster Reduction, and encourages the Inter-Agency Task Force for Disaster Reduction to continue its work in this regard; (A/RES/58/215 para2)

A link to climate negotiations was made the first time and kept in the following resolutions until today:

> . . .*encourages* the Conference of the Parties to the United Nations Framework Convention on Climate Change and the parties to the Kyoto Protocol to the United Nations Framework Convention on Climate Change to continue to address the adverse effects of climate change, especially in those developing countries that are particularly vulnerable, in accordance with the provisions of the Convention, and also encourages the Intergovernmental Panel on Climate Change to continue to assess the adverse effects of climate change on the socio-economic and natural disaster reduction systems of developing countries; (A/RES/58/215 para´6)

Since A/RES/60/196 (2005) a reference to the WCDR and the Hyogo Framework for Action was included into the Resolution as well as to the role of National ISDR Platforms.

> *Reaffirming also* the Hyogo Declaration and the Hyogo Framework for Action 2005–2015: Building the Resilience of Nations and Communities to Disasters, as adopted by the World Conference on Disaster Reduction, held at Kobe, Hyogo, Japan, from 18 to 22 January 2005, (A/RES/60/196)
> *Encourages* Governments, through their respective International Strategy for Disaster Reduction national platforms and national focal points for disaster risk reduction, in cooperation with the United Nations system and other stakeholders, to strengthen capacity-building in the most vulnerable regions, to enable them to address the socio-economic factors that increase vulnerability, and to develop measures that will enable them to prepare for and cope with natural disasters, including those associated with earthquakes and extreme weather events, and encourages the international community to provide effective assistance to developing countries in this regard; (A/RES/60/196 para5)

These references were kept (WSSD, WCDR, National Platforms and the Climate negotiations) in A/RES/61/200 (2006) and in the Resolution of 2008 A/RES/63/217.

World Conference on Disaster Reduction (WCDR), Kobe 2005

However, despite these resolutions, the review of the Yokohama Strategy for Action (2004) undertaken in the preparation to the World Conference for Disaster Reduction (WCDR) in January 2005 provided quite disillusioning findings:

In its report to the General Assembly the Secretary-General pointed out:

> Para 14. Since the Yokohama Strategy was adopted, there have been about 7,100 disasters resulting from natural hazards around the world. They have killed more than 300,000 people, and caused more than US$ 800 billion in losses. The UN Under-Secretary General for Humanitarian Affairs has indicated "that on average, with well over 200 million people affected every year by 'natural' disasters since 1991, this is seven times more than the average of 30 million people affected annually by conflict."
> . . .
> Para 22. While only 11% of people exposed to natural hazards live in low human development countries, they account for more than 53% of total recorded deaths. - The Hyogo Framework for Action 2005
> . . .
> Para 79. Particular significance has been given to the sociology of disasters and other human dimensions that highlight the relevance of vulnerability in conditioning people's exposure to risk. (Draft Review of Yokohama Strategy and Plan of Action for a Safer World A/CONF.206/PC(II)/3 8 September 2004)

In the General Assembly Resolution A/RES/58/214, the United Nations decided to convene a World Conference on Disaster Reduction in 2005 (para7).

The WCDR was the second World Conference on Disaster Reduction following Yokohama. Taking place in January 2005, still under the full impressions of the Indian Ocean Tsunami from December 26, 2004, the conference got the full attention of politicians and international media; 168 member states and more than 4,000 participants were present in Kobe. The member states voluntarily agreed on the Hyogo Framework for Action which provided the workplan for the period 2005–2015. The Document is structured around three strategic goals and five Priorities for Action which are summarized in Box 2.

The Hyogo Framework for Action provided the workplan for the ISDR systems for the period 2005–2015. The clear structure of the documents and the assignments of tasks in the implementation of the Framework made it necessary to analyze the existing structures and identify arrears where they could be improved. The need for a better interlinkage with the scientific community and a closer involvement of member states into the ISDR structures were identified. In order to address these topics it was decided to establish a Scientific Committee. Additionally the General Assembly agreed that every 2 years a Global Platform would be organized as a Forum for member states, UN agencies, scientific community, and civil society to meet.

In order to move from a focus on hazards and losses and to address the dynamic nature of risk UNISDR started a biannual publication "Global Assessment Report" (GAR) which was presented for the first time at the Global Platform 2009. This publication addresses the changing nature of risk. It builds on studies undertaken among others by UNDP and the World Bank.

While a number of advancements were reported in the 2009 GAR, major obstacles to improve disaster risk reduction were identified in the underlying root causes.

Poverty, lack of integration of disaster risk reduction into development planning, and weak governance structures were recognized as the main barriers. At the same time it became evident that it needs additional efforts to integrate disaster risk reduction firmly into the international debate on the negative effects of Climate Change. The decision of the Intergovernmental Panel on Climate Change (IPCC) to prepare a special report on "Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation" and its findings presented in November 2011 is a milestone in this direction.

The Global Platform 2009 meeting and the launch of the GAR were the major ISDR events in 2009. While they stimulated the discussions and contributed to a further integration of disaster risk reduction in the development agenda, a number of gaps were identified. The issue of disaster statistics is not sufficiently addressed. Until today the disaster reduction community relies on three main sources, the sigma database from SwissRE, the NATCAT Service of Munich Reinsurance, and EMDAT, the database of the Center for the Research and Epidemiology of Disasters. The same is true for the important topic of cost-benefits of disaster reduction. A study of the World Bank addressing this issue "Natural Hazards, UnNatural Disasters – The Economics of Effective Prevention" was published in 2010.

Box 2

Strategic goals

12. To attain this expected outcome, the Conference resolves to adopt the following strategic goals

(a) The more effective integration of disaster risk considerations into sustainable development policies, planning, and programming at all levels, with a special emphasis on disaster prevention, mitigation, preparedness, and vulnerability reduction
(b) The development and strengthening of institutions, mechanisms, and capacities at all levels, in particular at the community level, that can systematically contribute to building resilience to hazards
(c) The systematic incorporation of risk reduction approaches into the design and implementation of emergency preparedness, response, and recovery programs in the reconstruction of affected communities

Priorities for action

14. Drawing on the conclusions of the review of the Yokohama Strategy, and on the basis of deliberations at the World Conference on Disaster Reduction and especially the agreed expected outcome and strategic goals, the Conference has adopted the following five priorities for action:

1. Ensure that disaster risk reduction is a national and a local priority with a strong institutional basis for implementation.
2. Identify, assess, and monitor disaster risks and enhance early warning.
3. Use knowledge, innovation, and education to build a culture of safety and resilience at all levels.
4. Reduce the underlying risk factors.
5. Strengthen disaster preparedness for effective response at all levels (Hyogo Framework for Action, 2005).

The midterm review of the Hyogo Framework for Action

In order to investigate the effectiveness of the Hyogo Framework for Action, a midterm review was carried out. It was stated that

> . . ."We are still far from having empowered individuals to adopt a disaster risk reduction approach in their daily lives and demand that development, environmental and humanitarian policies and practices be based on sound risk reduction measures" (HFA MTR, Foreword the Special Representative of the Secretary-General for the implementation of the Hyogo Framework for Action, p 9)

In the document of the Hyogo Framework for Action it was declared that its implementation "will be appropriately reviewed" (HFA, IV Implementation and follow-up, A. General Considerations, para 29, p 14). The terms of reference of a Midterm Review were discussed in three Plenary sessions of the Global Platform 2009. It was decided to carry out the Midterm Review based on the following five analytical tools:

1. A Literature Review
2. Outcomes of structured workshops held at regional and national level
3. Selected in-depth studies
4. One-on-one interviews with key policy makers
5. Online debates

To provide advice on the MTR an Advisory Group of senior experts in disaster risk reduction, donor representatives, evaluation experts, and civil society were established. One of the challenges identified in the review process was: "Measuring progress against the expected outcome of reducing the loss of lives and assets due o disasters is difficult in the absence of a commonly agreed baseline at the time of the HFA adoption and of regular, standardized data collection by governments on disaster losses." (HFA Midterm Review, 2.1 Challenges, p 18)

While the Midterm Review noted that: ". . .significant progress has been made over the past five years in disaster risk reduction and that the adoption of the HFA 2005 has played a determinant role in pushing this process across

international, regional and national agendas . . .” it also was concluded “. . . that these connections, strongly driven by the disaster risk reduction community, have not been fully internalized in the ways in which international development assistance agencies, some government institutions, and the United Nations are institutionally and financially organized to manage disaster risk reduction.” (HFA MTR, Suggestions for accelerating implementation of the Hyogo Framework for Action, p 55)

Based on these findings an institutional reassessment is suggested: “. . .where disaster risk reduction is placed within the international national and regional agencies to ensure that critical functions such as mainstreaming for sustainable development, strategic advice, monitoring of implementation, and reporting on impacts can effectively influence development policies and plans.” (HFA MTR, Suggestions for accelerating implementation of the Hyogo Framework for Action, p 56)

The conclusion and recommendations address the key point of a further implementation of disaster risk reduction. In order to be able to measure progress they ask for targets to be set, “. . .standards to ensure quality in the delivery. . .” and “International, national and local level accountability mechanisms should be encouraged and developed to help measure action taken and progress achieved. . .” (HFA MTR, Conclusions and recommendations for the way forward, p 70)

In order to strengthen the ISDR system the improvement of government for disaster risk reduction at international and national level and an assessment of the effectiveness of National Platforms is proposed. The MTR of the HFA started the debate about the expected outcomes of the HFA by 2015 and actions to be taken. At the same time it already launched the debate about a Post 2015 Disaster Risk Reduction Framework.

Special thematic foci throughout IDNDR and ISDR

Starting with the IDNDR two selected core topics were put prominently on the agenda of disaster reduction. The following points will introduce how Early Warning and the El Nino phenomenon have been addressed.

Early Warning was seen as one of the most effective instruments to save lives and reduce losses caused by disasters. Thus, the development and implementation of local, regional, and global early warning centers was formulated as one of the goals of IDNDR by the Scientific and Technical Committee.

At the World Conference 2004 in Yokohama, a specific technical committee session was devoted to this subject.

> Subsequently, at its forty-ninth session, the General Assembly called for improvements and better coordination within the United Nations system with regard to natural disasters and similar disasters with an adverse effect on the environment. The General Assembly, in its resolution 49/22 B, placed this initiative distinctly within the concerted efforts of implementing the Yokohama Strategy and Plan of Action, and thus within the framework of IDNDR (A/54/132 – E/1999/80, para 22).

In order to address this complex issue scientifically and to get a State of the Art on Early Warning, the First International Conference on Early Warning EWCI was organized in 1998 in Potsdam, Germany. In its final declaration participants emphasized:

> The Potsdam Early Warning Conference has identified major strengths and weaknesses in early warning capacities around the world. Participants repeatedly emphasized the multidisciplinary and multi-sectoral character of the early warning process. Although based on scientific and technology, early warning must be tailored to serve people’s needs, their environments, and their resources. Successful early warning requires unrestricted access to data that is freely available for exchange. Ultimately, all resulting information must be credible, and emanate from a single officially designated authority (Final Declaration EWC I, http://www.geomuseum.com/ewc98/).

The conclusions of the conference highlighted the importance of Early Warning in the framework of disaster reduction, put special emphasis on the multi-sectoral and interdisciplinary character of Early Warning, and the need to support the implementation of early warning systems on the local level.

1. Early warning represents a cornerstone of disaster reduction. It should, therefore, become a key element of future disaster reduction strategies for the twenty-first Century that are to be formalized in the conclusion of the IDNDR.
2. Effective early warning depends upon a multi-sectoral and interdisciplinary collaboration among all concerned actors, as demonstrated during the Potsdam Early Warning Conference.
3. While early warning capabilities must continue to be strengthened at the global level, it is important that greater emphasis be given to developing capacities that are relevant, and responsive to, the needs of local communities (Conclusion EWC I).

The Final report of the Scientific and Technical Committee of the International Decade for Natural Disaster Reduction (A/54/132/Add.1-E/1999/80/Add.1) shared these opinions (para 37–38).

Following the end of IDNDR and the establishment of ISDR and 5 years after EWCI, the Second International Conference on Early Warning (EWCII) took place in 2003 in Bonn, Germany. The subtitle of EWCII “Integrating Early Warning into Public Policy” expressed the concept of EWCII. It was based on the recognition of increasing scientific knowledge on early warning but a gap on the side of integration into public policy. Thus, the conference aimed to establish links between science and policy. The conference statement emphasized this goal and asked for the establishment of an early warning platform to sustain the dialogue.

> Calls for the integration of early warning systems into government policies and requests the organizers to disseminate widely to authorities at all levels the relevant guidelines recommended by the Conference, governments and relevant

> organizations including the private sector to support the implementation of the early warning programme as recommended by the Conference and to integrate the programme into disaster reduction strategies at all levels, the early warning programme to focus on: (i) integration of early warning into relevant development policies and programmes; (ii) improvement of data collection, facilitating access to relevant data and forecasting; (iii) enhancement of capacities; (iv) people centered warning systems in particular ensuring gender balance and a; (v) platform to sustain the early warning dialogue. "Conference Statement EWCII"

The international community followed this suggestion and in early 2004 an Early Warning Platform (later on renamed to: Platform for the Promotion of Early Warning "PPEW") was established. As one of the first tasks, PPEW developed the International Early Warning Programme (IEWP), which was launched at the WCDR 2005 in Kobe.

The program is a vehicle by which partner organizations cooperate and develop shared and systematic approaches to advancing early warning systems worldwide. IEWP aims to:

- Develop international dialogue and a common framework for action, and promote early warning in policy debates and as a development priority
- Collate and disseminate good practices and other information on early warning systems
- Define and support capacity building projects in priority areas of need, involving humanitarian and development communities
- Develop improved tools and techniques, including guidelines and performance standards for early warning systems, and formulate priorities for further research and development (International Early Warning Programme)

Almost at the same time, following the Indian Ocean Tsunami, December 2004, the Secretary General asked the ISDR secretariat to carry out a Global Survey of Early Warning Systems.

In his March 2005 report to the Summit on the Implementation of the Millennium Declaration *In larger freedom: towards development, security and human rights for all*, he requested that a global survey of capacities and gaps for early warning systems be undertaken:

> The countries of the Indian Ocean region, with the help of the United Nations and others, are now taking steps to establish a regional tsunami early warning system. Let us not forget, however, the other hazards that people in all regions of the world are exposed to, including storms, floods, droughts, landslides, heat waves and volcanic eruptions. To complement broader disaster preparedness and mitigation initiatives, I recommend the establishment of a worldwide early warning system for all natural hazards, building on existing national and regional capacity. To assist in its establishment, I shall be requesting the International Strategy for Disaster Reduction secretariat to coordinate a survey of existing capacities and gaps, in cooperation with all United Nations system entities concerned, and I look forward to receiving its findings and recommendations (In larger freedom: towards development, security and human rights for all Report of the Secretary-General (A/59/2005)).

The Survey coincided with the preparation to a Third International Conference on Early Warning (EWCIII) 2006 in Bonn, Germany, an initiative which was also fueled by the tragic event of the 2004 Tsunami. The subtitle "From knowledge to action" underlined the intention to move to the implementation of early warning systems.

The basic aims of the conference were:

- To identify unused potentials in all areas of early warning
- To identify and launch specific early warning projects of high priority and illustrate the bridging of gaps
- To stimulate discussion and action toward concrete follow-up projects
- To discuss proposals for global integration of early warning systems whenever feasible and useful

The outcomes, a project portfolio of 100 peer-reviewed early warning projects and guidelines for the implementation of early warning systems, were very practically oriented in order to support these aims.

The Global Early Warning Systems Survey was presented at EWCIII. The survey report recommends the development of a globally comprehensive early warning system, rooted in existing early warning systems and capacities. It also recommends a set of specific actions toward building national people-centered early warning systems, filling in the main gaps in global early warning capacities, strengthening the scientific and data foundations for early warning, and developing the institutional foundations for a global early warning system. (Global Early Warning Systems Survey, Summary)

The Survey reached the following overall conclusion:

> Nevertheless, there are significant inadequacies in existing early warning systems, as illustrated by the experience of the Indian Ocean tsunami in late 2004, Hurricane Katrina in the Gulf of Mexico in 2005 and other recent events such as heat waves, droughts, famine, wildfires, tsunami, floods and landslides. Early warning systems especially in developing countries lack basic equipment, skills and financial resources and are for certain hazards even nonexistent. A major challenge is to integrate the knowledge and insight of relevant social and economic communities into the predominantly technically based existing systems.
>
> 13. One of the survey's key findings is that the weakest elements in early warning systems are the dissemination of warnings and the preparedness to respond. This is true for developing and developed nations alike. Warnings may fail to reach all those who need to take action, including local authorities, community-based organizations and the public at large, and often the warnings are not properly understood or may not be taken seriously. A good understanding by the public and by community organizations of their real vulnerabilities and the risk posed by an event is often lacking. Root causes of such failures appear to be inadequate political commitment, weak coordination among an often-diverse group of actors, and insufficient public awareness and participation in the development and operation of early warning systems. (Global Early Warning Systems Survey, Summary)

Following these major initiatives the work on early warning obtained momentum in a sense that major players

of the UN family like the World Meteorological Organization (WMO) became more active. The PPEW became the focal point for the Indian Ocean Tsunami Consortium in order to coordinate the implementation of a Tsunami Early Warning system in the Indian Ocean together with international key players. Even national funding bodies incorporated these developments into their funded thematic themes. For example, the BMBF (German Federal Ministry of Education and Research) launched a key research program on "Early Warning Systems in Earth Management" within their research program "Geotechnologies."

At the fifty-second session in 1998 with Resolution A/RES/52/200 (2 March, 1998) the first time a special resolution on: "International cooperation to reduce the impact of the *El Niño* phenomenon" was adopted by the General Assembly of the United Nations. The resolution made reference to a number of Resolutions on IDNDR, established a clear link to the Yokohama Strategy for a Safer World, and requested the Secretary General to develop a strategy within the IDNDR to integrate the El Niño into the International Framework of Action for the Decade.

Recalling its resolutions 44/236 of 22 December 1989, 48/188 of 21 December 1993, 49/22 A of 2 December 1994, 49/22 B of 20 December 1994, 50/117 A and B of 20 December 1995 (A/RES/52/200)

> 2. Calls upon States, relevant intergovernmental bodies and all others involved in the International Decade for Natural Disaster Reduction to participate actively in the financial and technical support for Decade activities, including those related to international cooperation to reduce the impact of the El Niño phenomenon, in order to ensure the implementation of the International Framework of Action for the Decade, in particular with a view to translating the Yokohama Strategy for a Safer World: Guidelines for Natural Disaster Prevention, Preparedness and Mitigation and its Plan of Action into concrete disaster reduction programmes and activities; (A/RES/52/200 para2)
>
> 4. Requests the Secretary-General to facilitate, within the framework of the Decade, an internationally concerted and comprehensive strategy towards the integration of the prevention, mitigation and rehabilitation of the damage caused by the El Niño phenomenon, including the development of long-term strategies which take into due consideration the need for technical cooperation, financial assistance, the transfer of appropriate technology and the dissemination of existing scientific knowledge, as part of the Decade's activities, the International Framework of Action for the Decade and the Yokohama Strategy for a Safer World: Guidelines for Natural Disaster Prevention, Preparedness and Mitigation and its Plan of Action, and taking into account the relevant parts of the Programme of Action for the Sustainable Development of Small Island Developing States (A/RES/52/200 para 4)

In the follow-up to this resolution the government of Ecuador established together with WMO and ISDR the International Center for the study of the El Niño phenomenon at Guyaquil. A development which was welcomed by the Resolution on El Niño in 2005.

> Welcomes the efforts of the Government of Ecuador, the World Meteorological Organization and the inter-agency secretariat for the International Strategy for Disaster Reduction which led to the establishment of the International Centre for the Study of the El Niño Phenomenon at Guayaquil, Ecuador, and to its opening in February 2003, and encourages those parties to continue their efforts for the advancement of the Centre; (A/RES/59/232)

This positive comment was accompanied by a request to governments and international organizations to support the work of the center.

> Calls upon States, relevant intergovernmental bodies and all others involved in the International
> Decade for Natural Disaster Reduction to participate actively in the financial and technical support for Decade activities, including those related to international cooperation to reduce the impact of the El Niño phenomenon, in order to ensure the implementation of the International Framework of Action for the Decade, in particular with a view to translating the Yokohama Strategy for a Safer World: Guidelines for Natural Disaster Prevention, Preparedness and Mitigation and its Plan of Action into concrete disaster reduction programmes and activities; (A/RES/59/232)

In the latest resolution on the "International cooperation to reduce the impact of the El Niño phenomenon" of 2007 (A/RES/61/199) the support provided to the center was positively welcomed together with a strong plea to maintain the center.

> Welcomes the activities undertaken so far to strengthen the International Centre for the Study of the El Niño Phenomenon, through collaboration with international monitoring centres, including the national oceanographic institutions, and efforts to enhance regional and international recognition and support for the Centre and to develop tools for decision–makers and Government authorities to reduce the impact of the El Niño phenomenon; (A/RES/61/199)
>
> Underscores the importance of maintaining the El Niño/Southern Oscillation observation system, continuing research into extreme weather events, improving forecasting skills and developing appropriate policies for reducing the impact of the El Niño phenomenon and other extreme weather events, and emphasizes the need to further develop and strengthen these institutional capacities in all countries, in particular in developing countries; (A/RES/61/199 para 7)

The International Center for the Study of the El Niño Phenomenon is still operational and continues to work today.

Conclusion

The international community undertook an important move when it agreed to address the issue of increasing losses caused by hazards through development and implementation of disaster reduction strategies. The initiative was borne out of the sustainable development discussion. The focus on technical solutions was enlarged in the mid-1990s and sociocultural aspects were integrated and considered equally important. Consequently the conceptual discussion moved from preparedness and response to long-term aspects. Until today, however, disaster risk reduction is very much rooted in the humanitarian community. It is only there where solid commitments with regard to a percentage of funding earmarked for disaster

risk reduction activities are made. The integration of disaster risk reduction into development policies still needs to be improved. A reason for this situation might be the decision of the United Nations to place IDNDR and later on ISDR under the umbrella of the Under Secretary General for Humanitarian Affairs.

The structure which links UN level to the national level through National Platforms provides a number of opportunities for the integration of disaster risk reduction in a concerted way through different levels. However, it has to be stated that the available synergies and added values of this structure have not been utilized to the extent possible.

The current debate about negative effects caused by climate change and the recognition of adaptation as equally important to mitigation became a new driving force. Although links have been made in a number of Resolutions on "Natural Disasters and Vulnerability" by the General Assembly following the WSSD in 2002, disaster risk reduction as being one important part of adaptation to climate change needs to be further promoted in order to ensure the necessary integration. The IPCC Special Report is an important step in this direction.

Since the beginning of the debate major improvements have been made. However a number of important issues still need to be addressed.

- The conceptual evolution to capture the development of risk and its dynamics illustrates an important improvement made. However, following disasters still need to be assessed in detail and comprehensive vulnerability assessments are required in order to be able to build back better.
- The existing data basis needs to be improved in order to base the analysis of risk and its development on a sound foundation. Statistical agencies should be encouraged to collect systematically risk relevant data.
- Decision makers need to be convinced to invest money into risk reduction scientific information on cost-benefit of risk reduction. This would allow to implement an extremely useful tool. The study undertaken by the World Bank may become a reference point for this discussion.
- The GAR identified the underlying root causes as major problems for the reduction of risk. In order to overcome this burden it is needed to establish firm links between the different stakeholders (politicians, decision makers, scientists, civil society actors, disaster managers, and private sector) and establish cross-border and international cooperation.
- The debate about a Post 2015 agreement on disaster risk reduction needs to take place in the context of the Millennium Development goals and the sustainable development agenda in order to ensure that DRR remains visible in the international agenda.

Definition

Internet. An electronic communications network that connects computer networks and organizational computer facilities around the world

Introduction

Increasing the usage and accessibility of information is widely recognized as a key requirement: before, during, and post natural hazard events, and with an increasing global population and encroachment into hazardous areas there is a greater emphasis on reducing the risks generated, of which the Internet is well placed to be involved in as a tool in this process.

The Indian Ocean Tsunami (2004) and Hurricane Katrina (2005) revealed the coming of age of the internet as an effective tool for natural hazard information, facilitating the exchange of information and increasing the speed of communication, sparking a wave of realization to the capabilities of internet application and *applications* within the field. Free and easy access to a wealth of satellite imagery, made available by various groups during these events, raised expectations and awareness to the internet's applicability, both to the public and the scientific community, and the topic continues to grow with these realizations.

Natural hazards and the internet

In the last 20 years, the internet has grown from a simple group work tool for scientists at CERN (European Organization for Nuclear Research) into a complex global information space with an estimated two billion users worldwide. With multiple connection points ranging from desktop computers to laptops, mobile phones to data warehouses, the internet has rapidly become one of the most effective methods for the distribution and coordination of information, and has become firmly integrated into everyday life; whether it is sending emails to your research partners or reading the latest journal article online, internet use has become a seamless part of facilitating information across networks.

It is this ability to facilitate information that is a useful component in the field of natural hazards, and was formally identified as such in a report in 1995 by the IDNDR (International Decade for Natural Disaster Reduction), who raised a call for better application of current information technologies to enhance the accessibility and to increase the understanding of warnings by a greater number of people. This point has since been widely enforced and repeated by various international and national reports and policy documents, and has spread to all areas of activity within the field of natural hazards, whether it is pure scientific research or ground-based field work dealing with communities and policy makers.

Growth of the internet and global access has allowed the reachability for natural hazard information and the introduction of high-speed data transfer systems and processors, overall reductions in costs, and the rapid development of computer technologies has resulted the capabilities and applications we see today – collaboration between individuals or research groups can be instant, secure, and timely, regardless of distance constraints. Users from anywhere around the world can link to up-to-date feeds of earthquake activity at the United States Geological Survey, browse and download vast directories of remotely sensed global data at NASA's Jet Propulsion Laboratory, or view Italy's Istituto Nazionale di Geofisica e Vulcanologia volcano database, all at the click of a button. Hundreds of thousands of websites currently exist, with more and more created every day, allowing users to track hurricanes, pinpoint earthquake locations, and read reports from the field or laboratory in real time.

While the use of the internet has spread, it is important to note however that less affluent countries,

which are often those in greatest need of assistance, are technologically vulnerable and have problems with technical security, often lagging behind in technical expertise, computer literacy, and often, basic literacy. Rural communities are also experience issues, as the internet can be an unattainable commodity in remote regions and areas with poor technological infrastructure; although the combination of satellite and wireless mesh networks guaranteeing broadband communications is reducing this, it is not without cost, and therefore out of reach to those unable to meet the associated financial burdens. There are also issues with usability for those with disabilities, especially blindness, as the internet is primarily a visual medium, although there are software suites, browser add-ons, and website design guidelines that can be employed to make the internet suitable to such needs; this can especially be an issue in event reactionary postings, where following guidelines and establishing accessible sites or applications might be sacrificed to allow accessibility to the wider audiences.

Development and growth

Like many tools available for assisting with natural hazard processes, the internet is relatively young and is in a constant state of evolution in order to meet user's needs as the technology and tools available develop – by the time you read this there will already be numerous new examples of its application. Browser technology development has allowed the growth of these kinds of applications with the introduction of what are known as Rich Internet Applications (RIA). Currently, the main technology for delivering RIAs is AJAX (Asynchronous JavaScript and XML), although there are some alternatives which are mainly based on Flash technology. Two new technologies, AJAX and image tiling have also improved the performance and response times of internet applications significantly, resetting the "gold standard" and expectations of users. These have been responsible for the explosion of mapping products illustrating natural hazard information as developers are able to combine vast catalogs of data with available applications, but only serve up the immediate area a user is interested in viewing.

The success of the web has turned the browser into a central application, whose standardized capabilities can be exploited by applications such as mapping, video and audio streaming, funding generation, and blogs; creating a useable platform to seamlessly integrate and distribute information. Compared to print-based encyclopedias and traditional libraries, the internet has enabled a sudden and extreme decentralization of information and data; making tools and databases increasingly accessible to stakeholders at all levels, and removing the cost and time frame issues of traditional print.

Examples of this can be seen in services like ReliefWeb, which collates information from websites of international and nongovernmental organizations, governments, research institutions, and the media for news, reports, press releases, appeals, policy documents, analysis, and maps related to humanitarian emergencies worldwide, and then delivers it in a variety of formats for use. Data and news can be published instantly and made globally accessed at the push of a button, providing a common virtual "space" and "place" for discussion and collaboration, eliminating physical limitations and boundaries – meetings no longer need to be physical constructs, and can take place through instant voice or video communication. There are increasing numbers of online journal versions where content can be read in advance of print versions, often featuring interactive content that could not exist in another format.

Where traditionally internet applications only provided one-way information sharing from servers to clients, the introduction of natural hazard-specific standards like CAP and the wiki-like applications, allow multiple users to upload their own information and share it with other users. Common Alerting Protocol (CAP) is an XML-based data format for exchanging public warnings and emergencies between alerting technologies, allowing a warning message to be consistently disseminated simultaneously over many warning systems to many applications. Organizations are now able to provide feeds of standardized data that can be utilized easily by external users, the *USGS Recent Earthquake* RSS feed is a prime example, which can be seen embedded as news sites, within maps using background coordinate fields, or pulled into other applications to run models.

Virtual communities

Online communities have grown from the internet, easily connecting people worldwide, they exist in many different sizes, with some communities supporting the communication of a small circle of close friends, whereas others support tens of thousands of people in a single group. These range from mailing list discussion groups to fund-raising drives, to those involved broadly in natural hazards down to the smallest of niche areas of research, and allow connections to be easily made in a virtual environment between those who may never meet face-to-face to connect with one another. Twitter and Facebook are becoming major players in this area, with Facebook trialling services such as an "I'm Safe" button for their users in event-specific locations to let others in their social connections know they are alive after an event, and scientists able to track #hashtags or words on Twitter through data mining to get damage assessments based off users posts with location information. Social networks, while much more ad hoc and unstructured, contain a wealth of data; Facebook has some 800 million users and an estimated 250 million tweets are sent every day.

Web 2.0

Increasing technical mobility and familiarity of users is driving changes in the content and features offered, forcing content providers to reevaluate the services they

are offering. The revolution of Web 2.0 is defined by Tim O'Reilly as the network as platform, spanning all connected devices; Web 2.0 applications are those that make the most of the intrinsic advantages of that platform: delivering software as a continually updated service that gets better the more people use it, consuming and remixing data from multiple sources, including individual users, while providing their own data and services in a form that allows remixing by others, creating network effects through an "architecture of participation," and going beyond the page metaphor of Web 1.0 to deliver rich user experiences.

Chief among these rules are the principals to build applications that harness network effects to get better the more people use them, and the importance of democracy. Crowdsourcing, the process of outsourcing tasks to a distributed group of people that can take place offline and online, has emerged out of this principal with efforts like those seen post-Christchurch in the comparison of pre- and post-earthquake satellite imagery to create damage assessments through the online Tomnod Disaster Mapper. Users were given two images to compare with different building damage estimates to categorize structures based on satellite image interpretation. While the validity of such results could always be called into question due to poor data or malicious efforts, the important point is that it can work with pools of verified experts and that there are vast networks of potential workers that can be connected through the internet.

The most dramatic example of Web 2.0 democracy is not in the selection of ideas, but their production and the ability to engage with users. With little to no knowledge of internet technologies, users are increasingly able to generate their own content, whether this be a simple Google Map with pinpoint locations denoting field sites, or a personal blog tracking a research area. People appropriated the technologies such as forums, bulletin boards, blogs, and online donation options, and personal websites are also being used to coordinate activities ranging from academic conferences to grassroots responses to disasters. Adoption of these resources has been widespread and has seen various National scientific groups and global organizations such as the United Nations disseminating information via services such as Twitter, and even the generation of podcasts by universities on iTunes that users can subscribe to.

Summary

Through continuous development and application, space and place are becoming increasingly conceptual notions, with the ease of developing communication connections and links worldwide. The combination of the internet and applicable applications offers a treasure trove of approaches, paradigms, and methods, with which hazards and disasters can be explored, modeled, and analyzed to assist with the mammoth task of bringing together global natural hazard efforts. It has the potential to be a focal linchpin for connecting the various arms of research organizations and interests that this subject encompasses.

ISOSEISMAL

Valerio Comerci
ISPRA – Institute for Environmental Protection and Research, Roma, Italy

Synonyms

Isoseismal line

Definition

An isoseismal (line) is a contour or line on a map connecting points of equal intensity relating to a specific earthquake and confining the area within which the intensity is the same.

Discussion

When an *earthquake* occurs, its intensity at a given site is determined through the classification of observed effects on humans, buildings, and on the natural environment. Today, these kinds of data are acquired from *macroseismic surveys* and, in some countries, also from standard questionnaires distributed to the public. The results are then compared to the effects classified in an *intensity scale*, in order to assign intensity values. All of the assigned values are subsequently placed onto a map; the zones with the same intensities are then bounded by the isoseismal lines and marked with a roman number (corresponding to the degree of intensity). The significance of isoseismals depends

on the number of observations in each place and on the close distribution of the places. If the number of recorded data at one's disposal is considerable, the isoseismals depict the variation of intensity throughout the whole area affected by the *earthquake* (Davison, 1921, 124, 127).

When an *earthquake* occurs inland, generally the isoseismals are closed curves, irregularly shaped and concentric, with the intensity degrees increasing as one moves toward the inner curve; when an *earthquake* occurs in a coastal region or offshore, the isoseismals open out toward the area, in the sea, where no data exist.

The first occasion on which the variation in the intensity was represented by isoseismal lines was the investigation, conducted by Robert Mallet (1862), of the great 1857 Neapolitan *earthquake*, in southern Italy (Davison, 1921, 99). The isoseismals are currently employed for evaluating the severity of *earthquakes* occurred before the availability of instrumental records, and for comparing these *historical events* with more recent seismic events. Moreover, the isoseismals allow one to locate an approximate *epicenter* of pre-instrumental *earthquakes*, besides indicating the direction of the seismogenic fault (Davison, 1921, 127): the elongation axis of the inner lines can be oriented according to the strike of the fault.

Finally, the isoseismals are useful for *earthquake hazard* assessment and for communicating *earthquake risk* to the population.

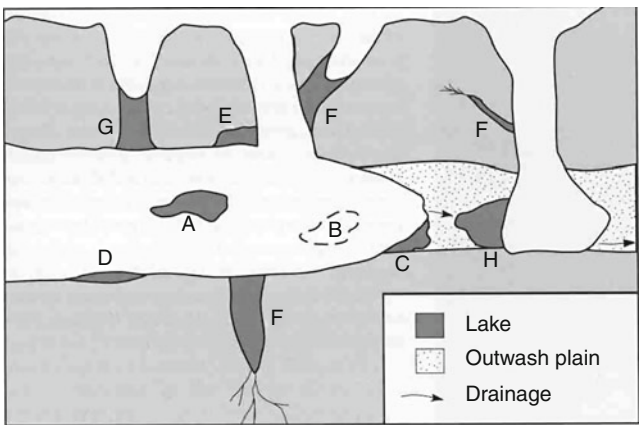
JÖKULHLAUPS

Marten Geertsema
British Columbia Forest Service, Prince George, BC, Canada

Synonyms

Glacial lake outburst floods; Glacier burst



Definition

Catastrophic floods resulting from the breaching of glacier-dammed lakes occur in many regions of the world with glaciers. Some lakes drain and fill frequently, whereas others remain empty for years after draining, or never fill again. The resulting floods are referred to as jökulhlaups, an Icelandic term meaning *glacier burst.* Jökulhlaups are orders of magnitude larger than normal nival (snow melt) floods in the same basins – they can be very destructive. They are also called GLOFs, short for Glacial Lake Outburst Floods.

Discussion

Most glacier-dammed lakes occur at the margins of glaciers, but some are located beneath, within, or on top of glaciers (Figures 1 and 2). Glacier-dammed lakes usually drain through subglacial tunnels. The tunnels rapidly grow in size as the flowing water melts the surrounding ice. When the outflow ceases, the tunnels close by plastic flow of ice, allowing the lake to refill. Many lakes drain during or after the melt season in the summer or early fall, but drainage can occur at any time of the year. The hydrograph of jökulhlaups show an exponential increase in discharge followed by an abrupt decline (Figure 3). Water temperature decreases markedly during the jökulhlaup because the water discharging from the lake is colder than that of the background flow of the river.

Glacier-dammed lakes may go through cycles of growth and decay. Lakes will drain once a threshold of glacier thinning and retreat is reached. Lakes may also form when an advancing glacier dams a tributary or trunk valley. As glaciers continue to thin and retreat, both lake volumes and flood magnitudes decrease. Jökulhlaups can be expected to increase in frequency initially with global warming, as new lakes form, and eventually taper off as ice thins and retreats. Because glacier-dammed lakes can be in various stages of development at the same time, one can expect more jökulhlaups in different locations as most of the Earth's glaciers continue to thin and retreat. Mountain villages and infrastructure in the Himalayan

Jökulhlaups, Figure 3 Graph showing relationship between water temperature and discharge during a jökulhlaup at Tulsequah Glacier, British Columbia.

regions are especially at risk from destructive outburst floods.

Jökulhlaups may also be caused by subglacial volcanic eruptions. This happened in Iceland in 1996 when Gjálp volcano erupted beneath Vatnajökull glacier. The resultant flood was second in discharge only to that of the Amazon River.

During deglaciation several thousand years ago, several enormous jökulhlaups are known to have occurred. Ice-dammed Glacial Lake Agassiz (North America) drained through various outlets at different times. Its final outburst flood occurred about 8,200 years ago when it released enough freshwater into the North Atlantic to raise global sea level by 40 cm. This event changed the thermohaline circulation of the Atlantic Ocean, and caused global cooling for many decades. Glacial Lake Missoula also drained catastrophically on a number of occasions. The Missoula floods carved deep channels into basalt and

impacted Idaho, Washington, and Oregon. There is also evidence for large-scale sheet flooding beneath Pleistocene ice sheets in various regions of the world.

KARST HAZARDS

Viacheslav Andreychouk, Andrzej Tyc
University of Silesia, Sosnowiec, Poland

Synonyms

Hazards in karst areas

Definition

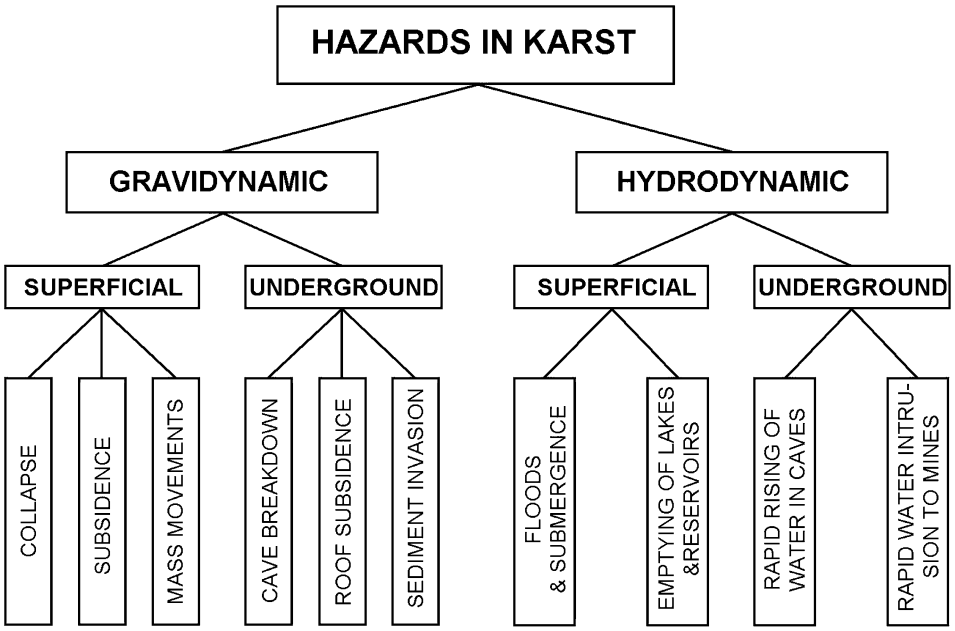
Karst. All processes, forms, and landscape related to dissolution and efficient underground drainage in soluble rocks (e.g., limestone, dolomite, marbles, chalk, gypsum, or salt).

Karst hazards. Natural and human-induced hazards in karst areas, connected with the nature of karst.

Collapse. The gradual or rapid failure of roof rock or caprock into an underground cavity manifested on the surface by collapse (natural) or subsidence (human-induced) sinkholes.

Subsidence. The process of gentle and continuous surface deformation, manifested on the surface by shallow depressions.

Introduction



Karst hazards are an important example of natural hazards. They occur in areas with soluble rocks (carbonates, mostly limestone, dolomite, and chalk; sulfates, mostly gypsum and anhydrite; chlorides, mostly rock salt and potassium salt; and some silicates, quartzite and amorphous siliceous sediments) and efficient underground drainage. Karst is one of the environments in the world most vulnerable to natural and human-induced hazards. *Karst hazards* involve fast-acting processes, both on the surface and underground (e.g., collapse, subsidence, slope movements, and floods) and their effects (e.g., sinkholes, degraded aquifers, and land surface). They frequently cause serious damage in karst areas around the world, particularly in areas of intense human activity. *Karst threat* is the potential hazard to the life, health, or welfare of people and infrastructure, arising from the particular geological structure and function of karst terrains. The presence of underground cavities in the karst massif masks the threat from the hazards of collapse. This means that in some instances, the potential threats from karst, which are inherent features of the karst environment, become hazards. They range in category from potential to real.

The term (*karst hazards*) is related to two other terms, used mostly in applied geosciences, particularly engineering geology – *risk assessment* and *mitigation*. Risk is the probability of an occurrence, and the consequential damages are defined as hazards. Risk assessment is the determination of quantitative or qualitative value of risk related to a concrete situation and a recognized hazard. Quantitative *risk assessment* requires calculations of two components: the magnitude of the potential loss and the probability that the loss will occur. Risk assessment is a step in a *risk management*. *Mitigation* may be defined as the reduction of risk to life and the environment by reducing the severity of collapse or subsidence, building subsidence-resistant constructions, restricting land use, etc.

Classification of karst hazards

Karst hazards can be divided into two main groups: *gravidynamic* (a wide group of gravitational processes in karst) and *hydrodynamic* (relating to water circulation and violent changes of the water regime in karst) (Figure 1) (Andreychouk and Tyc, 2005). Both kinds of hazards can occur on the surface and/or underground. Natural or human-induced collapses and subsidence as well as mass movements often accompanying these processes are examples of *superficial gravidynamic hazards*. *Underground gravidynamic hazards* include cave or cavity breakdown, collapse of consolidated internal cave

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

Karst Hazards, Figure 1 The main types of hazards in karst terrains.

sediments, and invasion cavities by unconsolidated sediments. Hydrodynamic hazards connected with the surface of karst terrains (*superficial hydrodynamic hazards)* include floods (e.g., in poljes), submergence of karst springs, and emptying of lakes or reservoirs. Rapid karst water intrusion into mine galleries and sudden rising of waters in caves (a hazard for cave exploration and show caves) are examples of *underground hydrodynamic hazards*. Hazards in karst terrains are usually rapid and frequently catastrophic, but there is also a group of evolutionary, slow-acting hazards such as saltwater intrusions into karst aquifers and pollution of karst waters (Andreychouk and Tyc, 2005; Parise and Gunn, 2007).

Gravidynamic karst hazards

The collapse of bedrock into underlying cavities is one of the most serious and common hazards in karst areas. Although large collapse sinkholes are known from many karst terrains in the world, the largest and most spectacular, called tiankeng (sky holes), occur in tropical karst (Ford and Williams, 2007). Rock collapse as a result of the failure of the cave roof is a rare event, with few recent cases reported. Nearly all recent cases of collapse are subsidence sinkholes (e.g., dropout, suffosion, caprock, or cover-collapse sinkholes) induced by human activity in karst (Waltham et al., 2005).

Human-induced dewatering of unconsolidated sediments covering karstified rock is the most important cause of subsidence sinkholes. Lowering of the groundwater table due to intense water pumping for water supplies and draining the rock mass for mining or quarrying produces a cone of hydraulic depression below the rockhead of the karstified rock and consequently loss of buoyant support from the water. Human-induced changes to the hydrodynamic conditions of groundwater circulation in karst aquifers produce conditions favorable for collapse and subsidence. As a result, numerous subsidence sinkholes, mainly caprock sinkholes, occur in karst areas affected by water exploitation or mining. Their size depends on dimensions of the underground cavity, the type and thickness of the caprock, and they vary widely in diameter and depth, from a few meters to hundreds of meters (Tyc, 1999; Parise and Gunn, 2007; Waltham et al., 2005). The large subsidence sinkhole in Winter Park, Florida, is one of the best known and most studied in the world (e.g., Beck, 2005; Waltham et al., 2005; Ford and Williams, 2007). Nearly 150,000 m^3 of unconsolidated cover sediments have disappeared into underground cavities after collapse (Waltham et al., 2005).

Due to the high rate of dissolution of gypsum, collapse and subsidence sinkholes are a far greater hazard in gypsum karst than in carbonate karst (e.g., Pinega or Perm regions in Russia, Podolia and Bukovina in Ukraine). In the gypsum karst of the Urals, there are regions with density of sinkholes up to 200 per km^2 and very high rate of sinkhole appearance up to 3,0 per km^2 per year (Klimchouk and Andreychouk, 1996; Andreychouk, 1996, 1999). Rapid and extensive dissolution occurs when groundwater circulation reaches salt deposits. This can result in extremely dangerous hazards. Removal of salt by solution mining commonly induces development of regional subsidence (continuous deformations on a regional scale). Salt mining and leakage from the rock

mass overlying the salt deposits can cause the development of enormous underground cavities, consequently replaced by breccia pipes and finally, manifested on the surface by spectacular large subsidence sinkholes. One of the best examples is the sinkhole that developed in 1986 over the world's largest potash mine at Berezniki (Urals, Russia) (Figure 2) (Andreychouk, 2002).

Numerous subsidence sinkholes in areas of mining and water extraction cause hazards to engineering, construction, and sometimes to human life. The high density of sinkholes transforms some regions into *karst badlands* (e.g., some industrial areas in pre-Urals – Russia and western Ukraine, Figure 3). Collapse of bedrock in karst areas is of a rapid and unforeseen character and is usually accompanied by a range of physical phenomena including acoustic, luminous, pneumatic, seismic, and hydrodynamic events. These phenomena can constitute an additional hazard – slight earthquakes (see *Induced Seismicity*) or explosions of rock fragments.

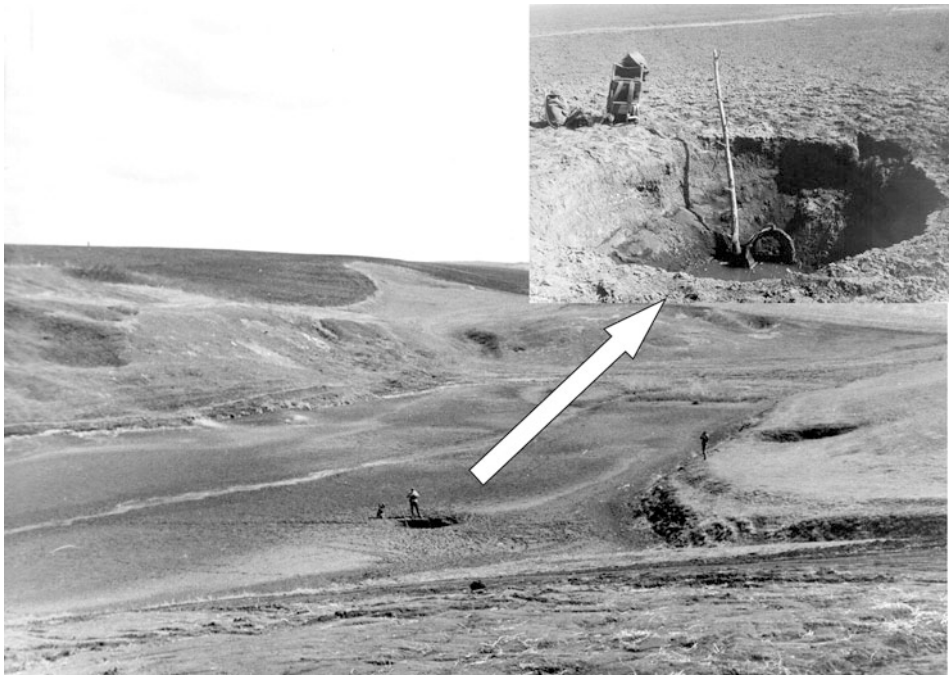
Another *karst hazard* of the *gravidynamic* type is the process of ground subsidence, the gradual and gentle lowering of the surface without any distinct breaking of the caprock. Shallow depressions resulting from subsidence develop in gypsum karst, mostly, where there is solution of rocks at shallow depth (Ford and Williams, 2007). The intensity of the subsidence varies from several millimeters to several meters per year. Depressions are sometimes of large dimensions, up to several square kilometers across. Ground subsidence in karst is less dangerous than sinkhole failure and is a more predictable hazard. The gradual and gentle development of subsidence potentially makes it possible to develop a protection strategy. In karst areas with a shallow groundwater table, collapse and subsidence sinkholes as well as larger subsidence depressions can fill with water and form lakes (Figure 4).

Karst Hazards, Figure 2 Catastrophic subsidence sinkhole over the world's largest potash mine in Berezniki area, Urals, Russia (Photo V. Andreychouk).

Limestone and gypsum are very prone to different types of landslides or rockslide avalanches – mass movements that cause serious hazards in karst areas. Mass movements can occur on slopes and in the sides of large collapse or subsidence sinkholes. The most hazardous occur where thick limestone strata overlay slick, impermeable strata such as shales that are dipping downslope. Such settings are favorable for downslope detachment, the movement of limestone, and can cause landslides. Heavy rain or earthquakes are important triggers for such mass movements.

Cave roof failure (breakdown) and sediment invasion of cave passages are the most dangerous *underground gravidynamic hazards*. Susceptibility to ceiling breakdown is related to the structural integrity of the cave roof (thickness of bedding, density of fractures, etc.) and the width of its unsupported span. Breakdown stabilizes when the span of the bed is less than the critical width for its thickness and a tension dome is formed. In caves located below perched aquifers, separated from the cave space by poorly permeable sediments, invasion of liquefied unconsolidated sediments can occur. Cave roof failure and sediment invasion can cause damage to the cave space. Both hazards are a danger to cavers during exploration. Permanent monitoring of roof stability and other geotechnical parameters are used to minimize both hazards in show caves. Liquefaction and consequent sediment invasion can cause damage to the infrastructure of show caves.

Hydrodynamic karst hazards



Floods and *submergence* are periodic processes in karst that pose superficial hydrodynamic hazards. *Floods* and *submergence* mostly occur in flat karst depressions such as poljes (e.g., Dinaric Karst in Mediterranean Europe) or depressions in tropical or subtropical karst (e.g., south China, Vietnam, or Cuba). Karst is susceptible to rapid changes and the rising of water levels, resulting from overflowing of groundwater onto the karst surface through karst forms in the depression bottom flooding farmlands and roads. In the past, boats were typical equipment on farms located in frequently flooded poljes such as those in the Dinaric Karst. Flooding and submergence of flat karst depressions is a natural occurrence in karst, so flood hazard management systems are in place in areas where this occurs. Much more hazardous and less predictable than floods are rapid *emptying of lakes* and *reservoirs*. This is quite common in areas where karst lakes or artificial reservoirs are perched above the regional karst water table. Development of subsidence sinkholes in the lake bottom can cause rapid emptying of the lake over periods ranging from minutes or hours to several days (Figure 5).

Karst Hazards, Figure 3 High density of subsidence sinkholes in the area of Olkusz lead and zinc mines, South Poland – example of karst badlands (Photo M. Dobrzański).

Karst Hazards, Figure 4 Large-scale subsidence in settled region of potash mine, vicinity of Kalush, western Ukraine (Photo V. Andreychouk).

Karst Hazards, Figure 5 Rapid emptying of artificial lake as a result of collapse of bottom sediments and its drainage by subsidence sinkhole, Bukovina, Ukraine (Photo V. Andreychouk).

Sudden emptying of lakes or reservoirs is dangerous to fish and other aquatic animals. Such phenomena are known primarily from flat and lowland karst terrains on Russian Plain and Wolyn and Bukovina in Ukraine.

Rapid rising of water in caves caused by heavy rains is a serious underground hydrodynamic hazard in karst areas. Depending on the rainfall and the morphology of the cave system, the water level can rise rapidly from several to several tens of meters and, on rare occasions, even several hundreds of meters. In flat areas, whole horizontal cave systems and, in alpine karst, some horizontal passages can be completely flooded. Rapid rising of water is very dangerous for cavers exploring deep cave systems in high mountains and cave systems with active water flows in flat areas. Quite a large number of accidents involving cavers being trapped by underground flooding in caves in the Alps, Pyrenees, and Caucasus have been fatal. Flooding of show caves can cause damage to their infrastructure.

Rapid water intrusions into mines exploiting karst deposits are very dangerous hazards. These can occur in bauxite, nickel, lead, zinc, iron, gypsum, and salt mines in the karst and in coal or other mines adjacent to the karst (e.g., Kizelovski coal basin; Severouralsk bauxite deposits and Berezniki potassium salt deposits in Urals, Russia; Olkusz lead-zinc ore deposits in Poland; Tyc, 1999; Andreychouk, 2002). Water-filled cavities or watering zones in the karst rock commonly drain into galleries during the mining operation (Figure 6). Rapid, sometimes violent, inflow of large amounts of water into the mine gallery causes great risk for miners and machinery.

Gasodynamic karst hazards

Concentrations of carbon dioxide (CO_2) are often considerably higher in caves than in the open air with caves having CO_2 levels of 2–6% and higher. Such high concentrations can result from CO_2 migration from a deeper part of the Earth's crust, the activity of microorganisms in the caves, or from the diffusion of soil CO_2 into the caves. High concentrations (over 5–7%) in cave air can pose a serious danger to human life (*gasodynamic hazards*). Fatal CO_2 intoxication of cavers in caves with high concentrations of CO_2 has been reported. Some caves with poor ventilation are hazardous due to relatively high concentrations of radon, sometimes also found in basements and crawl spaces of houses built on karst.

Summary

Karst hazards are an important example of natural hazards, which occur in areas with soluble rocks (carbonates, sulfates, or chlorides). Karst hazards can be divided into two main groups: *gravidynamic* and *hydrodynamic*. Both kinds of hazards can occur on the surface and/or underground. Additionally, high concentrations (over 5–7%) of CO_2 in cave air can pose a serious danger to human life and can be called as *gasodynamic hazards*.

Karst Hazards, Figure 6 Large amount of water inflow from karst conduit into mine gallery, Olkusz lead and zinc mine, south Poland (Photo J. Jackowski).

Karst hazards affecting karst areas all over the world can be fully appreciated only through a multidisciplinary approach, combining expertise from different fields, including speleology, karstology, engineering geology, hydrology, hydrogeology, geophysics, geochemistry, and biology.

Krakatau

Introduction

The Indonesian volcano of Krakatoa is one of the best known on Earth, primarily as a consequence of a catastrophic explosive eruption in 1883. This event took an estimated 36,417 lives, mainly due to associated tsunamis, and was detected on tide gauges and barometers around the world.

Discussion

Krakatoa is an island volcano located in the Sunda Strait between the south coast of Sumatra and east coast of Java (lat: 6.102°S long: 105.423°E). The volcano is one of

more than 130 active volcanoes in Indonesia, which form an arc stretching from Sumatra in the west to New Guinea in the east. The volcanic arc is fed by magma formed as a consequence of the northeastward subduction of the Indo-Australian Plate beneath the Sunda Plate. Indonesian volcanoes, including Krakatoa, are typically characterized by the violent eruption of viscous magmas, generating extensive ash-fall, hot ash and debris flows, volcanic mudflows (lahars), and, where adjacent to water, tsunamis.

The current height of Krakatoa is 813 m. Prior to the 1883 eruption, Krakatoa island comprised three volcanic cones, Rakata, Danan, and Perboewatan, with Rakata the highest at 820 m. The 1883 event destroyed the latter two cones, leaving only a remnant of Rakata. Currently, Krakatoa comprises four islands, Sertung, Panjang, a remnant of the original Krakatoa, and Anak Krakatoa (Child of Krakatoa). Located centrally between the other three islands, Anak Krakatoa is the new active center, building itself up to a height of 300 m since breaching the sea-surface in 1927. Recently, relatively minor eruptions have occurred from 2000 to 2001 and from 2007 to 2009, adding – on average – around 5 m to the height of the cone each year.

Prior to the 1883 eruption, the activity of Krakatoa is not well documented. Eight mild to moderate eruptions are recorded in the 1,000 years before 1883, the latest almost 200 years earlier in 1684. There is serious speculation, based on historical records, of a cataclysmic eruption in 416 AD, leading to the collapse of an "ancestral" Krakatoa and the formation of a 7 km-wide caldera, leaving as remnants the Verlaten, Lang, and Krakatoa islands that existed prior to the 1883 eruption. The Javanese *Book of Kings* notes that in the year 338 Saka (416 AD), "a thundering sound" was heard from a volcano in the Sunda Strait that eventually "burst into pieces" causing the land to be inundated by the sea, which swept away people and property. An alternative version of events, which also remains unverified, argues for this major eruption occurring in 535 AD and holds it responsible for a significant deterioration of the global climate in 535–536 AD.

Reports of seismic activity in the vicinity of Krakatoa in the years leading up to 1883 argue for magma accumulation and ascent over a long period. The first evidence at the surface took the form of steam venting in May 1883, three months before the climactic eruption. By mid-June, eruption columns were carrying ash and pumice several kilometers into the atmosphere, and activity continued to escalate through July. The paroxysmal phase commenced on August 26, with a 27 km high eruption column leading to extensive hot ash and pumice fall across the region and onto ships 20 km distant in the Sunda Strait. The climax came the following day, with four cataclysmic explosions loud enough to be heard 4,653 km away at Rodriguez Island in the Indian Ocean, and 4,600 km distant at Alice Springs in Australia. While the series of explosions was clearly associated with the destruction of the volcano, the precise course of events and the cause of the extreme explosions remain a matter for conjecture. Possibilities include partial submarine collapse of the edifice, exposing the pressurized magma reservoir to seawater, or violent magma mixing due to the emplacement of hot, basaltic magma into the main body of cooler, more silica-rich, and more viscous dacite magma.

Determining the sources of the catastrophic tsunamis that inundated the shores of Sumatra and Java has also proven problematical, although these are now generally regarded to have been formed by the entry into the sea of massive hot pumice flows (known as ignimbrites) generated by the gravitational collapse of the eruption column. The tsunamis had run-up heights of up to 46 m on the Java coast, and carried sufficient strength to loft 600 ton coral boulders far onto the shore and to destroy the 40 m high lighthouse at Anjer on the west coast of Java. Although most deaths (in excess of 34,000) resulted from the tsunamis destroying 165 communities, more than a thousand lives were lost in the vicinity of Ketimbang (southern Sumatra) by surges of hot ash and gas that traveled the 40 km across the sea surface before climbing the southern slopes of the island.

The legacy of the eruption was the destruction of much of the original island of Krakatoa, the formation of a 250 m deep caldera, and a dramatically altered sea floor topography, which included an area of more than 1.1 million km^2 covered by ignimbrite deposits. Further afield, loading of the atmosphere by dust and sulfuric acid aerosols led to meteorological effects worldwide, including spectacular sunsets, rings around the Sun, and "blue" moons. Global average temperature fell by 1.2°C for a number of years, while the cooling effect could be detected in the oceans well into the twentieth century.

Summary

After the 1815 eruption of Tambora, also in Indonesia, Krakatoa hosted the second most lethal eruption of the last 250 years. The total volume of material erupted is estimated at between 22 and 25 km^3, corresponding to a score of six on the Volcano Explosivity Index. The eruption was also important in another context, with the advent of undersea telegraph cables making it possible, for the first time, for news of a major catastrophe to spread across the world in just a few days. The eruption, therefore, was a key media event as well as a major expression of volcanic power.

LAHAR

Richard B. Waitt
U.S. Geological Survey, Vancouver, WA, USA

Synonyms

Volcanic mudflow; Debris flow

Definition

A lahar is a flowing slurry of rock debris and water originating on the slopes of a volcano. The term may also mean the deposit of such a flow.

Discussion

Characteristics: Lahars contain grains from clay to large boulders. The flowing material is water-lubricated sand or mud, but the whole mixture maybe more than half of incorporated cobbles and boulders. Volumes can reach 10^9 m^3 and peak discharge may exceed 10^7 m^3/s. Depending on proportions of freshly erupted volcanic debris and snow or water, temperatures range from nearly 100°C to 0°C but are typically below 50°C. Flowing lahars peak swiftly and wane more slowly, passing any one place within minutes to a couple hours but sometimes lasting several hours.

Origin: Lahars can originate by eruption of hot fragmental debris onto snow or ice. A melting mass then flows swiftly downslope, incorporating more and more ash and rock from the volcano's slopes. Some large lahars initiate from volcanic debris avalanches. If the avalanche consists of rock highly altered to clay, almost all the flowing mass becomes lahar, for instance, the Osceola Mudflow off Mount Rainier, USA. But if the avalanche is rocky, its groundwater can escape, incorporate loose sand, and flow downvalley – as in May 1980 at Mount St. Helens, USA. Lahars may initiate by eruption through a crater lake, as at Kelut in Indonesia or by breakout of a crater lake, as at Ruapehu in New Zealand. Lahars may originate from torrential rainfall during or after eruption of voluminous ash, as at Merapi in Indonesia, Pinatubo and Mayon in the Philippines, and Unzen in Japan. Large lahars occasionally originate by breakout of a debris-dammed lake on a volcano's lower flank.

Downstream evolution: An initially watery lahar may incorporate more debris from the channel and increase the initial flow volume by many times. Lahars moving down a volcano's flanks flow at 10–40 m/s but slow downvalley. A dense lahar may at first overrun river water, incorporating enough to dilute the mass into an intermediate (hyperconcentrated) flow or even muddy-water flow.

Distribution: Lahars radiate from a volcano. They scour and drape steep valley reaches and accumulate in gentler downstream reaches far beyond the volcano's flanks. Here they may spread widely and inundate areas far beyond the delivering valley. Empirical runout models can estimate areas inundated by future lahars.

Hazard: A lahar can sluice down a valley and burst fast and deep upon a town, smashing or removing almost all structures. Tens of thousands of people have perished from lahars, most infamously at Nevado del Ruíz in Colombia in 1985. Close monitoring of an impending eruption, assessing probable runout in valleys at risk, and effective and timely communication to people in the way can mitigate the hazard to human life if not to infrastructure.

LAND DEGRADATION

Matija Zorn, Blaž Komac
Anton Melik Geographical Institute, Ljubljana, Slovenia, Slovenia

Definition

Land degradation is a natural or human-induced process (Figure 1) that negatively affects the land to function effectively within an environmental system and can be defined as a process of degrading land from a former state. Land degradation is closely related to sensitivity, resilience, and carrying capacity of land, as well as to vulnerability of people living on and from these lands. It may be defined as the loss of utility or potential utility, or reduction, loss, or change of features or organisms which cannot be replaced (Barrow, 1991). A pure anthropogenic definition of land degradation is the loss of a sustained economic, cultural, or ecological function due to human activity in combination with natural processes (Bush, 2006).

Mechanism

Mechanisms that initiate land degradation include physical, chemical, and biological processes. Important among physical processes are a decline in soil structure leading to crusting, compaction (including oxidation of organic soils leading to subsidence), hard-setting (crusting, induration, formation of plinthite and duripans), *erosion*, *natural disasters*, desertification, anaerobism, environmental pollution, and unsustainable use of natural resources. Significant chemical processes include acidification, leaching, salinization, decrease in cation retention capacity, fertility depletion, and accumulation of toxic metals. Biological processes include reduction in total and biomass carbon, and decline in land biodiversity. The latter comprises important concerns related to eutrophication of surface water, contamination of groundwater, and emissions of trace gases (CO_2, CH_4, N_2O, NO_x) from terrestrial/aquatic ecosystems to the atmosphere. Thus, land degradation may be defined as a biophysical process driven by socio-economic and political causes. Some lands or landscape units are affected by more than one process.

Depending on their inherent characteristics and the climate, lands vary from highly resistant, or stable, to those that are vulnerable and extremely sensitive to degradation. Fragility, which is sensitivity to degradation processes, may refer to the whole land, a degradation process (e.g., *erosion*) or a property (e.g., soil structure). Stable or resistant lands do not necessarily resist change since fragile lands may degrade and become less capable of performing environmental regulatory functions.

Terms commonly associated with land degradation are soil degradation and desertification. While there is a clear distinction between "soil" and "land" (the term "land" refers to an ecosystem comprising land, landscape, terrain, vegetation, water, climate), there is often no clear distinction between the terms "land degradation" and "desertification." Usually desertification refers to land degradation in arid, semiarid, and sub-humid areas due to anthropogenic activities. Some 33% of the Earth's land surface (42 million km^2) is subject to desertification.

Because of different definitions and terminology, a large variation in the available statistics on the extent and rate of land degradation exists. Two principal sources of data include the global estimates of land degradation in drylands (desertification) by Dregne and Chou (1994), and of land degradation by the "Global Assessment of Human Induced Soil Degradation" (GLASOD assessment) (Oldeman, 1994). According to the first source degraded lands in dry areas of the world amount to 3.6 billion hectares or 70% of all global drylands. According to the second source the global extent of degraded land (by all processes and all ecoregions) is about 2 billion hectares, i.e., 562 million hectares of arable lands, 685 million hectares of permanent pastures, and 719 million hectares of forests or woodlands. Both assessments, however, are qualitative and do not refer to a quantitative and reliable database (Eswaran et al., 2001; Bush, 2006).

Some causes of land degradation

The anthropogenic causes of land degradation are mainly agriculture-related (agricultural intensification, cropland expansion, livestock extension, shifting cultivation without adequate fallow periods, absence of soil conservation measures, cultivation of fragile or marginal lands, unbalanced use of fertilizers and pesticides, possible problems arising from faulty planning or management of irrigation, use of high-yield hybrid crops, etc.). It is estimated that up to 40% of the world's agricultural land can be considered as degraded (Kertész, 2009). The anthropogenic causes of

Land Degradation, Figure 1 Land degradation can be either human induced, e.g., as a result of mining activity (on the *left*; Cave del Predil, NE Italy), or induced by natural processes, e.g., Stovžje landslide (around 2 million cubic meters) (on the *right*; Stovžje, NW Slovenia) (Photographer: Matija Zorn).

land degradation are as follows: land clearing (deforestation, clear-cutting, and overlogging), agricultural depletion of soil nutrients, urban sprawl, irrigation, land pollution, quarrying and mining, other industrial causes and vehicle off-roading. Other socioeconomic driving forces include population growth and density, migration patterns, land-use policies, lack of education, conflicts, wars, poverty, rapid technological change, etc. The results are accelerated *erosion*, removal of nutrients, soil acidification or alkalinization, salinization, destruction of soil structure, loss of organic matter, etc.

Severe land degradation affects a significant portion of the Earth's arable lands, decreasing the wealth and economic development of nations. The link between a degraded environment and poverty is direct and intimate. As the land resource base becomes less productive, food security is compromised and competition for dwindling resources increases.

Land degradation affects also waters (rivers, wetlands, and lakes) because soil, along with nutrients and contaminants associated with soil, are delivered in large quantities to environments that respond detrimentally to their input. Land degradation, therefore, has potentially disastrous effects on lakes and reservoirs that are designed to alleviate flooding, provide potable water, irrigation, and generate hydroelectricity.

Overcutting of vegetation occurs when people cut forests, woodlands, and shrublands to obtain timber, fuelwood, and other products at a pace exceeding the rate of natural regrowth. This is frequent in semiarid environments, where fuelwood shortages are often severe.

Overgrazing is the grazing of natural pastures at stocking intensities above the livestock-carrying capacity; the resulting decrease in the vegetation cover is a leading cause of *erosion*.

Soil compaction is a worldwide problem, especially with the adoption of mechanized agriculture. It has caused yield reductions of 25–50% in some regions of Europe and North America, and between 40% and 90% in West African countries. On-farm losses through land compaction in the USA have been estimated at US$1.2 billion per year (Eswaran et al., 2001).

Nutrient depletion as a form of land degradation has a severe economic impact at the global scale, especially in sub-Saharan Africa. In Zimbabwe, soil erosion results in an annual loss of N and P alone, totaling to US$1.5 billion. In South Asia, the annual economic loss is estimated at US $600 million for nutrient loss by erosion, and US$1,200 million due to soil fertility depletion (Eswaran et al., 2001).

An estimated 950 million ha of salt-affected lands occur in arid and semiarid regions, nearly 33% of the potentially arable land area of the world. Productivity of irrigated lands is severely threatened by buildup of salt in the root zone. In South Asia, annual economic loss is estimated at US $500 million from waterlogging, and US $1,500 million due to salinization. Potential and actual economic impact globally is not known (Eswaran et al., 2001).

Land degradation due to population growth occurs as a consequence of land shortage. Population pressure also operates through other mechanisms. Improper agricultural practices, for instance, occur only under constraints such as the saturation of good lands under population pressure which

leads settlers to cultivate too shallow or too steep soils; plow fallow land before it has recovered its fertility; or attempt to obtain multiple crops by irrigating unsuitable soils.

Time and regional overview

Land degradation is not a recent process; it has gone on for centuries or even millennia, e.g., medieval deforestation and soil erosion in Central Europe or in Mesoamerica (Maya culture), salinization of arable land in ancient Mesopotamia or the total land degradation on the Easter Island, to contemporary Brazil where characteristics of nearshore deposits show major impacts of modern urbanization. Today, the major driver of land degradation in Africa is the conversion of marginal lands for agriculture; it is also connected to rural poverty. In Asia, land degradation problems are connected to land-use practices, particularly agricultural expansion and intensification. In Australia, more than half of farmland requires treatment for land degradation; land degradation is the continent's most important environmental issue. In Europe today, urban sprawl, increasing transportation network, and intensive agriculture are the major reasons for land degradation. In North America, land degradation is associated with agricultural expansion, intensification, and industrialization. In South America, the agricultural expansion and the intensified use of natural resources are responsible for land degradation.

Land degradation will remain an important global issue as it has an impact on agronomic productivity, the environment, and its effect on food security and the quality of life. The livelihoods of more than 900 million people in more than 100 countries are directly and adversely affected by land degradation. Wider information on the economic impact of land degradation by different processes on a global scale is not available (Eswaran et al., 2001). Some information for local and regional scales is available and has been reviewed by Lal (1998), e.g., productivity of some lands has declined by 50% due to soil erosion and desertification. Yield reduction in Africa due to past soil erosion may range from 2% to 40% (mean loss of 8.2%); and in South Asia, annual loss in productivity is estimated at 36 million tons of cereal equivalent valued at US $5,400 million by water erosion, and US $1,800 million due to wind erosion. It is estimated that the total annual cost of erosion from agriculture in the USA is about US $44 billion per year, i.e., about US$247 per ha of cropland and pasture. On a global scale the annual loss of 75 billion tons of soil cost the world about US $400 billion per year, or approximately US $70 per person per year (Eswaran et al., 2001).

Although land degradation is a global issue, it has not received the attention that it deserves. One of the reasons is that United Nations Agenda 21 emphasizes land degradation mainly through desertification, so that other aspects of land degradation receive only casual mention.

Dealing with land degradation

At least two schools of thought have emerged regarding the prediction, severity, and impact of land degradation. One school believes that it is a serious global threat posing a major challenge to humans in terms of its adverse impact on biomass productivity and environment quality. Ecologists, soil scientists, and geoscientists primarily support this argument. The second school, comprising primarily economists, believes that if land degradation is a severe issue, why have market forces not taken care of it. Supporters argue that land managers (e.g., farmers) have vested interest in their land and will not let it degrade to the point that it is detrimental to their profits (Eswaran et al., 2001).

Land degradation results from mismanagement of land and thus, deals with two interlocking, complex systems: the natural ecosystem and the human system. Interactions between the two systems determine the success or failure of resource management programs. To avert the catastrophe resulting from land degradation the following concepts from Eswaran and Dumanski (1994) are relevant:

- Environment and agriculture are intrinsically linked, and research and development must address both of them.
- Land degradation is as much a socioeconomic problem as it is a biophysical problem.
- Land degradation and economic growth, or lack of it (poverty), are intractably linked; (poor people are in a weak position to provide the stewardship necessary to sustain the resource base. As a consequence, they move farther down the poverty spiral – a vicious cycle set in motion).
- Implementation of mitigation research to manage land degradation can only succeed if land users have control and commitment to maintain the quality of the resources.
- The focus of agricultural research should shift from increasing productivity to enhancing sustainability, recognizing that land degradation caused by agriculture can be minimized and made compatible with the environment.
- Land use must match land quality; appropriate national policies should be implemented to ensure this occurs to reduce land degradation (a framework for evaluation of sustainable land management is a powerful tool to assess such discrepancies and assure sustainability).

There are several international organizations and scientific associations dealing with land degradation, such as Food and Agriculture Organization (FAO) of the United Nations (e.g., The Land Degradation Assessment in Drylands project – LADA), United Nations Environmental Programme (UNEP), The Office to Combat Desertification and Drought (UNSO) of the United Nations Development Programme (UNDP), World Meteorological Organisation (WMO), The Working Group on Land Degradation and Desertification of the International Union of Soil Sciences, Commission on Land Degradation and Desertification (COMLAND) of the International Geographical Union, International Union for Conservation of Nature (e.g., Commission on Ecosystem Management), etc. Some global conventions related to land degradation

are United Nations Convention to Combat Desertification (UNCCD), United Nations Convention on Biological Diversity, and the United Nations Framework Convention on Climatic Change.

Summary

Land degradation is a natural or human-induced process that negatively affects the land. In general, it refers to the processes that negatively affect the land's natural functions of water, energy, and nutrient acceptance, storage, and recycling, leading to a decline in land productivity. Humans are the major drivers of land degradation through socioeconomic and political pressures. Mechanisms that initiate land degradation include physical (decline in soil structure leading to crusting, compaction, hard-setting, *erosion*, *natural disasters*, desertification, anaerobism, environmental pollution, unsustainable use of natural resources, etc.), chemical (acidification, leaching, salinization, decrease in cation retention capacity, fertility depletion, etc.), and biological (reduction in total and biomass carbon, decline in land biodiversity, etc.) processes.

LAND SUBSIDENCE

Brian R. Marker
London, UK

Definition

Subsidence is the mainly vertical downward displacement of the Earth's surface generally due to insufficient support from beneath, a superimposed load, or a combination of both. It can arise from natural causes, human activities, or, often, by human activities destabilizing natural systems. Collapse is sudden, and sometimes catastrophic, land subsidence. Settlement, or down-warping, is a process of moderate and relatively slow downward displacement of the ground.

Introduction

Subsidence results from a wide variety of circumstances and processes. Some are well understood but others are not. It can be a widespread and major constraint causing substantial increased costs and delays to new development; damage to existing development, infrastructure, and land; and, sometimes, deaths and injuries. But causes of subsidence can also be localized. Whittaker and Reddish (1989) provide a good general overview of subsidence.

Many events affect property, development, and people worldwide every year; so, it important to be aware of the potential for subsidence and, where appropriate, to investigate, monitor, and treat the ground to safeguard structures, the public, property prices and to encourage

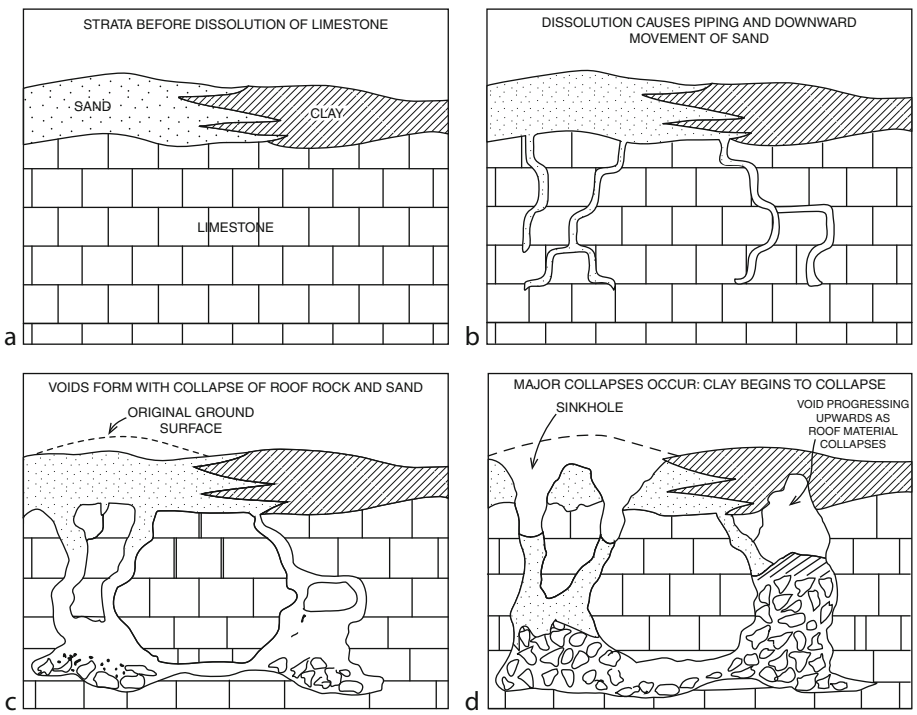
investment that is essential for reclamation and regeneration. Unfortunately, while the potential for many types of subsidence can be identified, the precise locations and times of many types of damaging events cannot usually be predicted confidently.

Types of land subsidence

Land subsidence is most commonly and geographically widespread associated with:

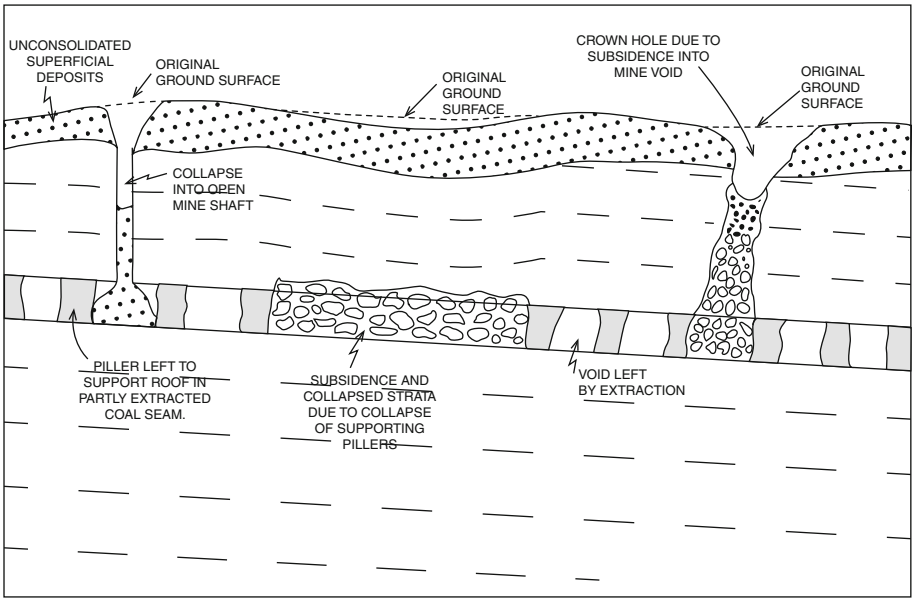
- Underground cavities, both natural (Figure 1) and man-made (Figures 2 and 3)
- Vertical displacement of the ground due to fault activation by earthquakes
- Withdrawal of fluids or gas from the ground
- Compression of weak and/or water-logged soils under superimposed loads, because of vibrations, or withdrawal of support (Figure 4)

Less frequent or extensive causes are linked to lateral movements of the ground, permafrost, and subsurface erosion within unconsolidated soils (Table 1).



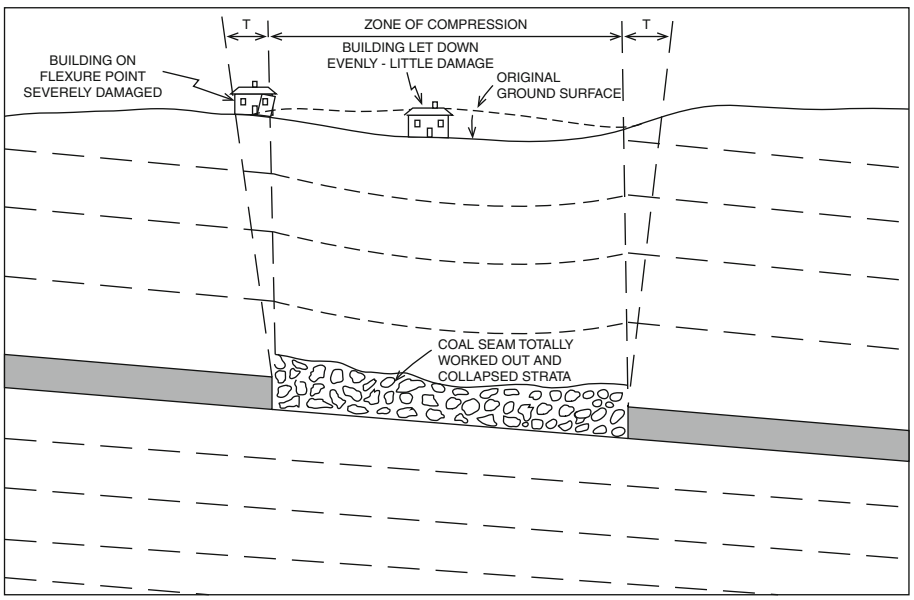
Effects vary greatly. Some types of subsidence are localized, affecting only a few square meters. But some events affect square kilometers (e.g., general mining subsidence) and even tens of square kilometers (e.g., some earthquake subsidence). Displacements vary between many meters and a few millimeters but even modest displacements can be sufficient to disrupt foundations of buildings. Some events are sudden (e.g., from earthquakes, mine and cave collapses) leading to injuries and loss of life, while others involve slow down-warp over periods of years (e.g., slow dissolution of strata, pumping of fluids and gas). In these, the ground surface may be gradually depressed below local ground water level or beneath peak flood levels. This is a particular problem where extraction of fluids takes place in low-lying river deltas and coast plains. Sudden subsidence is often the final result of processes that have progressed over a long time. Many subsidence events are triggered by increased inputs of water (e.g., rainfall, melt water, or leaking pipes) into potentially unstable strata.

Voids often form and subsidence processes take place beneath natural or man-made superficial deposits. Differential subsidence may occur where a structure or infrastructure is built straddling boundaries between contrasting materials, for instance, at the margin of an infilled pit or quarry, or across an active geological fault. Therefore, caution is needed when evaluating sites in subsidence-prone areas.



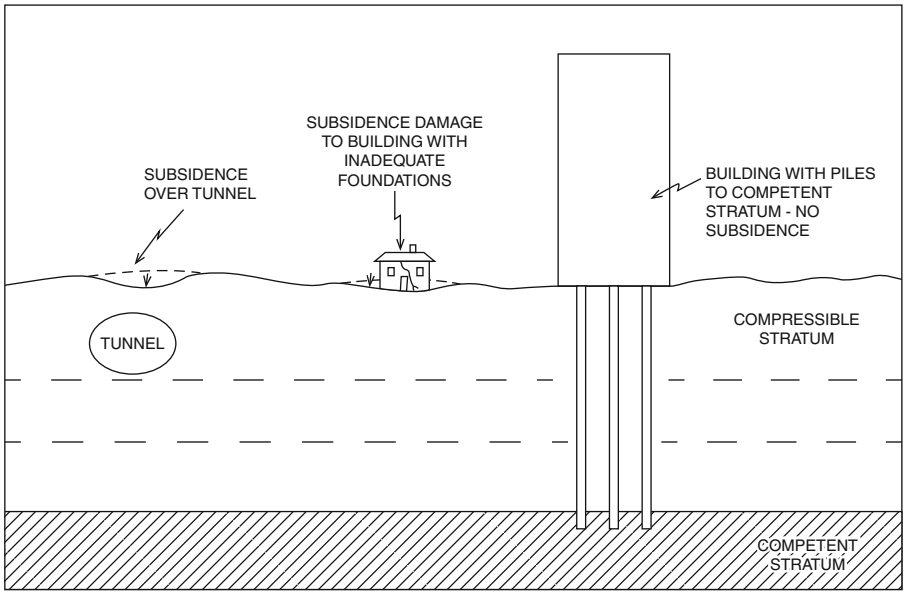
Investigation

Most subsidence problems affecting recent and new development result from failure to recognize, properly investigate, or to fully evaluate subsidence potential often because:



- This type of problem is not expected in the area concerned
- The site investigation is not appropriate for the circumstances or is inadequately funded
- Precautionary or remedial measures that are adopted are not appropriate for dealing fully with the hazard

Land Subsidence, Figure 1 Development of land subsidence due to dissolution of bedrock.



Land Subsidence, Figure 2 Subsidence over mined ground in an area of partial extraction.

Land Subsidence, Figure 3 Subsidence over mined ground in an area of total extraction. *T* zone of tension and surface flexuring.

Problems can be reduced by ensuring that: geological conditions are properly investigated; ground subsidence is taken into account when developing planning policies and determining planning applications; site investigations are properly designed and provide all of the information needed for planning decisions; and adequate planning conditions and building control measures are imposed.

Careful site investigation including walk over surveys, direct ground investigations including drilling, trial pits, and trenches (Bell, 1975) and indirect methods such as ground geophysics (Carpenter et al., 1995) and remote sensing (Donnelly and McCann, 2000; Strozzi et al., 2003; Ge et al., 2007; Wright and Stow, 1999), supported, if available, by archive information (Freeman Fox, 1988; Howard Humphreys and Partners, 1993), usually provide

Land Subsidence, Figure 4 Subsidence due to building of surface structures on, and tunneling in, compressible strata.

a reasonable definition of potential problems and basis for designing solutions against all but the most extreme events.

There is an important role for generalized information contained in databases and hazard and risk maps (e.g., Kim et al., 2006) if these are made easily available to those who are considering development of land. Information pitched at this broader level can also assist land use planners in making decisions on allocations of land (zoning) for specific purposes and deciding what information is needed to make sound decisions on individual planning applications (DTLR, 2002).

Remediation and treatment

Some subsidence takes place on such a large scale and so suddenly that little can be done, except to provide help. Large sinkholes may measure many tens of meters across, or seismic subsidence may be appreciable. However, for many types of subsidence, sound investigation and precautions normally allow development to proceed safely although the cost of necessary work on a few sites may make small developments economically unviable. Ground subsidence can be dealt with in a number of ways depending on the cause and scale (see, for instance, National Coal Board, 1982; Kratsch, 1983; Healy and Head, 1984; Driscoll and Skinner, 2007):

- Localized areas of potential instability can be fenced off and the land above can be used for agriculture or nature conservation purposes or can be left vacant.
- Shallow voids can be excavated and backfilled.
- Voids of modest size can be infilled by injection of cement or rock paste, or by underground emplacement of granular fill.
- Shafts and wells can be capped using a concrete plug or a wire cage filled with aggregate.
- Foundations can be designed and constructed to bridge across fairly small cavities.
- Compressible soils can be strengthened.
- Minor subsidence can be dealt with by underpinning foundations.

It is sensible to record treatment that has been undertaken in a readily accessible place for use by redevelopers of sites.

Responsibility and liability

If subsidence results from human activity, such as mining, the responsibility for dealing with problems and, if appropriate, paying compensation usually rests with the mining company or its successors. In many countries, the responsibility for dealing with other types of subsidence rests with the land or property owner. However, they may have a claim against consultants if ground investigations were inadequate and hazards have not been properly defined. Ground investigation firms usually have professional indemnity insurance to cover any possible claims against them. In most developed countries, if no responsibility or liability can be proved, costs usually fall on the relevant local government authority either directly or through, for example, re-housing displaced persons. Insurance against costs of subsidence is widely available, but insurance companies may charge unaffordable premiums or

Land Subsidence, Table 1 Factors associated with land subsidence

Subsidence-prone situations		Comments	Example references
Underground cavities	Dissolution of soluble strata	The most geographically and geologically widespread soluble strata consist of limestone and dolomite. These frequently contain caves, tunnels, and fissures, formed during percolation and flow of groundwater, that may remain as empty voids or infilled partly or wholly with sediments, collapse debris, or water. Similar features develop, less extensively, in gypsum deposits. Sudden subsidence into voids forms sink holes. Slow dissolution may let the surface down by gentle down-warping. Salt deposits are also soluble but are generally absent near the ground surface, except in arid areas, due to past dissolution and are not usually a direct cause of subsidence.	Beck, 2003; Cooper, 1998; Gutiérrez, 1996; Milan Vic, 2003; Waltham et al., 2004
	Lava tubes and tunnels	Some flows develop hard surface crusts beneath which molten lava flows and, if drained away, leaves tubes, tunnels, and gas cavities.	Waltham et al., 2004, 129–137
	Mines and shafts	Voids associated with mining, particularly shallow mining, are major causes of subsidence. The type of mining influences the nature of subsidence. Partial extraction mines, leaving pillars supporting the mine roof, can remain stable for long periods, but mechanical failure of pillars, withdrawal of hydrostatic support when water is withdrawn from mine voids, or erosion of fissures and joints in the mine roof can lead to sudden subsidence. In long-wall mines (usually for coal), the whole seam is extracted and controlled subsidence is allowed behind the progressing working face leading to relatively gentle surface down-warping. Particular problems may arise where differential subsidence is caused by mining through geological faults. Ground around mine shafts can collapse into the void, especially if affected by downward percolation of water, if these have not been properly sealed.	Arup Geotechnics, 1992; Bell et al., 2000; Kratsch, 1983; National Coal Board, 1982; Ren et al., 1987
	Cellars, tunnels and wells	The excavation of tunnels, particularly in unconsolidated or poorly consolidated soils, can cause surface displacement. Other man-made cavities in previously developed land can become buried and forgotten following demolition, disasters or war damage can also present a localized hazard.	Rodriguez-Roa, 2002
Withdrawal of fluids	Extraction of water, oil, gas or brine	Extraction of fluids and gases under natural or induced pressure allows compaction of unconsolidated or poorly consolidated strata with consequent general subsidence of the ground surface and associated fissuring.	Addis, 1988; Davis and Boling, 1983; Donaldson et al., 1995; Holzer and Johnson, 1985; Milliman and Haq, 1996; Phien-wej et al., 2006
Vertical displacement	Faulting or down-warping associated with seismic events	Earthquakes can cause vertical downward displacement of sections of the Earth's crust. These may be localized or, sometimes, more extensive. Instances are known that have affected tens of square kilometers.	Shennan and Hamilton, 2008
Lateral movements	Salt, clay, and shale	Salt deposits deform and flow in response to pressure and can cause subsidence. Clay and shale can also behave plastically.	Jackson et al., 1994
	Soil creep and landslides	Gradual downward movement under the force of gravity of soils on slopes and mass movements in landslides can open fissures in the ground that may persist and become concealed.	Humpage, 1996

Land Subsidence, Table 1 (Continued)

Subsidence-prone situations		Comments	Example references
Compressible, collapsing and shrinking soils	Loading of soils	Unconsolidated or poorly consolidated superficial deposits (e.g., loess, some sands and silts) become compacted if placed under a load such as a building, tip, or reservoir.	CUR Centre for Civil Engineering, 1996; Dudley, 1970
	Vibration	Vibrations from earthquakes, machinery, or activities such as pile driving can cause liquefaction of water-logged unconsolidated sediments that can be associated with subsidence if the resulting water-sediment mixture can either flow away laterally (e.g., "running sands") or be ejected from the ground (e.g., "mud or sand volcanoes").	Berrill and Yasuda, 2002; Jeffries and Been, 2006; Seed and Idriss, 1982
	Shrinking clays	Some clays swell in the presence of water and shrink when these dry out (e.g., in drought conditions or when water is withdrawn by trees). Shrinking causes subsidence of the ground and can cause significant damage to overlying constructions.	Doornka, 1993; Hammer and Thompson, 1966
	Peat	Peat consists of water-logged fibrous plant material that is compressible under load. If peat is drained, the plant debris rapidly dry out and collapse from a fibrous to a granular state with substantial loss of volume causing substantial surface subsidence.	Gambolati et al., 2006; Wösten et al., 1997
	Infilled sites	Depressions in the ground including valleys, quarries, and ponds are commonly infilled prior to construction. Fills may sometime be poorly compacted and variable in physical properties. Landfill sites containing substantial quantities of putrescible material are constructed to allow for reductions of volume, and consequent subsidence, as organic materials decompose.	Charles, 2001; Emberton and Parker, 1987; Suter et al., 1992
Permafrost		Frozen ground in polar or mountain regions contains ice in layers and masses as well as in pore spaces between grains in soils. Summer melting affects the surface layer leaving marshy conditions above ground that remains frozen but the extent of permafrost has been decreasing in recent years. This melting and drainage can give rise to subsidence as can foundations beneath heated buildings if precautions are not taken.	McFadden and Bennett, 1991; Nelson et al., 2001
Underground fires		Coal and peat deposits can burn underground either as a result of spontaneous combustion or human activities with consequent surface subsidence and fissuring.	Ide et al., 2010; Kuenzer et al., 2007
Subsurface erosion	Piping	Flowing groundwater or leakage from water pipes can form erosion cavities in unconsolidated sediments beneath resistant overlying material if the water and entrained sediments flow away.	Bonelli et al., 2006; Parker et al., 1990
	Burrows	Animal burrows can occasionally be extensive or large enough to cause very localized ground subsidence.	Dolbeer et al., 1994

withdraw cover in areas where subsidence is frequent and expensive (Edwards, 1995).

Conclusion

A wide variety of mechanisms cause land subsidence events sometimes large scale, causing major disasters, whereas others are gradual or localized, but even these can lead to significant economic losses as time passes. The extent to which events can be predicted and taken into account in planning for development varies. Sound ground investigation normally establishes whether a subsidence hazard is present allowing suitable precautionary or remedial measures to be identified although sometimes it can be imprudent or uneconomic for development to proceed. For existing development, treatment often is only undertaken after the event. While effects of minor subsidence on buildings can be treated, major events are likely to lead to demolition, major works on the site or, in some cases, cannot be remedied. Where human actions lead to subsidence, some compensation may be obtainable, but for other circumstances, redress can be obtained but only if there is adequate insurance cover. Subsidence hazard mapping is an important step in planning for development or safeguarding existing development in any subsidence-prone area.

LAND USE, URBANIZATION, AND NATURAL HAZARDS

Brian R. Marker
London, UK

Definitions

Land use: This concerns the ways in which land is utilized and developed (e.g., residential, industrial, commercial, agriculture, forestry, etc.) or conserved (e.g., to protect natural and seminatural habitats or endangered species).

Urbanization: This is the process of growth of population centers to become towns, cities, megacities, and metropolitan areas.

Urban areas: These are variously defined making it difficult to generalize and to compare statistics. These are often expressed in terms of the density of population per unit area. A fairly widely used figure is 400 persons per km^2 but geography plays a strong part in national definitions. For instance, in the USA, a figure of 386 per km^2 in a census block (but with additional conditions relating to surrounding blocks) is used, compared with a density of 200 per km^2 in Australia, or 4,000 per km^2 in Japan. An alternative approach is to consider a minimum area containing a certain number of residents (e.g., 1,500 census residents in an area of 20 ha in the United Kingdom). In some cases, separate areas are regarded as linked if these are less than 200 m apart (many European countries), whereas in Norway, for example, groups of houses less than 400 m from a main urban area are regarded as part of that area. Therefore, caution is needed in comparing statistics from different sources.

Megacities: These are also variously defined but a much quoted statement, employed by UNESCO, is an area with a population in excess of 10 million. Other definitions vary

between 5 and 10 million people whereas some prefer to quote a population density (e.g., 2,000 people per km^2). The terms "megapolis" or "megalopolis" are sometimes used for megacities.

Metropolitan areas: These consist of associations of towns and cities that have expanded until limited areas of open countryside remain between them. A frequently quoted example is the series of urban areas in the northeast of the USA extending between New York and Washington DC.

Introduction

Land is required for food, water, and other natural resources; conservation of varied habitats; and buildings and infrastructure. Therefore, sustainable use of land is important. The management and development of land depend on identification and implementation of the most appropriate uses, for the short and long term, in social, economic, and environmental terms. Urbanization is a persistent trend in human societies. Many towns become cities and then grow into megacities or metropolitan areas by progressive expansion and amalgamation with nearby settlements. While definitions of these areas vary, the important point is that urbanization concentrates people into limited areas. This has economic benefits but consequent pressures on urban land use and the surrounding areas that provide food and natural resources, as well as increasing the vulnerability of urban populations and development to natural hazards.

Land use

Land is used in many ways: for agriculture, forestry, industry, housing, schools, hospitals, power generation plants and commerce; and infrastructure such as roads, reservoirs, ports, airports, communications systems and power and pipe-lines. Some land may be protected from development in the interests of conservation of biodiversity and cultural heritage (McCall et al., 1996). In developed countries, and increasingly in developing countries, urbanization is placing pressure on those resources (Fujita, 1991).

In the past, and still in some places, decisions on land use were made by individuals in small localized communities that were generally in reasonable harmony with their surrounding environment. But societies have become more complex and developed systems for regulating land use and controlling environmental impacts including the following:

- Planning for development – under which planning authorities set out policies and criteria for appropriate uses and prospective developers submit proposals for land use. These are scrutinized by local, regional, or central government agencies within the context of their policies, and criteria for development are either approved, subject to conditions, or refused; and, if permitted, enforced by those bodies to a greater or lesser extent
- Environmental permitting – for control of emissions and management of waste through regulations that are enforced by agencies of government
- Guidance on good practices – in particular, to encourage the agricultural, forestry, and fisheries sectors to undertake activities and precautions to improve productivity without environmental degradation (Culshaw et al., 2009; Marker et al., 2003).

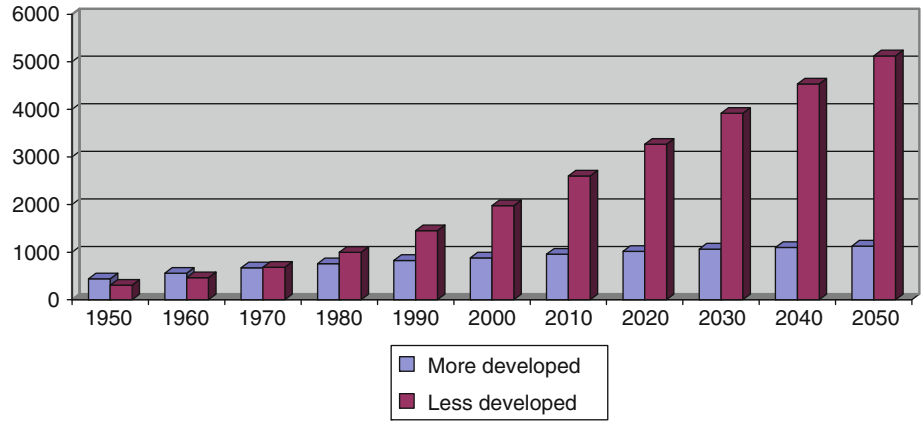
While population dynamics and economic growth are major drivers in planning for development, sustainability requires a wide range of environmental, social, and economic factors to be taken into account (McCall et al., op cit; Marker, 2009). An important aspect is identifying areas that are vulnerable to hazards and making sure that development is either limited or undertaken with appropriate precautions in those zones (Pelling, 2003).

Urbanization

Many existing urban areas grew as industry, commerce, and trade developed. These are linked by complex transport, water and energy distribution systems; and require sophisticated waste management and waste water handling facilities (Flint and Flint, 2001). Rapid urbanization in developed countries, linked to industrialization, occurred in the late eighteenth to early twentieth centuries, but is happening today in developing countries as people migrate from the countryside (Fuchs, 2002). In contrast, in some cities in developed countries central urban populations are shrinking and suburbanization is taking place (Genske and Ruff, 2009).

The average annual growth of urban population between 2005 and 2010 in less developed countries was about 3.4 times that in more developed countries with, in 2010, about 75% of the population in more developed countries being urban compared with only 45% in less developed countries (Table 1; UN DESA, 2011a), whereas the proportion of people living in urban areas is thought to have overtaken the proportion in non-urban areas for the first time within the past few years.

But the longer-term trend and expectations are more dramatic. Between 1950 and 2010, the urban population in more developed countries increased about 2.1 times but in less developed countries rose about 8.5 times. In 1950, there were more urban dwellers in more developed countries than in less developed countries but in the mid-1980s the numbers became similar. Projections to 2050 suggest that, by then, there could be over 4.5 times the number of urban people in present less developed countries than in more developed countries (Figure 1; UN DESA, 2011b).



Natural hazards and impacts

Many urban areas are subject to natural disasters due to local geological, geomorphological, hydrological, and climatic conditions. Towns and cities of the Pacific Rim, for instance, are vulnerable to seismic events and volcanic eruptions (Arias et al., 2001; Chester et al., 2000), whereas

Land Use, Urbanization, and Natural Hazards, Table 1 Selected urban population statistics

	Total population 2010 (millions)	Urban populations 2010 (millions)	Urban population 2010 (%)	Average annual growth of urban population 2005–2010 (%)	Urban population living in slums 2005–2007 (%)

settlements located on coasts, deltas, and rivers are often susceptible to major floods (Berz, 2000). Hazards also affect the nearby countryside but the potential severity of impacts is greater in urban areas because:

(a) Urbanization concentrates population, development, and infrastructure leading to greater potential losses and, therefore, higher risks
(b) Rapid growth may outstrip the capacity of infrastructure to cope, for instance, drainage may be inadequate increasing flood potential, and may be accompanied by poor standards of construction making buildings more liable to damage with consequently higher casualties (Mitchell, 1999).

In developed countries, financial losses due to hazard events in urbanized areas are often large but losses of life and injuries are fewer but, in developing countries, there is often greater loss of life and more injuries compared with financial losses for a given magnitude of event. That is because, in developed countries, land and real estate prices are higher, building codes are generally stricter and better enforced, and transport and other infrastructure is often better able to cope with post-event rescue and relief operations and reconstruction (Mitchell, 1995). Although impacts on urban areas tend to be greater in human and financial terms, impacts outside urban areas are also important because of loss of crops that are needed to feed towns and cities, and disruption to transport routes. Sensible land use planning and management is important in both.

Urban management should include assessment of all potential hazards and appropriate steps at planning policy and site development stages. Risks can be reduced if buildings are constructed to survive expected events or if potentially hazardous ground is reserved for open space uses. But, even if that is done, the intention can be frustrated. Especially in developing countries, inward migrants to cities often set up home in poorly constructed slums on land that has been deliberately kept vacant, placing the most vulnerable members of society at the greatest

risk (Marker 2009). It is also important to plan and practice emergency responses; site essential facilities such as hospitals and fire stations in least vulnerable areas (Boullé et al., 2002); and ensure that key evacuation and access routes are, as far as possible, protected to ensure resilience to adverse events (Godschalk, 2003; Institution of Civil Engineers, 1995; Kreimer et al., 2003; United Nations, 2002; Valentine, 2003).

Planning on the basis of past experience is insufficient because of environmental, social, and economic changes. It is important to consider changes to vulnerability, risk, and resilience for a possible range of future conditions (Kraas, 2007; Romero Lankao and Qin, 2011) so that key threats, adaptation measures, interactions between strategies and measures, and limits to adaptation can be identified (Birkmann et al., 2010) and governance arrangements can be improved (Tanner et al., 2009).

Conclusions

It is important to take account of natural hazards when planning and managing development, whether in urban areas or the surrounding countryside, and to minimize risk and to maximize the effectiveness of post-event responses. This can be done through hazard assessment and appropriate zoning of land uses, ensuring that development is designed and constructed to survive likely events, and allowing for likely changes in the coming years. It is also important that attention should continue to be paid to the issue even if there have been no recent damaging events because complacency is likely to lead to future damage or disaster.

LANDSAT SATELLITE

María Asunción Soriano
Universidad de Zaragoza, Zaragoza, Spain

Synonyms

ERTS

Definition

Landsat is the name applied since 1974 to a program of unmanned satellites whose main objective is the study of the surface of the Earth.

Discussion

The Landsat program includes seven satellites. Before 1974 the program was known as the ERTS (Earth Resources Technology Satellite). The satellites were launched in 1972, 1975, 1978, 1982, 1984, 1993 (failed), and 1999 (Landsat 7). Two of them, Landsat 5 and 7, are still active. The missions and commercialization of results of these civilian satellites have generally been managed by agencies of the US Government (NASA, NOAA and the US Geological Survey) although between 1984 and 2001 a private company was contracted for the purpose (NASA, 2010).

The orbit of Landsat satellites is Sun-synchronous near polar at an altitude of 918 km for Landsat 1, 2, 3 and 705 km for the remaining satellites. The spacecraft completes just over 14 orbits per day, covering the entire Earth between 81°N and S latitude every 18 days for the three first Landsats and 16 days for the rest. Some side lap of orbits occurs especially in north latitudes (around 80%). There is a Worldwide Reference System for the images where each scene is designated by path and raw numbers.

The systems on board Landsat satellites have been modified over time, increasing their resolution. The best known are the Multispectral Scanner System (MSS), the Thematic Mapper (TM) and the Enhanced Thematic Mapper Plus (ETM+). All are cross-track scanning systems with an oscillating mirror that scans a width of 185 km on the ground. In the MSS (Landsat 1–5), four different wavelength intervals (four bands) of the electromagnetic spectrum are detected, two included in the visible and two in the reflected infrared interval. Their spatial resolution is 79 by 79 m. The TM (Landsat 4 and 5) detects seven bands, three in the visible, three in the reflected infrared and one in the thermal infrared interval. The spatial resolution is 30 by 30 m, except in the thermal infrared (120 by 120 m). The main modifications in the ETM + (Landsat 7) are the addition of a panchromatic band with a 15 m spatial resolution and the improvement of the resolution of the thermal infrared band (60 m) (NASA, 2010). The system detectors sense the energy from the ground and transform it into electrical signals that are codified in a binary system and later transformed into gray levels with an intensity proportional to the energy received (i.e., no energy is black and the maximum energy is white), generating an image similar in appearance to black and white photographs (Sabins, 1987). The combination of three bands enables color images to be obtained (false color only in the case of the MSS because of the absence of the blue wavelength interval, and both true and false in the TM and ETM+).

The Landsat Program has been providing data about the Earth's surface that have proved very useful in the fields of Geology, Forestry, Agriculture, Cartography, Urban change, dynamic environments, etc. The main customers of these images are researchers, governments, commercial users, and educators.

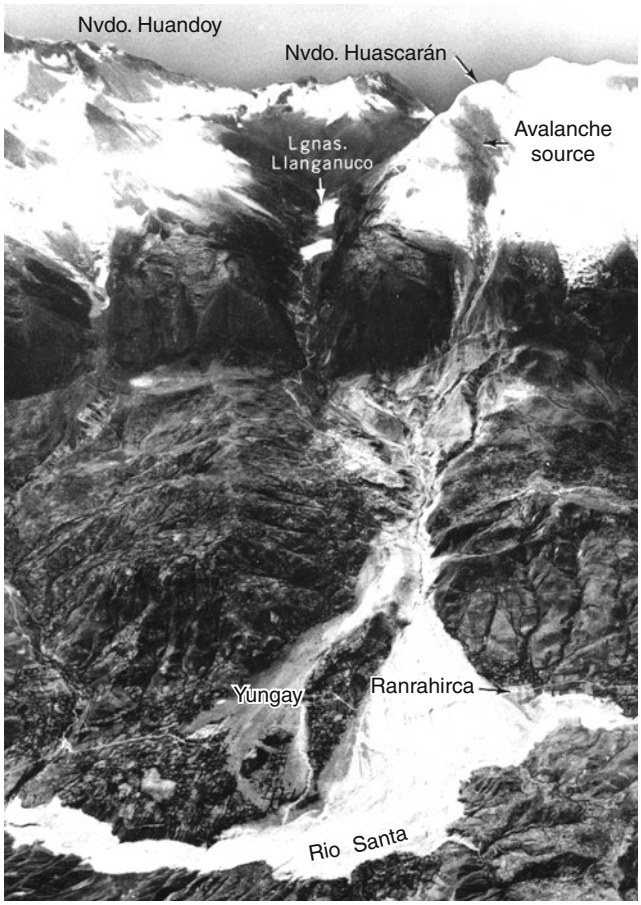
LANDSLIDE



John J. Clague
Simon Fraser University, Burnaby, BC, Canada

Definition

A *landslide* is the failure and movement of a mass of rock, sediment, soil, or artificial fill under the influence of gravity. (*Soil*, as used here, is the thin layer that directly underlies the land surface formed by pedogenic processes.)

Introduction

Globally, landslides kill thousands of people each year and cause tens of billions of dollars in damage (Centre for Research on the Epidemiology of Natural Disasters, 2012). One of the most deadly landslides on record occurred during an earthquake in Peru on May 31, 1970. A streaming mass of blocky debris produced by a failure on Nevados Huascaran killed 8,000 inhabitants of the town of Yungay (Figure 1; Plafker and Ericksen, 1978;

Landslide, Figure 1 Oblique view of Nevados Huascaran and the path of the debris flow that overran the town of Yungay on May 31, 1970, killing about 8,000 people. (George Plafker, U.S. Geological Survey).

Evans et al., 2009). Landslides were also responsible for thousands of the more than 70,000 fatalities of the Sichuan (Wenchuan) earthquake in southwest China in 2008. Large landslides can also block rivers, creating impoundments and upstream flooding. When overtopped after the reservoirs reach full-pool level, the dams may fail, producing devastating downstream floods. In some cases, however, seepage through the dams is greater than inflow into the reservoir and the dams and the impoundments may persist indefinitely.

Landslides range in volume from less than one cubic meter to tens of cubic kilometers. They are primarily associated with mountainous terrain but also occur in areas of low relief, for example, in roadway and building excavations, mine-waste piles, and river bluffs. Landslides may travel only short distances and leave their deposits at the base of the source slope. In some cases, however, they can run-out far from their sources; in the case of some lahars, the travel distance may be tens of kilometers.

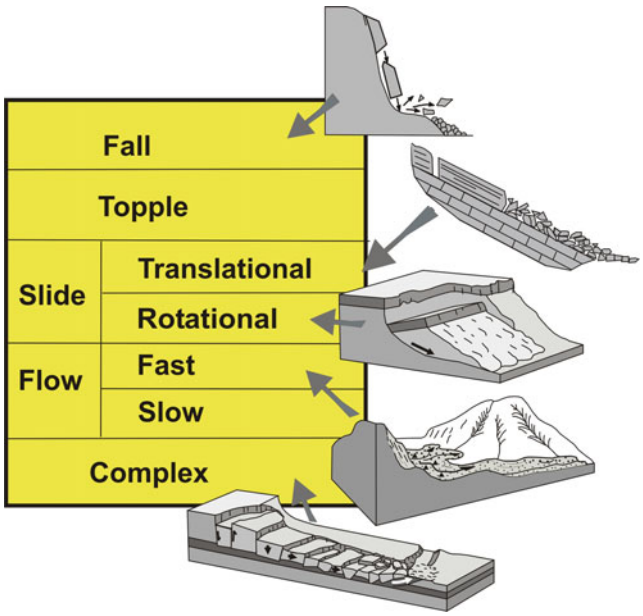
Types of landslides

Landslides are classified on the basis of their velocity, the type of movement, and the source material (Figure 2; Cruden and Varnes, 1996). They move at rates ranging from millimeters per year to more than 100 m per second. Source materials range from unconsolidated sediments to lithified rocks. Perhaps the most landslide-prone unconsolidated sediments are silts and clays, but all other types of sediments may fail under certain circumstances. Crystalline and metamorphic rocks that are massive and have few joints or fractures are most resistant to slope failure; these rocks include some granitoid rocks and most non-foliated metamorphic rocks. In contrast, strongly foliated metamorphic rocks, including phyllites, schists, gneisses, and bedded sedimentary rocks, and any rock that is strongly jointed, fractured, or faulted, may fail where structural elements or stratification dip in the same direction as the slope. Some of the most failure-prone rocks are pyroclastic deposits and lavas found on the slopes of stratovolcanoes. Topography is, of course, also important. All other things being equal, steeper slopes are more likely to fail than gentler ones, because gravitational driving forces increase as a slope becomes steeper. The presence or absence of water can be critically important because it exerts a strong influence on the type of movement. The classification scheme shown in Figure 2, although simplified, provides an understanding of the range and complexity of landslides.

Falls involve rolling and bouncing of rock and, less commonly, sediment from cliffs or down steep slopes. Initial failure occurs along steeply inclined fractures or other discontinuities in rock or sediment. This process is responsible for cones and aprons of talus, which are common landforms in mountains. Large blocks and boulders sometimes roll or bound beyond the foot of the talus slope, causing loss of life and property damage (Holm and Jakob, 2009). Numerical models have been created to estimate, for a given slope, the "rockfall shadow" – the zone vulnerable to boulder run-out. Rockfall is also common along some roads and railways (Figure 3).

Although relatively small, rockfall is among the most costly of all types of landslides. In addition to economic losses due to traffic delays, the costs of scaling, blasting, and grouting threatening rock faces and removing debris from roads and rail lines are considerable.

Topples involve the forward rotation of rock or sediment about a pivot point under the influence of gravity. Movement occurs along steeply inclined fractures. Topples range from shallow movements to deep-seated displacements of large volumes of rock. The process operates almost imperceptibly, with movement rates commonly in the range of millimeters to centimeters per year, but a threshold of stability may be reached, at which time the material suddenly fails, producing a fall or a slide.



Slides involve the downslope translational movement of rock or sediment along a discrete surface (Voight, 1978).

They are subdivided into translational and rotational types, although many slides are complex phenomena, involving both types of movements.

Translational sliding takes place on planar or undulating surfaces dipping in the direction of the slope. The basal failure plane may be a bedding plane, foliation, a fault, or a tight set of joints. The basal failure plane is bordered by the head and marginal scarps, which may be joints or faults. The slide mass commonly disintegrates as it moves downslope, but the fragments tend to retain their positions with respect to one another.

Rotational sliding involves translation of rock or sediment along a curved, concave-upward failure surface, producing what are termed slumps (Figure 4). This style of movement involves extension at the head of the slump and compression at its toe. The result is one or more steep down-stepping scarps at the headwall and bulging of the toe. Movement rates range from millimeters per hour to meters per second.

Flows are a large and varied group of landslides that share one similarity – the failed material moves in the manner of a fluid. In wet flows, rock fragments are partly supported by interstitial water. Debris flows are the most common type of wet flow; they consist of mixtures of water, rock fragments, and plant detritus that move down steep stream courses or ravines as slurries and, less commonly, down open slopes without lateral confinement (Figure 5; Jakob and Hungr, 2005). Most debris flows are triggered by heavy rainfall or by rain on snow. Those that move down the flanks of volcanoes are called lahars. This group includes very large flows caused by melt of snow and ice during eruptions glacier-clad volcanoes. The Osceola lahar, which traveled down valleys on the north and east flanks of Mount Rainier in Washington state about 5,600 years ago, covered an area of about 550 km^2 and had a volume in excess of 3 km^3 (Crandell, 1971; Scott and Vallance, 1995). The smaller Electron lahar, which is about 500 years old, traveled more than 50 km from its source on the west flank of Mount Rainier. Mudflows are similar to debris flows, but the solid fraction consists of sand, silt, and clay, with little or no gravel or coarser material. Debris flows and mudflows can travel at speeds of up to a few tens of meters per second.

Landslide, Figure 2 Simplified classification of landslides.

Landslide, Figure 3 Rockfall on the Trans-Canada Highway near Yale, British Columbia (Duncan Wyllie).

Landslide, Figure 4 Slump in unconsolidated sediments along Thompson River at Ashcroft, British Columbia. The slump happened in 1897 (J. J. Clague).

Landslide, Figure 5 Debris flow tracks on steep slopes above Wahleach Lake in the Cascade Range, British Columbia (J. J. Clague).

Flows of water-saturated sediment are also common on slopes underlain by permafrost in the Arctic (McRoberts and Morgenstern, 1974). The failure plane is shallow, at the contact between the permanently frozen ground and the overlying active layer. These flows can occur on slopes as low as a few degrees and are especially common-along river and coastal bluffs underlain by ice-rich sediments. As climate warms, as is expected through the remainder of this century, the active layer in permafrost terrain may thicken, leading to an increase in the numbers of these flows.

Sediment flows also happen in oceans and lakes, especially off deltas, at the heads of submarine canyons, and at the seaward edges of continental shelves. Those that travel down submarine canyons into deep ocean waters are termed turbidity currents. Submarine landslides are especially common on the foreslopes of rapidly prograding deltas, such as those at the mouths of fiords in Norway, British Columbia, and Greenland (Prior and Bornhold, 1988), and off the mouths of some of the world's largest rivers, for example, the Mississippi, Congo, Ganges, and Indus rivers.

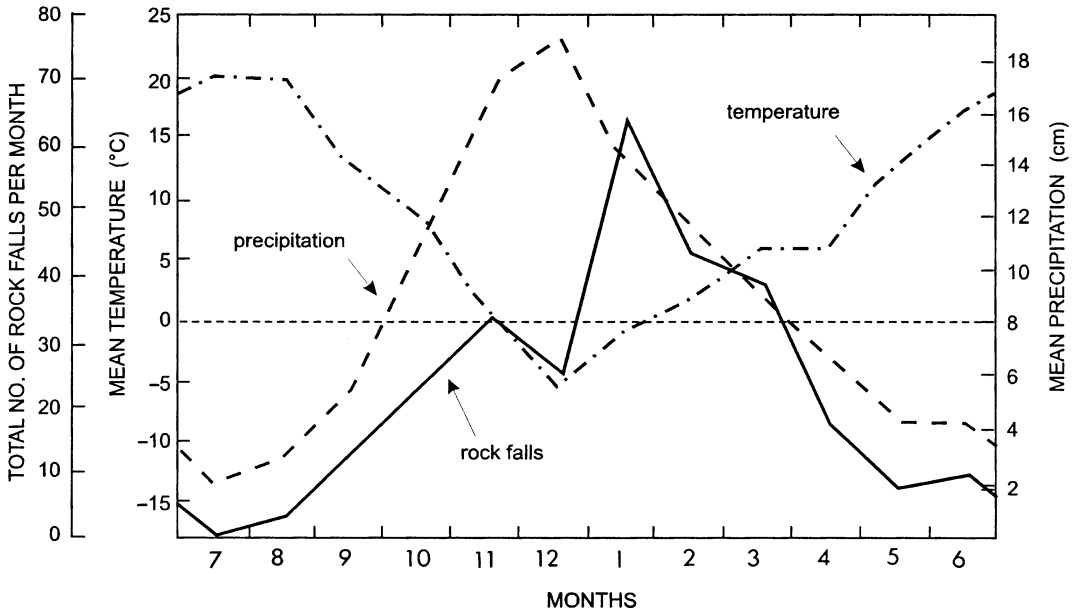
Rock avalanches (also known as sturzstroms) are large flows of fragmented rock that contain little or no water. They flow due to the release of energy by particle interactions and particle comminution. Rock avalanches are the fastest of all landslides, in some cases achieving speeds of 100 m per second or more. They also travel long distances where unimpeded by topography. Rock avalanches are far less common than other types of

Landslide, Figure 6 The Frank Slide, which occurred in April 1903, is a classic rock avalanche. It involved the failure of about 30 million cubic meters of limestone. The rock rapidly fragmented and streamed onto the valley floor at high velocities. The debris was deposited as a sheet over an area of over 2 km^2 (Geological Survey of Canada).

landslides, but are important and of scientific interest because of their long travel distances and the destruction and death they cause. One of the most famous examples is the Frank Slide, which killed about 70 people in the mining town of Frank, Alberta, in April 1903 (Figure 6; Cruden and Krahn, 1978). Many mechanisms have been proposed to explain the high mobility and long run-out of rock avalanches (see recent review by Hewitt et al., 2008). Examples include travel of the debris on a thin layer of air, generation of high pore pressures at the base of the flow by entrainment of water, and forces generated by rapid and extreme comminution of particles. The discovery of rock avalanche deposits on other planets suggests that explanations involving trapped air and water are likely invalid.

Many landslides do not fit comfortably into existing classification schemes. Prominent examples include *sackung* and *lateral spreads*. Sackung, a German verb meaning "to sag," is deep-seated downslope movement of large, internally broken rock masses, with no single, well-defined basal failure plane (Zischinsky, 1969). Movement is manifested at the land surface by cracks, trenches, and scarps at mid and upper slope positions, and by bulging of the lower slope. Lateral spreading involves extension of a slab of earth material above a nearly flat shear plane. The moving slab may subside, rotate, disintegrate, or flow. Lateral spreading in silts and clays is commonly progressive – failure starts suddenly in a small area, but spreads rapidly, ultimately affecting a much larger area. Lateral spreading commonly results from liquefaction of a subsurface sand layer. An unusual form of lateral spreading is the failure of what are termed "quick clays." Thick glaciomarine clays were deposited on isostatically depressed coastal lowlands in some areas of Canada, Scandinavia, and Alaska near the end of the Pleistocene and subsequently elevated above sea level due to rebound of the crust. Quick clays are sensitive, meaning that they may liquefy and flow when disturbed (Rankka et al., 2004). A famous example is the Leda clay, deposited in lowlands bordering the St. Lawrence River and its tributaries in southern Quebec and Ontario (Eden and Mitchell, 1970; Smalley, 1980). Landslides in the Leda clay have caused much damage and loss of life during the past few centuries (Evans et al., 1997).

Finally, many landslides, including most large ones, are *complex*, that is, they involve more than one type of movement. A rockslide, for example, may evolve into a debris flow by entraining water or saturated sediments along its path. The 1970 Nevados Husacaran landslide, mentioned above, is an example of a complex landslide. It started as a large slide or fall of rock and ice, but soon transformed into a debris flow.



Causes and triggers

When considering landslides, it is important to understand the difference between their causes and triggers, although in practice, the two concepts define end points on a continuum. The *cause* of a landslide is the combination of external and internal factors that, over time, leads to failure. The main causes of landslide are geological (lithologic and structural), steep topography, weathering, erosion, subsurface solution, depositional loading at the top of an unstable slope, a change in climate, and human disturbance. In contrast, a landslide is *triggered* by a single event such as an earthquake, rainstorm, volcanic eruption, or a series of freeze-thaw cycles (Wieczorek, 1996).

Moderate and large earthquakes commonly trigger rockfalls, slides, and debris avalanches. Very large

(magnitude >7) earthquakes in mountainous terrain may trigger rockslides, large slumps, and rock avalanches. Debris flows and small rockfalls are commonly triggered by intense rain. Rainwater infiltrates sediment and fractures in rock, raising water pressures in these materials and inducing failure. Many rockfalls are triggered by frequent freeze-thaw cycles (Figure 7). When water in fractures freezes, its volume increases by about 9%, sufficient to induce large tensile forces on the rock bounding the fractures. Volcanic eruptions trigger lahars (Figure 8) and, in some cases, huge flank collapses, such as happened at the onset of the cataclysmic eruption of Mt. St. Helens in May 1980.

Many landslides, including some large ones, occur without known triggers. Slopes may slowly deteriorate over centuries or millennia to the point that they fail of their own accord. An example of a large landslide without a known trigger is the Hope slide, which occurred in

Landslide, Figure 7 Average monthly rockfall frequency and weather over the period 1933–1970 in the Fraser Canyon (From Evans and Savigny, 1994; Modified from Peckover and Kerr, 1977).

Landslide, Figure 8 Aftermath of a huge lahar that swept through the town of Armeio in Colombia on November 13, 1985, killing 20,000 of its 29,000 inhabitants. The lahar was triggered by an eruption of Nevado del Ruiz, which melted snow and glacier ice on the summit.

southwest British Columbia in January 1965 (Mathews and McTaggart, 1978). Weather conditions in the lead-up to the landslide were not unusual and no earthquakes occurred at the time of failure. Interestingly, however, a large (magnitude 7) earthquake, with an epicenter approximately 50 km south of the site of the landslide, occurred in 1872 (Bakun et al., 2002). Although the seismic acceleration at the landslide site during this earthquake may have been greater than 0.2 g, the slope did not fail. Rather, the unstable slope deteriorated over the next 93 years sufficiently to reach the threshold of failure without the requirement of a significant trigger.

The water content of slope materials is an important factor in their stability. Slopes that are stable in arid environments may fail in humid ones, and some rock slopes in areas where temperatures frequently fluctuate above and below freezing are vulnerable to rockfall. Even in arid environments, however, heavy rainfall can trigger widespread slope instability. In any case, water enters slopes along fractures, faults, and permeable strata. Under conditions of poor drainage, pore pressures may rise within the slope, increasing the likelihood of failure. Vegetation reduces this effect by intercepting rainfall and, through evapotranspiration, reducing the amount of water in slope materials. Tree roots also act to stabilize near-surface earth materials on slopes.

Climate warming, which is expected later in this century, may increase annual or seasonal precipitation in some areas (Solomon et al., 2007), thereby increasing the frequency of rockfalls, debris flows, debris avalanches, and perhaps other types of landslides there. Of critical importance will be changes in the frequency of extreme rainfall events. A rise in extreme storms in an area would certainly increase the frequency of debris flows and probably rockfalls. Similarly, areas that become more arid are likely to experience more frequent or more intense wildfires, with an attendant loss in vegetation leading to increased soil failure. The incidence of rockfalls from high mountain slopes may also increase in the future due to thaw of alpine permafrost (Noetzli and Gruber, 2009). Ice within fractures in rock that is now below 0°C will melt if air temperatures rise above the freezing point over much of the year, possibly destabilizing already marginally stable rock slopes (Fischer et al., 2006; Huggel, 2009).

Recognition and mitigation of landslide hazards

The first step in landslide hazard mitigation is to identify and assess the hazard (Schuster and Kockelman, 1996). This assessment involves: (1) determining the age and frequency of past landslides from geologic evidence and historical records and (2) assessing ground conditions where failure might occur. The second step is mitigation to minimize risk to people and property. Mitigation measures are of three types: (1) restrictions on land use, (2) monitoring and early warning, and (3) corrective and defensive works.

Land-use restrictions

If a site is deemed too hazardous and the risk cannot be reduced to an acceptable level, development may be disallowed or restricted. Such determinations must be made carefully and with a sense of what is acceptable because limitations on land use commonly have economic consequences – the full value of the land may not be realized. Whether a risk is perceived as acceptable or unacceptable depends on social and economic factors. In general, less risk is tolerated in wealthy countries than in poor ones. In wealthy countries, knowledge of past landslides is generally taken into account during development. For this reason, land-use restrictions are more commonly accepted in these countries than in poor ones. The high level of risk that people in some poor countries accept, largely because they have few or no options, contributes to the greater loss of life from landslides in these countries than elsewhere.

Monitoring and early warning

Rockfalls, small slumps, opening and widening of ground cracks, and tilting of trees precede many large landslides. Observation or instrumentation of unstable slopes may provide early warning of their imminent catastrophic failure.

Advanced technologies are providing new opportunities to monitor potentially hazardous slopes. Very small movements of the ground can be detected using satellite remote sensing tools, notably InSAR (Interferometric Synthetic Aperture Radar). A powerful tool for producing highly precise digital elevation models of unstable slopes is LIDAR (Light Detection and Ranging), which uses laser pulses to measure the time delay between transmission of a pulse and detection of the reflected signal. LIDAR uses millions of pulses to produce a model of the Earth surface in an area of interest. Comparison of images acquired over time may reveal slow slope movements that could precede catastrophic failure (Oppikofer et al., 2008).

Corrective and defensive works

Corrective and defensive measures include reforestation, control works, and protective structures. Careful management of forests reduces the likelihood of some types of landslides. Reforestation of logged or burned slopes, in combination with other corrective measures, may stabilize debris source areas. Control works, including dykes along stream channels, deflection dams and dykes, and debris retention basins, provide protection against debris flows. Steep rock slopes along highways and railways can be stabilized with retaining walls, anchored beams, rock bolts, bulkheads, toe buttresses, metal nets and fences, and ditches (Wyllie, 1991). Unstable slopes can be dewatered with tunnels or permeable pipes. Stabilization of large bedrock slides and sagging slopes requires extensive surface and subsurface drainage.

Summary

Landslides are a near-global hazard, but are most common in areas of high relief where steep and moderate slopes are common. Landslides are classified according to type of movement (falls, topples, slides, slumps, flows, sags), type of material (rock, unconsolidated sediments), and velocity (slow, fast). The most important cause of landslides is geology – failure generally occurs on weak planes in rock, including stratification, foliation, joints, or faults; and poorly lithified rocks and non-lithified sediments are generally more prone to failure than lithified materials. Almost as important is water, which increases the mass of the earth material and therefore the gravitational driving force; water also penetrates joints, fractures, and permeable strata, possibly elevating pore-water pressures to the threshold of failure. Landslide triggers are related to, but distinct from, causes. They are the phenomena that raise the slope above the threshold of failure. The most common triggers of landslides are severe storms, earthquakes, volcanic eruptions, and human activity. In the case of human activity, loading the top of an unstable slope or removing material from its base may trigger a landslide, as both increase the gravitational driving force on the slope. Human activity, however, can also increase the stability of a slope, for example, by loading the toe of the slope or by dewatering unstable materials. Landslide hazards can be mitigated by land-use restrictions, monitoring, warning systems, and corrective and defensive structures.

LANDSLIDE DAM

Reginald L. Hermanns
International Centre for Geohazards, Geological Survey of Norway, Trondheim, Norway

Synonyms

Debris dam; Quake lake

Definition

Landslide dams are formed by landslide (see entry *Landslide*) deposits or moving landslides which block a permanent or ephemeral water course leading to the formation of a natural reservoir which fills with water and/or sediments. The term quake lake is used in the case that the landslide was triggered seismically, this term became established as a name for a landslide-dammed lake in southwestern Montana triggered by an earthquake on August 17, 1959; it then became more widely used after the 2008 Wenchuan China earthquake that triggered hundreds of large valley-damming landslides.

Introduction

Landslide dams range in size from a few cubic meters in volume and a few decimeters high (e.g., that can block a drainage ditch beside a road), to a dam several cubic kilometers in volume and several hundreds of meters high that can block an entire mountain valley. In all cases, the damming adds to the hazard (see entry *Hazard*) of the landslide due to combinations of flooding of the valley upstream of the dam, diversion of the water course, and catastrophic flooding of downstream areas if the dam fails. However, in the *natural hazard* literature, the term "landslide dam" is most often used to describe larger landslide blockages that form lakes more than several meters deep (Schuster, 2006).

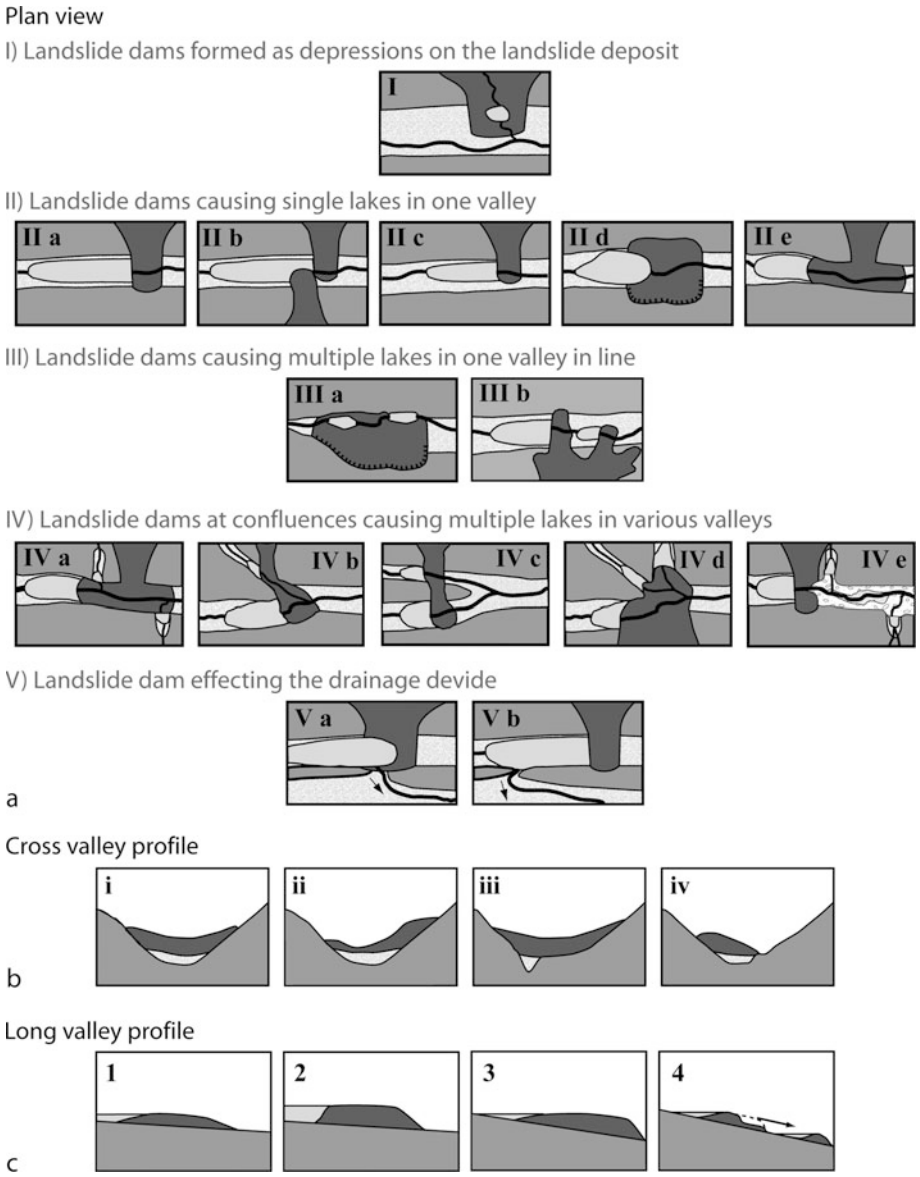
Large landslides in all mountain environments have formed natural dams which have resulted in upstream lakes (Costa and Schuster, 1988; Evans et al., 2011a). Often these are related to earthquake triggering of landslides, and single earthquakes have formed more than hundreds of dams (quake lakes) (Evans et al., 2011a). Impounded lakes can have capacities of more than 10 km^3, as in the case of lake Sarez which is impounded by the Usoi dam (see entry *Usoi Landslide and Lake Sarez*) in Tajikistan; with a volume of 16 km^3 this is the largest rockslide dam reservoir on Earth (Alford and Schuster, 2000; Ischuk, 2011; Stone, 2009). The height of this natural dam is 670 m and its volume is 2.2 km^3. Despite the large volume of such dams, they are not necessarily stable. Half of all dams formed in the twentieth century with a volume in excess of 20×10^6 m^3 have breached within the following 7–3,435 days (Evans, 2006), often releasing much of the dam water and causing catastrophic floods downriver that causes significant destruction and loss of life (e.g., Groeber, 1916; Zevallos et al., 1996; Evans et al., 2011b). In history the *landslide dam* with highest reported death toll (100,000) was the result of the breach of a dam on the Dadu river in Sichuan, China, on June 11, 1786; this had formed only 10 days earlier after being triggered by an earthquake (see entry *Earthquake*) of ~M 7.8 (Dai et al., 2005). In general, there is an agreement that those dams which fail catastrophically, are usually new and ~80% of catastrophic dam failures occur within the first year of dam existence (Costa and Schuster, 1988; Ermini and Casagli, 2003; Evans et al., 2011a). However, landslide dams which survive their first years of existence can become stable landforms that control the geomorphic developments of valleys for thousands of years (e.g., Hermanns et al., 2004; Schuster, 2006; Hewitt, 2006). Such dams and their remains have to be recognized as such in the geological record in order to not misinterpret these landforms with landforms related to tectonic or climate-driven landscape evolution (Hewitt et al., 2011). Due to the large volume of water stored and the steep gradient caused in the river profile these dams have often been used for hydropower generation (e.g., Duman, 2009; Hermanns et al., 2009). Based on this experience, rockslides have been triggered artificially by explosives in the former Soviet Union to construct dams in remote areas rapidly and at

low costs (e.g., Aduschkin, 2011; Korchevskiy et al., 2011) for hydropower generation, but also for debris flow protection. Nevertheless, much older dams have also breached and have caused catastrophic floods (e.g., González Díaz et al., 2001; Hermanns et al., 2004).

Classification of landslide dams

The first widely used classification of landslide dams emphasized the relation of the *landslide* deposit to valley and impoundment morphology. It proposed six different types of dams, based mainly on the two-dimensional distribution of the *landslide* deposit in a single valley and the dam plan form (Costa and Schuster, 1988). The recent increase in identification of landslide dam deposits (Evans et al., 2011b) has revealed some limitations of this classification. For example, landslide dams are not two-dimensional; they have a three-dimensional distribution in relation to valley morphology (Dunning et al., 2005; Strom and Pernik, 2006) which affects the formation and long-term stability of impoundments. A new classification system (Hermanns et al., 2011a, Figure 1) not only takes into account the three-dimensional relation of *landslide* bodies to valley morphology, but also the common phenomena of (a) lakes formed on the landslide deposit itself, (b) formation of multiple landslide dams in a valley, (c) landslide dams at confluences of two or more river valleys that may give rise to more than one lake, and (d) the rarer but special case of landslide dams affecting drainage divides.

Landslide dam failure and outburst floods



Most landslide dams fail by overtopping (Costa and Schuster, 1988; Evans et al., 2011a) when the landslide-dammed lake fills with water and *erosion* of the dam crest starts downcutting into the deposit. However, overtopping by displacement waves (see entry *Landslide Triggered Tsunami, Displacement Wave*) caused by a mass movement (see entry *Mass Movement*) into the landslide-dammed lake has also been reported and is considered a serious threat when large unstable slope areas or glaciers exist above the lake (Hermanns et al., 2004; Stone, 2009). Other failure modes are piping (e.g., Meyer et al., 1994; Quenta et al., 2007), progressive upstream erosion (see entry *Erosion*) (Hancox et al., 2005), and sliding collapse of the downstream face of the dam (Dunning et al., 2006). All of these processes are self-accelerating because the more the water escapes growth, the higher the outflow velocity becomes and the faster the material is eroded. Hence, landslide dam *erosion* often results in breaching. Peak discharges during such failures can be several times the seasonal peak discharge of a river and have volumes of several tens or more than 100,000 m^3/s (e.g., Abbott, 1848; Zevallos et al., 1996; González Díaz et al., 2001; Evans et al., 2011a). Such discharges can flood large portion of the river valleys downstream and lead to the damage and destruction of bridges, villages, agricultural land, and hydropower facilities in the days that the wave moves downriver (Evans et al., 2011b). More than 1,000 km long valleys can strongly be affected by these masses of water and solids (González Díaz et al., 2001; Schuster, 2006; Evans et al., 2011a) flushing downstream. This downstream flush of sediments is not restricted to the breach event itself but lasts over years and leads to aggradations through the river system (Hancox et al., 2005; Davies and Korup, 2007).

Hazard assessment of landslide dams

Hazard (see entry *Hazard*) assessment of landslide dams includes assessment of flooding of the upriver area, stability assessment of the dam, assessment of a potential catastrophic outburst flood, and assessment of the longer-term river aggradation and flood hazard downstream. While the first step is straightforward and restricted to outline the surface area below the minimum dam crest level, stability assessment of the dam itself and of potential outburst floods is a severe challenge. Geotechnical stability calculations similar to stability calculations for artificial earth- and rock-filled dams are especially challenging because they require knowledge of parameters such as grain size distribution, permeability, and groundwater flow which are difficult and expensive to obtain and have been used only in limited occasions (e.g., Meyer et al., 1985, 1994; Bianchi Fasani et al., 2011). Limited data exists for grain size distribution of eroded rockslide dams in the Italian Apennine (Casagli et al., 2003); however, landslide dam material varies significantly depending on the properties of the initial slide material and the landslide type (see entry *Landslide Types*) (Weidinger, 2011). This difference in material can significantly influence the life span of a dam. Therefore, geomorphic parameters have been used to group dams in stability domains (Ermini and Casagli, 2003; Korup, 2004), for example, height of the dam and size of drainage system and the upstream basin. However, although these domains are a good approximation, they cannot be used as a rule (Hermanns et al., 2011b) and the three-dimensional relation between dam form and valley must also be assessed (Hermanns et al., 2009, 2011a).

The breach of a dam can also be analyzed by hydraulic models that base upon principles of hydraulics, sediment transport, and soil mechanics used in software simulation programs (e.g., Fread, 1993) and also give the breach-outflow hydrograph (see entry *Hydrograph, Flood*). Physical hydraulic modeling has also been used to assess peak outflows and test numerical models (Davies et al., 2007).

The downstream flooding of a potential dam breach can be assessed using empirical peak discharge estimation (e.g., Evans, 1986; Walder and O'Connor, 1997); hydraulic models (see above); and simulation of downstream propagation of outburst floods, debris floods, and debris flows (see entry *Debris Flow*) using GIS-based programs (e.g., O'Brien, 2003; Iverson et al., 1998).

Landslide Dam, Figure 1 Classification system for rockslide dams based upon the three-dimensional distribution of rockslide debris (*dark gray*) within the valley (*light gray* = valley slopes, *dotted fill* = valley fill) with (**a**) showing the plan view distribution, (**b**) the cross valley profile, and (**c**) the long valley profile (Summarized after Hermanns et al., 2011a).

Risk management of landslide dams

Often, due to the size of outburst floods and the length of valleys which can be affected, a landslide dam failure cannot be mitigated with flood protection (see entry *Flood Protection*) structures. In order to allow for more time-consuming prevention measures, high-capacity pumping is often a first step to reduce an imminent hazard of dam breaching (Evans et al., 2011a; Schuster and Evans, 2011). Long-term stability of dams is best sought by constructing by-pass tunnels and spillways (Evans et al., 2011a; Schuster and Evans, 2011). Spillways may not always prevent the dam from failure (Zevallos et al., 1996; Schuster and Evans, 2011) because of retrogressive erosion (see entry *Erosion*) due to the fast outflow; however, they have been shown to reduce the upstream and downstream impacts by reducing the crest level at failure and thus, the water volume. In any case, monitoring of the inundation of the valley upriver the dam and of the dam itself has to start immediately after dam formation and early warning systems (see entry *Early Warning Systems*) might be the only cost-effective nonstructural mitigation (see entry *Mitigation*) measure against significant loss of life during outburst floods (Droz and Spasic-Gril, 2006). In the very recent past, a combination of such

measures have been applied at both the Hattian Bala landslide dam formed by a rock avalanche triggered by the M 7.6 October 2005 earthquake and the Hunza dam formed on January 4, 2010, both in Pakistan. Spill ways were dug at both sites to lower the lake level, early warning systems got installed, and people were evacuated from potential flood areas (Evans et al., 2011a; Delaney and Evans, 2011). At both sites no breaching occurred after dam overtopping along the spill ways, and outflow stabilized only shortly after overtopping and erosional modification of the spill way. The Hattian landslide dam breached unfortunately on February 9 in 2010 after heavy rainfall and a slide on the downstream side of the dam (Konagai and Sattar, 2011). At the Hunza site stabilization work was ongoing in 2011 focusing on widening the spill way and lowering of the lake level (Delaney and Evans, 2011).

Summary

Landslide dams occur in all mountain terrains and form lakes with water volumes which can be in excess of 1 km^3. They often form in mountain regions when earthquakes trigger large landslides. Due to the relative short life of most of these dams and often catastrophic failure, urgent has to be given including assessment of upriver inundation and catastrophic downstream flooding. As dam stabilization methods are time-consuming, expensive, and often impractical, the only feasible method to save lives may be the immediate evacuation (see entry *Evacuation*) of the downstream valley. Slower-filling landslide-dammed lakes may be drained by diversion tunnels, and natural landslide dams can even be used for hydropower generation assuming they are confidently assessed as stable (which can only be the case after they have been stable for many years). Landslide dams have also been constructed artificially by triggering large landslides in narrow valley sections with explosives for hydropower generation but also for debris flow protection.

LANDSLIDE IMPACTS

Michael James Crozier[1], Nick Preston[1], Thomas Glade[2]
[1]Victoria University of Wellington, Wellington, New Zealand
[2]University of Vienna, Vienna, Austria

Definition

Consequences experienced by natural or human systems as a result of landslide activity are referred to as *landslide*

impacts. These can result from direct physical damage or indirect disruption of economic and social activities. Impacts may be experienced immediately at the time of the initial event or be manifest some time afterward. They may be confined solely to the landslide site or be experienced off-site, at some distance from the landslide. The degree of impact can range in magnitude and in the extreme cases can result in human disasters and catastrophes.

Physical and human context

Landslides are defined here according to Cruden and Varnes (1996) and Dikau et al. (1996) as "the movement of a mass of rock, earth, or debris down a slope." However, *landslide impact* is a much more difficult concept to define because it is subjective and depends to a large extent on the system under consideration (whether physical or human) and the values placed on components of those systems. For example, impacts in the social context may range through loss of life, community disruption, damage to buildings and infrastructure, and disruption to means of production and wider economic activity. On the other hand, impacts to elements of the physical system can be viewed as part of a natural geomorphic process and from this perspective are less likely to be construed as *negative* impacts. In terms of geomorphic landscape development, landslides contribute significantly to landform evolution in a number of ways. Landslide processes transport sediments and rocks downslope and are, thus, a major contributor to the overall sediment cycle: erosion – transport – accumulation – compaction – uplift – and again erosion (Hancox et al., 2005).

The degree of impact produced by landslides depends partly on factors such as their volume, velocity of movement, depth of displaced mass, and the extent of disruption of the displaced mass, which together constitute landslide *intensity* (Glade and Crozier, 2005). The other major factor that determines the degree of impact is the sensitivity of the receiving system. In social systems, this is reflected by the concepts of vulnerability and resilience (Hufschmidt and Glade, 2010) whereas in natural systems, sensitivity is influenced by such factors as connectivity between hillslope and fluvial systems (Korup et al., 2004), vegetation cover, and other geological and geomorphological characteristics. The spatial and temporal occurrence of landslides also influences the magnitude of impact in an area over time. Landslides can occur in widely different configurations. They can be single events ranging from small magnitude (e.g., minor volumes with short displacements) to large magnitudes (e.g., collapses of complete slope segments with extensive travel distances). Alternatively, landslides that are triggered by large storms or earthquakes (Keefer, 1984) may involve the simultaneous occurrence of numerous landslides, ranging from localized multiple events involving tens to hundreds of landslides occurring over a few square kilometers, to large regional landslide events producing 10,000 failures or more over hundreds of square kilometers (Crozier, 2005). Some research on spatial landslide data using geospatial analytical techniques suggests that magnitude-frequency distributions have a common form irrespective of the type of landslide and the triggering agent, for example, landslides triggered by rainstorms or earthquakes (Guzzetti et al., 2002; Malamud et al., 2004).

Assessing and managing impacts

The probability of consequences (expected impacts) arising from landslide activity is referred to as landslide-related *risk* (see entry *Risk*). Hazard and risk management is now a well established practice and depends primarily on the assessment and evaluation of risk. Conventionally landslide risk is treated as a function of hazard (the frequency of a given magnitude of landslide), the elements at risk (e.g., people or structures), and their vulnerability. Risk determined in this way is evaluated in terms of its level of tolerability and potential treatment options available to reduce risk.

As with all hazards, the ability to predict occurrence in time and space has a bearing on the ability to determine risk and take mitigating or evasive measures and ultimately to prevent or reduce impact. If the physical system is well understood, susceptibility maps or even hazard maps can be made that will identify the location and probability of occurrence respectively (Guzzetti et al., 2006). For certain location-specific landslides such as debris flows and lahars which tend to reoccur along the same pathways, warning systems can be developed to allow evasive action and reduce impact (Bell et al., 2009). However, the record of landslide activity used to determine frequency and magnitude relationships has often been established on the basis of historic natural conditions and does not reflect more recent destabilizing effects of human activity, such as creation of reservoirs, deforestation, and surcharging of slopes with water from leaking utilities or disposal of waste in unstable localities.

All landslides involve some degree of impact. Significant impacts change landscapes and can affect humanity. Effects vary from surface modifications resulting from slow creep processes up to fatalities caused by mobilization of large masses of sediment or rocks. The nature of impact and consequences for society are discussed below.

Physical and human controls of impact severity

The impacts from landslides and associated consequences are closely related to landslide intensity, magnitude, and frequency of occurrence as well as the pattern of occurrence. Glade and Crozier (2005) discussed the impacts with respect to displacement and movement mechanisms and were able to draw some broad correlations with landslide type (such as fall, topple, rotational slide, translational slide, and flow). However, individual characteristics of landslide behavior, such as velocity (Table 1) and contextual factors, such as degree of exposure of individuals (Table 2) are generally much more

Landslide Impacts, Table 1 Classification of speed of movement and related impacts, according to Cruden and Varnes (1996) and Australian Geomechanics Society (2002)

Speed class	Description	Velocity (mm/s)	Typ. Velocity	Probable destructive significance
7	Extremely fast	5×10^{3}	5 m/s	Disaster of major violence, buildings destroyed by impact of displaced material, many deaths, escape unlikely
6	Very fast	5×10^{1}	3 m/min	Some lives lost; velocity too great to permit all persons to escape
5	Fast	5×10^{-1}	1.8 m/h	Escape evacuation possible; structures; possessions and equipment destroyed
4	Moderate	5×10^{-3}	13 m/ month	Some temporary and insensitive structures can be temporarily maintained
3	Slow	5×10^{-5}	1.6 m/ year	Remedial construction can be undertaken during movement; insensitive structures can be maintained with frequent maintenance work if total movement is not large during a particular acceleration phase
2	Very slow	5×10^{-7}	16 mm/ year	Some permanent structures undamaged by movement
1	Extremely slow			Imperceptible without instruments, construction possible with ***precautions***

Landslide Impacts, Table 2 Vulnerability of a person being affected by a landslide in open space, in a vehicle and in a building, based on Wong et al. (1997)

Location	Description	Vulnerability of a person		
		Data range	Recommended value	Comments
Open space	Struck by rockfall	0.1–0.7	0.5	May be injured but unlikely to cause death
	Buried by debris	0.8–1	1	Death by asphyxia
	Not buried, but hit by debris	0.1–0.5	0.1	High chances of survival
Vehicle	Vehicle is buried/crushed	0.9–1	1	Death almost certain
	Vehicle is damaged only	0–0.3	0.3	High chances of survival
Building	Building collapse	0.9–1	1	Death almost certain
	Inundated building with debris and person is buried	0.8–1		Death is highly likely
	Inundated building with debris, but person is not buried	0–0.5	0.2	High chances of survival
	Debris strikes the building only	0–0.1	0.05	Virtually no danger

important determinants of the degree of impact than landslide type alone.

Direct impacts lead to immediate consequences. Houses and infrastructure might be displaced, damaged, or destroyed, farmland might be removed or covered by debris and/or people might be injured or killed. Indirect effects, on the other hand, include disruption of the normal socioeconomic activities, for example, production losses may occur if people are prevented from attending their workplace or road blockages prevent supply of raw material for manufacturing or export of products.

Short-term impact causes only temporary interruption or distortion of human activity. In contrast, some effects can last for extended periods, or indeed the consequences may be permanent. For example, a major landslide into a river may cause avulsion and the creation of a new channel or even reversal of drainage direction. Similarly, constant creep of a slope may require continuous adaptation to ongoing movement, for example, the city of Ventnor, Isle of Wight is located on a large landslide and requires regular maintenance (e.g., Ibsen and Brunsden, 1996). On the other hand societies might be affected so badly, that the affected people suffer from continuous trauma (Catapano et al., 2001) or preexisting industrial activity cannot be resumed. The duration of social impact depends on community resilience, which in turn is related to a number of factors including the available resources, the strength of community networks, the level of insurance, and the external support.

Scenarios of system change

The wide range of landslide impacts both in type and severity demand intensive research in order to offer sustainable solutions. Of particular importance is assessment of the possible increase of landsliding driven by environmental changes, including climate change and potential human interventions associated with development. Examples of such interventions are direct slope

modifications (e.g., undercutting, leveling, changed drainage pattern, etc.) or indirect effects through vegetation change. Development, however, is driven by population increase, accelerating rates of urbanization and demand for increased living standards. These demographic and social trends have been closely linked to increase in risk from landslides and other hazards (Cendrero et al., 2006).

In this respect, process-based landslide studies play a major role in estimating effects in scenarios of future environmental and social changes. If these studies focus on single and distinctive failures, applicable geotechnical and engineering methods range from rockfall modeling based on lump mass approaches and debris flow routing based on modified flow laws to landslide failures applying soil mechanical principles. If the problem is widespread and distributed over a large region, then totally different, spatially focused methods have to be applied to assess the future likelihood of failure (Glade and Crozier, 2005). Recent examples of such widespread failures are landslides resulting from the 2008 Wenchuan, China or 2005 Pakistan earthquake (e.g., Sato et al., 2007) or failures following a thunderstorm such as that occurred in1999 in Venezuela (Larsen et al., 2001) or in the Collazzone area, Umbria, Central Italy (Guzzetti et al., 2006).

Irrespective of the type of investigation, landslide scenarios only have relevance for stakeholders and decision makers if they are coupled with information on possible consequences, including the implications of social trends. These consequences can be assessed based on a variety of methods ranging from classic heuristic approaches such as expert opinion or detailed landslide risk analysis involving modeling (Risk).

Summary

Landslides are part of normal landform evolution. Our landscapes would not appear as they are, and sediment flux on hillslopes and within river systems would not function as effectively without landslides. Impacts of landslides occur on various levels. Impacts have significance for both natural environments (e.g., removal of soil from the upper slopes and accumulation on the slope foot or in the adjacent fluvial system) and for human systems (e.g., human lives, economic activity, infrastructure, and the built environment). In a strict philosophical sense, "negative" consequences for the natural environment do not exist. However, it is evident, that society has to assume responsibility for many of the negative consequences associated with landslides. To judge the extent of exposure to landslides is crucial, but it is also important to employ appropriate adaptation and coping strategies.

Future work on landslide impact has to be threefold. First, more research is required on the full range of landslide types, associated triggering mechanisms, and the controlling factors such as slope geometry, material properties of lithology and regolith, hydrological patterns, and vegetation. Second, there is a need to fully understand the role of human intervention and social systems such as coping strategies in influencing the degree of impact. Third, and most importantly, the linkage between the landslide system and the societal dimensions (Bell and Glade, 2004), its change over time (e.g., Hufschmidt and Crozier, 2008), and the possible consequences have to be explored. Only then, are we able to understand our coupled natural environment and slope systems better and are able to reduce the impact of landslides.

LANDSLIDE INVENTORY

Javier Hervás
Joint Research Centre, European Commission, Ispra (Va), Italy

Synonyms

Inventory of slope movements; Landslide archive; Landslide database; Landslide register; Mass movement inventory

Definition

A landslide inventory is a detailed register of the distribution and characteristics of past landslides.

Discussion

For each landslide recorded in an inventory, core information usually includes a unique identification code, landslide site name (for major landslides), location (geographical coordinates, municipality, province or county, region or state), type of landslide, date of occurrence if known or last reactivation, state of activity, and volume (or surface extent). Additional information may include landslide geometry (surface dimensions, depth of failure surface), geology (lithology, structure, material properties), hydrogeology, land cover or use, slope geometry, triggering cause, impact (e.g., casualties, damage expressed in economic value or in descriptive terms), remedial measures, surveying methods and date, and surveyor's name and bibliographical references. Complementary data such as illustrations (ground or aerial photographs, drawings) and monitoring data (type of instrumentation, rate of movement) can sometimes be found in an inventory. However, since much of the above-mentioned data are rarely available or expensive to collect, most existing landslide inventories only contain a subset of these data. Moreover, they do not usually include the same level of information for all landslides.

Landslide inventory data can be collected by aerial photointerpretation, field surveys and instrumentation, bibliographical research (e.g., scientific publications, technical reports, newspapers, historical chronicles, previous inventories, and geological maps), satellite and airborne remote sensing techniques, and interviews, depending on the scope and scale of the inventory and available resources.

Landslide inventories usually consist of a spatial component (i.e., the inventory map), showing landslide spatial distribution, and an associated alphanumeric component including the above-mentioned landslide-related information. On the maps, individual (sometimes clustered) landslides can be represented as dots, lines, or closed lines (polygons), depending mainly on the surface extent and shape of the landslides in relation to the map scale. Occasionally, large-scale inventory maps may also differentiate landslide source and deposit areas and depict features such as scarps, ridges, troughs, and ponds for large landslides. Today, digital landslide inventories are built on spatial databases using geographical information systems (GIS) technology for relatively simple inventories and relational database management systems (RDBMS) with geospatial data management capabilities or combined with GIS technology for comprehensive inventories.

Landslide inventories provide useful although spatially limited information on landslide distribution and occurrence for scientific, planning, decision-making, and other purposes. They are particularly valuable to generate landslide density maps and, especially, susceptibility, hazard, and risk maps, which are essential tools for devising risk reduction measures. Landslide inventories should be periodically updated, especially after a major landslide-triggering event such as a big rainstorm or earthquake.

Synonyms

Landslide-triggered tsunami (see entry *Tsunami*), displacement wave, non-seismic tsunami, and other terms such as surface wave, mega-tsunami, giant wave (see also titles in reference list) or even *seiche* have been used (e.g., *Stone, 2009*), although these waves are not standing oscillations in a (semi)closed basin.

The term "landslide-triggered tsunami" is a widespread term and has been used for waves caused by the impact of a landslide (see entry *Landslide*) into a water body or caused by a subaqueous landslide, whereas the term "displacement wave" has been used mainly for rock and/or ice avalanche/fall triggered waves in mountain lakes.

Definition

The term "*tsunami*" is Japanese and translates as "sudden wave in a harbor," referring to waves not visible on the open water which build up near the shore. It is used for earthquake-triggered waves (seismic tsunami) and waves triggered by the displacement of water by mass movements (see entry *Mass Movement*) or asteroid impact (non-seismic tsunami). In the following, we use the term "non-seismic tsunami" as a general term for waves triggered by a mass movement and specifically the term "displacement wave" for waves triggered by subaerial mass movements, whereas the term "landslide-triggered tsunami" is used for those waves triggered by subaqueous landslides. The initial wave amplitude (wave height) for displacement waves measures often several meters, tens or hundreds of meters which is in contrast to landslide-triggered tsunami that are in general in the order of a few meters or less.

Introduction

Non-seismic tsunamis occur in a multitude of environments, including the continental margins, ocean islands, fjords, natural and artificial lakes and rivers (Moore and Moore, 1984; Hendron and Patton, 1987; Grimstad and Nesdal, 1990; Evans, 2001; Tappin, 2009; L'Heureux et al., 2011, 2012; Harbitz et al., 2012). A number of records show that devastating displacement waves with a large loss of life may occur from subaerial *landslides* (e.g., Sicily, Calabria in 1783, Graziani et al., 2006; Mt. Unzan, Japan in 1792, Siebert et al., 1987; Vajont, Italy in 1963, Hendron and Patton, 1987). In some regions of the world, such as the fjords of western Norway, displacement wave sourced by subaerial rock avalanches (see entry *Rock Avalanche* (*Sturzstrom*)) have taken place several times during the last century often resulting in large loss of life (e.g., Blikra et al., 2006; Hermanns et al., 2012).

Until recently, and despite landslide-triggered tsunamis such as the Grand Banks in 1929 (e.g., Heezen et al., 1954; Piper and Asku, 1987) and those associated with the Good Friday 1964 earthquake in Alaska (e.g., Lee et al., 2003), historic submarine landslides were rarely identified as a source for devastating landslide-triggered tsunamis. It was not until 1998, when a submarine slump (see entry *Slide and Slump*) caused the devastating tsunami in Papua New Guinea in which 2,200 people died, that the threat from submarine mass movement was fully recognized (Tappin et al., 2001, 2008).

Displacement waves caused by rockslides, or collapse of a glacier into a water body

The highest displacement wave ever recorded during a *historical event* was observed at Lituya Bay, Alaska, on July 9, 1958 (Miller, 1960). Here the 524-m-high wave was sourced by a 4.3-km^3 rockslide previously triggered by an *earthquake*. In 1783, at Calabria in Sicily, a cliff collapsed into the sea and created a relatively small (8.3 m run-up) but devastating displacement wave that killed 1,500 people (Graziani et al., 2006). Run-up heights in the order of a several tens of meters are common for these types of events (e.g., Blikra et al., 2006; Hermanns et al., 2006; Naranjo et al., 2009). *Ice avalanches* from collapsing glaciers into moraine lakes are considered as one of the major *glacier hazards* in the Peruvian Andes, as displacement waves overtop and erode the moraine dams leading to catastrophic downstream *flash floods* (Reynolds, 1992). Similarly, the importance of *landslides* along reservoirs became especially obvious during the *disaster* of the *Vajont dam*, Italy, on October 9, 1963, where a *landslide* caused a 250-m-high displacement wave overtopping the dam. The *flash flood* down valley

destroyed several villages and killed nearly 2,000 people (Hendron and Patton, 1987). Since then such displacement waves have been recognized as a serious *geohazard* for dams, whether they are man-made or not (e.g., Hermanns, et al., 2004).

Displacement waves in the ocean and on lakes surrounding volcanoes

The earliest record of displacement waves from volcanic flank collapse is from the *eruption* at the island of Thera, also known as *Santorini*, in the Cycladic Islands, Greece, about 3,600 years B.P. during the Late Bronze Age. This event had profound impacts on civilization in the Aegean and eastern Mediterranean region (McCoy and Heiken, 2000). Early records are also known from Japan where catastrophic volcanic collapse events at Hokkaido in 1640 and 1741 resulted in over 700 and 2,000 fatalities, respectively (Nishimura et al., 1999; Satake, 2007). In 1792, the *hazard* posed by such events became clear with the collapse of Mt. Unzen and the accompanied *debris avalanche* that swept into the Ariaka Sea. The 100-m-high wave resulted in the loss of more than 10,000 lives (Siebert et al., 1987). More recently, the flank collapse of Mount St. Helens on May 18, 1980 led to an improved understanding of the processes of flank failure and their potential to create devastating displacement waves. During this event a lobe of the *debris avalanche* entered into Spirit Lake and caused a 260-m-high displacement wave (Voight et al., 1983). During the past 20 years, flank collapses causing *debris avalanches* have been documented on multiple *volcanoes* around the world and are also mapped in the surrounding of most island *volcanoes* (e.g., Moore, 1964; Labazuy, 1996; Ward and Day, 2001; Krastel et al., 2001; Paras-Carayannis, 2004). These partial collapses can have volumes in the order of several hundred km^3 and modeled displacement wave heights can be several hundred or up to 1,000 m high (Ward and Day, 2001; McMurtry et al., 2003; Løvholt et al., 2008). Conspicuous deposits containing marine sediments were found far above sea level on multiple volcanic islands (Moore and Moore, 1984; Tanner and Calvari, 2004). On the island of Lanai, Hawaii, these date back to 101–134 ka (Moore and Moore, 1988) indicating the order of *recurrence intervals* of this particular *marine hazard*.

Landslide-triggered tsunamis caused by submarine landslides

It is well known today that a sudden displacement of the seafloor through catastrophic sliding or slumping has the potential to displace large volumes of water, generating *tsunami*s that can affect coastal areas and offshore infrastructure (Murty, 1979; Jiang and LeBlond, 1992). Landslide-triggered tsunamis have large run-up heights close to their source, but have far-field effects that are smaller relative to the initial wave height than *earthquake*-generated *tsunami*s (Okal and Synolakis, 2004). The 1998 Papua New Guinea landslide-triggered tsunami, which resulted in over 2,200 casualties, showed how catastrophic such types of events can be (Imamura and Hashi, 2003). There are numerous submarine *landslides* at all scales mapped along continental margins, fjords, and lakes. One of the most studied examples is the giant Storegga slide which occurred 8,200 years ago off the edge of the Norwegian shelf in the North Atlantic (Bugge et al., 1988; Bryn et al., 2005). The 3,500 km^3 Storegga slide caused a landslide-triggered tsunami wave up to more than 12 m high along the Norwegian coast (Harbitz, 1992; Bondevik et al., 2003), 20 m high on the Shetland Islands (Bondevik et al., 2005), 3–5 m high in Scotland (Smith et al., 2004) and even reached the coast of Greenland in at least four waves (Wagner et al., 2007). The evolution of the *landslide* is probably representative of similar slides along the Norwegian margin (Solheim et al., 2005). Failure took place after the end of the last deglaciation by translational and retrogressive sliding along specific marine clay layers. Destabilization prior to failure was associated to rapid loading from glacial deposits and generation of excess *pore-water pressure* considerably reducing the effective strength of the sediments. In this case, climatic processes led to a preconditioning of slope instability and a subsequent failure was most likely triggered by an *earthquake* due to isostatic rebound of the crust following the ice retreat (Bryn et al., 2005).

Hazard assessment of non-seismic tsunamis

Historical examples of non-seismic tsunamis in different environments demonstrate the potential catastrophic *hazard* of such events on coastal populations and infrastructures, but also on offshore installations (e.g., Miller, 1960; Siebert et al., 1987; Hendron and Patton, 1987; Grimstad and Nesdal, 1990; Blikra et al., 2006; Naranjo et al., 2009). Assessment of the *hazard* and *risk* posed by non-seismic tsunami waves is at an early stage, although our understanding of the processes has advanced significantly over the past decades. The scientific community has now a fairly good understanding of *landslide* processes affecting coastal and submarine areas, but the precise forecasting of *landslides* is still a challenging task. Also, there is still a paucity of data to fully understand how slope failures relate to the generation of displacement waves. Some attempts to evaluate the *hazard* and *risk* posed by non-seismic tsunamis have been performed (e.g., Blikra et al., 2005; Moscardelli et al., 2009; Lacasse and Nadim, 2009). A first task in such a study is to locate and identify a potential volume and geometry of unstable sediments or rocks which could affect a significant body of water (e.g., Day et al., 1999; Blikra et al., 2005). In a next step, the displacement wave propagation can be modeled to assess the area of impact (e.g., Harbitz, 1992; Tinti et al., 1999; Ward, 2001; Løvholt et al., 2008). Here, several parameters must be taken into account since the magnitude of displacement

wave generated by a *landslide* depends on (1) volume of moving material, and especially the morphology of the front area, (2) water depth of the water body, and (3) velocity, while the magnitude of a landslide-triggered tsunami rather depends on (4) volume of moving material, (5) water depth where the *landslide* occurs, (6) acceleration and initial velocity of the *landslide*, (7) rheology of the failed sediments and the dynamics, and (8) distance to shore and the seafloor morphology (e.g., Pelinovsky and Poplavsky, 1996; Sælevik et al., 2009; L'Heureux et al., 2011).

Risk management for displacement waves

Disastrous non-seismic tsunamis are caused by large subaerial or submarine *landslides* where physical *mitigation* is difficult or sometimes impossible. Some large *deep-seated gravitational slope deformations* have been stabilized by large-scale drainage systems in order to avoid destructive displacement waves, as in the *mitigation* related to hydropower reservoirs in British Columbia, Canada (Watson et al., 2006). The *mitigation* of displacement waves is so far mainly handled by passive or non-physical *mitigation* measures, including the implementation of *monitoring* systems, *early warning systems*, and *evacuation* plans. However, sea walls and dikes used to protect coastal areas against *storm surges* might also protect coastal areas against non-seismic tsunamis. *Monitoring* and *early warning systems* of *landslides* related to the generation of displacement waves have been implemented in reservoir in British Columbia (Watson et al., 2006) and at the Åknes rockslide site in western Norway (Blikra, 2008). Recent advances in deep-ocean *tsunami* measurement technology (e.g., DART buoys) coupled with *tsunami* forecast model have demonstrated that *tsunami* impact can be predicted before it reaches the affected coastlines (Percival et al., 2011). Such systems were developed to detect *earthquake*-triggered *tsunamis* but could also be used for the early warning of non-seismic tsunamis. *Hazard* maps, pre-defined *evacuation* routes, and preparedness on all society levels and sectors are essential for the total *early warning system*.

Summary

Displacement waves caused by the impact of a *landslide* into a water body and landslide-triggered tsunamis caused by submarine *landslides* pose a major *hazard* along the surrounding coast lines and lake shores. Displacement waves related to volcanic collapses have, in general, a long *recurrence interval* of several thousand up to millions of years. Submarine slides and subaerial *landslides* into water bodies are more frequent, and in some regions several can take place in a century. With the exception of narrow mountain valleys below artificial and natural mountain lakes where displacement waves can affect tens of kilometer long mountain valleys, these waves affect only coastal areas and offshore installations. Depending on the magnitude of the event and the geological settings, results may be catastrophic with loss of lives and total destruction of infrastructure. Similar to *earthquake*-triggered *tsunami* waves, hazardous displacement waves are difficult to mitigate. However, our increasing knowledge of *landslide* processes coupled with the validation of our *tsunami* modeling codes from *historical events* and improved *risk assessment* strategies gives the opportunity to elaborate *hazard mapping* that can be used in *risk mitigation* strategies.

LANDSLIDE TYPES

David Cruden
University of Alberta, Edmonton, AB, Canada

Synonyms

Landslide classification; Landslide description; Landslide names

Definition

Landslides, movements of masses of rock, earth, or debris down slopes, have observable characteristics (activity, rate of movement, moisture content, material, type of movement). Landslides with similar characteristics belong to the same landslide type.

Introduction

What can you usefully observe about a landslide? How can these observations be succinctly and unambiguously described? These are questions which have found answers in classifications of landslides. The International Union of Geological Sciences Working Group on Landslides has developed an international consensus on landslide classification which has been summarized in the Multilingual Landslide Glossary (WP/WLI, 1993b). This classification, the Working Classification, has been used in the latest edition of the Transportation Research Board's Special Report (Turner and Schuster, 1996) to update Varnes' (1978) widely used classification. Highland and Bobrowsky (2008) provide an accessible version.

The criteria used in the description of landslides (Cruden and Varnes, 1996) follow Varnes (1978) in emphasizing type of movement and type of material. A landslide can be described by a word describing the material and a second word describing the type of movement. The divisions of materials are unchanged from Varnes (1978): rock, debris, and earth. Movements have been divided into five types: falls, flows, slides, spreads, and topples. The sixth type proposed by Varnes (1978), complex landslides, has been dropped from the formal classification, though the term "complex" has been retained as a description of the style of activity of a landslide. Complexity can also be indicated by combining the five types of landslide in the ways suggested below.

The name of a landslide can become more elaborate as more information about movement becomes available. Adjectives can be added in front of the two nouns to build up the description of the movement. A preferred sequence of terms in naming the movement, a progressive

narrowing of the focus of the descriptors, first in time, then in space, from a view of the whole landslide to parts of the movement and to the materials involved, would follow a typical landslide reconnaissance. The recommended sequence, Activity, Rate of Movement, Moisture Content, Material, Type of Movement, is the sequence of sections in this entry.

Activity

Under activity, broad aspects of landslides are described that should focus the initial reconnaissance of movements before more detailed examination of materials displaced (WP/WLI, 1993a, b). The terms Varnes (1978) considered relating to age and state of activity, with some of the terms from sequence or repetition of movement, have been regrouped under three headings: State of Activity, which describes what is known about the timing of movements; Distribution of Activity, which describes where the landslide is moving; and Style of Activity, which indicates how different movements contribute to the landslide.

State of activity

Active landslides are those that are currently moving. Landslides which have moved within the last annual cycle of seasons but which are not moving at present are described as suspended. A landslide which is again active after being inactive may be called reactivated.

Inactive landslides are those which have last moved more than one annual cycle of seasons ago. This state can be subdivided. If the causes of movement apparently remain, then the landslides are dormant. Perhaps, however, the river which had been eroding the toe of the moving slope has itself changed course and the landslide is abandoned. If the toe of the slope had been protected against *erosion* by bank armoring or other artificial remedial measures have stopped the movement, the landslide can be described as stabilized. Landslides often remain visible in the landscape for thousands of years after they have initially moved. Landslides which have clearly developed under different geomorphological or climatic conditions perhaps thousands of years ago can be called relict.

Distribution of activity

Varnes (1978) defined a number of terms that can be used to describe the activity distribution in a landslide. Movement may be limited to the displacing material or the rupture surface may be enlarging, continually adding to the volume of displacing material. If the rupture surface is extending in the direction opposite to the movement of the displaced material, the landslide is said to be retrogressing. If the rupture surface is extending in the direction of movement, the landslide is advancing. If the rupture surface is extending at one or both lateral margins, the landslide is widening. Confined movements have a scarp but no rupture surface visible in the foot of the displaced mass; displacements in the head of the displaced mass are taken up by compression and slight bulging in the foot of the mass. If the rupture surface of the landslide is enlarging in two or more directions, Varnes (1978, p. 23) suggested the term "progressive" for the landslide while noting this term had also been used for both advancing and retrogressing landslides. This term is also current for describing the process, progressive failure, by which the rupture surface in some slides extends. The possibility of confusion seems sufficient now to abandon "progressive" in favor of describing the landslide as enlarging. To complete the possibilities, terms are needed for landslides in which the volume of displacing material can be seen to be reducing with time and for those landslides where no trend is obvious.

Movements such as rotational slides and topples may stop naturally after substantial displacements because the movements themselves reduce the gravitational forces on the displaced masses. Alternatively, rock masses may be dilated by movements that rapidly increase the volumes of cracks in the masses and cause decreases in fluid pore pressures within these cracks. However, to conclude that the displacing mass is stabilizing because its volume is decreasing may be premature; the activity of rotational slides caused by *erosion* at the toe of slopes in cohesive soils is often cyclic. The term "diminishing" for a landslide whose displacing material is decreasing in volume seems free of undesired implications. Landslides whose displaced materials continue to move but whose rupture surfaces show no visible changes can be simply described as moving.

Style of activity

The way in which different movements contribute to the landslide, the style of the landslide activity, can be described by terms from Varnes (1978, p. 23). There, complex landslides are defined as exhibiting at least two types of movements. The term is limited here to movements in which the types are in sequence: a topple in which some of the displaced mass subsequently slid is a complex rock topple, rock slide. Not all the toppled mass slid, but no significant part of the displaced mass slid without first toppling. Notice that some of the displaced mass may be still toppling whereas other parts are sliding.

We can use a former synonym of complex, composite, to describe landslides in which different types of movement occur in different areas of the displaced mass, sometimes simultaneously. These different areas of the displaced mass show different sequences of movements. WP/WLI (1993a, b) adopted the convention of treating the higher of the two movements as the first movement and the lower of the two movements as the second movement in the absence of more definite information.

A multiple landslide shows repeated movements of the same type, often following the enlargement of the rupture surface. The newly displaced masses are in contact with previously displaced masses and often share a rupture surface with them. In a retrogressive, multiple, rotational slide, two or more blocks have each moved on curved rupture surfaces tangential to a common generally deep rupture surface.

A successive movement is identical in type to an earlier movement but, in contrast to a multiple movement, does not share displaced material or a rupture surface with it.

Single landslides consist of a single movement of displaced material often as an unbroken block. They contrast with the other styles of movement which require disruption of the displaced mass or independent movements of portions of the mass.

Rate of movement

The IUGS Working Group (1995) modified the rate of movement scale given in Varnes (1978, Fig. 2:1 u). The seven divisions of the scale are now adjusted to increase in multiples of 100 by slightly increasing the uppermost limit of the scale and decreasing the lowest limit of the scale. These two limits span ten orders of magnitude (from 0.5×10^{-6} to 5×10^{3} mm/s).

The important division between very rapid and extremely rapid movement approximates the speed of a person running (5 m/s.). Some extremely rapid movements have been called *avalanches*. Another important boundary is between the slow and very slow classes (1.6 m/year), below which some structures on the landslide are undamaged. Terzaghi (1950, p. 84) identified slope movements "proceeding at an imperceptible rate" as "*creep*." The many uses of "creep" have been discussed by Varnes (1978, p. 17); the term should be replaced by either very slow or extremely slow, applied to the other landslide descriptors.

Materials

Varnes (1978) suggested four terms derived from simple observations of the water content of the displaced material: (1) dry, no moisture; (2) moist, contains some water but no free water – the material may behave as a plastic solid but does not flow; (3) wet, contains enough water to behave in part as a liquid, has water flowing from it, or supports significant bodies of standing water; (4) very wet, contains enough water to flow as a liquid under low gradient.

These terms should be used to describe the masses displaced by the landslide. The water content of the displaced masses may give useful guidance for assumptions about the water content of the displacing materials while the materials were displacing. However, soil or rock masses may drain quickly after displacement, and individual rock or soil masses may have water contents which differ considerably from the average water content of the displacing material. In some fine-grained soils, the boundaries between the terms may correspond approximately with Atterberg limits – the shrinkage, plastic, and liquid limits separating dry, moist, wet, and very wet soils, respectively.

We can follow Varnes (1978) in describing materials in landslides as either rock, a hard or firm mass that was intact and in its natural place before the initiation of movement, or soil, an aggregate of solid particles generally of minerals and rocks which has either been transported or formed by the weathering of rock in place. Gases or liquids filling the pores of the soil form part of the soil.

Soil is further divided into debris and earth. Debris contains a significant proportion of coarse material: 20–80% of the particles are larger than 2 mm and the remainder are less than 2 mm. Earth describes material in which 80% or more of the particles are smaller than 2 mm; it includes a range of materials from nonplastic sand to highly plastic clay.

Types of movement

In this section, the five kinematically distinct types of landslides are described in the sequence fall, topple, slide, spread, and flow.

A soil or rock *fall* starts with detachment from a steep slope along a surface on which little or no shear displacement takes place. The material then descends largely through the air by falling, saltation, or rolling. Movement is very rapid to extremely rapid. Except when the displaced mass has been undercut, falling is preceded by small sliding or toppling movements which separate the displacing material from the undisturbed mass. Undercutting typically occurs at the toe of cliffs undergoing wave attack or in the eroding banks of rivers.

A *topple* is the forward rotation out of the slope of a mass of soil or rock about a point or axis below the center of gravity of the displaced mass. Toppling is sometimes driven by gravity exerted through material upslope of the displaced mass and sometimes through water in cracks in the mass. Topples may lead to falls or slides of the displaced mass depending on the geometry of the moving mass, the geometry of the surface of separation, and the orientation and extent of the kinematically active discontinuities. Topples range from extremely slow to extremely rapid, sometimes accelerating throughout the movement.

A *slide* is a down slope movement occurring dominantly on surfaces of rupture or relatively thin zones of intense shear strain. Movement is usually progressive; it does not initially occur simultaneously over the whole of what eventually becomes the surface of rupture. Often the first signs of ground movement are cracks in the original ground surface along which the main scarp of the slide will form. The displaced mass may slide beyond the toe of the surface of rupture covering the original ground surface of the slope which then becomes a surface of separation.

In a *(lateral) spread*, there is an extension of a cohesive mass combined with a general subsidence of the fractured mass of cohesive material into softer underlying material. The rupture surface is not a surface of intense shear. Spreads may result from *liquefaction* or flow and extrusion of the softer material. Varnes (1978) distinguished spreads, typical of rock, which extended without forming an identifiable rupture surface from movements in cohesive soils overlying liquefied materials or materials which are flowing plastically. The cohesive materials may also subside, translate, rotate, disintegrate, or liquefy and flow.

Clearly these movements are complex, but they are sufficiently common in certain materials and geological situations that a separate type of movement is worth recognizing.

A *flow* is a spatially continuous movement in which surfaces of shear are short-lived, closely spaced, and not usually preserved. The distribution of velocities in the displacing mass resembles that in a viscous liquid. The lower boundary of the displaced mass may be a surface along which appreciable differential movement has taken place or a thick zone of distributed shear. There is then a gradation from slides to flows depending on the water content, mobility, and evolution of the movement. Debris slides may become extremely rapid *debris flows*, *debris avalanches*, as the displaced material loses cohesion, gains water, or encounters steeper slopes.

Summary

An initial reconnaissance of a landslide might be expected to describe the activity and the materials displaced in this particular type of landslide. This format lends itself to the creation of simple databases suited to much of the database management software now available (WP/WLI, 1990). The information collected can be compared with summaries of other landslides (WP/WLI, 1991) and used to guide further investigations and mitigative measures. Further investigation increases the precision of estimates of the dimensions and confidence in the descriptions of activity and material and in the hypotheses about causes of the movement. The new information may finally be added to the database to influence the analysis of further landslides. These databases can be expected to form the foundations of systems for landslide *risk assessment and management* (Cruden and Fell, 1997).

[2]Geological Survey of Finland (GTK), Espoo, Finland

Synonyms

City planning; Regional planning; Spatial planning; Territorial development; Town and country planning

Definition

Land-use planning is defined as the whole comprehensive, coordinating planning at all scales (from national to local), which aims at an efficient and balanced territorial development.

Introduction: natural hazards and their relevance for land-use planning

Natural hazards are usually defined as extreme natural events that have the potential to damage societies and

individuals. These extreme events occur in closed time spans of seconds or weeks, after which the initial state before the extreme event is sometimes reached again. Longer lasting natural processes, such as climate change and desertification, might pose certain threats or trigger hazards, but do not belong to hazards sensu stricto. Most natural hazards arise from the normal physical processes operating in the Earth's interior, at its surface, or within its enclosing atmosphere (Schmidt-Thomé, 2006).

"Land-use planning operates on the presumption that the conscious integration of (particularly public) investment in sectors such as transport, housing, water management, etc., is likely to be more efficient and effective than uncoordinated programmes in the different sectors" (ODPM 2005). Thus, the core element of land-use planning is to prepare and make decisions about future land use. This can be specified for different scales as follows:

Regional planning/development: the task of settling the land use and development by drawing up regional plans or programs. Regional planning is required to specify aims of land-use planning which are drawn up for an upper, overall level and sets a framework for decisions on land use taken at the local level within land-use planning of the municipalities. Depending on the planning system of a country, there might even be textual and cartographic determinations and information which typically range on a scale from 1:50,000 to 1:100,000.

Urban land-use planning: creation of policies at local/municipal level to guide land and resource uses. The main instrument of land-use planning is zoning or zoning ordinances, respectively. Local land-use planning normally consists of two stages with specific planning instruments on each of these: first, a general or preparatory land-use plan (scale from 1:5,000 to 1:50,000) for a whole municipality and second, a detailed land-use plan for small part of it, mostly legally binding (scale 1:500 to 1:5,000).

Each hazard has a spatial dimension (it takes place somewhere). Space can therefore be defined as an area where human beings and their artifacts are threatened by spatially relevant hazards. However, spatially relevant does not mean land-use planning relevance. The reaction of tolerating or altering risk can be understood as an integrated part of the given socioeconomic structures with land-use planning as a certain part of a reaction. Land-use planning makes decisions for society regarding if and how certain spaces will be used. Therefore, land-use planning more or less influences vulnerability with regard to natural (and technological) hazards.

Land-use planning is responsible for the development of a particular land-use area (where the sum of hazards and vulnerabilities defines the overall land-use risk) and not for a particular object or thread (e.g., sectoral engineering sciences). Land-use planning must adopt a multi-hazard approach in order to appropriately deal with risks and hazards in a land-use context (Greiving, 2002). There is a tradition of land-use planning research for single hazards (coastal flooding, river flooding, earthquakes, nuclear power plants), an integrated research approach to land-use relevant hazards has only recently been undertaken by a few authors in Europe (Egli, 1996; Greiving, 2002), whereas in the USA the role of land-use planning has been highlighted in several publications (e.g., Godschalk et al., 1999 or Burby, 1998; both with further references).

The land-use character of a hazard can either be defined by land-use effects that might occur if a hazard turns into a disaster or by the possibility of an appropriate land-use planning response. This also opens up questions about the relevance of different levels of land-use planning as well as the relationship to sectoral planning. Relevant for land-use planning are those hazards where frequency and/or magnitude of the event itself can be influenced by land-use planning or where mitigation actions influence land use. If this is not the case, like for meteorite impacts or pandemics, nevertheless it might be of interest for a sectoral planning division or an emergency response unit.

The normative dimension of natural hazards

One of the most serious problems in the context of dealing with natural hazards in land-use planning is represented by external effects: a land use and temporal inconsistency between chances and risks which are related with every decision making about a future land use or a concrete investment at a certain location. A classic example for this planning problem is represented by the (intra-generational) conflict between actors which are located upstream and downstream: A municipality located upstream might profit from the chances of a suitable location for an industrial area located on the flood plains of a river and could protect this area by means of a dike. The direct consequence of this action would be an increased flood risk for downstream located areas because of the reduced flood plain capacities in combination with flood waves that would occur faster and with a higher peak.

In terms of sustainable development, this conflict can be described as an intra-generational conflict. Aside from this, intergenerational aspects have to be taken into consideration. Intergenerational justice can be understood as a second prerequisite for reaching a balance of chances and risks. The "Theory of Justice" based the necessity of a consensus about normative regulations on a consensus with the righteous interests of future generations instead of just a consensus of people who are actually alive now. The "Veil of Ignorance" or the view of short-term chances hinders an appropriate estimation of long-term negative affects that might threaten mainly future generations (Rawls, 1971, p. 328). The greater the persistence of possible harmful impacts on an event or decision, the greater the importance and problems related to a decision that accepts consequences from hazardous events (Berg et al., 1995, p. 30). For example, the Chief Building Inspector had justified a governmental responsibility for building safety standards after the Loma-Pieta-earthquake as follows: "I represent, in absentia, the unknown future user" (Godschalk et al., 1999, p. 494). This example indicates that planning-related decisions based on a consensus of all stakeholders could fail

Land-Use Planning, Table 1 Strength and weaknesses of land-use planning in the context of dealing with natural hazards.

Task	Milestones	Potential of land-use planning	Description
Risk assessment	Assessment and appraisal of long-term impacts on the human-environmental-system such as climate change	Fair	Based on impact studies, regional planning is essential. A strength of comprehensive planning is the traditionally integrated view on different change processes (demography, economy, environment, climate)
	Identification of interaction between land uses and hazards	Good	Assessments can easily be integrated in the strategic environmental assessment which is obligatory for any land-use plan or program
	Assessment of frequency and magnitude of extreme events (exposure)	Poor	This is clearly a task for specialized authorities, like water management and terrain mapping, where land-use planning does not have competence in assessment
Risk management	Adaptation of existing land-use structures (settlements, infrastructure)	Poor	For regulatory planning, adaptation of existing structures is difficult because of given private property rights. Requires suitable approaches based on incentives and communication to private households
	Avoidance of non-adapted developments	Good	This focus of planning is very much about future developments. The effectiveness of actions depends partly on existing regulatory frameworks (zoning instruments)
	Keeping disaster prone areas free of further development	Good	If conforming planning systems have regulatory zoning instruments at hand it is possible to keep free of areas prone to extreme events
	Differentiated decisions on land use: Acceptable land-use types according to the given risk	Fair	Possible, but usually not effective with regard to existing settlement structures
	Relocation/retreat from threatened areas	Poor	Again in conflict with property rights. Full compensation is normally needed, which fails mostly due to the lack of financial resources. Possible in areas with shrinking population where the existing building stock will be (partly) deconstructed based on planning strategies (e.g., Eastern Germany)

in relation to the temporal and, as mentioned above, land-use dimensions. The same decision is possibly based on free market transactions. Even if all participants of a transaction of land designated for construction would come to an agreement, they might fail in relation to an unacceptable use of common pool goods.

The core elements of sustainable development were laid out in the Rio Declaration in 1992. The development of societies cannot be sustainable in view of increasing risks from natural and technological hazards (Lass et al., 1998). The US National Science and Technology Council states, "Sustainable development must be resilient with respect to the natural variability of the earth and the solar system. The natural variability includes such forces as floods and hurricanes and shows that much economic development is 'unacceptable brittle and fragile'" (FEMA, 1997, p. 2). A resilient community is one that lives in harmony with nature's varying cycles and processes including earthquakes, storms, and floods as natural events, which cause harm only for a non-sustainable society (Godschalk et al., 1999, p. 526). A fourth criterion should be added to sustainability's economic, social, and ecologic aspects (Greiving, 2002): Sustainability can be understood as a mission for the development of mechanisms for adaptation of societies to future consequences of present processes.

Decisions based on normative findings, made by supranational (like the European Union) or national policies as a framework for regional and local weighting-up processes within land-use planning, can take the interests of future generations into account.

Risk management and land-use planning

Risk management is defined as adjustment policies that intensify efforts to lower the potential for loss from future extreme events, i.e., risk management is characterized by decisions of stakeholders. Decision making is a normative, politically influenced strategy about

Land-Use Planning, Table 2 Contribution of land-use planning and supporting instruments to risk management strategies.

Risk management strategy	Regional planning/development	Local land-use planning	Supporting instruments
Long-term prevention	Fostering resilience as planning strategy, i.e., by following the robustness principle		Tax system; strategies for reducing greenhouse gas emissions
Mitigation of hazard impacts (nonstructural)	Maintenance or reinforcement of protective features that absorb or reduce hazard impacts (mangroves, retention areas, etc.)	E.g., local rain water infiltration adapted to land cultivation	Economic incentives; communication strategies
Mitigation of hazard impacts (structural)	Secure the availability of space for protective infrastructure	Protective infrastructure; Obligations for the design of individual buildings; Retrofitting of existing buildings	Communication strategies
Vulnerability reduction	Spatial development concepts like decentralized concentration	Keeping hazard-prone areas free of further developments	Financial incentives for reallocation of threatened objects
Preparedness, response, recovery	–	Allocation of critical infrastructure outside hazard-prone areas; Rebuilding planning	Emergency plans; Information and training; Risk awareness

Source: Based on Greiving and Fleischhauer, 2006, p. 119

tolerating or altering risks. The authority in charge (democratically legitimized) has to decide the main planning goals to deal with hazards.

Risks due to natural hazards mean a certain challenge for many stakeholders involved in risk governance. The International Risk Governance Council defines risk governance as a "process by which risk information is collected, analysed and communicated and management decisions are taken" (IRGC, 2005). The assessment and management of risks are embedded in a communication process.

As risk assessment and management can be interpreted as an ongoing process, it is often illustrated as the disaster management cycle by which public and private stakeholders plan for and reduce the impact of disasters in the pre-emergency phase (mitigation and preparedness), react in the emergency phase (response) and in the post-emergency phase (recovery).

At all points of the cycle, appropriate actions lead to a reduction of damage potential, reduced vulnerability, or a better prevention of disasters. Land-use planning most likely does not play a decisive role in all phases of the disaster management cycle but it has some specific functions in risk management.

The action decided upon is the result of a weighting process between different management options that can be structured along the triangle "resistance-resilience-retreat" (Greiving, 2004; Greiving and Fleischhauer, 2006): Resistance is the protection against (all) hazards by means of structural measures. Resilience can be defined as minimization of the risk to life and property when a disaster occurs and retreat is the abandonment of risky areas.

Even though land-use planning is considered to be an important instrument to cope with climate change induced impacts, it is limited in its powers and can only solve parts of the problem (Schmidt-Thomé and Greiving, 2008). The following table indicates to what extent land-use planning is able to handle natural hazards. It is divided into assessment and management (Table 1).

Risk assessment is a task for sectoral planning authorities. Land-use planning plays a minor role in this context and can be understood as an important end user of hazard related information provided by sectoral planning. Hazard maps with a scale of about 1:2,000 to 1:10,000 are necessary for the enforcement of restrictions of land use at the municipal land-use planning level.

Due to its coordinative role and responsibility, land-use planning is relevant and responsible for nonstructural adaptation measures as part of risk management strategies. There are several zoning-related instruments that can improve nonstructural mitigation and some supporting instruments that promote planning initiatives (Table 2).

Climate change in general, but particularly as a triggering factor for many natural hazards, is particularly troublesome for Europe with its existing settlement structures, cultural landscapes and infrastructures which have been developed over centuries. Mitigation and prevention actions, carried out by spatial planning, are under such circumstances less effective than in countries which are still growing rapidly in terms of population and the built environment. Here, disaster prone areas can be kept free from further development whereas most of these areas are in Europe already built-up. However, this problem calls for authorities to improve public risk awareness and

to look for means to mitigate this problem due to cooperative solutions (Fleischhauer et al., 2006).

The Strategic Environmental Assessment (SEA), which came into force through EU Directive 2001/42/EC in 2001, offers a suitable procedural frame for risk assessment and embedding risk management in decision making by land-use planning. The use of impact assessment methodologies encourages a more informed approach to planning and regional development. The identification of cumulative impacts highlights areas where land-use planning needs to focus on adaptation measures designed to deal with several impacts similarly. Planning is mainly able to guide future developments. Adapting existing settlement structures can be seen as the main challenge for regulatory land-use planning because of given private property rights. Risk governance is regarded as an important success factor for the development of adaptation strategies, and in this context, land-use planning has an important role to play (see EC, 2009, Ribeiro et al., 2009; Swart et al., 2009).

Summary

Land-use planning prepares and endorses decisions about future land use. It is specified in different scales from regional planning/development and in most countries sets the framework for detailed planning at a local, i.e., municipal level. One of the main instruments of local land-use planning is zoning or zoning ordinances, respectively. Local land-use planning normally consists of two stages: a general, or preparatory land-use plan; and detailed land-use plans. Land-use planning is responsible for the development of a particular land-use area (where the sum of hazards and vulnerabilities defines the overall land-use risk) and not for a particular object or thread (e.g., sectoral engineering sciences). The involvement of land-use planning is only institutionalized in some countries. Currently, single hazard concepts dominate in land-use planning. Multi-hazard approaches to appropriately deal with the potential sum and interaction of hazards and risks are seldom found in practice. Land-use planning is limited in its powers and can only solve parts of the problem. Its coordinative role and responsibility is relevant and responsible for nonstructural adaptation measures as part of risk management strategies. The adaptation of existing settlement structures is a main challenge for regulatory land-use planning, e.g., due to private property rights. Therefore risk governance is regarded as a tool to support land-use planning in the development of adaptation strategies.

LATERAL SPREADING

Steven L. Kramer
University of Washington, Seattle, WA, USA

Synonyms

Liquefaction

Definition

Lateral spreading is the finite, lateral movement of gently to steeply sloping, saturated soil deposits caused by earthquake-induced liquefaction.

Discussion

The movement of soil deposits undergoing lateral spreading can range from a few centimeters to a few meters, and can cause significant damage to buildings, bridges, pipelines, and other elements of infrastructure. Lateral spreading often occurs along riverbanks and shorelines where loose, saturated sandy soils are commonly encountered at shallow depths. Structures supported on shallow foundations, pavements, and buried pipelines are particularly susceptible to damage from lateral spreading.

Lateral spreading occurs as the generation of porewater pressure in the soil resulting from earthquake shaking reduces the stiffness and strength of the soil. Under the action of the static stresses required to maintain equilibrium under sloping ground conditions, each cycle of seismic stress causes incremental deformation of the soil. The deformations generally originate in soils at shallow depths beneath the ground surface, and can cause cracking and severe disruption, as well as horizontal and vertical displacements, of the ground surface (Figure 1).

Lateral Spreading, Figure 1 Lateral spreading damage at Capital Lake in Olympia, Washington, following the 2001 Nisqually earthquake.

The level of ground deformations caused by lateral spreading is influenced by the ground slope, depth of the water table, density of the soil beneath the water table, and the strength of the ground shaking caused by the earthquake. The mechanics of lateral spreading are quite complex, so ground surface deformations are currently predicted using empirical models calibrated against lateral spreading behavior observed in past earthquakes. Subsurface ground deformations can also be important, particularly for structures such as bridges supported on piles that extend through liquefiable soils into underlying stable deposits.

Mitigation of lateral spreading hazards usually involves densification, reinforcement, or cementation of the liquefaction-susceptible soil. A wide variety of construction methods are available to reduce lateral spreading hazards.

Synonyms

Magma; Molten rock

Definition

Lava is molten rock that reaches the Earth's surface through a volcano or fissure. When the molten rock solidifies the resulting rock is called igneous rock. The igneous rock can originate from different sources. Some rocks originate deep in the Earth's mantle whereas others can originate high within the Earth's crust directly underneath a vent. Dependent on the origin, the composition of the crystallized rock is different and therefore provides some hint where the rock came from and what the interior of the Earth looks like.

The erupted lavas usually can be distinguished into three major types: basaltic, andesitic, and rhyolitic lava. Basaltic lava is an extrusive rock of "mafic" composition (high in iron, magnesium, and calcium) with relatively low silica content, andesitic lava has an intermediate silica content, and finally rhyolitic lava has a "felsic" composition (high in sodium and potassium) with silica content greater than 68 vol%.

The vast majority of lava on Earth, more than 90% of the total volume, is estimated to be basaltic in composition (that includes most of our ocean floors). Andesites and other lavas of intermediate composition account for most of the rest, whereas silica rich rhyolitic flows make up about 1% of the total. In recent times, the volume of lava flows, for example, in Hawaii ranges up to 0.5 km^3. One of the largest lava eruptions in historic times is reported from the Laki fissure in Iceland in 1783, which had a volume of 12 km^3 and traveled up to 88 km from its source. There are prehistoric basaltic lava eruptions like the material that formed the Columbia River plateau called Large Igneous Provinces, which produced a volume that exceeded 1,200 km^3.

Because of their lower silica content, the basaltic lavas are usually very fluid. In Hawaii, one measured lava flow had a speed of 30 km/h. In contrast, the movement of silica-rich lava may be too slow to perceive. In addition, because of the high viscosity of rhyolitic lava the flow is usually not more than a few kilometers from their vents.

LEVEE

Joann Mossa
University of Florida, Gainesville, FL, USA

Synonyms

Dike (dyke); Embankment

Definition

Levee an embankment produced naturally by river sedimentation or constructed by humans to prevent flooding.

Natural levees

Natural levees are ridges formed by overbank flooding, which deposits sand and silt-size sediments adjacent to the river channel (Brierley et al., 1997). In low-lying areas, natural levees are the highest topographic features and thus were preferential locations for both prehistoric and more recent settlement (Hudson, 2005).

Artificial levees

Artificial levees are often built upon natural levees for purposes of flood protection and damage reduction. They are generally built from sediment, and may be reinforced with concrete, rock, and/or vegetation. Artificial levee construction dates back thousands of years in the valleys of the Indus and Nile rivers, Mesopotamia, and China. By confining the flow of the river, artificial levees produce higher water levels and velocities (see Zong and Chen, 2000). If levees are set back from the river, there is more capacity for floodwaters and greater potential for flood protection. Artificial levees provide primary or secondary protection to a lowland, and are used with structures to route waters through floodways away from populated areas. Locations surrounded by a ring of levees, such as New Orleans, Louisiana, U.S.A. are vulnerable to flooding from many directions.

Levee hazards

Flood hazards still occur despite the presence of levees. Levees may be overtopped during extreme floods, during wind-driven surges, or because environmental conditions such as sea level or land level have changed since the levee was constructed. Breaches (crevasses) can develop in weaker portions of both natural and artificial levees. Locations with seepage and sand boils, especially in weak materials, are often where these breaches occur. If the overbank flow is of sufficient magnitude and floodplain conditions are appropriate, breaches may lead to avulsions.

Levees have also been intentionally destroyed for a variety of reasons. Some examples include the downstream dynamiting of the levee near Caernarvon to protect New Orleans in the Mississippi River flood of 1927, selective blasting of levees during the Mississippi River flood of 1993, and dynamiting of upstream levees in 1998 to protect Wuhan, a city of over seven million along the Yangtze River in China, where flooding occurred nonetheless. The Chinese destroyed levees on the Yellow River in 1938 to disrupt the invading Japanese, whereas the Germans blew up levees in the Netherlands during wartime in 1945.

Thus, although levees are built to protect lowlands from flood hazards, these areas are vulnerable nonetheless to both storms and human decisions. The presence of artificial levees allows for development and more intense land use, but the price is a false sense of security and a lifetime of maintenance and repair.

LIGHTNING

Leopoldo C. Cancio
Colonel, Medical Corps, U.S. Army, Fort Sam Houston, TX, USA

Definition

Lightning is a sudden, massive discharge of electrical current, most commonly arising from thunderstorms (but rarely from forest fires, volcanic eruptions, or dust storms). Lightning discharges can be classified as cloud-to-ground, cloud-to-cloud, cloud-to-air, or cloud-in-cloud. Lightning is the second leading cause of weather-related death, as well as a fascinating (and incompletely understood) natural phenomenon.

History

Since ancient times, lightning has both stimulated awe and symbolized the divine. Lightning is the instrument by which Zeus, in the *Iliad* Chap. VIII, acts against the Achaeans: "Then he thundered aloud from Ida, and sent the glare of his lightning upon the Achaeans; when they saw this, pale fear fell upon them and they were sore afraid." Among the most beautiful passages in the Bible are references to lightning. Psalm 144:6 depicts it as a manifestation of God's power, and the psalmist prays, "Cast forth lightning, and scatter them: shoot out thine arrows, and destroy them." In Matthew 24:27 Jesus foretells his second coming: "For as the lightning cometh out of the east, and shineth even unto the west; so shall also the coming of the Son of man be." In Luke 10:18, He gives the 70 disciples power over evil, saying: "I beheld Satan as lightning fall from heaven." In Surah 13 of the Quran (Al Ra'ad, "The Thunder"), lightning is a manifestation sent by God by which He reveals Himself: "It is He Who doth show you the lightning, by way both of fear and of hope: It is He Who doth raise up the clouds, heavy with rain. Nay, thunder repeateth His praises, and so do the angels, with awe. . ."

Our understanding of lightning as the result of electrical activity within clouds, and more specifically our ability to protect ourselves by means of the lightning rod, are attributed to Benjamin Franklin. In 1751, a series of five letters written by Franklin to a fellow of the Royal Society of London were published as *Experiments and Observations on Electricity, Made at Philadelphia in America*, describing various electrical experiments. In the fourth letter, he hypothesized: if two electrified gun barrels "will strike at two Inches distance, and make a loud Snap; to what great a Distance may 10,000 Acres of Electrified Cloud strike and give its Fire, and how loud must be that Crack!" In the fifth letter, he proposed the lightning rod, "to fix on the highest Parts of those Edifices upright Rods of Iron. . .Would not these pointed Rods probably draw the Electrical Fire silently out of a Cloud before it came nigh enough to strike, and thereby secure us from that most sudden and terrible Mischief!" In the fifth letter he also proposes an experiment: a man would stand in a sentry box on a high tower. A lightning rod would extend skyward from the box. During a rainstorm, then, the man "might be electrified, and afford Sparks, the rod drawing fire to him from the Cloud."

In his 1767 review, *The History and Present State of Electricity*, Joseph Priestley recounts the brave enactment of that proposal by two French philosophers, assisted by a priest and an artisan, in May 1752. The priest "drew sparks from the bar of a blue colour, an inch and a half in length, and which smelled strong of sulphur. He repeated the experiment at least six times in the space of about four minutes. . .each experiment taking up the time, as he, in the stile of a priest expresses himself, of a *Pater* and an *Ave*. In the course of these experiments he received a stroke on his arm. . .such as might have been made by a blow with the wire on his naked skin. . ." Priestley also describes Franklin as carrying out his famous kite-flying experiment a month later: "Dr. Franklin, astonishing as it must have appeared, contrived actually to bring lightning from the heavens, by means of an electrical kite, which he raised when a storm of thunder was perceived to be coming on." In Franklin's 1753 description of and advocacy for the lightning rod in *Poor Richard's Almanac* he sought to reconcile faith and reason – the sense of lightning as a manifestation of God's power and the new concept of lightning as an understandable and controllable natural force. "It has pleased God in his Goodness to Mankind, at length to discover to them the Means of securing their Habitations and other Buildings from Mischief by Thunder and Lightning." (Krider, 2006).

Lightning physics

According to a hypothesis advanced by C.T.R. Wilson in 1920, thunderstorms play a central role in energizing the Earth and its atmosphere, which together can be viewed as a *global electric circuit*. Even during fair weather, the Earth's surface is charged negatively, and the air positively; lightning serves to deliver negative charge to the ground. The atmosphere above 60 km is conductive due to the presence of free electrons, a zone sometimes called the *electrosphere*. Lateral currents flow both in the

The opinions or assertions contained herein are the private views of the author, and are not to be construed as official or as representing the views of the Department of the Army or Department of Defense.

electrosphere and across the highly conductive surface of the planet (Rakov and Uman, 2003).

Lightning is generated when a voltage difference develops within a thundercloud, or between a thundercloud and the ground. A conventional view is that these conditions are created when ice particles (*hydrometeors*) in thunderclouds form and then fracture. Through a poorly understood process, smaller crystals tend to develop a positive charge, and larger crystals a negative charge. Gravity causes positively charged crystals to move upward within the cloud and negatively charged crystals to move downward. This gives rise to a potential difference between the lower and upper portions of the cloud, and between the lower portion of the cloud and the ground. When the voltage exceeds 2–3 million Volt per meter, arcing occurs. This model is problematic, however, because the strongest fields actually observed within thunderclouds are about ten times lower. An alternative hypothesis, *runaway breakdown*, was advanced by Gurevich and colleagues. Cosmic ray particles impacting the upper thundercloud generate electrons with sufficient energy (*runaway electrons*) that the drag or braking force exerted by air molecules diminishes, in essence serving as a catalyst for a lightning stroke (Dwyer, 2005).

The initial pathway through which current travels is called the *leader*, is relatively invisible, and opens an ionized channel between cloud and ground in a series of steps. Just before this *stepped leader* reaches the ground (at a height of 50–100 m), an *upward streamer* propagates from the ground to the leader. Once this channel is opened between the cloud and the ground, a much greater current passes through it called the *return stroke*, which results in the visible lightning bolt. The electric current involved in lightning strikes is direct (DC). The amount of DC delivered by a lightning strike, on the order of 30,000–50,000 amp, is far greater than that inflicted by the usual man-made electrical contact. The duration of exposure is, on the other hand, much shorter, approximately 10–100 ms. This brief current causes the release of a large amount of heat, raising temperatures to approximately 30,000 K, which in turn causes a "thermoacoustic blast wave" or thunder. The overpressure generated by thunder at the source may approach 100 atm. (Lee et al., 2000).

Lightning may follow one of several paths upon interacting with a body. Casualties may sustain a *direct strike*, a *contact injury* (lightning strikes a conductive object touching the casualty), a *side flash* (lightning splashes from a nearby object onto the casualty), *ground current* (lightning travels through the ground then into the casualty), or an *upward streamer* (rarely, lightning passes upward from the casualty). In addition, thunder may cause *blast injury*, manifested, for example, by tympanic membrane rupture or by blunt trauma when the casualty is thrown (Ritenour et al., 2008).

During a direct strike, the primary current arc travels outside rather than through the body, a phenomenon known as *flashover*. This would seem protective, but the immense current likely generates large magnetic fields perpendicular to the body surface, which in turn induce secondary electric currents within the body. These secondary currents may cause cardiac arrest and other internal injuries, even without external evidence of injury. When lightning hits the ground causing a ground current, current spreads out from the contact point such that if a casualty is standing nearby with feet apart, the potential difference between the feet may approximate 1,500 V. As a result, injuries are more severe when a person's feet are apart than when they are together. When lightning directly strikes the upper body, a very large potential difference between the upper and lower body is established. A brief, large current flow will result. The duration is generally not sufficient to cause Joule heating, but can damage muscle and nerve cells by mechanisms such as electroporation (Bier et al., 2005).

Electroporation, also known as *electropermeabilization*, features reorganization of lipids in the cell membrane into "pores" as a result of an imposed transmembrane potential. This results in a large increase in membrane permeability that significantly augments the work necessary to maintain transmembrane concentration gradients. When cellular metabolic energy stores become depleted, ATP-driven ion pumps can no longer compensate for the rapid diffusion of ions through the damaged cell membrane. If the membrane does not then seal itself, cell death will occur. Skeletal muscle and nerve cells are especially susceptible to electroporation because of their length, which is directly proportional to their transmembrane potential. Some suggest that the delayed neurological sequelae following lightning injury are due largely to the gradual effects of electroporation.

Epidemiology

Today, given the unchanged destructive power carried by lightning, and its daily frequency, it is extraordinary that deaths due to lightning are not more common. Remarkably, at any moment in time, about 2,000 thunderstorms are occurring over about 10% of the planet's surface (Rakov and Uman, 2003). Space-based optical sensors have made it possible to document lightning strike frequency with accuracy. Worldwide, strike density is highest in central Africa (over 50 flashes per km^2 per year) and rare over the open ocean. In the USA, central Florida is the leading region for lightning strikes.

Lightning is the second leading cause of weather-related death in much of the world. The epidemiology of lightning injury is well described only for certain areas of the world, and significant underreporting of both injuries and deaths has been demonstrated by comparing disparate databases. The annual number of deaths reported in the USA is approximately 60, and given underreporting, may be as high as 70. With a USA population of 300 million, this gives a death rate of 0.20–0.23 per million. A South African study noted a much higher rate of 6.3 deaths per million inhabitants for the Highveld, a region consisting predominantly of urban poor – suggesting the influence not only of strike frequency, but

also of factors such as building construction and availability of safety information. In the USA, the largest number of deaths occurs in two southern states: Texas and Florida. On the other hand, during 1968–1985, the highest number of deaths per inhabitants in the USA was reported for the rural Rocky Mountain states of Wyoming, at 1.96 per million, and New Mexico at 1.70. At the same time, the national average was 0.61 per million.

The month of July consistently features the largest number of casualties in the USA. In India, the peak months are the monsoon season of June to September. The opposite pattern is noted south of the equator in Australia and South Africa. In Singapore, an equatorial country, two peaks are observed in April and November. Worldwide, most injuries take place in the afternoon (1,200–1,800 h local times) (Ritenour et al., 2008).

Despite rising population, the number of lightning deaths in the USA decreased from 377 during 1891–1894 to 239 during 1991–1994 (Holle et al., 2001). From the 1950s until the 1990s, there was a slight decrease in the per person risk of lightning injury or death (Curran et al., 2000). A likely explanation for this finding is a decrease in the number of individuals involved in farming, and an increase in the proportion of the population living in an urban setting. Similar long-term decreases in the number of lightning injuries and fatalities were observed in England and Wales over the period 1852–1990. In that region, the mean annual number of lightning deaths decreased from 20.5 for 1852–1859 to 4.2 for 1980–1989. This occurred despite a doubling of the population, implying an eightfold decrease in the risk of death (Elsom, 1993). Improved medical care is likely improving survival following lightning strikes. One paper based on the US *Storm Data* database concluded that the ratio of injuries to deaths increased from two in 1959 to about seven in 1994 (Curran et al., 1997).

The typical lightning casualty is a young man who is engaging in outdoor work (such as farming or construction) or recreation. Men are five times more likely to be struck by lightning than are women (Center for Disease Control and Prevention, 1998). Young people (ages 10–29 years) are at greatest risk in several series. Over time, some regions have noted a decrease in outdoor-work-related injuries, and an increase in outdoor-recreation-related injuries. However, a significant fraction of lightning injuries in the USA takes place indoors. Improvements in building design in developed countries likely reduced the number of indoor injuries between the 1890s and 1990s. Lightning injury may afflict individuals riding bicycles, motorcycles, or boats. Lightning has also struck aircraft in flight, resulting in fatalities; engineering improvements have made aircraft safer from this threat.

Prevention of injury

The first key to prevention of lightning injury is adherence to the building codes which have evolved since the invention of the lightning rod. The primary reference in the USA is the National Fire Protection Association's Standard for the Installation of Lightning Protection Systems (NFPA-780).

Equally important is a high level of awareness, particularly for those working or recreating outdoors during the thunderstorm season. Lightning is often associated with cumulonimbus rain clouds, but may precede the rainstorm and may even strike with blue skies overhead (a "bolt from the blue"). Lightning may rarely occur during snowstorms, presaged by *graupel* (soft hail or snow pellets). The "30-30 rule" states that a flash-to-thunder interval of less than 30 s places one at risk of lightning strike, and mandates shelter for 30 min after the last strike is seen or heard.

A third key to prevention is to seek shelter in a safe place during a thunderstorm. When thunder is heard, personnel should seek shelter in a building or enclosed vehicle. Alternatively, there is a relatively safe triangle near walls, no closer than 1 m to the wall, and no farther from the wall than the wall's height. Trees or tall objects, high ground, water, open spaces, metal objects, and ungrounded buildings, such as shacks and huts, should be avoided. Instinctively, persons may seek shelter under isolated trees during thunderstorms, but this increases strike risk. Holding a metal object during a storm is particularly dangerous, and was associated with over 60% of Florida lightning injuries. Indoors during a thunderstorm, appliances should be turned off and the telephone should not be used.

A final key to prevention is appropriate immediate action. When stranded in the open, it is best to crouch with the feet and knees together rather than lying flat. An impending hit may be signaled by a crackling sound, a visible glow (*St. Elmo's Fire*), a tingling sensation, and/or hair standing on end. The correct response is to crouch immediately with the feet together.

Several popular lightning myths are false. These include the notion that lightning never strikes in the same place twice or always hits the tallest object; and that it is dangerous to touch a lightning victim after a strike (Ritenour et al., 2008).

Injury and treatment

Lightning usually affects multiple organs simultaneously, and has several unique effects on the body. The combination of acute life-threatening multisystem injuries and long-term neuropsychiatric sequelae make the multidisciplinary team approach championed by burn centers appropriate for lightning survivors. Thus, lightning injury is one of the burn center referral criteria published by the Committee on Trauma of the American College of Surgeons (Ritenour et al., 2008).

Cardiopulmonary resuscitation

First responders must approach lightning casualties as if they had sustained high-energy blunt trauma. Airway, breathing, and circulation should be rapidly assessed, and full spine immobilization should be strongly

considered. Immediate cardiopulmonary resuscitation (CPR) may be required. The most common cause of death is cardiac arrest (asystole or ventricular fibrillation) at the moment of injury, caused by a massive DC "countershock." Respiratory arrest may also occur due to both chest muscle paralysis and suppression of respiratory centers in the brainstem. Thus, lightning victims may face two highly lethal "hits": primary cardiac arrest, followed by respiratory arrest and secondary cardiac ischemia. Those patients who do not sustain cardiopulmonary arrest at the time of injury may subsequently die of various complications, but this is less likely. The cardiovascular response also features a massive catecholamine release through an unknown mechanism, which may be manifested (in patients who do not arrest) by hypertension, tachycardia, nonspecific electrocardiographic (EKG) changes, and contraction-band myocardial necrosis. In a few patients, fatal lightning injury may occur in the absence of any obvious external or internal injury. This finding has been attributed to the induction of current by strong magnetic fields, sufficient to cause cardiac arrest.

The American Heart Association (AHA) and the European Resuscitation Council have published recommendations for CPR of lightning victims. Advanced Cardiac Life Support (ACLS), and defibrillation should be performed as needed. Because respiratory arrest may persist even after the return of spontaneous circulation, advanced airway management and bag-valve ventilation may be required. Lightning patients may respond to resuscitation even when they appear dead, and even when the interval between injury and resuscitation is prolonged. Thus, the AHA recommends "vigorous resuscitative measures. . .even for those who appear dead on initial evaluation." (Anonymous, 2000).

Lightning may strike several people at once, creating a mass casualty situation that requires the sorting of casualties (*triage*). Under other circumstances, it might be reasonable to triage patients who appear dead to the "expectant" category during a mass casualty scenario. In the case of lightning, however, apparently dead patients should probably be treated first ("immediate" category), since they may respond well to CPR and may only require ventilation.

Lightning casualties may require ongoing intravenous fluid resuscitation, particularly if hypotension or muscle breakdown (*rhabdomyolysis*) is present. Hypotension should also prompt a search for sources of bleeding secondary to blunt trauma.

Skin

There are four types of skin lesions that can result from lightning: linear, punctate, "feathering," and thermal. *Linear burns* tend to follow areas of high sweat concentration, such as under the breasts and arms, and down the middle of the chest. They are generally small, from 1 to 4 cm in diameter. They may be present initially, or develop over several hours, and are thought to be due to vaporization of water on the skin's surface. *Punctate burns* are small, multiple, closely spaced circular burns. *"Feathering" lesions* do not represent a burn, and the epidermis and dermis are normal. Lichtenberg figures, also known as keraunographic markings, are one example. These fern-like, branching, arborizing, serpiginous, or fractal patterns are pathognomonic for lightning, but are often not present. Upon pathophysiologic examination they consist of extravasation of blood in the subcutaneous tissues. Lichtenberg figures are evanescent, and usually disappear after several hours without known residua. *Thermal injury* may occur if the patient is wearing metal objects (e.g., zippers), or if clothing ignites. Patients with lightning injury rarely suffer from extensive tissue destruction or large cutaneous burns. Thus, lightning burns – in contrast to other electric injuries – should generally be treated conservatively as they are usually superficial, and tend to heal quickly. Standard wound care procedures should be employed.

Muscle

Extremities may appear cool, blue, or pulseless due to transient vasospasm; this phenomenon may also feature keraunoparalysis (see below). Emergent fasciotomy and debridement should be considered for patients with elevated compartment pressures or other clear evidence of intramuscular compartment syndrome. However, steady improvement of the cool extremity, with subsequent return of pulses, is the more likely outcome. Although extensive muscle damage following lightning strike is unusual, patients with myoglobinuria should be treated as for high-voltage electric injury, to include aggressive fluid resuscitation.

Central nervous system

Central nervous system (CNS) injury is common in lightning victims. According to Cherington's (2003) classification, the four groups of CNS injury include: Immediate and Transient Effects, Immediate and Prolonged Effects, Possible Delayed Neurological Syndromes, and Trauma from Falls or Blast. *Immediate and Transient Effects* are common, and include loss of consciousness, confusion, amnesia, and headaches, paresthesias, weakness, and *keraunoparalysis*. Keraunoparalysis (Charcot's paralysis) is specific to lightning injury. It features transient paralysis and loss of sensation, especially in the lower extremities; it lasts 1 to several hours and then resolves. Keraunoparalysis may be a result of intense catecholamine release because it is often accompanied by pallor, vasoconstriction, and hypertension. However, patients with such neurologic deficits should be assumed to have spinal injury until proven otherwise. *Immediate and Prolonged Effects* feature the sequelae of significant neurological injury, such as postarrest cerebral anoxia. *Possible Delayed Neurological Syndromes* are those which may be related to lightning, but which present in delayed fashion. These include motor neuron diseases and movement disorders. *Trauma from Falls or Blast*

include closed head injuries such as subdural or epidural hematomas and subarachnoid hemorrhages. In addition, lightning injury may be associated with long-term neuropsychological impairment. Common complaints include fatigue, lack of energy, poor concentration, irritability, and emotional lability. Post-traumatic stress disorder is another common problem, occurring in about 30% of survivors. Cognitive testing may reveal memory, attention, and visual-reaction-time abnormalities. Some patients will meet criteria for depression. Of course, these effects may cause significant vocational and interpersonal difficulty, and early neuropsychiatric intervention is urged.

Eye and ear

Because of the blast overpressures generated by a lightning strike, patients frequently present with tympanic membrane rupture, and more rarely with more severe otologic injuries such as sensorineural deafness or vestibular injury. A wide variety of eye injuries can be caused by lightning strike. The most common of these is "lightning cataract," the presentation of which may be delayed by years. Dilated or nonreactive pupils are not considered a reliable sign of brain death in the early postinjury period.

Summary

Despite man's ancient fascination with lightning, our understanding of lightning physics remains incomplete. Improved building codes and a transition away from agricultural work for the majority of persons in developed countries has led to a decrease in the number of lightning deaths per year. Nevertheless, lightning remains one of the leading causes of weather-related death. Awareness of lightning hazards is the key to prevention.

LIQUEFACTION

Steven L. Kramer
University of Washington, Seattle, WA, USA

Definition

Liquefaction is a term used to describe the loss of soil strength and/or stiffness due to the generation of porewater pressure in saturated soil subjected to rapid loading. Liquefaction is most commonly triggered by earthquake ground shaking, but may also be caused by non-seismic loading (e.g., train traffic, rapid deposition of sediment, or construction vibrations).

Damage

Liquefaction has caused extensive damage in many historical earthquakes. Liquefaction damage is usually caused by the excessive ground deformations that result from the weakening and/or softening of liquefied soil. Liquefaction is frequently accompanied by the development of sand boils, small to large piles of ejecta brought to the ground surface by pressurized groundwater. Extensive weakening due to porewater pressure generation can cause soils that were stable prior to earthquake shaking to become unstable. When such soils support a building (Figure 1) significant weakening can cause foundation failure. When they underlie a slope, weakening can cause landsliding (Figure 2) to occur. Even under level ground, liquefied soils can densify as porewater pressure dissipates leading to significant post-earthquake settlement

Liquefaction, Figure 1 Liquefaction-induced foundation failure of Kawagishi-cho apartment buildings in 1964 Niigata earthquake.

Liquefaction, Figure 2 Flow slide along bank of Lake Merced, San Francisco.

(Figure 3). Ground deformations associated with liquefaction can be predominantly horizontal or vertical, or may include both components. The deformations can range from centimeters to hundreds of meters and can develop slowly or very rapidly. The evaluation and mitigation of liquefaction hazards is an important part of geotechnical engineering practice in seismically active areas of the world.

Liquefaction hazard evaluation

Evaluation of liquefaction hazards at a particular site generally involves three primary activities: evaluation of the susceptibility of the in situ soil to liquefaction, evaluation of the potential for initiation of liquefaction under the levels of ground shaking anticipated at the site, and evaluation of the expected effects of liquefaction.

Susceptibility

A number of factors control the susceptibility of soil to liquefaction, and not all soils are susceptible to liquefaction. Liquefaction results from the generation of high porewater pressure, which can only occur when the soil is saturated; dry and partially saturated soils, therefore, are not susceptible to liquefaction. Also, the high permeability of gravelly soils will generally not allow them to sustain high porewater pressure, so gravels are generally

Liquefaction, Figure 3 Liquefaction-induced settlement of Hotel Sapanca following 1999 Kocaeli earthquake.

not susceptible to liquefaction unless bounded by lower-permeability zones that impede the drainage of porewater. The generation of high porewater pressure is also retarded by soil plasticity, so clayey soils are generally not susceptible to liquefaction (although some clay-rich sediments can exhibit macro-behavior that shares certain characteristics of the behavior of liquefiable soils). The most susceptible sediments are non-plastic fine-grained (silty) materials with contrasted granulometry, such as alternately homogeneous fine sands or silts. Indeed, most occurrences of liquefaction in historical earthquakes have been observed to occur in such materials.

Liquefaction-susceptible soils are found in a relatively narrow range of geological environments. Processes that sort soils into uniform particle sizes and deposit them in loose states produce soils with high liquefaction susceptibility. Fluvial deposits, and colluvial and aeolian deposits, when saturated, are frequently susceptible to liquefaction. Alluvial, lacustrine, and estuarine deposits can also be susceptible to liquefaction. The combinations of soil type and groundwater conditions required for liquefaction susceptibility are commonly found in and along rivers and shorelines. Since important transportation and lifeline facilities such as bridges and ports are also located in such areas, they are frequently impacted by liquefaction in strong earthquakes.

Initiation

The initiation of liquefaction requires rapid loading of sufficient amplitude and duration to produce high porewater pressure in the soil. The level of porewater pressure required to trigger liquefaction depends on the initial (pre-earthquake) density and stress conditions in the soil. If the initial shear stress required to maintain static equilibrium is greater than the shear strength of the soil after it has liquefied (the residual strength of the soil), flow liquefaction can occur; if not, liquefaction can still occur through a mechanism known as cyclic mobility.

Flow liquefaction is triggered when rapid loading of sufficient amplitude brings the stress conditions in the soil to a critical point at which the structure of the soil skeleton becomes unstable and rapidly breaks down. As the structure collapses, compressive stresses are transferred from the soil skeleton to the porewater so the intergranular, or effective, stress decreases. As a result, the shear strength, which is proportional to the effective stress, also decreases. The extent of the strength loss depends on the density of the soil; if the soil is very loose, the residual strength may be extremely low. Large, unidirectional ground movements are then driven by the difference between the shear stress required for static equilibrium and the residual strength. If the residual strength drops to a value so low that the stress difference is large, the deformations will be both rapid and large.

The phenomenon of cyclic mobility in liquefiable soils is quite complicated. The cyclic shear stresses induced in the soil by earthquake shaking cause an incremental rise of porewater pressure. If the shaking is strong enough and of sufficient duration, the porewater pressure may instantaneously reach the level of the initial effective stress, at which point the effective stress will be zero. At that point, the stiffness of the soil is extremely low, allowing it to strain significantly in response to the initial and earthquake-induced shear stresses. Dilation eventually causes the stiffness to increase, but the initial static shear stress will cause strain to accumulate preferentially

in one direction. The amplitude of the final, permanent strain will depend on the level and duration of ground shaking. Integrating these strains over the thickness of the liquefied soil layer yields the permanent displacement of the ground surface. These displacements develop in a series of increments and usually cease to accumulate after earthquake shaking has ended. In some cases, however, redistribution of porewater pressure following earthquake shaking can lead to delayed ground movements.

The resistance of a soil to liquefaction depends most strongly on its in situ density. Because in situ density is very difficult to measure, liquefaction resistance is usually correlated to in situ test indices such as standard penetration resistance (Seed et al., 1985; Idriss and Boulanger, 2008), cone penetration resistance (Robertson and Wride, 1997), or shear wave velocity (Andrus and Stokoe, 2000). These indices, which are readily and commonly measured in the field, serve as proxies for density. Liquefaction potential is usually expressed in terms of a factor of safety against liquefaction, which is computed as a ratio of capacity (liquefaction resistance) to demand (liquefaction loading). Design factors of safety, which reflect both uncertainty in the evaluation process and the potential consequences of liquefaction, are typically on the order of 1.2–1.5; higher design factors of safety provide greater conservatism than lower values. Probabilistic liquefaction potential analyses are becoming more commonly used in practice.

Effects of liquefaction

The initiation of liquefaction can have a number of damaging consequences. The extent of the damage caused by liquefaction is usually related to the density of the soil and strength of the ground motion, with all deleterious effects increasing with decreasing density and increasing ground motion level.

Ground shaking

Liquefaction can have a strong effect on earthquake ground motions, and hence on the seismic performance of structures founded on liquefiable soil deposits. Prior to the initiation of liquefaction, a soil deposit will typically be able to transmit both high and low-frequency components of ground motions to the surface. The softening of the soil that occurs upon initiation of liquefaction, however, causes high-frequency components to be reflected downward from the bottom of the liquefied layer rather than being transmitted to the surface. At the same time, the softening of the profile causes low-frequency components to be amplified. The sudden change in soil profile characteristics causes a change in the character of the surface motion – acceleration levels generally drop and displacement levels increase following the initiation of liquefaction.

Instability

The weakening and softening that occurs following initiation of liquefaction can lead to mass movement of sloping soil deposits. When the residual strength of a liquefied soil is lower than the shear stress required to maintain equilibrium, flow liquefaction can lead to the occurrence of flow slides. Such slides occur suddenly with the unstable soils moving at high velocities over distances of tens to hundreds of meters. Although they are not common, flow slides can cause disastrous damage and loss of life.

When the ground slope is flat enough and/or the soil density high enough, the residual strength will exceed the shear stress required to maintain equilibrium. Under such conditions, flow sliding is not possible but damaging deformations associated with cyclic mobility can occur. These deformations, referred to as lateral spreading, result from the softening of a liquefied soil, which allows the incremental development of horizontal and vertical soil movements. Lateral spreading displacements can range from a few centimeters to several meters. Whereas the movements caused by lateral spreading are much smaller than those associated with flow sliding, lateral spreading occurs much more commonly than flow sliding and is responsible for significantly greater total losses in most earthquakes.

Settlement

After earthquake shaking has ended, the high porewater pressure in a liquefied soil will dissipate resulting in volumetric compression, which ultimately leads to ground surface settlement. This settlement typically occurs relatively quickly – within hours to a couple days following the earthquake. It can occur in an irregular pattern, however, thereby causing damage to structures supported on shallow foundations, as well as pavements, buried pipelines, and other elements of infrastructure. The use of deep foundations, such as piles that extend through the liquefied zone and derive their support from underlying non-liquefiable soils, can prevent the structure itself from settling. Settlement-related building damage can still occur, however, if utilities entering the building from the surrounding ground are not designed with flexible connections that can accommodate the settlement. Settlement of the approaches can render a bridge impassable if hinged approach slabs do not provide a transition from the approach embankment to the bridge deck. The amount of post-liquefaction settlement depends on the density and thickness of the liquefied soil and on the strength of the earthquake shaking.

Mitigation of liquefaction hazards

Since liquefaction is caused by the buildup of high porewater pressure, techniques for mitigation of liquefaction hazards have focused on reducing the tendency of the soil to generate high porewater pressure. That tendency is most closely related to the density of the soil; as a result, most liquefaction hazard–mitigation techniques focus on soil densification. The soils that are most susceptible to liquefaction tend to be densified efficiently by vibration. Vibro techniques involve the insertion and removal of a torpedo-shaped vibrating probe, often accompanied by the addition of gravel or crushed rock, on a grid pattern

across a site. The stone columns left behind in such a process provide reinforcement and drainage benefits in addition to the densification associated with their installation. Dynamic compaction involves repeatedly dropping heavy (6–30 t) weights from heights of 10–30 m on a grid pattern across a site. The combination of impact stress and vibration can densify the soil to depths of 9–12 m. Blasting with time-delayed charges placed at multiple depths in multiple boreholes has also been used successfully to densify liquefiable soils. Liquefaction hazards can also be mitigated by injecting or mixing cementitious material into the soil. Permeation grouting injects low-viscosity liquid grout (aqueous suspensions of micro-fine cement, silica and lignin gels, phenolic and acrylic resins, or other materials) into the voids of the soil without disturbing the soil skeleton. Intrusion grouting injects stronger and more viscous grout materials under pressure sufficient to fracture the soil, leaving behind a network of intersecting lenses of hardened grout. Soil mixing and jet grouting use mechanical and hydraulic means to mix the in situ soil with cement grout leaving behind columns of hard, strong "soilcrete" that can resist liquefaction and the ground deformations it can cause.

Summary

Liquefaction is an important seismic hazard that has produced significant damage to the natural and built environments in past earthquakes. Although the phenomenon is quite complex, progress has been made in the evaluation and mitigation of liquefaction hazards. Nevertheless, it remains an active area of research as geotechnical engineers seek more reliable and economical ways to evaluate and mitigate those hazards.

LIVELIHOODS AND DISASTERS

J. C. Gaillard
The University of Auckland, Auckland, New Zealand

Definition

The concept of livelihood reflects the ability of people to sustain their daily needs and draws on the combination of a large array of resources which are natural, physical, human, social, financial, and political in nature. These resources strongly interplay with the ability of people to face the threat of and recover from the impact of natural hazards. Therefore strengthening livelihoods and making them sustainable is a crucial component of disaster risk reduction.

Defining livelihoods

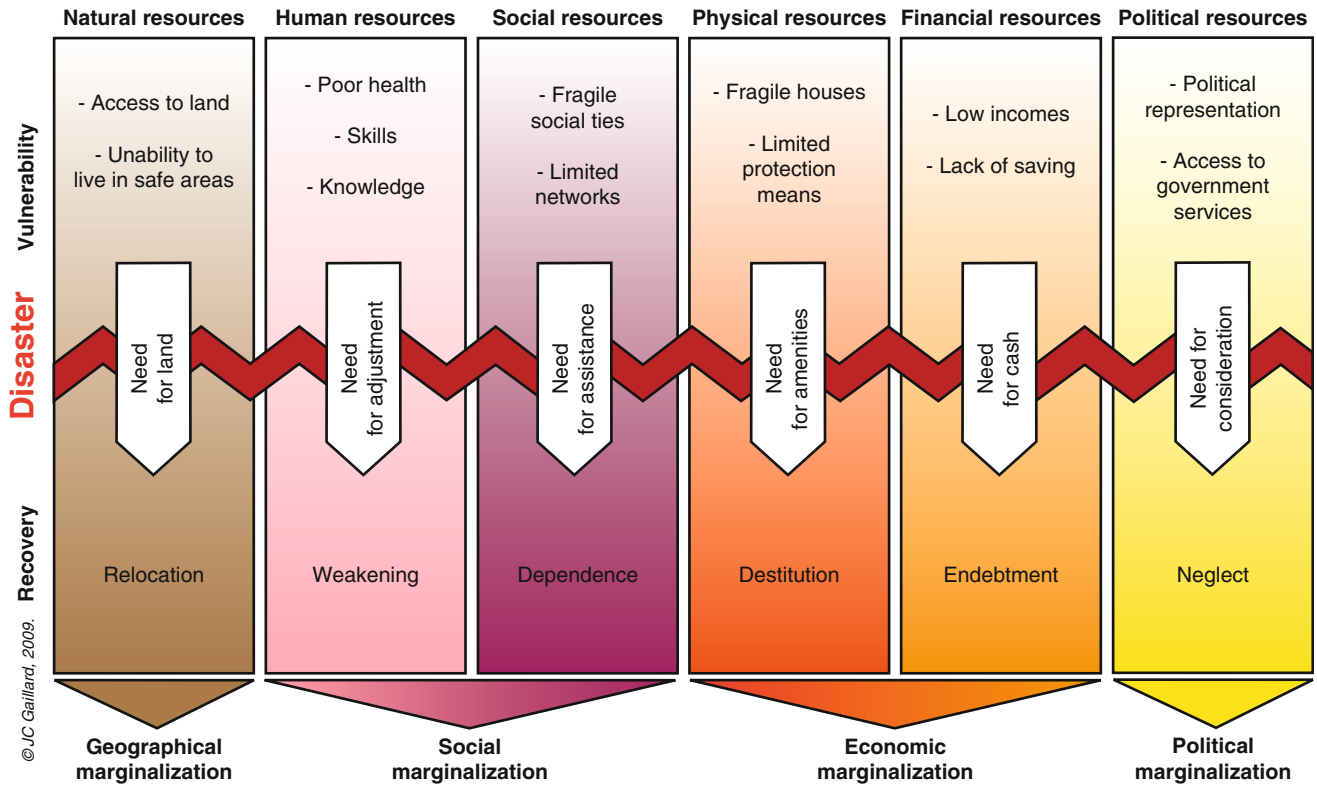
The concept of livelihood emerged in the 1980s as an alternative to the technocratic concept of "employment" to better describe how people struggle to make a living (Chambers and Longhurst, 1986; Swift, 1989). It emphasizes people's view of their own needs. According to Chambers and Conway (1991, p. 1) sustainable livelihoods comprise "people, their capabilities and their means of living, including food, income and assets. Tangible assets are resources and stores, and intangible assets are claims and access. A livelihood is environmentally sustainable when it maintains and enhances the local and global assets on which livelihoods depend, and has net beneficial effects on other livelihoods. A livelihood is socially sustainable which can cope with and recover from stress and shocks, and provide for future generations." Livelihoods thus refer to the means and capacities required to sustain durably people's basic needs. Basic needs are vitally linked to food, but also include shelter, clothing, cultural values, and social relationships.

The capacity to meet food and other basic needs depends on assets and capitals (Scoones, 1998). The use of the term "capital" has however been criticized for its economic nature which does not reflect the entire range of resources upon which people resort to make a living (e.g., de la Peña, 2008). As part of its sustainable livelihood framework, the Department For International Development (1999) distinguishes five types of resources (hence replacing "capital" in view of the foregoing criticism): natural resources (land, water, forest, air, and other natural resources), human resources (health, skills, and knowledge), social resources (kinship, social networks, and associations), financial resources (cash, saving, credit, jewelry, and other valuables)

and physical resources (housing, infrastructures, work implements, livestock, and domestic utensils). Wisner (2009) and Gaillard and Cadag (2009) further identify institutional and political resources which include the interface with formal governance and access to government-linked services, information, and overall to the larger political scene. The extent, strength, and diversity of resources condition people's capacity to produce their own food. It also commands the capacity to purchase food should it not be supplied by the household itself. In the latter case, the availability of food depends on the larger political economy framework (Start and Johnson, 2004). The availability and extent of resources is indeed deeply dependent on claims and access. Claims refer to rights and capacities/power to ask for some external support to sustain basic needs should people be unable to meet them by themselves. Claims thus depend on the extent of people's social, economic, and political networks and relationships. It is complemented by access which is the opportunity to use available stores and resources or obtain food, employment, technology, and information (Chambers and Conway, 1991). As underlined by Sen (1981, 1986), people's claims for and access to livelihoods thus go beyond the specific availability or unavailability of resources but encompass the capability or entitlement to use available resources. Watts and Bohle (1993) emphasize that entitlement reflects people's empowerment evident in class relationships and the larger distribution of economic wealth, social opportunities, and political power within the society.

Livelihoods and people's ability to face natural hazards

People's ability to face natural hazards depends on their vulnerabilities and capacities (e.g., Wisner et al., 2004; Gaillard, 2010). Vulnerability in facing natural hazards reflects their susceptibility to be harmed should the threatening phenomenon occur. It basically reflects people's ability to live in safe places and, if they are compelled to settle in a hazardous area, on their awareness of, access to, and ability to successfully apply means of protection. Capacities refer to the resources people possess to resist and cope with disasters. As for livelihoods, capacities encompass the ability to either use and access needed resources and thus goes beyond the sole availability of these resources. All these factors are closely related to people's livelihoods and everyday life (Davis et al., 2004; Wisner et al., 2012).



The nature, strength, and diversity of livelihoods are crucial in defining people's vulnerabilities and capacities in facing natural hazards (e.g., Twigg, 2001; Cannon, 2003; Wisner et al., 2004; Gaillard et al., 2009). People whose livelihoods are sustainable in the face of natural hazards prove to be less vulnerable and equipped with capacities to face environmental shocks. Resources essential in the sustainability of livelihoods are crucial in defining vulnerability too. People's ability to live in hazard-safe places depends on access to land (natural resources). Skills and knowledge (human resources) enable the diversification of activities and thus lessen households' dependence on natural resources in the event of an adverse climatic or geologic event. Incomes and savings (financial resources) are obviously important to purchase food in time of scarcity but also to build resistant houses and to access other means of protection. Furthermore, pawning or selling of valuable belongings often allows to generate additional cash should required. Social networks and kinship (social resources) are critical in providing alternative support in time of crisis. The fragility of physical resources, i.e., infrastructures (including public buildings, hospitals, schools, and housing) and working implements (such as boats and farming implements), is another crucial factor in the face of natural hazards. Ultimately people's vulnerability and capacity in facing natural hazards is tied to powerlessness, i.e., the lack of political resources, as it prevents access to other forms of resources. People's vulnerability can therefore not be dissociated from livelihoods sustainability. On the other hand, livelihood sustainability is similarly tied to people's vulnerability to natural hazards. Disasters often destroy the environment, damage physical resources, kill relatives, and drain savings, therefore endangering people's livelihoods and ability to sustain their everyday needs on the long run.

The concept of sustainability implies that basic needs are met on a quotidian basis. Considering everyday life is therefore crucial in understanding both livelihoods sustainability and vulnerability in facing natural hazards. Factors which determine both sustainability of livelihoods and vulnerability to natural hazards are similarly rooted in daily life. Many people deliberately choose to face natural hazards to sustain the daily needs of their household. Indeed, the threat related to food insecurity always weight heavier than the threat linked to natural hazards. Sustaining one's minimum food intake is the human most basic need and is rooted in daily life. Threats to everyday needs, especially to food security, are almost always more pressing than threats from rare or seasonal natural hazards. Strategies to cope with natural hazards are also often anchored in daily life. Most are adjustments in everyday activities of the affected people rather than extraordinary measures adopted to face extreme and rare natural events (Gaillard et al., 2009).

Livelihoods and people's ability to recover from disasters

The ability to recover in the aftermath of a disaster further reflects the nature, strength, diversity, and sustainability of people's livelihoods (e.g., Gaillard and Cadag, 2009). The aptitude of disaster survivors to recover is first dependent on the nature and diversity of their pre-disaster livelihoods. Those who struggle to recover are often those who extensively rely on one form of resource which is heavily impacted by the disaster, e.g., natural resources.

The strength of livelihoods is another critical factor of recovery. Important financial resources enable people to save money, which may be tapped in time of hardship to fasten recovery. Similarly people with alternative skills and knowledge have an easier time to adjust to changing

Livelihoods and Disasters, Figure 1 Interactions between livelihoods, pre-disaster vulnerability, and post-disaster recovery.

social and economic environments. Both physical and mental health also matters as disasters most frequently aggravate pre-event fragility for those most frequently affected, for example, the children, elderly, people with mental and physical disabilities. In time of disasters, alternative sources of support such as loaning money depend on the extent of social networks, that is, social resources, and the ability to pay back, financial resources, too. Entitlement to land ownership is of primary importance when disasters force people to relocate. Access to political resources and representation is also essential to benefit from post-disaster recovery programs provided by the government, nongovernment organizations (NGOs), and international institutions. The needs of those groups and survivors which are invisible on the everyday political scene, i.e., illegal settlers, ethnic and gender minorities, people with disabilities, are often neglected in disaster recovery.

Sustainability of livelihoods also turned out to be essential to the ability of the survivors to overcome disasters. Stability in livelihoods prevents a sharp decrease in households' incomes, thus preventing them to plunge into chronic endebtment. The loss of one or more relatives and lingering long-term decrease in available social resources often turned out to be a key determinant of people's ability to recover from a disaster. Those with some physical resources may sell or pawn them but on the long run, this strategy endangers their ability to sustain their daily life, especially when assets sold or pawned are cattle, farming implements, or fishing boats. Post-disaster relocation also affects the sustainability of livelihoods. It is often impossible to rely on the same resources than in the area of origin because land is lacking for farmers and skills are insufficient for urban settlers relocated in rural areas or fishermen relocated in mountainous locations.

The ability of those affected by disaster to recover is actually strongly dependant on their pre-disaster vulnerability. Disasters are amplifiers of everyday hardship (Baird et al., 1975; Maskrey, 1989). They do not level down people resources so that all survivors are equal in recovery. Following disasters, the rich are still rich, and sometimes richer, and the most able to recover quickly (Quarantelli and Dynes, 1972) while the poor are often poorer and struggle to recover. Disasters basically increase the everyday need for resources which make up people livelihood (Figure 1). For the most vulnerable coping with these increasing needs means falling in further marginalization.

Assessing the sustainability of livelihoods in the face of natural hazards

Livelihoods rarely refer to a single activity. It includes complex, contextual, diverse, and dynamic strategies developed by households to meet their needs (Chambers, 1995; Scoones, 1998, 2009). Furthermore, livelihoods and

livelihood resources and strategies vary in time and space from one place to another, and from one season to another. For these reasons, understanding and assessing the sustainability of livelihoods is a challenge for researchers and practitioners engaged in development and disaster risk reduction.

Traditional research methods such as short interviews with key informants and questionnaire-based surveys are usually of limited help as they fail to encapsulate the complexity of livelihoods. Interestingly, the concept of livelihood emerged among the same group of researchers and practitioners who foster the use of participatory action research methods (e.g., Chambers, 1994). These methodologies encourage the participation of those who are most concerned, the people, in the evaluation of their own resources and strategies to assess strength and sustainability. Participatory methods encompass a large array of tools which range from listing, ranking, profiles, and Venn diagrams to transect walk, community drama, and participatory mapping, which are always conducted as part of group discussions to foster dialogue and exchange of ideas.

A number of analytical frameworks provide useful approaches to sustainable livelihoods (e.g., Hoon et al., 1997; Department For International Development, 1999) but only a few tools have been developed with the specific objective to assess the vulnerability and sustainability of those livelihoods in the face of natural hazards. Existing tools include the Community-based Risk Screening – Adaptation and Livelihoods tool or CRiSTAL developed by a consortium of NGOs and international research institutes (International Institute for Sustainable Development, 2007). CRiSTAL consists in a series of tables which integrate both hazardous phenomena, including changing climatic patterns, and people's resources. It thus provides a useful overview of the potential impact of hazards on the overall livelihood strategies.

Participatory 3-Dimensional Mapping or P3DM (Gaillard and Maceda, 2009) has also recently been used to provide a spatial analysis of livelihood resources and strategies in the face of natural hazards. All forms of resources may be plotted on the map but some which are not location based such as interpersonal and power relationships are more difficult to capture. Yet P3DM proves to be a very useful tool which helps people in visualizing intangible threats to their resources. Furthermore, it turns out to be a very powerful tool for participatory planning and strengthening of livelihoods.

Outlook: Reinforcing livelihoods to reduce disaster risks

Strengthening people's livelihoods is crucial to sustainable disaster risk reduction as it enables local communities to live with risk on an everyday basis (Benson et al., 2001; Cannon et al., 2003; Twigg, 2004). It is actually often impossible to prevent people from settling in hazardous areas, because these same locations often provide resources on a daily basis, as in the case of fertile floodplains and coastal zones with fisheries. Focusing on livelihoods simultaneously addresses people's ability to sustain their daily needs and their capacities to face natural hazards. It further favors the integration of disaster risk reduction into development policy and planning since the actions required for reinforcing livelihoods basically fall within the realm of development programs.

Enhancing livelihood sustainability emphasizes five areas of focus: creation of working days, poverty reduction, well-being and capabilities, livelihood adaptation, vulnerability and resilience, natural resource base sustainability (Scoones, 1998). Strategies to enhance livelihood sustainability should thus be people centered, multilevel and holistic, dynamic and sustainable (Department For International Development, 1999). The sustainable livelihood approach is being widely used by government agencies and NGOs to foster development both in urban and rural settings (e.g., Chambers, 1995; Hoon et al., 1997; Devereux, 2001; Scoones, 2009). It is now applied to disaster risk reduction and post-disaster recovery (e.g., Sanderson, 2000; Twigg, 2001; Cannon, 2003; Cannon et al., 2003; Wisner et al., 2004; Kelman and Mather, 2008).

Reinforcing livelihoods to reduce disaster risks required both action from the bottom up and measures from the top down. Bottom-up actions refers to community-based disaster risk reduction or CBDRR. CBDRR spurs the participation of local communities in the assessment and reduction of disaster risk in links with their daily livelihoods (e.g., Anderson and Woodrow, 1989; Maskrey, 1989). On the other hand, top-down actions from national authorities and international institutions should facilitate people's access to a large range of resources to reinforce their livelihoods, including those resources which would protect these livelihoods from the harm of natural hazards. Such actions necessitate a political will and commitment on the side of the governments to blend development policies with disaster risk reduction. Focusing on livelihoods in disaster risk reduction and development is a long-term investment as it enables to equally address poverty and vulnerability and locate both within the context of everyday life. The two approaches mutually benefit from each other as development contributes to reducing vulnerability and vulnerability reduction participates in the reinforcement of livelihoods.

LOESS

János Kovács, György Varga
University of Pécs, Pécs, Hungary

Synonyms

Bluff formation (Mississippi Valley region); Lehm (Alsace, France); Löss (Germany)

Definition

Loess is a homogeneous, typically nonstratified, porous, friable, slightly coherent, often calcareous, fine-grained, silty, pale yellow or buff, windblown (aeolian) sediment.

Loess consists mainly of quartz particles predominantly of silt with subordinate grain sizes ranging from clay to fine sand (Muhs and Bettis, 2003; Pye, 1995; Smalley, 1975). It generally occurs as a widespread blanket deposit that covers areas of hundreds of square kilometers and tens of meters thick. Loess covers areas extending from north-central Europe to eastern China as well as the Mississippi Valley and Pacific Northwest of the USA; and the Pampas in South America (Muhs and Bettis, 2003). Loess is

generally buff to light yellow or yellowish brown, often contains shells, bones, and teeth of mammals, and is traversed by networks of small narrow vertical tubes (frequently lined with calcium-carbonate concretions) left by successive generations of grass roots, which allow the loess to stand in steep or nearly vertical faces (Smalley et al., 2001). Loess is now generally believed to be wind-blown dust of Pleistocene age carried from desert surfaces, alluvial valleys, and outwash plains, or from unconsolidated glacial or glaciofluvial deposits uncovered by successive glacial recessions but prior to invasion by a vegetation mat (Muhs and Bettis, 2003; Smalley et al., 2001). The mineral grains composed mostly of quartz and associated heavy minerals, feldspars, and clay minerals are fresh and angular, and are generally held together by calcareous cement. In some regions, for example, Moravia, Tajikistan, and China, more than ten successive loess formations are separated by red to dark brown paleosols. Etymology: German Löss, from dialectal (Switzerland) lösch, "loose," so named by peasants and brick workers along the Rhine valley where the deposit was first recognized.

Because the grains are angular, with little polishing or rounding, loess will often stand in banks for many years without slumping (Smalley and Derbyshire, 1991). The thickness of collapsible loess is as much as 20 m in the loess terrains worldwide. Dry loess can sustain nearly vertical slopes, being perennially undersaturated. However, when locally saturated, it disaggregates instantaneously. Such hydrocompaction is a key process in many slope failures, made worse by an underlying terrain of low-porosity rocks. Gully erosion of loess may yield very high sediment concentrations. Characteristic vertical jointing in loess influences the hydrology. Enlarged joints develop into natural subsurface piping systems (subsidence), which following collapse produce a "loess karst" terrain. Foundation collapse and cracked walls are common, many rapid events following periods of unusually heavy rain. Slope failure is a major engineering problem in thick loess terrain, flow-slide and spread types being common (Derbyshire, 2001). The results are often devastating in both urban and rural areas. An associated hazard is the damming of streams by landslides.

MACROSEISMIC SURVEY

Roger M. W. Musson
British Geological Survey, Edinburgh, UK

Definition

The term "macroseismic survey" refers to the process of gathering information on how strongly an earthquake was felt in different places.

Discussion

It has long been standard practice in earthquake investigation to gather information on the distribution of effects of any recent earthquake. Indeed, before the introduction of reliable seismometers, this was really the only way to study an earthquake. Generally, the results of such a study are presented as a map of intensity, often contoured as isoseismals. A macroseismic survey generally comprises two parts. The most heavily damaged area needs to be examined firsthand, and the damage to individual buildings recorded. This task ideally should be conducted in collaboration with engineers qualified to assess the original strength of the damaged buildings. This is referred to as a field investigation of the earthquake. Data collection for the wider felt area of the earthquake, at non-damaging intensities, is usually done via questionnaires. Various strategies for the dissemination of questionnaires have been practiced in the past, including appeals for information published in newspapers, sending questionnaires to local officials, and maintaining a network of volunteer observers who can be relied on to fill in details after an earthquake has occurred. Today, the dominant method of collecting questionnaire data is over the internet. After even a moderate-sized event in a populated area, tens of thousands of responses can be collected very quickly via an institute's web site, and these can then be processed in real time using an automatic intensity assessment algorithm. This also has the great advantage that the results of the survey are visible immediately on the web site, rather than appearing only in a journal paper or bulletin some months later, and this is an excellent method of conveying seismological data to the general public in a timely and informative way.

Definition

Magma is liquid or molten "rock."

Discussion

Magma is liquid rock which is a fluid comprised of a mixture of crystals and gas. When solidified it becomes an igneous rock. It is magma when below ground and lava when above ground. The chemical composition of magma/lava plays a major role in determining eruption characteristics and the hazard potential of a volcano. Magmas vary in composition dependent on a number of factors, in particular their plate tectonic affinity (Perfit and Davidson, 2000). Basaltic magmas are common along ocean ridges, hot spots, and continental plateaus. Magmas with higher silica contents (Andesite, Dacite, and Rhyolite) are common along subduction zones and intra-plate tectonic settings. The composition, along with crystal and gas content, controls the viscosity, temperature, and explosivity of the magma. Composition combined with pressure dictates the proportions of liquid, gases, and solids. These proportions have a strong controlling influence on the style of eruption. Basaltic (or mafic) lavas have low viscosity and are the least explosive, except in certain circumstances where there is interaction with water. As magma increases in silica content (referred to as felsic or sometimes siliceous magmas [reflecting high silica content], for example, Gillespie and Styles, 1999; Rogers and Hawkesworth, 2000; Thorpe and Brown, 1993), the explosivity tends to go up because the rise in silica creates an attendant rise in viscosity. As the magma rises to the surface (and as it crystallizes with lowering temperatures, exsolving fluids), the fluid phase (dominated by H_2O and CO_2) within the magma begins to exert pressure on the liquid phase. The exsolving bubbles, expanding as the magma rises, combined with growing crystals, increase the pressures within the magma (Scandone et al., 2007), causing a decrease in the density of the melt resulting in more rapid rise. The culmination of the ascent, high fluid pressures, and high viscosity magmas is an explosive eruption, common at stratovolcanoes. High silica, low fluid pressure magmas flow sluggishly with little or no explosive activity. Such magmas often "stall" at high crustal levels forming small stocks or sills, or larger plutons. If they egress to the surface, they flow only with great difficulty, forming domes or flow domes.

Earthquake measure; Earthquake severity; Earthquake size; Magnitude scale

Definition

Magnitude Measures. A variety of scales and calculations to measure, characterise and catalogue the size of an earthquake in terms of the seismic waves generated and energy released by the event.

Introduction

The size and damaging effects or severity of an earthquake are described by measurements of both magnitude and intensity. The quantification of the size of an earthquake has been considered by seismologists for many decades. A variety of different measures have been produced to estimate and report the magnitude of a seismic event. Many attempts have been made to develop a uniform scale to measure earthquake magnitude (Kanamori, 1983) but this goal has not always been achievable due to the changes in instrumentation used over time, changes in seismic data processing techniques as well as developments in the distribution of seismic monitoring stations. As a result of these influences a variety of *magnitude scales/measures* have been developed and reported which have been used at various times and locations around the world. As the science of earthquakes (seismology) has developed further advances have been made in the quantification of a seismic event. In order to provide a historical continuity of the measurements made relationships needed to be developed between the various earthquake size measuring schemes. As earthquakes are the result of complex geophysical processes it is not a simple matter to find a single measure of the size of an earthquake (Kanamori, 1978).

There are two fundamental parameters that can be used to describe the size of an earthquake. The *magnitude* of a seismic event characterises the relative size of the earthquake. It can be considered as a measure of the amount of energy released during the seismic event. For each earthquake there is only one magnitude. The *intensity* of a seismic event describes the severity of the earthquake in terms of the physicals effects on the ground, people and buildings in the area affected. For each earthquake there are many intensities depending on the location and distance from the epicentre, underlying geology, types and styles of buildings and structures present in the affected zone.

Magnitude is a logarithmic measure of the size of an earthquake based on instrumental data (Bormann et al., 2002). The measurement of magnitude is based on the amplitude of the resulting seismic waves recorded on a seismogram once the amplitudes are corrected for the decrease with distance due to geometric spreading and attenuation (Stein and Wysession, 2003).

Seismic waves

The fault rupturing process that takes place during an earthquake generates elastic waves within the earth which propagate away from the rupture front. Different types of seismic waves are generated each with different velocities and travel paths. Two fundamental types of waves are created; compressional, longitudinal waves and shear, transverse waves. The fastest P or Primary Waves travel through the body of the earth together with the slower S or Secondary Shear Waves. At the surface of the earth these two types of motion can combine to form complex surface waves. These surface waves have much higher amplitudes than the P and S waves and are therefore much more destructive as their energy is concentrated near the earth's surface. Such surface waves can be further subdivided into Rayleigh or Love Waves which both have longer periods and arrive after the P and S waves on the seismogram. Rayleigh Waves have an elliptical motion similar to that of water waves whereas Love Waves have a motion that is horizontal and perpendicular to the direction of propagation. Near the earthquake epicentre the largest recorded wave is the short period S Wave. At greater distances the longer period Surface Waves become dominant. The various magnitude scales set out to measure the fundamental properties of these different waves in order to estimate the magnitude of the seismic event.

Quantification of earthquake size

Earthquakes can be quantified with respect to various physical properties of the source site. These include the length of the fault that ruptures, the area of the fault, the fault displacement, particle velocity and acceleration of the fault motion, duration of faulting, amount of radiated energy as well as the complexity of the fault motion (Kanamori, 1983). It is not possible to represent all of these parameters by a single number such as the magnitude of the earthquake but the magnitude of a seismic event does have value in allowing an initial analysis and cataloguing of an earthquake to be undertaken.

The majority of *magnitude measure* scales that are in use are empirical in nature. A magnitude M is determined from the amplitude A and period T of the various seismic waves detected by a seismometer, recorded by a seismograph on a seismogram. The formulas used to derive an estimate of the earthquake magnitude contain constraints such that magnitude value scales can be correlated over a certain magnitude range (Kanamori, 1983).

The first widely used *magnitude measure* or scale was developed by Charles Richter in 1935 (Richter, 1935). This work was further developed with Beno Gutenberg in 1945 (Gutenberg, 1945a). Initially the magnitude scale was calculated on the maximum amplitude of the largest waveform detected from the seismic event. Subsequently the use of surface waves was included and then measurements of the body wave. Since this initial work many other magnitude scales have been developed for both local and global application utilising differing aspects of the seismic signal generated during an earthquake.

In order to overcome some of the localised issues of the early magnitude scales and their inability to differentiate larger magnitude earthquakes, a magnitude measure was developed that was based on a key seismic parameter, the Seismic Moment. The Seismic Moment is related to some of the key physical parameters of the fault which has ruptured during the seismic event. This Seismic Moment has been incorporated into a Moment Magnitude Scale (M_W) by considering the seismic energy radiated during the earthquake. The Moment Magnitude Scale is now the most frequently quoted scale in describing the size of an earthquake along with the corresponding Seismic Moment of the event.

Seismic moment

One of the major advances in the development of magnitude scales was the concept of 'seismic moment' (Kanamori, 1978). The Seismic Moment is considered to be the most accurate and comparable measure of an earthquake and can be considered as a measure of the irreversible inelastic deformation in the fault rupture area (Kanamori, 1977). The measure is completely independent of the type of seismograph used to record the seismic event. The Seismic Moment is a parameter that measures the overall deformation at the source of the seismic event (Kanamori, 1977). It has an important bearing on global phenomena such as tectonic plate motion, polar motion and on the rotation of the earth. The Seismic Moment can be interpreted in terms of the strain energy released in an earthquake. It measures the amount of energy released rather than the size of the seismic waves which are affected by the depth of the event and the geology of the rocks that the waves pass through. The Seismic Moment is related to the final static displacement after the earthquake. The Seismic Moment M_0 is defined thus:

$$M_0 = \mu \bar{D} A \quad (1)$$

Where:

M_0 = *Seismic moment* (*measured in* dyn. cm *or* N.m)

μ = *Rigidity or shear modulus of the rock at the source* (*fault*) *depth*

$\bar{D}$ = *Average slip or displacement on the fault after rupture*

A = *Surface area of the fault rupture zone*

It is termed Seismic Moment as Area × Stress gives a Force, and Force × Distance gives a Moment.

Seismic energy

Conventionally the energy E released by an earthquake has been estimated via the magnitude – energy relationship developed by Gutenberg and Richter (Gutenberg, 1956):

$$Log\, E_S = 1.5\, M_S + 11.8\, (E_S\, in\, \text{Ergs}) \quad (2)$$

$$Log\, E_S = 2.45\, m_B + 5.8\, (E_S\, in\ \text{Ergs}) \quad (3)$$

These equations hold well for most earthquakes but tend to underestimate for very large earthquakes which have a fault rupture length of 100 km or greater. Kanamori (1977, 1994) considered the change in strain energy during a seismic event with a fault rupturing. He stated that if the stress drop during an earthquake is complete the following equation holds:

$$E_S \approx \frac{\Delta\sigma}{2\mu} M_O \quad (4)$$

Where:

E_S = *Seismic energy radiated by the seismic source as seismic waves*

M_O = *Seismic Moment*

$\Delta\sigma$ = *Stress drop*

μ = *Rigidity or shear modulus of the rock at the source (fault) depth*

The relationship between the slip or displacement in an earthquake, its fault dimensions and its Seismic Moment is closely tied to the magnitude of the stress released by the earthquake. This is known as the stress drop, the difference between the stress before and after fault rupture. The earthquake releases the strain energy that has accumulated over time around the fault area (Stein and Wysession, 2003). The stress drop, averaged over the fault can be approximated:

$$\Delta\sigma \approx \frac{\mu \bar{D}}{L} \quad (5)$$

Where:

$\bar{D}$ = *Average slip or displacement on the fault after rupture*

L = *Fault characteristic dimension of the fault rupture*

The average slip on the fault that ruptures can also be estimated from the Seismic Moment where:

$$\bar{D} \approx \frac{c\, M_0}{\mu\, L^2} \quad (6)$$

Where:

c = *Fault shape factor.*

The specific relationship and values of c depend on the fault shape and fault rupture direction. This allows the stress drop to be calculated for a variety of fault morphologies.

For a Circular Fault:

$$\Delta\sigma \approx \frac{7}{16} \frac{M_0}{R^3} \quad (7)$$

For a Rectangular Fault (Strike Slip):

$$\Delta\sigma \approx \frac{2}{\pi} \frac{M_0}{w^2 L} \quad (8)$$

For a Rectangular Fault (Dip Slip):

$$\Delta\sigma \approx \frac{8}{3\,\pi} \frac{M_0}{w^2 L} \quad (9)$$

Where:

R = *Fault radius*

W = *Fault width*

Kanamori (1983) stated that by utilising the relationship between Seismic Moment and seismic wave energy the energy can be estimated thus:

$$E_S \approx \frac{M_O}{2\,x\,10^4} \;\; as \;\; \frac{\Delta\sigma}{\mu} \sim 10^{-4} \quad (10)$$

The conventional magnitude scales discussed in detail elsewhere are said to saturate when the rupture dimensions of the earthquake exceeds the wavelength of the seismic waves used for the magnitude determination, usually between 5 and 50 km (Kanamori, 1977). This saturation leads to an inaccurate estimate of the energy released in very large earthquakes. The energy can however be estimated from the calculated Seismic Moment as it is possible to correlate the seismic energy with the Moment Magnitude, M_w:

$$E_S \approx \frac{M_O}{2\,x\,10^4} \quad (11)$$

$$Log\, E_S = Log\, (M_0) - 4.3 \quad (12)$$

And:

$$M_W = \frac{2}{3}\, Log\, M_0 - 10.7 \quad (13)$$

So:

$$M_W = \frac{2}{3}\, Log\, (E_S.20000) - 10.7 \quad (14)$$

$$Log\, (E_S) = \frac{3}{2}\, M_W + 11.8\, (E_S\, in\ \text{ergs}) \quad (15)$$

To illustrate that Seismic Moment and seismic energy are different, Seismic Moment is quoted in dyn.cm (CGS units) or N.m (SI units) and seismic energy in Erg (CGS) or Joules (SI), even though the units are equivalent (Stein and Wysession, 2003). 1 erg = 1 dyn.cm and 1 erg = 10^{-7} J. The radiated energy is only $1/2 \times 10^4$ or 0.00005 of the Seismic Moment released. This is because the Seismic Moment is not energy per se but is related to the stress change over the earthquake source region which gives the Seismic Moment dimensions of dyn.cm:

$$\frac{dyn}{cm} \cdot cm^3 = dyn.cm \tag{16}$$

Note however that E_S is not the total energy released by an earthquake. It is only the estimated amount of energy radiated as seismic waves. Other energy is released as gravitational, frictional or heat energy. E_S only represents this small fraction of the total energy release during a seismic event.

Moment magnitude scale, M_W

The key concept of Seismic Moment led to the development of a Moment Magnitude Scale, M_W (Hanks and Kanamori, 1979) which more closely relates the measure of size to the tectonic effects of an earthquake. Traditional *magnitude measure* scales, discussed elsewhere, are said to saturate at large magnitudes leading to considerable underestimation of the size of very large earthquakes. These magnitude scales tend to only measure the localised failure along the crustal fault zone rather than the gross wide scale fault characteristics (Hanks and Kanamori, 1979). In order to represent the size of an earthquake as a dislocation phenomenon along a fault the Seismic Moment M_0 is considered to be the most adequate measure (Utsu, 2002). It is the most fundamental parameter that can be used to measure the strength of an earthquake caused by fault slip.

Kanamori (1977) compared the earthquake energy-moment relationship with the magnitude-energy relationship developed by Gutenberg and Richter (Gutenberg, 1956) where E_S is expressed in ergs and M_0 in dyne.cm:

$$E_S = \frac{\Delta\sigma}{2\mu} M_O \tag{17}$$

$$Log\, E_S = 1.5\, M_S + 11.8 \tag{18}$$

As $\Delta\sigma/\mu \approx 10^{-4}$ (Kanamori, 1983):

$$Log\, M_0 = 1.5\, M_S + 16.1 \tag{19}$$

As has been stated previously M_S values saturate for great earthquakes with $M_0 > 10^{29}$ dyn.cm or more such that Eqs. 2 and 3 do not hold for such large earthquakes. Kanamori (1977) and Hanks and Kanamori (1979) proposed a new Moment Magnitude Scale, M_W which overcame these issues of saturation by the incorporation of the calculated Seismic Moment:

$$M_W = \frac{2}{3}\, Log\, M_0 - 10.7\ (M_0\ in\ \text{dyn.cm}) \tag{20}$$

$$M_W = \frac{2}{3}\, Log\, M_0 - 6.1\ (M_0\ in\ \text{N.m}) \tag{21}$$

The Seismic Moment does not saturate. For example the Great Alaskan Earthquake of 1964 was recorded as $M_S = 8.4$ whereas on the Moment Magnitude Scale as $M_W = 9.2$.

Other significant magnitude scales

Magnitude scales general form

When attempting to estimate the magnitude of a seismic event the amplitude of the seismic wave is used to determine the earthquake size once the amplitudes have been corrected for the decrease with distance from the epicentre due to geometric spread and attenuation. *Magnitudes scales* thus have the following general form:

$$M = Log\, \frac{A}{T} + F(\Delta, h) + C_S + C_R \tag{22}$$

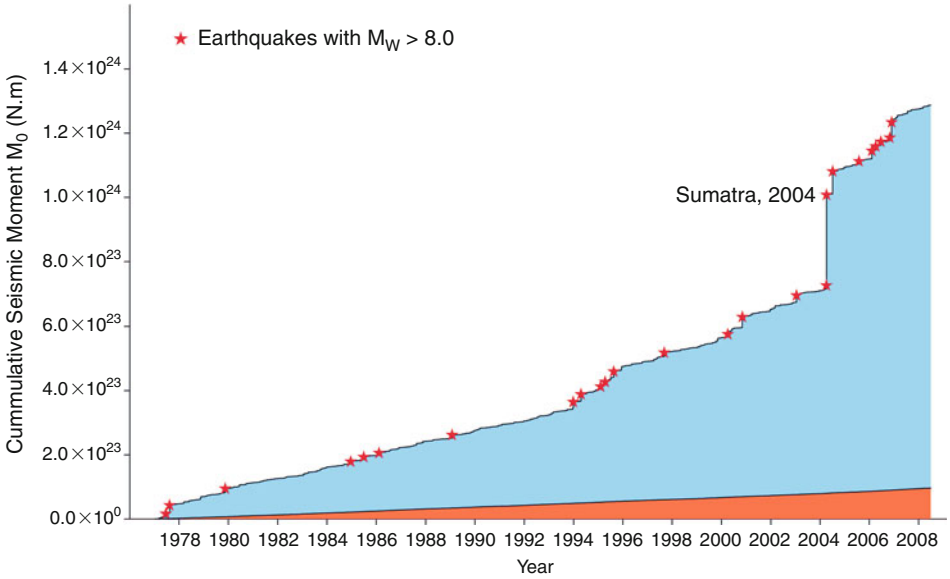
Where:

M = Estimated magnitude of earthquake

A = Amplitude of the signal recorded on the seismogram

T = Dominant period of the signal recorded on the seismogram

F (Δ, h) = A calibration function used for the correction of the variation of amplitude with the earthquakes depth (h) and distance in degrees or kilometres (Δ) from the epicentre to the seismometer recording station



C_S = *Station correction factor*

C_R = *Region correction factor*

Magnitude measurements scales are thus logarithmic in nature. A unit increase in magnitude will correspond to a 10-fold increase in seismic wave amplitude and a 32-fold increase in associated seismic energy. Various scales have been developed for local or teleseismic (distant) events. Distance measurements for local events are usually quoted in kilometres and in degrees for more distant events (1° = 111.19 km).

Local wave magnitude scale, M_L

The earliest *magnitude measurement* scale was introduced by Charles Richter in 1935 to assess the size of earthquakes occurring in Southern California (Richter, 1935). He developed a *local* magnitude scale (M_L) which is often referred to as the 'Richter Scale'. The magnitude of the earthquake was calculated from the amplitude of the seismic waves measured on a specific seismograph, the Wood Anderson Torsion Instrument. Equation 23 details the formula used along with calibration charts to calculate M_L. This equation is only applicable to shallow earthquakes measured in Southern California occurring within 600 km of the Wood Anderson instrument. Richter's original magnitude scale was further developed in 1945 by

Magnitude Measures, Figure 1 Cumulative moment of all earthquakes in the Harvard University CMT catalogue from the Global Seismographic Network between 1977 and 2009. The field shaded light blue reflects the cumulative moment of earthquakes with $M_W \geq 6.5$. The field shaded *orange* reflects the cumulative moment of earthquakes with $M_W \geq 5.0$ to < 6.5. *Red stars* indicate the dates of earthquakes with $M_W \geq 8.0$. The contribution of the December 2004 Sumatra earthquake to the total cumulative moment is the largest step in the curve.

Gutenberg (Gutenberg, 1945a) to include seismic events of any epicentral distance from the recording station and for deeper focal depths as well as not being dependant on the type of seismograph used to record the event. A further two magnitude scales were developed from this early work, one dealing with *surface waves*, M_S, and another with *body waves*, M_B, (seismic waves that travel into and through the body of the Earth). Richter magnitudes in their original form are no longer quoted as most earthquakes do not occur in California and today Wood Anderson seismographs are rare (Stein and Wysession, 2003). M_L is a good indication of the structural damage that an earthquake can cause due to the recording frequency of the Wood Anderson seismograph being close to the resonant frequency (the frequency most likely to cause damage) of many buildings at around 1 Hz.

$$M_L = Log\, A_{Max} - Log\, A_0(Richter,\ 1935) \qquad (23)$$

To allow for possible local recording station effects (Hutton and Boore, 1987; Boore, 1989) a 'station term' is introduced:

$$M_L = Log\, A + 2.76\, Log\, \Delta - 2.48$$

Where:

A_{Max} = *Peak motion on a specific instrument (Wood Anderson seismograph)*

A_0 = *curve correction factor for the effect of distance, tabulated in Richter (1958)*

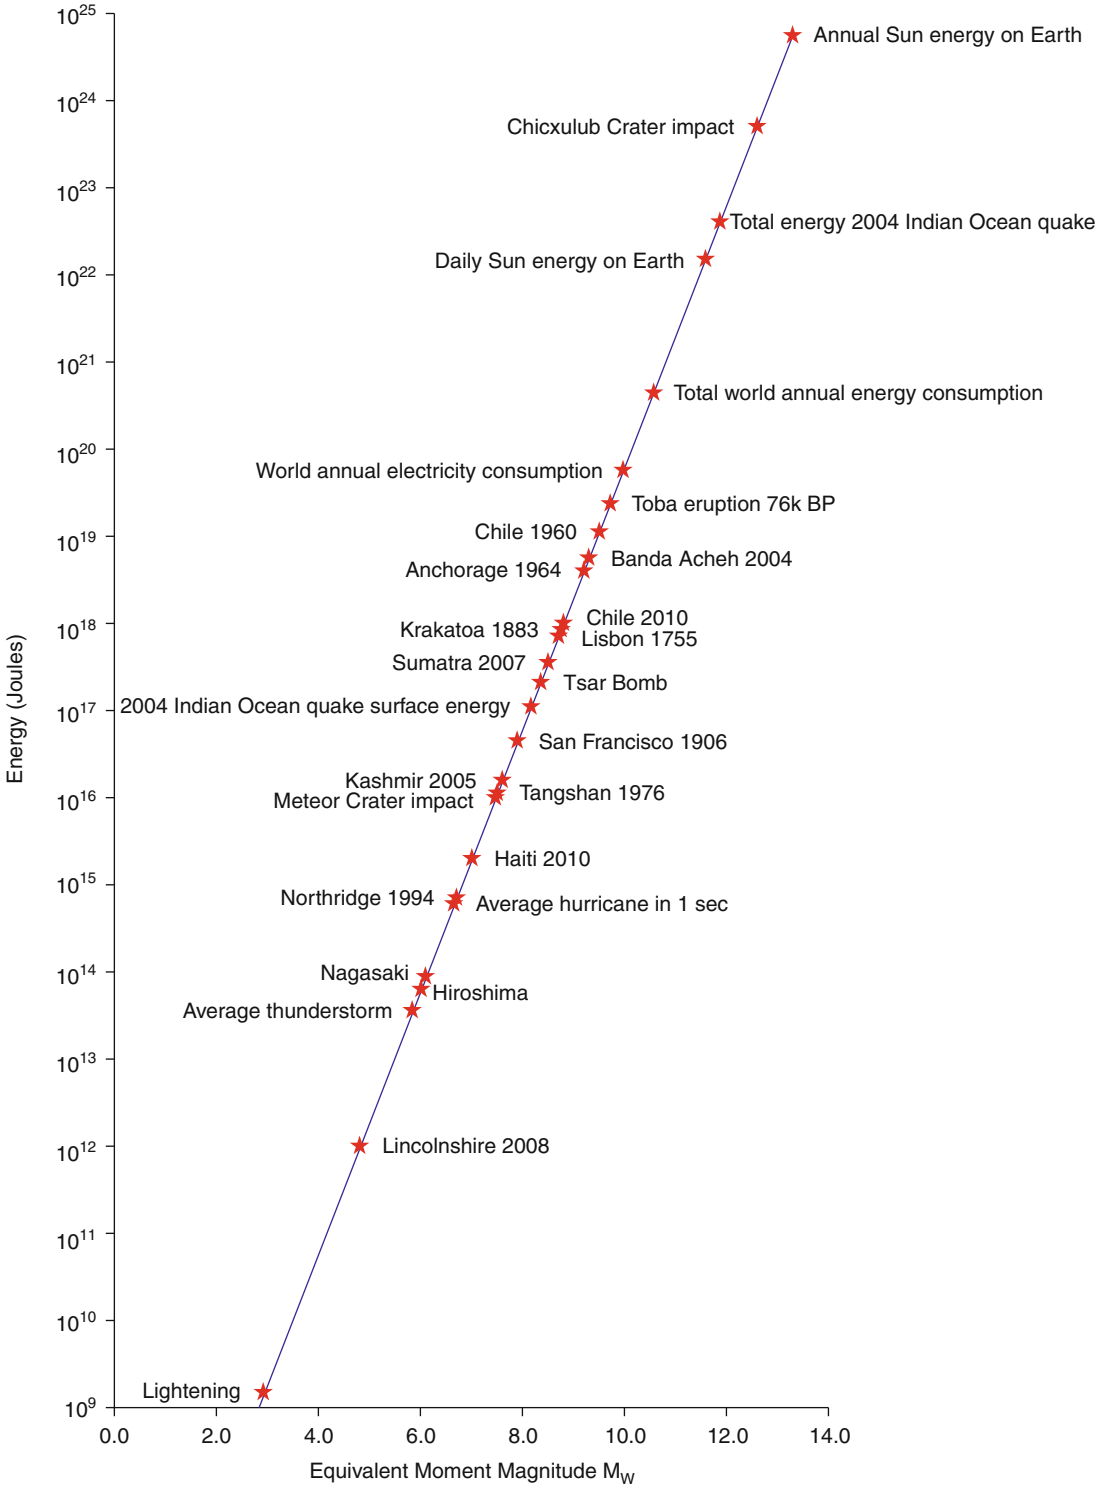
These correction factors are only truly valid for southern California. Other site specific correction factors have been developed for other 'local scales' around the world. In the UK the British Geological Survey uses the Hutton and Boore (1987) distance correction factor when estimating M_L for local UK earthquakes (Booth, 2007).

Surface wave magnitude scale, M_S

The M_S scale (Gutenberg, 1945a) use the amplitude of the surface seismic waves for earthquakes that are located between 2° and 160° epicentral distance from the recording station, with wave periods between 18 and 22 s and where the epicentre depth is less than 50 km. This scale will saturate at $M_S \geq 8$. A significant step in the development of the M_S scale was the publication of what was termed the Moscow-Prague Formula (Karnik et al., 1962). For shallow earthquakes where surface waves are generated, the magnitude of the event can be derived thus:

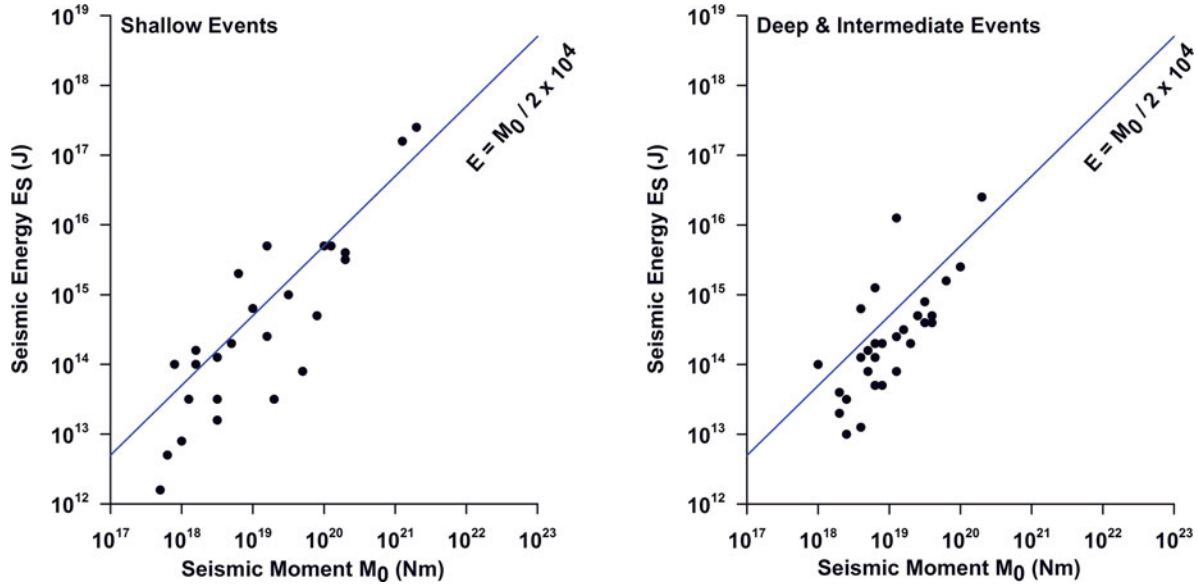
$$M_S = Log\, \frac{A}{T} + 1.66\, Log\, \Delta + 3.3 \qquad (24)$$

Where:



A = *Maximum amplitude of the Rayleigh Wave*

Δ = *Distance in degrees between* 2° *and* 160°, $h \geq$ 50 km



Alternatively M_S can be calculated from the Rayleigh Waves with a period of 20 s, wave forms which often have the largest amplitude (Stein and Wysession, 2003):

$$M_S = Log\, A_{20} + 1.66\, Log\, \Delta + 2.0 \qquad (25)$$

The Surface Wave Scale has sometimes been referred to as the Rayleigh Wave Scale (Marshall and Basham, 1973).

Magnitude Measures, Figure 2 A graph illustrating the equivalent Moment Magnitude M_W with respect to energy released by earthquakes and other phenomena.

Magnitude Measures, Figure 3 Relationship between seismic moment M_0 and energy E_S for shallow events and intermediate to deep events according to Vassiliou and Kanamori (1982). The *solid line* indicates the relation $E_S = M_0//(2 \times 10^4)$ suggested by Kanamori (1977) on the basis of elastostatic considerations (Modified from Kanamori, 1983).

Body wave magnitude scale, m_B and M_B

In 1945 Gutenberg (1945b) utilised the seismic body waves to determine a Body Wave Magnitude which is used for earthquakes measured at distances greater than 600 km from the source:

$$M_B = Log\,\frac{A}{T} + F_{Old}\,(\Delta, h) + s + c \tag{26}$$

Where:

A = *maximum amplitude of the various body wave phases of the generated seismic waves*

F_{Old} = *distance correction factor*

s, c = s is the station correction and c is a correction only applied to large earthquakes (*Abe*, 1981)

Gutenberg and Richter (1956, 2010) later revised the scale (m_B) by improving the distance function F and omitting the correction factor for large earthquakes:

$$m_B = Log\frac{A}{T} + F(\Delta, h) + s \tag{27}$$

In the m_B scale magnitude values are compiled from the seismic wave period $\geq$0.1 and $\leq$3.0 s and where the epicentral distance is $\geq 5^\circ$. This scale represents the size of an earthquake at its beginning. The usefulness of this scale for earthquakes with large fault dimensions and complex rupture mechanisms is limited (Kanamori, 1983). For relatively small events ($m_B \leq 5.5$) the scale is useful for the quantification of earthquakes at short wavelength periods.

Energy magnitude scale, M_e

From a study of the energy radiated from a set of global shallow earthquakes Choy and Boatwright (1995) defined an Energy Magnitude, M_e:

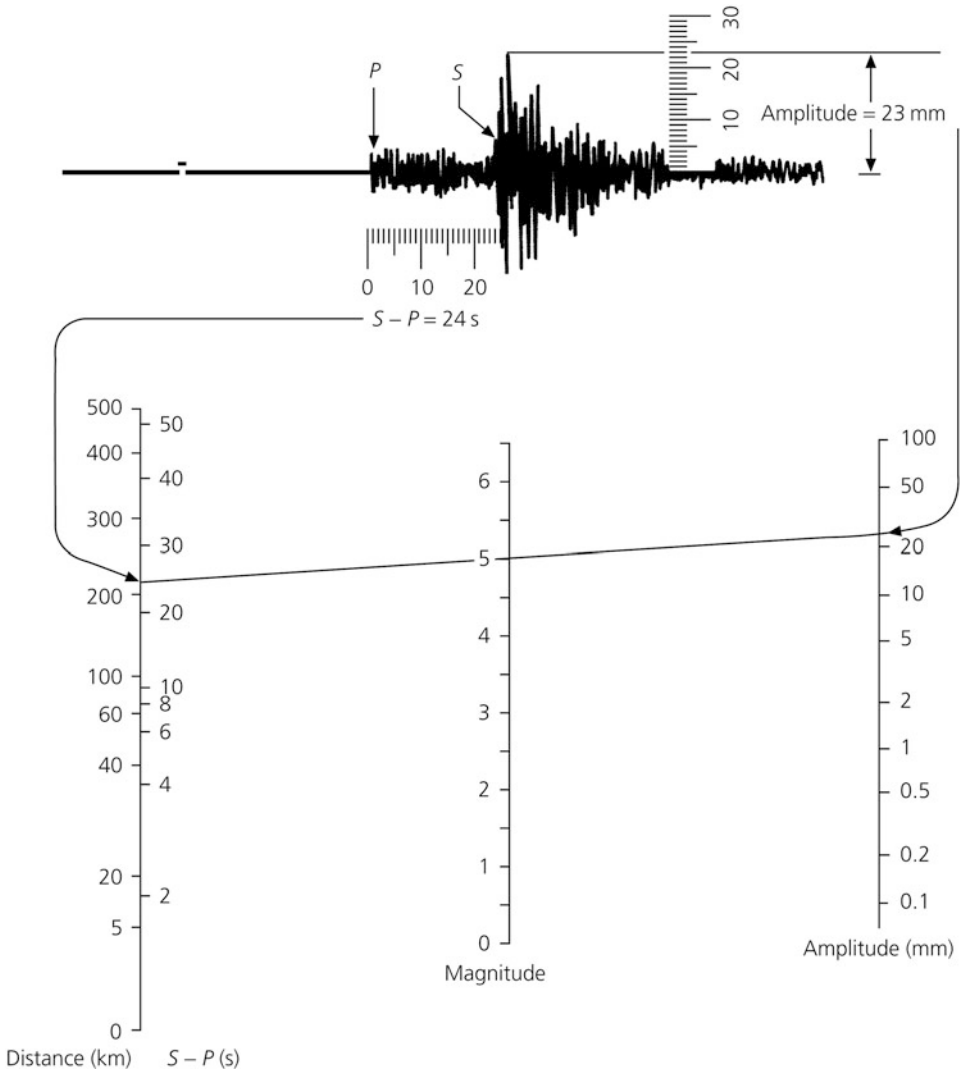
$$Log\,E_S = 4.4 + 1.5\,M_e \tag{28}$$

Or

$$M_e = \frac{2}{3} Log\,E_S - 2.9 \tag{29}$$

Where:

E_S = *Radiated energy* (N.m)



M_e is explicitly derived from energy whereas in the Gutenberg – Richter energy relationship (Eqs. 2 and 3) energy is derived from magnitude (Choy et al., 2001). The energy magnitude is complimentary to Moment Magnitude for assessing seismic potential. The energy E_s and Seismic Moment M_0 are related by the *apparent stress* if the increase in the Seismic Moment is a function of the dominant period of the data analysed but not the instrument or wave type (Boatwright and Choy, 1986):

$$\tau_a = \frac{\mu\, E_S}{M_0} \tag{30}$$

Where:

τ_a = *Average apparent stress*

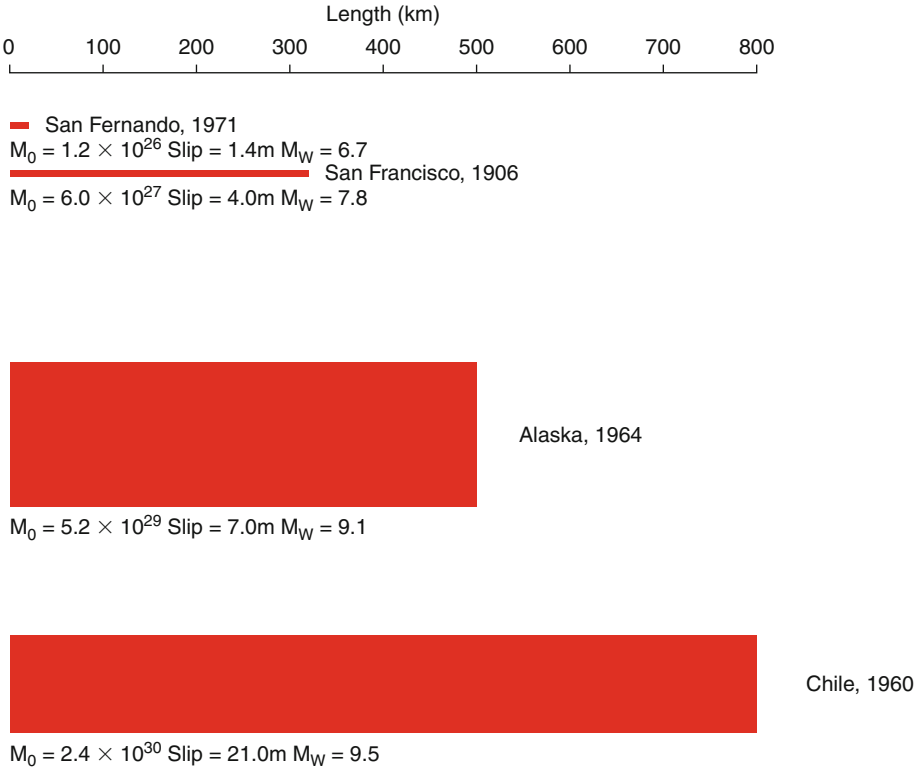
μ = *Rigidity or shear modulus of the rock at the source* (*fault*)*depth*

Magnitude Measures, Figure 4 The Richter local magnitude scale, M_L. The magnitude is found from the amplitude of the largest arrival and the S-P wave travel time difference (After Stein and Wysession, 2003; Bolt, 2006).

The apparent stress can also be a good indicator of the intensity of the seismic energy radiated relative to the size of the earthquake event as measured by the Seismic Moment. It is possible to estimate radiated energy from historical earthquakes. Choy and Boatwright (1995) demonstrated that in many seismic regions the average apparent stress τ_a can be regarded as the characteristic apparent stress field τ_c of the region such that:

$$M_e = \frac{2}{3}\left[Log\, M_0 + Log\, \frac{\tau_c}{\mu}\right] - 2.9 \qquad (31)$$

Where:



τ_c = *Characteristic apparent stress field*

This equation enables M_e and E_s to be estimated for an historical earthquake in a given tectonic setting and for a specific faulting type if the Seismic Moment is known (Choy et al., 2001).

Duration magnitude scale, M_D

This estimate of earthquake magnitude is derived from the duration of earthquake shaking or what is termed the coda length. The coda is the tail of a seismic signal, usually with exponentially decaying amplitudes which follow a strong wave arrival. The formulas used to derive M_D estimates vary for different geographical regions and for different seismographs. Duration Magnitude formulae have the following general form (Herrmann, 1975):

$$M_D = a_0 + a_1\, Log\, d + a_2\, \Delta \qquad (32)$$

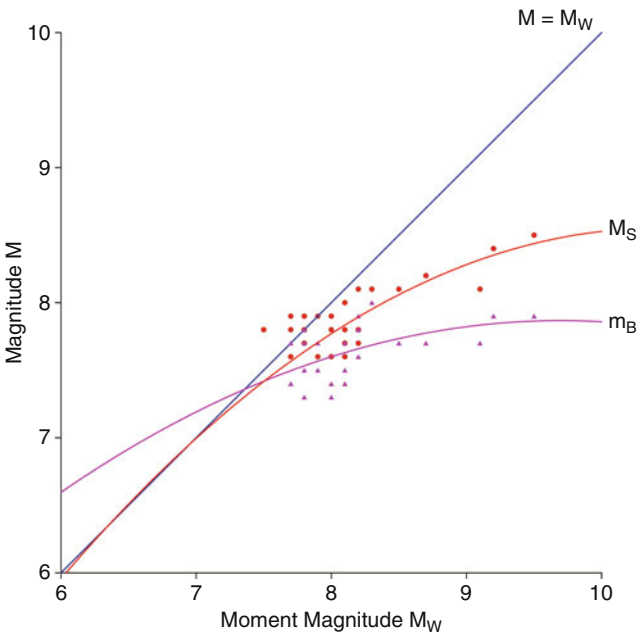
Magnitude Measures, Figure 5 Comparison of the magnitude of some significant earthquakes (After Stein and Wysession, 2003).

Where:

d = *Event duration* (*seconds*)

a_0, a_1, a_2 = *Site specific coefficients*

Aki and Chouet (1975) demonstrated that for earthquakes at epicentral distances shorter than 100 km the total duration of a seismogram is almost independent of distance and azimuth. Thus quick magnitude estimates from local events are feasible without knowing the exact distance of the stations to the source with the removal of the distance term from the equation. For example the Northern California Seismic Network calculates M_D thus (Lee et al., 1972):



$$M_D = 2.00\,Log\,d + 0.0035\,\Delta - 0.87 \qquad (33)$$

The scale can seriously underestimate magnitudes for events $M_L > 3.5$.

Nuttli magnitude scale, M_N

The M_N scale developed by Nuttli (1973) has been used in eastern North America and in particular Canada. The scale is based on the maximum amplitude of the Rayleigh surface waves for a frequency of 1 Hz:

$$M_N = Log\,\frac{A}{KT} + 1.66\,Log\,R - 0.1 \qquad (34)$$

Magnitude Measures, Figure 6 Relationship between magnitude scales illustrating saturation at higher magnitudes (Data from Abe and Kanamori, 1980; Kanamori, 1983).

Magnitude Measures, Table 1 Summary of various magnitude measurement scales

Symbol	Magnitude scale	Reference/source
M_L	Local magnitude	Richter (1935)
M_S	Surface wave magnitude	Gutenberg (1945a), Moscow-Prague formula (Karnik et al., 1962)
M_B	Body wave magnitude	Gutenberg (1945b) and Gutenberg and Richter (1956, 2010)
m_B	Body wave magnitude	Gutenberg and Richter (1956, 2010)
M_D	Duration magnitude	Herrmann (1975)
M_E	Energy magnitude	Choy and Boatwright (1995) and Aki and Chouet (1975)
M_N	Nuttli magnitude	Nuttli (1973)
M_{JMA}	Japan Meteorological Agency magnitude	Magnitude used by Japan Meteorological Agency
M_W	Moment magnitude	Hanks and Kanamori (1979)
M_{GR}	Gutenberg-Richter magnitude	Magnitude used in *Seismicity of the Earth*, Gutenberg and Richter (1954)
M_R	Rothe magnitude	Magnitude used in *The Seismicity of the Earth, 1953–1965*, Rothe (1969)
$M_{S\ PDE}$	Surface wave magnitude	Magnitude used in USGS preliminary determinations of epicentres catalogue
$M_{S\ ISC}$	Surface wave magnitude	Magnitude used in International Seismological Centre catalogue
$m_{B\ PDE}$	Body wave magnitude	Magnitude used in USGS preliminary determinations of epicentres catalogue
$m_{B\ ISC}$	Body wave magnitude	Magnitude used in International Seismological Centre catalogue
M_T	Tsunami magnitude	Abe (1989)
M_K	Kawasumi's magnitude	Kawasumi (1951)
M_U	Utsu magnitude	Magnitudes for earthquakes in Japan, 1885–1925, Utsu (1982)
M_C	Large earthquake magnitude	Purcaru and Berckhemer (1978)
M_N	Mantle wave magnitude	Brune and Engen (1969)

Modified from Kanamori (1983) and Utsu (2002)

Magnitude Measures, Table 2 Source parameters for some significant earthquakes

Earthquake	Date	Body wave magnitude m_B	Surface wave magnitude M_S	Fault area Length × Width (km^2)	Average dislocation (m)	Seismic moment M_0 (dyn.cm)	Moment magnitude M_W
San Fernando	1971	6.2	6.6	20 × 14 = 280	1.4	1.2×10^{26}	6.7
Loma Prieta	1989	6.2	7.1	40 × 15 = 600	1.7	3.0×10^{26}	6.9
San Francisco	1906		8.2	320 × 15 = 4,800	4.0	6.0×10^{27}	7.8
Alaska	1964	6.2	8.4	500 × 300 = 150,000	7.0	5.2×10^{29}	9.1
Chile	1960		8.3	800 × 200 = 160,000	21.0	2.4×10^{30}	9.5

After Stein and Wysession (2003)

Where:

R = Epicentral distance
A = Wave amplitude
K = Amplitude of the seismogram
T = Natural period of the seismogram

The Nuttli Magnitude Scale is used for epicentral distances >50 km and for instruments with a natural period smaller than 1.3 s. The scale has been used in preference to M_W for small to moderate earthquakes as the Moment Magnitude Scale is more difficult to estimate these low magnitude events.

Magnitude of Japanese earthquakes, M_{JMA}

The Japanese Meteorological Agency (JMA) has estimated the magnitude of shallow Japanese earthquakes utilising the following formula (Tsuboi, 1954):

$$M_{JMA} = Log\,(A_N^2 + A_E^2) + 1.73\,Log\,\Delta - 0.83$$

Where:

AN, AE = Maximum ground amplitude measured on the N – S and E – W compoments of horizontal Wiechert seismographs in JMA recording stations.

For deeper focus earthquakes in and around Japan Katsumata (2001) proposed a magnitude determination utilising regional velocity-amplitude data.

Relationship between scales

The vast majority of magnitude scales in use today stem from the one introduced by Richter in 1935. This scale has been extended by many seismologists to apply to data produced by various observational environments (Utsu, 2002). As new scales were developed they were in principle to provide equal value estimates to the same earthquakes or to the same earthquakes which radiated equal amounts of energy. However, systematic bias exists in the newly created scales when compared to the original

Richter model. Studies have demonstrated that there are systematic differences between M_L, M_S and m_B. A variety of scale interrelationship curves have been produced on order to compare and correlate various described and catalogued magnitudes. Utsu (2002) and Kanamori (1983) undertook a much more detailed analysis of various intra scale relationships (Figures 1–6, Tables 1, 2).

MARGINALITY

Ben Wisner
Oberlin College, Oberlin, OH, USA
University College London, UK

Synonyms

Discrimination; Exclusion

Definition

Marginality is a socio-spatial process of great importance in understanding and combating vulnerability to natural hazards. It severely limits the political voice and participation, economic and livelihood options, access to resources and information, as well as locational decisions of sub-groups within society. Caste, class, religious minority, and immigration status are often underlying causes of marginality.

Discussion

Groups in society may live in places that are spatially peripheral to the majority or live in conditions that severely limit their participation in decisions that affect their lives as well as their access to resources and information. Such conditions are sometimes invisible to the majority. In a disaster, such groups often suffer greater death, injury, and economic loss (as a proportion of their already limited assets), and experience difficulty recovering. In 1978, Wisner used the term eco-demographic marginality to describe the situation of semi-pastoral people on the lower slopes of Mt. Kenya, who were politically powerless, lived in an environment undergoing degradation, and whose livelihoods depended on crops and animals of low and fluctuating value in the market. Blaikie and Brookfield (1987) adopted and subsequently expanded Wisner's notion of marginality.

Marginality is a concept with considerable utility in vulnerability assessment and planning for disaster risk reduction as well as recovery planning. Because it embraces numerous aspects of situations "on the edge," both professional planners and focus groups composed of lay people may use it to identify groups and situations that would normally not receive attention when policy, plans, and projects are focused on the needs and capabilities of the "average" person or household. Many methods such as wealth ranking exist that facilitate focus group discussion of marginality (ProVention, 2010), and this kind of situation-specificity is vital to effective project planning and programming (Wisner, 2004). It also provides understanding of what Chambers (1983) called the "deprivation trap," and thus may add a degree of reality to sometimes overly optimistic interventions that assume, for example, that everyone has time to volunteer in self-help activities or that every adult understands what it is to lobby government. Reasons for social marginality include caste, occupational, class status; religion and ethnicity; immigration status; disability; sexual orientation; and in some societies, gender and age. Political marginality may overlap with the social, but may also reflect favoritism practiced by ruling parties and historically developed center–periphery divisions of national territory. Economic marginality may be due to land and resource allocations and market dynamics that exclude or burden some, while benefiting others. However, as Perlman noted (1976), this does not imply that an economy is "dual" – a modern economy side by side with pre-modern. Indeed, in many places, marginal people are exploited for their cheap labor or commodities, and this is a reason why marginality persists and underlies much of what the United Nations (2009) has called "extensive risk" in the face of extreme natural events.

MARINE HAZARDS

Tore Jan Kvalstad
Norwegian Geotechnical Institute, Oslo, Norway

Synonyms

Offshore geohazards; Submarine hazards

Definition

Marine geohazard. Geological site and soil conditions in the ocean bottom representing a potential source of harm.

Introduction

Marine "geo*hazards*" (see entry *Geohazards*) are related to geological processes in the marine environment that have created regional or local site and soil conditions with a potential of developing into failure events that could cause loss of life or damage to health, environment, or assets. The failure events can be tectonic seabed displacements, seabed accelerations, and seabed instabilities ranging from local slumping to large-scale slope instability involving mass movement and debris flow and turbidity currents. Rapid, large-scale seabed displacements and downslope mass transport may generate tsunamis. Failure events where expulsion of gas, oil, water, and mud may flow uncontrolled from overpressured submarine reservoirs are often related to oil and gas production, but may also occur naturally through fractures and seeps to seabed and submarine mud volcanoes.

The event-triggering sources can be ongoing geological processes or human activities that change the seabed conditions or affects deeper strata mechanically or by pressure and temperature changes.

Marine hazards are of concern for the offshore petroleum industry with huge investments in wells, offshore structures, flowlines, and pipelines, but may also affect infrastructure related to telecommunications and electric energy transmission cables, the rapidly growing offshore wind power industry as well as fisheries. Also communities, industries, and infrastructure in the near-shore and shoreline area can be affected by submarine slide events reaching the shoreline, by earthquake or slide-generated tsunamis, and also by pollution from natural seeps and uncontrolled expulsion of oil.

Geological processes

Consideration of large-scale geological processes like "*plate tectonics*" and long-term climate changes are important for evaluation of marine "*hazards*." The major part of subduction zones where the oceanic crust is underthrusting continental plates is located in the oceans. This is where the most destructive earthquakes occur and the associated change in seabed level may generate tsunamis.

Long-term climate changes, especially during the last part of the Pleistocene, led to repeated "*sea level changes*" of more than 100 m. This affected the coastal zones and the continental shelves and margins on a global basis. Glacial erosion and transport of terrigenous sediments to the shelves and over the shelf edge by grounded glaciers to the continental slopes led to rapid progradation of the continental shelves along northern part of the Atlantic Ocean during glacial periods. The continental shelves and shallow water areas elsewhere were severely affected by changes in water depth and shoreline position, leading to wave, current, and river erosion and suspension of sediments. The finer fractions were transported seaward with tidal and wind-driven currents and the coarse grained sediments as hyperpycnal and turbid flows toward and locally over the shelf edge to the continental slopes.

Regional geological conditions and processes control the sedimentation rate, the thickness, and the type of marine sediments. The major river deltas of the world and the glacial fans on the margins along the North Atlantic and Arctic Seas are areas dominated by high sediment input that may lead to a combination of sloping seabed and overpressured sediments prone to slope instability and also representing a hazard for drilling operations for the petroleum industry. (In overpressured sediments, the ground water pressure is higher than hydrostatic pressures.)

Overpressures may also be generated by diagenetic changes of minerals under increased pressure and temperature transforming the mineral structure into a denser configuration under expulsion of excess water. Overpressured clayey sediments have generally lower strength, are less dense, and are more easily deformed than fully consolidated sediments.

Earthquakes

Major "*earthquakes*" originating in the oceanic subduction zones may generate enormous tsunami catastrophes like the December 26, 2004, Sumatra event (see entry *Tsunami*) and the March 11, 2011, Tohoku events in the west cost of Japan.

For marine structures and installations, the "*earthquake*" generated ground accelerations may cause damage in the same way as for buildings and structures on land. Severe earthquakes may also trigger submarine slope failures as the sediment strength can be reduced due to cyclic stress variations during the earthquake shaking. In a worst-case scenario, the slide event may transform to a tsunami generating mass flow and cause damage to marine installations and infrastructure in the slide initiation area and in the pathway of mass flow.

Earthquake-induced fault displacements may deform and damage well casings, pipelines, cables, and structures located at or crossing the fault.

An induced earthquake is a term that is assigned to human-induced seismicity. In the marine environment, this is mainly connected to microseismicity caused by extraction of oil and gas leading to reservoir compaction, changes in the stress conditions in the reservoir and overburden sediments and along faults. With increasing reservoir compaction the likelihood of larger displacements and damage to well casings increase.

Sediment strength and pore water pressure

Slope stability

The stability of the seabed depends on the strength of the sediments relative to the destabilizing forces. In a slope the shear strength of the soil will have to exceed the downslope component of gravity to prevent slope failure. If other external forces (like inertia forces under earthquake loading) are acting, even higher strength will be required. Submarine slide events can be initiated either by increased downslope loading, steepening of the slope by top accumulation or toe erosion, and reduction of the shear strength of the sediments under monotonic or cyclic shear stress variations.

Soils most susceptible to large-scale instability are marine sediments with a loose mineral grain structure. These sediments are typically hemipelagic clays and sands deposited at high sedimentation rates causing overpressure generation, lower effective stresses, and thus lower strength. These soils are susceptible to increase in pore water pressure and reduced strength when subjected to rapid changes in shear stress. The combination of excess pore pressure from rapid sedimentation and pore water pressure increase during undrained shearing is the main factor in development of submarine slide events.

Enormous submarine slide area have been mapped on the continental slopes, especially in and near in the major river deltas, Nile, Niger, Amazon, etc. and glacial fans. The slope angle is typically very low, from less than 1° to a few degrees. The understanding of the geomechanical processes involved in the triggering and development of these slide events is a key element in evaluation of marine slide hazards.

Submarine landslides are generally much larger than onshore landslides (Brunetti et al., 2009). While the larger terrestrial landslides are found to fall in the range 10^6–10^7 m^3, the larger submarine slide events are reported to have volumes of several 1,000 km^3. This is due to the long-term sedimentation under stable conditions not affected by yearly climate variations, but more dependent on the major sea level variations over 100,000 years.

The Storegga Slide is one of the largest submarine slide events worldwide. It is located at the mouth of the Norwegian trench next to and partly cutting into the North Sea Fan, a major glacial depocenter. The upper slide scar has a length of about 300 km, the downslope extension of the slide area is about 250 km, and the run-out distance of slide debris and turbidites is about 800 km. The estimated slide volume is in the range 3,000–3,500 km^3. The Storegga Slide was mapped and investigated in much detail as the Ormen Lange gas field was located in the slide scar (Solheim et al., 2005). The slide event took place about 8,200 calendar years before present and generated a major tsunami hitting the coastline of Norway, Scotland, the Faeroes, and Shetland (Bondevik et al., 2005).

The average slope angle from the toe area to the top of the upper slide scar is about 0.6°, and the slide event can be explained by existence of overpressures, a retrogressive slide process, and the sensitivity of the marine clays that formed the preferred slip planes (Kvalstad et al., 2005).

The long run-out distance of submarine landslides leads to extensive hazard zones in downslope direction and is a major source of concern for subsea installations, pipelines, and cables located below potential slide areas.

Retrogressive slide development is also observed, where the slide scar progressively moves upslope over distances of tens of kilometers.

Mud diapirs and mud volcanoes

Overpressured soils will typically have lower strength than soils that are fully consolidated under the weight of the overburden sediments, i.e., hydrostatic pore pressure conditions. This may lead to development of deep-seated failure processes (*Deep-seated Gravitational Slope Deformation*) under the delta front where there is a decrease in overburden stress in seaward direction. This gradient in overburden stress leads to compression and formation of anticlines in the toe area of the delta and growth fault

generation as the delta deposits are deformed and displaced seawards. With increasing compression, the anticlines may transform to diapirs that gradually penetrates the overburden sediments and reaches the seabed. The slopes of the diapir flanks can be high and cause slope instability.

Mud (clay) diapirs are observed in most of the major delta areas, but have also been generated in compression zones like the accretionary prisms forming in the major subduction zones and in tectonic compression zones between continental plates in the Caucasus-Caspian Sea area.

Mud diapirs may transform into "*mud volcanoes*" where overpressured water and gas transports fractures the sediment to seabed and transports sediments from deeper layers to the surface generating debris flows down the flanks of the volcano. Diapirs tend to form stratigraphic traps for oil and gas along the flanks and are thus attractive to the petroleum industry. The hazard related to slope failure and possible mud flows has to be considered when locating wells and field installations in this environment.

Salt diapirs

Deformation of salt sheets by the weight of the overburden sediments, tectonic forces, and buoyancy effects (salt is lighter than the overburden sediments) may generate a very irregular seabed topography. The Sigsbee Escarpment in the Gulf of Mexico (GOM) is an example of the extreme morphology created by salt tectonics. The lower escarpment has a variable height, typically between 300 and 800 m with slopes typically between 8° and 25° with numerous slide scarps that locally can be even steeper. For the oil industry the irregular topography created by salt diapirs can be a serious hazard concerning slope instability, mass flow, and impact on installations (Jeanjean et al., 2003).

Shallow gas and shallow water flow

Overpressured shallow formations represent a drilling hazard. In deep-water areas the problem is exaggerated as the window for mud weight between preventing collapse and generating fracture is narrower. If not properly evaluated and planned for in well design and drilling operations, overpressured sediments may lead to loss of fluid control followed by uncontrolled expulsion (blowout) of gas, water, and/or oil and in unconsolidated sands and uncontrolled sand production. This may lead to collapse of the reservoir and overburden sediment, cratering at the seabed, and collapse of wells and platform foundation. If gas is ignited at deck level, explosion damage and fire may totally damage the drilling platform/vessel and lead to fatalities.

Gas hydrates

Changes in pressure and temperature may lead to dissociation of "*gas hydrates*." Methane gas hydrates may exist in the marine sediments in water depths exceeding 300–500 m dependent on the seawater temperature. The thickness of the stability zone depends on the pore water pressure and the geothermal gradient. Changes in sea level and sea water temperature caused by global "*climate change*" or locally around wells due to heat flow during oil and gas production may lead to dissociation (melting). The hydrate is transformed to water and free gas. This is associated with volume expansion and may lead to a certain weakening and fracturing of the sediments around hydrate inclusions and generate gas migration toward seabed. The process is generally slow as the melting process is endothermic and gas expansion will increase the gas/water pressure tending to stabilize the melting process. Climate-induced changes in hydrate stability have been indicated as a possible trigger mechanism for submarine slides (Kayen and Lee, 1992). Interpretation of stratigraphy and location of slip surfaces relative to the stability zone of hydrates show in many cases no connection between hydrate melting and observed slide activity. This applies to many of the largest submarine slide events, where slide initiation has occurred at large depths unaffected by climate-induced changes in hydrate stability (mass flows in the Amazon Fan, the Storegga Slide, and others). The knowledge of hydrate melting effects on sediment strength and gas migration is still rather limited.

Identification and assessment of marine geohazards

Geohazard identification and assessment is based on interpretation of geophysical investigations of bathymetry and stratigraphy combined with geological and geotechnical boreholes with in situ testing, sampling, and laboratory testing. This allows characterization of the type and age of sediments as well as the material properties required for evaluation of the stability and run-out distance of potential slide events using analytical and numerical methods.

The likelihood of future events and size estimates are assessed using information of observed previous slide frequencies interpreted from seismic profiling, dating of post-slide sediments, and probabilistic slope stability analysis.

Summary

Marine hazards are generally similar to natural hazards on land like earthquakes, slope failures and mass flows. One of the main differences is rooted in the marine depositional environment which allows similar conditions to develop over large areas over long time spans. This leads to submarine slide volumes that can be several orders of magnitude larger than events on land. Another difference is the sediment-water interaction vs. sediment-air interaction. This may increase the damage potential, especially with respect to tsunami

generation by major earthquakes along the subduction zones and submarine slope failures generating mass flows.

MASS MEDIA AND NATURAL DISASTERS

Wojciech Biernacki
University School of Physical Education in Cracow, Krakow, Poland

Introduction

Natural hazards become disasters only when they intersect human social and economic aspects (Quarantelli, 1998). Indeed the effects are exacerbated when the hazard exposes the social vulnerability of an affected community and its inability to recover without assistance (Etkin and Dore, 2003). When disasters occur, the resultant impacts are not solely limited to the geographical boundaries of the event. Today it is common for media reports and graphic images to radiate into communities and households across the globe (Bankoff, 2001). Since the 1960s, global exposure to hazards has escalated because of this enhanced media coverage and because the average number of natural disasters reported worldwide has almost doubled every decade (Pelling, 2003). Media reporting now provides an almost live experience of natural disasters that may be occurring on the other side of the world, a situation in which such a broad audience would have little or no chance of actually experiencing (CNN effect). As a consequence such imagery presented in media broadcasts may considerably affect one's social perception of environment. Such information is readily available through technological advances, globalization, the Internet, and growing number of media outlets which have access to satellite technology.

Role of media

Among media functions played in modern society as defined by McQuail (1994), two are worth mentioning with regard to natural disasters. Most broadcasts related to hazards strongly approach the issue according to media coverage analysis. However, when the physical distance between location of the natural disaster and the location of the broadcast recipient is significant, the news itself acquires entertainment characteristics owing to the absence of reality.

Natural disasters are "attractive" as news items to media outlets since such events are easy to judge in terms of newsworthiness. The reason for this is that both reporters and editors employ professional news values in selecting and writing their news stories about topical issues. Research indicates that those newsworthy values include timeliness, conflict, prominence, significance, and human interest (Gant and Dimmick, 2000).

Not only do news reports provide audience with information about disasters, but also secondary productions from such events are meant to entertain (films, talk shows, etc.).

When considering the role of the media, it is important to recognize that the media is not just a conduit for information transfer, but it is also an "actor" and as such it is plagued with its own biases and agendas (Boykoff and Boykoff, 2004). Different communication formats, such as print media (e.g., newspaper broadsheet, tabloid, magazines, online sources) and audio/visual media (e.g., television broadcast, radio, video clips available online), play different roles in shaping social discourse. From a social impact perspective, advances in communication technology have permitted time and space to be compressed, thereby restructuring patterns of social interdependence and everyday "reality" (Thompson, 1999).

Print is constrained by space, whereas televised video is constrained by time. But due to the flexibility in their format, the space constraints of the print media are less problematic than the time constraints of televised media. Televised stories communicate less information and have a high emotional impact compared to the more detailed coverage of print stories that require greater mental effort to decode (Wanta, 1997).

International media coverage of environmental change and natural hazards plays an important role in setting and reinforcing public perceptions of issues and the social construction of events (Carvalho and Burgess, 2005; Boykoff, 2007). The news media are among the most important sources of information regarding natural hazards and other extreme events (McQuail, 1994), thereby significantly influencing how society and governments perceive and respond to hazards and disasters.

Consequently, the results of media coverage quality and quantity analysis are relevant and provide characteristics of disaster-related stories. According to them, such stories are rather poor quality scientific news as journalists have no background in science and spend little, if any, time reviewing technical documents related to natural hazards issues. Indeed they often prefer to quote a key, institutional (mainly not academic) informant. Media outlets rarely have specialists on staff for reporting general science and natural hazard-related stories (Pasquare and Pozzetti, 2007).

Social perspective

During the process of characterizing the impact of media coverage, researchers have developed a number of theories, the most popular entitled the hypodermic model. Agenda setting theory states that the media do not directly influence what the public think, but rather the media are successful in making issues salient or significant to the wider public. Social constructionists have the perspective that suggests while the mass media plays a strong role in presenting what constitutes "news" to the public, the audience "readers" undergo a complex process of reception and consumption that minimizes the media's potential impact on influencing public opinion (Pidgeon et al., 2003).

The real effect of media reporting appears to depend on numerous factors, among which the most important are: the nature of the recipient's media environment, the role played by media in their daily life, the level of information acquisition, and finally the subject matter of communicated information.

Drawing on the social constructionist perspective, researchers have argued that the definition and meaning attached to risks by society are fundamentally socially constructed. Social problems are defined by four groups of claims makers: community activists, the news media, corporate interests, and government officials (Anderson, 1997; Robinson, 2002).

In contrast, the limited media influence theory proposes that people in contemporary society are psychologically diverse because of the various experiences which form their personality. People belong to different social categories based on factors such as income, age, sex, etc. These categories are described by similar subcultures, beliefs, attitudes, and values. People in modern society are not isolated but rather united by social relation bonds based on family, neighborhood, and work.

On the other hand, individual differences, societal subcultures, and patterns of social relations induce people to choose, take advantage of, and interpret varied broadcasts in a highly selective way. Thus, as reception of media coverage is extremely selective and content interpretation miscellaneous, specific broadcasts have only limited influence on recipients (DeFleur and Dennis, 1996).

Summary

Direct media impact cannot be determined especially in the case of natural disasters. Personal experience and environment perception are essential to the human perception of reasons, frequency, and consequences of such events. Media broadcasts manage to reach a geographically varied audience. Finally, every news "reader" individually applies specific social and environmental filters against the communicated information.

Synonyms

Landslides; Mass wasting; Slope failures

Definition

Mass movement. A variety of processes that result in the downward and outward movement of slope-forming materials composed of natural rocks, soil, artificial fill, or combinations of these materials.

Introduction and significance of mass movements

Mass movements are important natural geomorphic agents that shape mountain landforms and redistribute sediment and debris to gentler terrain and water bodies. The earth mass may move in a number of ways: falling, toppling, sliding, spreading, flowing, or by their combinations. Gravity is always the primary driving mechanism, but it may be supplemented by water. Much of the Earth's landscape has been extensively modified by large-scale mass movements, but smaller mass movements have also exerted more chronic sculpting of mountainous terrain. Anthropogenic activities such as forest conversion, road and trail construction, prescribed fire, timber harvesting, residential development, grazing, mining, and mountain recreational uses have all exacerbated natural levels of mass movements, particularly those occurring in soil materials.

Most parts of the world have experienced some mass movements, although mountainous landscapes in regions of either significant tectonic activity or high rainfall are most susceptible. In particular, the circum-Pacific region is susceptible to mass movement because of the combined effects of high and intense rainfall, steep terrain, abundant earthquakes, volcanism, geological history, soil properties, and surface bedrock conditions (Sidle and Ochiai, 2006). The recent history of land cover change, proliferation of mountain road and trail systems, and concentration of people in high-hazard areas has also exacerbated soil mass movement in this region as well as increased risk of damage to property and loss of life. At particular risk today are developing nations in Southeast and East Asia, Latin America, and Africa, where montane forests are rapidly being converted to agricultural production, exotic plantations, residential development, recreation use, and pasture. Japan likely has the best documentation of historic mass movements; China, India, Pakistan, Bhutan, and Nepal have long, but incomplete histories of mass movement occurrence and damage. These East Asian regions are particularly susceptible because of prior and contemporary glaciation, tectonic uplift, frequent earthquakes, large storms, and episodic snowmelt (Sidle and Ochiai, 2006). Of the estimated 2,378 deaths attributed to mass movements worldwide from 1971 to 1974 (about 600 per year), 89% of these occurred in the circum-Pacific region.

Trigger mechanisms

Mass movements are triggered by a number of mechanisms, the most common of which is rainfall whereby a positive pore-water pressure develops in the regolith causing a loss in shear strength and subsequent failure. In some cases, these inputs of water sufficiently decrease shear strength by reducing soil suction and increasing the slope-parallel component leading to destabilization of slopes. Large earthquakes tend to trigger more catastrophic but lesser numbers of mass soil movements compared to rainfall mechanisms due to the localized combined effects of ground shaking and acceleration, as well as dynamic pore-water-pressure response. Ground shaking and freeze-thaw action are important initiation mechanisms for mass movements in rock materials. Given the difficulties in predicting earthquakes in real time, large mass movements triggered during seismic activity are typically unexpected and have caused some of the greatest loss of life of any such disasters. Other mass movement triggering mechanisms include snowmelt, rain-on-snow, volcanic activity and collapse, undercutting of slopes by running water or waves, glacial retreat, permafrost degradation, wildfire, and stress caused by windthrow of trees.

Types of mass movements

The term "mass movement" covers the full range of these gravitational slope-forming processes, including debris slides, debris avalanches, debris flows, rotational slumps, earthflows, soil creep, lateral spreads, solifluction, block glides, rockfalls, rockslides, volcanic collapses, lahars, dry ravel, dry creep, and rock creep. As such, the more generic term "landslides" is a subset of mass movements, because technically landslides would not include surface processes (e.g., dry ravel, dry creep) or slow plastic deformations without a specific failure plane (e.g., soil creep, rock creep). Varnes (1978) developed a widely used

classification system for landslides that incorporates the type of movement (falls, topples, rotational slides, translational slides, lateral spreads, flows, and complex slope movements) together with the type of material (bedrock or engineering soils). This classification is further subdivided based on the speed of movement and has later been modified using an elaborate set of descriptors (Cruden and Varnes, 1996). As such, the Varnes classification system has been widely used by geotechnical specialists, but has not proven as useful for land managers and planners dealing with practical mass movement problems. To facilitate this technology transfer need, Sidle and Ochiai (2006) proposed a simplified categorization of mass movements that includes the role of climate (the dominant trigger mechanism), incorporates surface mass wasting and plastic deformations, recognizes the importance of combination mass movements, and follows the terminology employed by Varnes (1978) as much as possible. The five functional categories described by Sidle and Ochiai (2006) include the following: (1) shallow, rapid landslides; (2) rapid, deep slides and flows; (3) slower, deep-seated landslides; (4) slow flows and deformations; and (5) surficial mass wasting. These broad categories of mass movement tend to be associated with different climatic and precipitation patterns and certain types of damages. An important practical component of this categorization is the linkage of different land use effects with various types of mass movements. This categorization did not initially include failures in rock materials, but can easily be adapted to include these as illustrated in the examples that follow.

Shallow, rapid mass movements

Shallow, rapid mass movements include debris slides, debris avalanches, debris flows, and shallow rockslides and falls. These mass wasting processes typically occur on relatively steep slopes ($>25^\circ$ slope gradient) with the failure plane generally located <2 m below the surface and oriented approximately parallel to the land surface. As such, the volume of these failures is usually small unless they extend long distances downslope and/or progress into larger debris flows in stream channels. The length-to-depth ratios are <0.1. Most of these mass soil movements are triggered by individual rain storms, usually a large amount of total rainfall with a period of higher intensity (Sidle and Ochiai, 2006). Additionally, these failures can initiate during snowmelt and seismic activity. Shallow, rapid failures in soil material usually involve a hydrologic discontinuity between the underlying low-permeability substrate (e.g., bedrock, till) and the more permeable soil, which facilitates the development of high pore-water pressures during rainstorms or snowmelt that triggers the mass movement. Soils typically have low cohesion with much of the shear strength being contributed by internal angle of friction and rooting strength of vegetation. These translational soil mass movements often initiate as relatively slower moving debris slides (<1 m year^{-1} to 0.3 m min^{-1}); as they progress downslope and water is incorporated they may transform into more rapid debris avalanches (0.3 m min^{-1} to >0.3 m s^{-1}) and with further liquefaction that may occur in steep headwater channels they may become very rapid debris flows (>3 m s^{-1}). Given their shallow depth, these mass movements are highly affected by land cover change and can increase when woody root reinforcement declines following forest conversion, timber harvesting, fire, or disease. Shallow rockslides and falls are more related to fractures, jointing, and bedding discontinuities as these rupture surfaces often provide the weak links in an otherwise stronger rock matrix. In some weaker or highly weathered rocks, the strength of the rock matrix is the limiting feature where failure occurs. Bedding planes dipping nearly parallel to the slope and closely spaced vertical joints are particularly susceptible scenarios for rockslides and rockfalls, respectively. Characteristics of rock "fractures" that predispose slopes to rockfall and slides include smooth fracture surfaces which have a low frictional component and infilling by weaker (particularly clay-rich) material. Strength of the rock mass itself is also important, especially as it relates to weathering processes. The initiation of rockfalls and rockslides is often more complex than shallow, rapid soil mass movements and may involve earthquakes or ground shaking, pore-water pressure, freeze-thaw action, and root wedging. Cutting into steep slopes for mountain road and railway construction as well as residential development can promote the initiation of rockfall and rockslides.

Rapid, deep-seated slides and flows

Rapid, deep slides and flows are similar to shallow, rapid mass movements except for their deeper failure plane (usually >5 m deep), which is often found in weathered or fractured bedrock. These consist of debris slides and avalanches, debris flows, bedrock slides, large rockfalls, and certain block glides and rapid earthflows. These mass movements typically occur after an extended rainy period (or snowmelt) followed by a large-to-moderate-sized storm. However, if interconnected preferential flow paths exist in the soil and weathered bedrock that facilitate the rapid routing of water to a failure plane, these failures may occur during an isolated rain event with a period of very high intensity (Sidle and Ochiai, 2006). The regolith material is not usually clay-rich as in slow, deep-seated mass movements. In some cases, liquefaction occurs along the sliding surface in saturated cohesionless materials just after the initial failure as a result of excess pore-water-pressure generation. Such liquefaction may lead to long-runout debris flows. In addition to rainfall and snowmelt, seismic activity can be an important trigger mechanism, particularly for bedrock slides and large rockfalls. During strong ground motion, pore-water pressures increase and the regolith may mobilize. Such large, rapid mass movements are common during major earthquakes in unstable terrain. While less common, collapses along flanks of volcanoes can be spectacular and very damaging

types of rapid, deep-seated mass movements. Movement rates of rapid, deep-seated mass movements are similar to or even greater than those of shallow, rapid mass movements. Due to size and unexpected nature of occurrence of these deep, rapid earthquake-triggered failures, they can cause considerable damage, albeit much less frequent than shallow, rapid landslides. Rapid, deep slides and flows differ from shallow, rapid mass movements in that the former are less sensitive to widespread land cover change. The mechanisms of deeper-seated rockfalls and rockslides are the same as that for shallower rock failures. These mass movements can encompass entire mountainsides and have generated some of the greatest disasters related to any mass movement type.

Slower, deep-seated landslides

Slower, deep-seated landslides generally move at rates $<1\ \mathrm{m\,day^{-1}}$ and include rotational slumps, earthflows, and lateral spreads. These mass movements all have a defined failure surface, which differentiates them from slow flows and deformations. They are generally larger than shallow, rapid mass movements and tend to move in response to multi-day or multi-week inputs of rainwater or snowmelt. Typically, once a critical threshold of groundwater accretes, movement commences with rates of movement increasing proportionally to the subsequent increases in groundwater within the failure zone. Complex preferential flow networks often develop in and around these mass movements due to the formation of tension cracks, differential movement in blocks of the failure, and internally drained features (e.g., sag ponds). These preferential flow paths can deliver substantial quantities of subsurface water to failure planes when fully connected causing surges in slumps and earthflows. In contrast, during drier periods essentially no movement may occur for months or even years. Soils and regoliths tend to be clay-rich and highly altered or weathered and exhibit plastic behavior over a wide range of water contents. Although slow, deep-seated mass movements occur throughout wide range of slope gradients, they commonly initiate on much gentler slopes (4°–25°) than shallow, rapid landslides (Sidle and Ochiai, 2006). Rotational slumps and earthflows often occur in combination; the initial movement typically occurs as a rotational failure, and the subsequent downslope movement of remolded material proceeds as an earthflow. Earthflows can be distinguished by a lobate shape near their terminus. Lateral flows and spreads occur in sensitive sand, silt, and clay materials, typically with gentle slope gradients. Lateral flows involve the lateral displacement of large masses of cohesive rock or soil that overlays a deformed or deforming mass of softer material (Cruden and Varnes, 1996). Initiation of lateral spreads is often due to ground shaking but can also occur when high pore-water pressure develops in the regolith during extended rainfall or snowmelt. Thereafter, liquefaction rapidly occurs at the sliding surface causing the overlying regolith to break up and spread. The rate of spreading can range from slow to quite rapid in spite of the low gradient; the largest, most rapid, and most destructive lateral spreads are triggered by large earthquakes. The general category of slow, deep-seated mass movements is not particularly susceptible to land cover change unless water is rerouted into the failure zone. These mass movements can be quite destructive, but typically do not cause fatalities due to their generally slower rate of movement; lateral spreads can be an exception.

Slow flows and deformations

Slow flows and deformations involve the plastic deformation of soil and rock material with rates of movement generally in the range of millimeters per year (Sidle and Ochiai, 2006). Unlike slower, deep-seated landslides, these mass movements do not have a specific failure plane. This mass movement category includes the very widespread process of soil creep, rock creep, and the less important process of solifluction. Soil creep is found on most hillslopes, and while it is influenced by slope steepness and clay content, it can occur across the full range of slope gradients and has been associated with many soil textures. The most active soil creep typically occurs in landscapes where slump-earthflow processes are prevalent. Such landforms are often hummocky, and evidence of soil creep is manifested in such features as curved trees, immature fluvial drainage systems, tilted fence lines, and tension cracks in the soil. While movement can occur in both shallow and deep regoliths, rates of creep are generally more rapid near the surface. Soil creep responds to long-term inputs of water rather than individual storm events. While soil creep can be damaging to foundations or along road cuts, more devastating consequences relate to the linkage of soil creep with larger-scale landslide processes. Soil creep can cause strain softening of clay-rich regoliths and subsurface erosion in less clayey deposits leading to the initiation of deep-seated landslides. Shallow soil creep is one of the primary infilling mechanisms of geomorphic hollows following shallow mass movement. Once these sites are recharged, another landslide may occur. Rock creep is the gravitational deformation of a rock mass that proceeds gradually but continuously downslope, sometimes concentrating at a specific depth but during other times spreading over various depths beneath a slope. The disturbed rock mass causes various features such as non-tectonic folds, faults, and other types of fractures, thus degrading the rock mass to rock debris and increasing the likelihood of catastrophic slope failure (Chigira, 2002). Such gravitationally unstable conditions can be induced by tectonic uplift, glacial erosion and retreat, and coastal or fluvial undercutting of slopes. Solifluction is a specialized type of very shallow earthflow found in periglacial environments that are typically underlain by permafrost; slope gradients range from as gentle as 2°–36°. This slow ($\leq 1\ \mathrm{m\,year^{-1}}$) mass movement type results from freeze-thaw action in fine-textured soils with most of the movement concentrated in the upper meter of the soil profile. Although confined mostly to arctic and subarctic regions, recent concerns

over the effects of global warming have renewed interest in solifluction processes.

Surficial mass movements

Even though dry ravel and dry creep are surface processes, they are considered mass movements because they are driven by gravity. These surficial mass movements involve the rolling, sliding, and bounding of surface soil grains, aggregates, and coarse fragments down steep hillsides, often forming talus cones at slope breaks (Sidle and Ochiai, 2006). Dry ravel and creep mainly initiate during active freeze-thaw periods and wetting-drying cycles. During such natural perturbations a loss of interlocking frictional resistance among soil aggregates or grains occurs loosening the material and subjecting it to downslope gravitational transport. While dry ravel and dry creep typically transport much less sediment to streams compared to other mass movements in steep terrain, they can be significant surficial processes on steep slopes with sparse vegetation covers, thin organic horizons, and/or soils that have been disturbed (particularly by fire). Under such conditions, slope gradients that approach or exceed the internal angle of friction of surface materials (≈38°–41°) typically experience active dry ravel and creep; on gentler slopes, ravel rates diminish substantially. The impacts of these surficial mass movements are generally restricted to maintenance requirements along road cuts, but in cases of extreme and widespread fire they can contribute significant sediment pulses to streams. Additionally, dry ravel is often an important infilling process after evacuation of geomorphic hollows by shallow landslides.

Summary

Mass movements are largely episodic processes driven by gravity that can severely impact people, property, and the environment depending on their location, size, and rate of movement. These are largely triggered by rainfall, but devastating mass movements are sometimes caused by earthquakes and volcanic activity. Certain mass movement processes like soil creep can exacerbate other processes like large-scale landslides, and combination mass movements (e.g., debris slides-avalanches-flows) are common occurrences. Land use practices can exacerbate particularly shallower mass movements, with road and other excavations into hillsides being particularly problematic.

Definition

Megacities are typically defined as metropolitan areas with more than ten million inhabitants, which show high growth dynamics and a high speed of change and development. While not necessarily facing substantially different or more severe hazards than other settlement types, their high concentration of administrative and economic functions can lead to risk that extends to the national level. However, megacities also have the best resource base to mitigate risk, and prepare for and recover from disaster events.

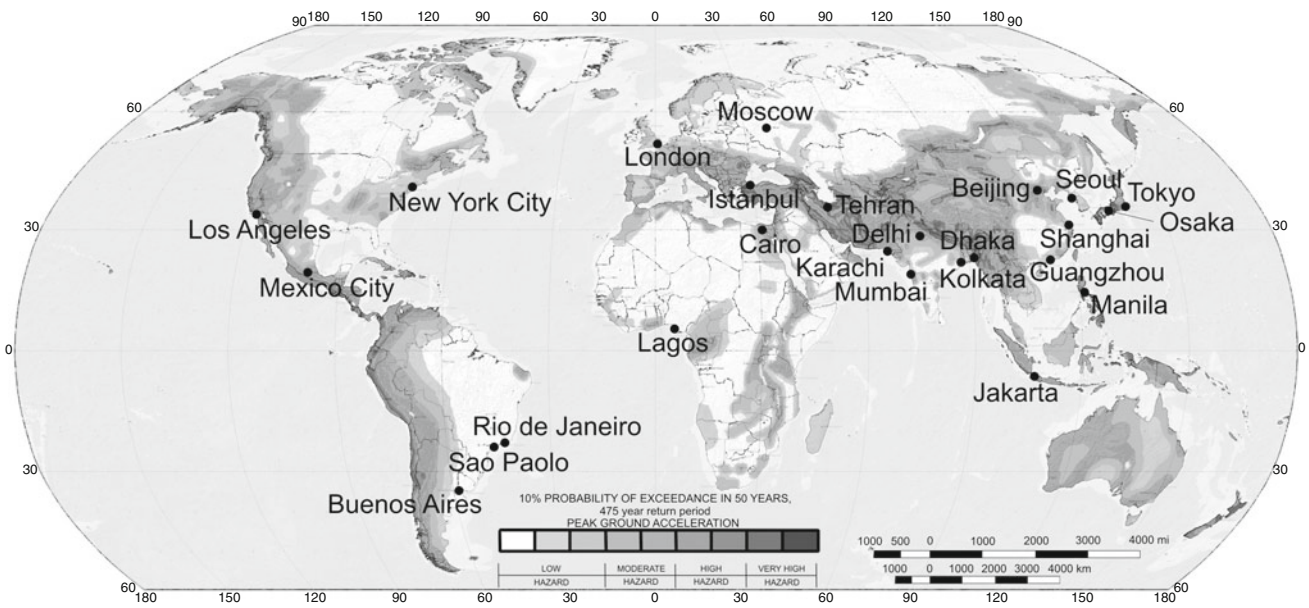
Introduction

The global population has been growing continuously since about the fourteenth century (Raleigh, 1999), though by no means evenly. An abrupt increase in what had been a relatively low and steady growth rate only began toward the middle of the twentieth century, reaching a brief peak increase of some 2.2% in the early 1960s. While it had taken some 160 years for the population to grow from one to three billion (by 1960), this doubled over the next 40 years. Today, the number stands at 7 billion, and is projected to grow to 9.1 billion by 2050. This rapid increase coincided with a second trend – people moving into cities. While in 1800 about 3% of the global population was urbanized, a strong acceleration began by the beginning of the twentieth century (ca. 9%), reaching 50% by 2008 (United Nations Population Division (UNPD), 2006). Within this broad urbanization process, a number of individual cities grew disproportionally. In 1900, only 15 cities had more than one million inhabitants, three of them (London, Paris, New York) above three million (Wenzel et al., 2007). Today, more than 300 cities house in excess of one million people. Adjusting for the trend, we now define megacities as agglomerations of more than ten million people (Thouret, 1999), though at times a threshold of eight million is used (Wenzel et al., 2007). By the year 2000, already 19 cities with populations of more than ten million existed. Only 5 years later already 25 such cities were identified (Brinkhoff, 2010), with greater Tokyo (approximately 34 million people in 2010) being the largest.

The global population and urbanization growth rates over the last century (Grimm et al., 2008) also show similarities with an increasing number of disasters associated with natural hazards (e.g., Guha-Sapir et al., 2004; Figure 1) that are marked by an even more pronounced increase since about the 1960s. This suggests a relationship between population growth and urbanization with disaster incidence and damage. Considered in general terms, the coincidence is readily explained by disaster risk theory – more elements at risk (people, infrastructure, assets), exposed to (even unchanging) hazards, will likely lead to more frequent damaging events and higher losses. At a detailed level, the picture is more complicated, as specific hazard exposures and vulnerabilities have to be considered (e.g., Kerle and Alkema, 2012; see entry *Risk*). In this entry, the particular relationship between natural hazards and disasters and megacities is described, considering the role of actual hazard exposure, vulnerability, and resilience and capacity, also in light of global climate change. It particularly highlights that the absolute number of inhabitants is less relevant; instead, the functional value, as well as the political, administrative, and economic importance of megacities in their respective countries now define megacities and strongly influence the hazard risk.

Megacities and Natural Hazards, Figure 1 Number of annual natural disasters between 1900 and 2007 in bold (primary axis, CRED 2009), and global population for the same period in hatched line (secondary axis). Inset shows estimated global urbanization rates between 1800 and today (United Nations Population Division (UNPD) 2006).

Hazard exposure of megacities



Of the 25 currently existing megacities, only six are not located in economically less developed countries (LDC). About half are exposed to substantial seismic hazard (Jackson, 2006), and all except six are situated in coastal areas (Figure 2). Those hazardous locations, however, they share with many smaller population centers. Megacities tend to occupy large areas (e.g., the Los Angeles metropolitan area covers more than 12,500 km^2). As such, given a comparable hazard setting, they are statistically more likely to get affected by an event than smaller cities or even rural communities. At the same time, a given event will likely affect a smaller fraction of a megacity area than it would in smaller cities or communities (Cross, 2001). Thus, in terms of direct exposure to environmental hazards, megacities do not show characteristics that significantly differ from smaller settlement types.

Disaster damage and the number of people killed or affected have been increasing in recent decades. Disaster statistics show that events affecting megacities have led to the highest monetary damages, such as the 1995 Kobe earthquake (part of greater Osaka; losses of > US$130 billion), reflecting the high accumulation of wealth. While some of these events have also killed many people (more than 6,000 during the Kobe earthquake), disasters outside megacities have been more devastating. The 1965–1967 drought in India caused some 1.5 million fatalities, whereas in 1970, a cyclone inundating coastal areas of Bangladesh killed an estimated 500,000 people. Disaster numbers, however, are strongly dependent on the specific location and extent of a disaster, and include an element of chance. With the exception of the 1923 Tokyo, 1976 Tangshan, and 1980 Mexico City earthquakes, major urban agglomerations have so far been spared by seismic events with a magnitude >7.5. However, an eventual direct hit of a megacity is seen as inevitable (Jackson, 2006), and capable of causing more than one million fatalities (Bilham, 2009). Whether a direct tsunami hit on a coastal megacity will lead to high fatality numbers or mostly infrastructure damage largely depends on the warning time. For tropical cyclones and impending volcanic eruptions, the other environmental hazards with destructive potential in megacities, the time to prepare is usually sufficient.

Damage is more usefully considered in relative rather than absolute terms. While perhaps causing less absolute physical damage in rural areas, the destroyed assets nevertheless often constitute a significant share of all possessions, especially in LDCs. Thus, in terms of economic consequence, less costly disasters outside megacities frequently have more severe and lasting effects than in large urban agglomerations that have broader means for rapid recovery.

The effect of megacities on hazard exposure

In addition to megacities encroaching on hazardous terrain, a range of environmental changes has been documented. Ongoing and projected climate changes strongly affect various aspects of the environmental system, with consequences for hazards levels. They relate in particular to hydrometeorological hazards, such as stronger windstorms, flooding, and general precipitation

Megacities and Natural Hazards, Figure 2 Global seismic hazard map, adapted from Global Seismic Hazard Assessment Program (GSHAP), and current megacities. About half of those are exposed to substantial seismic hazard (Jackson, 2006), and all except Sao Paulo, Mexico City, Delhi, Beijing, Moscow, and Tehran are located in coastal areas.

regime changes. Megacities themselves can also have effects on the hazards they are exposed to. Those can be effectively considered in the framework of urban ecology, which displays strong similarities with disaster risk theory (Kerle and Alkema, 2012). Several observations from an urban ecological perspective offer insights in the hazard exposure of large urban areas: (1) cities are seen as both the cause and the principal victim of environmental degradation (Weiland and Richter, 2009). As a major source of pollution, and due to their extensive resource requirements and energy consumption, they contribute to global climate change. However, with their high concentration of elements at risk and frequent location in coastal areas, these cities are also poised to be most affected by sea-level rise or stronger windstorms (Klein et al., 2003). (2) Global environmental changes are outpaced by local changes (Grimm et al., 2008). For example, urban temperature increases (urban heat islands) are faster than global warming rates, leading to rapidly rising secondary hazards (e.g., new disease vectors spreading, or increased ozone concentrations). (3) Major urban areas have ecological footprints hundreds of times their size, typically also evidenced by changes in their surrounding land cover and land use (Grimm et al., 2008). Hazard sources can be potentially far away, and the characteristics of the area in between strongly affect not only the hazard, but also vulnerability and capacity (e.g., widespread deforestation or river straightening versus comprehensive floodplain management). The threat of projected sea-level rises endangering megacities in coastal areas is at times compounded by large-scale subsidence, typically resulting from excessive groundwater extraction, such as in Jakarta or Bangkok.

Do megacities face megarisks?

Whether megacities automatically face disproportionate disaster risks has been a matter of intense scientific debate. If megacities are not exposed to exceptional hazards compared to smaller settlements in comparable locations, what else determines their risk? Risk is principally a function of all present hazards and their potential interactions and amplifications, and the type, value, and vulnerability of all elements at risk (see entry *Risk*). Vulnerability, that is, the susceptibility to suffer loss (see entry *Vulnerability*), which differs for physical assets, people, and their social structures, and economic and environmental systems, is further offset by capacity. This is defined as "the combination of all the strengths and resources available within a community, society or organization that can reduce the level of risk, or the effects of a disaster" (UN/ISDR 2004, p. 430). Here, it becomes apparent that risk in megacities is much less a function of the absolute population number, but more of its complexity and development level (Hansjürgens et al., 2008). While a city such as Tokyo, with an exceptional physical asset base, faces a high seismic hazard, the actual risk is limited because of great efforts to reduce vulnerability (e.g., by imposing strict building codes), and to increase the capacity of the city (e.g., by empowering the population on how to respond in a seismic situation). In particular, megacities in LDCs face higher risks (Cross, 2001; Wenzel et al., 2007). This is not only due to these cities being located in poorer countries with fewer means for risk mitigation measures. Instead, the trajectory of urban development is of major importance. While most megacities in richer countries grew over centuries, allowing time for support infrastructure to develop, those in LDCs experienced their most rapid growth in recent decades. For example, while the population of greater London already exceeded six million by 1900 and since then remained largely unchanged, Mumbai grew from some 800,000 to over 23 million in the same period. This led to infrastructure and functional development drastically lagging behind urban expansion, and explains why some 60% of Mumbai's residents live in informal settlements (Wenzel et al., 2007), which are widely considered to be more vulnerable to hazards. Another point influencing risk is the exceptional importance of megacities in LDCs. While all western megacities are important economic, political, and administrative centers in their respective countries, they are not primate cities comparable to Manila, Lagos, or Jakarta. This, in turn, influences risk positively and negatively. While a disaster in a western megacity would lead to substantial damage, and potentially national and international repercussions, it is unlikely to compromise the ability of the respective country to function economically or administratively, as critical functions are decentralized and some level of redundancy exists. Megacities in LDCs tend to have far higher concentrations of economic, political, and administrative power, and as such are more vulnerable to disruption affecting the entire country (Hansjürgens et al., 2008). The risks such megacities face are, therefore, to some extent nationwide risks. On the other hand, their singular importance also facilitates acquisition of resources needed for disaster response and reconstruction, at the expense of the rest of the country.

The assets of megacities

Many megacities, especially those that grew rapidly in recent years, are characterized by haphazard construction, insufficient infrastructure, unhygienic environments, and inadequate administrative and medical services, all with negative effects on vulnerability and capacity. Those limitations, however, are in part counterbalanced. In addition to the comparatively high ability to obtain resources for disaster response and reconstruction, their status as primate city leads to accumulation of knowledge and expertise, and a comparatively better knowledge of the existing hazards and risk. In addition, they allow an easier early warning of the population, a more timely response following an event (both with national means and international assistance), and in principle are better equipped to empower people on vulnerability reduction and disaster preparedness. The per-person cost of any risk reduction approach, be it engineering measures or installation of early warning infrastructure, is also much lower than in

smaller settlements. Creating more effective disaster risk management strategies, which have to draw on all elements of the political, administrative, and societal fabric of a city, is also facilitated by the high concentration of these elements in megacities.

Megacities and future disaster risks

The trend toward more and larger megacities is clear, with positive and negative consequences for disaster risk, posing especially high challenges for large agglomerations in LDCs. Given the generally high disaster risk, what can be effectively done to reduce it? Any form of risk mitigation and management is contingent on a solid understanding of existing risk. This is difficult as it has to include all present hazards and vulnerability types, as well as account for any present trends related to environmental degradation or climate change. This risk knowledge then forms the basis for sustainable urban development. Such planning has been performed for several megacities, such as Dhaka (Roy, 2009), Santiago de Chile (Heinrichs et al., 2012), or Istanbul (Wenzel et al., 2007), and broad recommendations for climate change adaptation in such settings have been made (Klein et al., 2003). The planning has to be integrative and consider the wider geographic setting. Given the reliance of resilient megacities on a healthy hinterland (Cross, 2001), the focus must not only be on reducing risk within the cities themselves. It is equally important to take measures that reduce the massive rural–urban migration that has been leading to a demographic imbalance that endangers the rural resource supply megacities depend on. The urban agglomerations also have to be surrounded by healthy ecosystems. Overall resilience, that is, the capacity to absorb shocks from disasters and recover, relies on proper functioning and interlinking of both human and ecological systems (Cross, 2001). As such, urban ecology considers integrative, transdisciplinary analysis of the diverse environmental, social, and political aspects as being central to urban disaster risk management, especially in megacities.

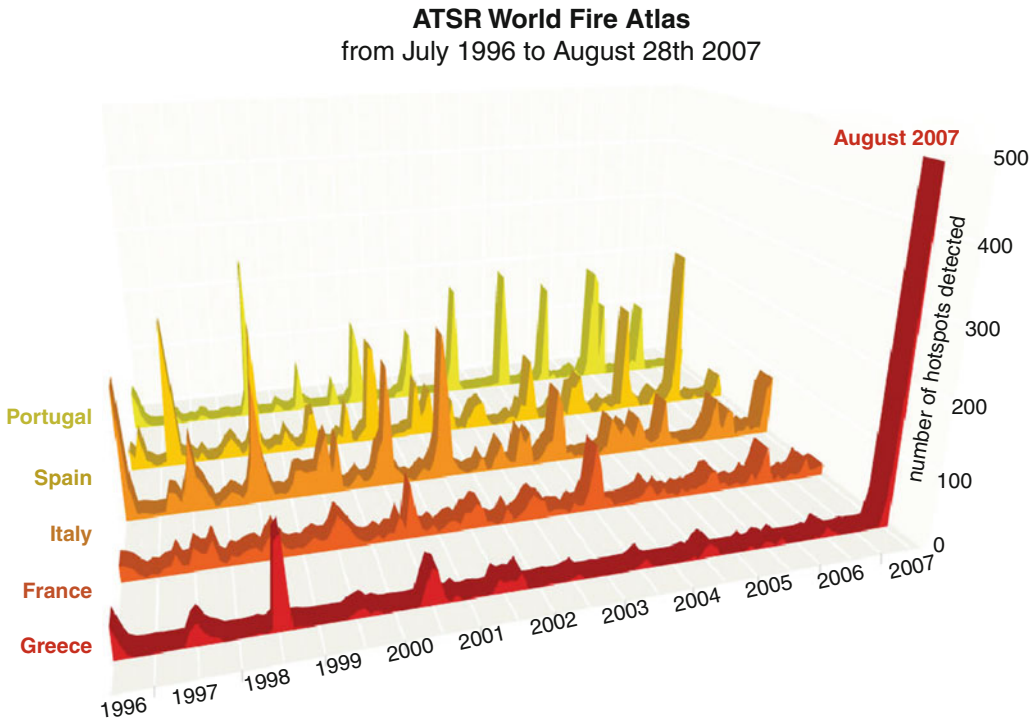
Greek fires; Mega-fires; Very large wildfires

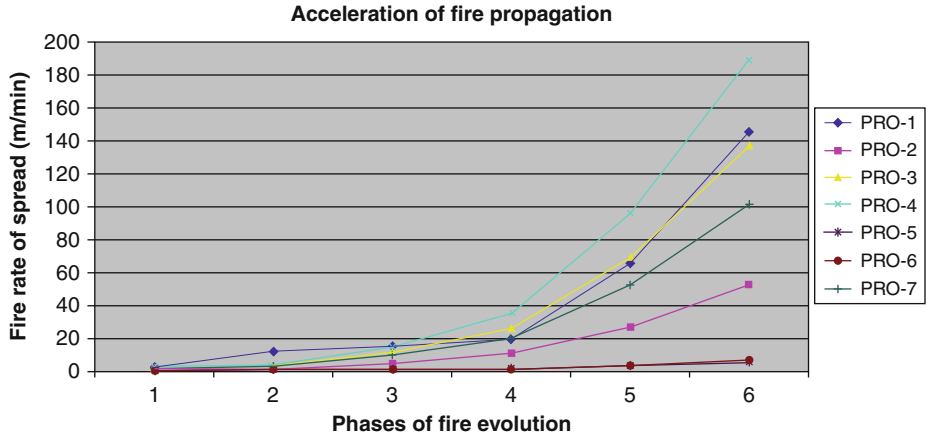
The fire management policy in Greece toward the summer of 2007

Forest fire is a major natural hazard in southern Europe, which is often directly related to climate change and anomalies of meteorological conditions, in particular increased temperature and scarcity of rainfall. Long dry periods combined with other extreme weather conditions contribute to the development of forest fires that in most cases originate by anthropogenic activity and often turn into very large conflagrations. Such fires can easily burn down large forest areas, as evident in particular in the Mediterranean region.



Greece is one of the EU countries most affected by the forest fires. Areas approximately 1,850,000 ha in size have been burned between 1955 and 2007, out of which 30% was burned during the last 7 years of this period. Up to 1973, fires used to occur with a relative low frequency and the average per annum area burned was 11,500 ha. One third of this area was classified as tall forests, mainly pine stands, whereas the remaining area was shrublands, pastures, and grasslands. Starting from 1974, the annually burned area increased rapidly peaking every 3–4 years (influenced by the combination of periodic favorable climatic conditions and societal fire causes). For instance, the area burned in 1974 was 36,000 ha, in 1977 some 49,000 ha, in 1985 about 80,000 ha, and in 1985 >100,000 ha (Eftichidis, 2007).

A significant increase of the burned area was recorded following the 1998 policy shift for fire suppression to the fire brigades from the forest service. This decision marked a clear change in fire management policy in Greece. Aggressive fire suppression succeeded the preventive forest management strategy previously applied with the objective of mitigating fire behavior and impact. Unfortunately, fires continued making new national records in the years 1998 (102,000 ha) and 2000 (157,000 ha). For a period of 6 years following the record year 2000, forest fires have been controlled effectively by applying a focused and aggressive fire suppression policy, giving the impression to the citizens that the problem was being managed properly. Figure 1 summarizes the statistics for fire suppression in the Mediterranean.



During the summer of 2007, following a long dry season, a series of fires started burning the unmanaged shrublands and pine forests in southern Greece and Peloponnese.

Fanned by favorable weather conditions and a significant volume of accumulated biomass, the 2007 fires in Peloponnese evolved to catastrophic mega-fires that burned >180,000 ha in 1 week with intensities far exceeding the capabilities of the firefighting infrastructure, including the addition of an unprecedented number of resources offered to the Greek government by several other countries.

In total, more than 3,000 fires were recorded over Greece, ravaging approximately 270,000 ha of forest,

Mega-Fires in Greece (2007), Figure 1 Forest areas burnt in the Mediterranean countries of the EU between 1996 and 2007 (Source ATSR World Fire Atlas).

Mega-Fires in Greece (2007), Figure 2 Local acceleration of fire propagation during very large fires.

olive groves, and farmland, according to data of the European Forest Fire Information System (EFFIS) of the JRC Ispra. On the Peloponnese, 177,265.4 ha was destroyed, consisting of 55% forests and natural lands, 41.1% agricultural lands, and 0.9% built-up areas (WWF Hellas, 2007).

The special characteristics of the 2007 forest fires, which distinguish them from past forest fires in Greece, can be summarized as follows (Xanthopoulos, 2007):

- Although the number of fires recorded was not remarkable, the extent of the burnt area was very large compared to previous years.
- Many fire episodes occurred at the same time in several locations.
- There was frequent restart of already suppressed fires.

The mega-fires issue in Greece

Forest fires can be classified according to the suppression effort needed to contain them into initial attack, extended attack, large fires, and mega-fires. These four types cover the continuum of severity that runs from very small, short-duration, and noncomplex events to extraordinarily large, long-duration, and very complex fires. The difficulty of managing forest fires changes dramatically moving from a normal accident to a serious event (extended attack fire) or an ultracatastrophe arises and a mega-fire emerges. Mega-fires occur when multiple fire spots and individually propagating fronts of flames merge into a superfront (Brooking Institution, 2005).

In order to depict the relation of the classification with the number of fire events, we can consider that the majority of fires (approx. 95%) are suppressed during the "initial attack," whereas 4% usually evolve and require "extended attack" operations. Therefore, only 1% of the total number of fires evolves to large fires and only few of these become mega-fires.

The main physical reason for the occurrence of mega-fires is the buildup of dead woody material and accumulation of live biomass in fire-dependent forest ecosystems that can fuel high-intensity events. It is quite common to have such a fire regime following long periods of drought and repeated heat waves during the summer. The situation can be worst due to insect infestations and diseases. Mega-fires create their own local wind field which sustains their propagation, independently of the weather conditions prevailing in the area. Since spotting (starting of new fires by flying embers) is common, mega-fires combined with extreme weather conditions burn out of control and continue burning until relief in the weather or a break in fuel source occurs. Firefighting mechanisms can manage fronts with fire line intensity to 2,500 kW/m, whereas mega-fires often reach intensities to 100,000 kW/m. Therefore, efforts to extinguish such fire fronts are quite futile (Viegas and Eftichidis, 2007).

Fire behavior is normally defined by the topography, the meteorological conditions, and the type of vegetation burned. However, the time since fire ignition is another factor that contributes to extreme fire behavior. Since mega-fires are characterized by their long duration, the time lapse is responsible for eruptive behavior of the fire in many cases. Considering that fires evolve differently through time, we can define a series of six phases for describing this evolution. This consists of (1) the starting condition, (2) the phase of reduction of the fuel moisture, (3) the phase of vegetation dehydration, (4) the phase of wind generation, (5) the phase of wind flow, and (6) the phase of the fire eruption. Time evolution of these phases is different for various forest fuels as shown in Figure 2 (Viegas and Eftichidis, 2007), using the Prometheus (Riaño et al., 2002) classification of forest vegetation to fuels.

The above observation is particularly important in cases of fires approaching villages in case the fire accelerates and surprises the inhabitants without giving them time for evacuation.

Mega-fires are not defined by their physical attributes (e.g., by their size). Instead, they are recognized as

"headline fires" in which operational limitations, public anxiety, media scrutiny, and political pressures collide. Beyond their impressive size, they are characterized by their complexity, their potential to overwhelm the capabilities and capacities of the fire suppression forces, and their extreme intensity and long duration. Due to the costs and damages associated with such events, mega-fires are often followed by policy or procedural changes. However, such changes are usually limited in improving firefighting operations and their sustainable hazard mitigation measures.

The 2007 forest fires of Greece record as the most catastrophic fire event in the country's history and the most catastrophic of the last few decades in Europe. The devastation includes the forests and agricultural lands, entire villages, infrastructure, and a large toll on human life (WWF Hellas, 2007). These fire events have been cited in the press as the fourth worst disaster due to forest fires worldwide since 1871 and by far the deadliest for humans in recent years.

Causes of the mega-fires: season of 2007 in Greece

The extended Greek forest fires of 2007 took place in a summer of three continuous heat waves. The exceptionally high summer temperatures, following a winter drought, made the resinous pine forests more flammable than usual and created very favorable conditions for extensive fires.

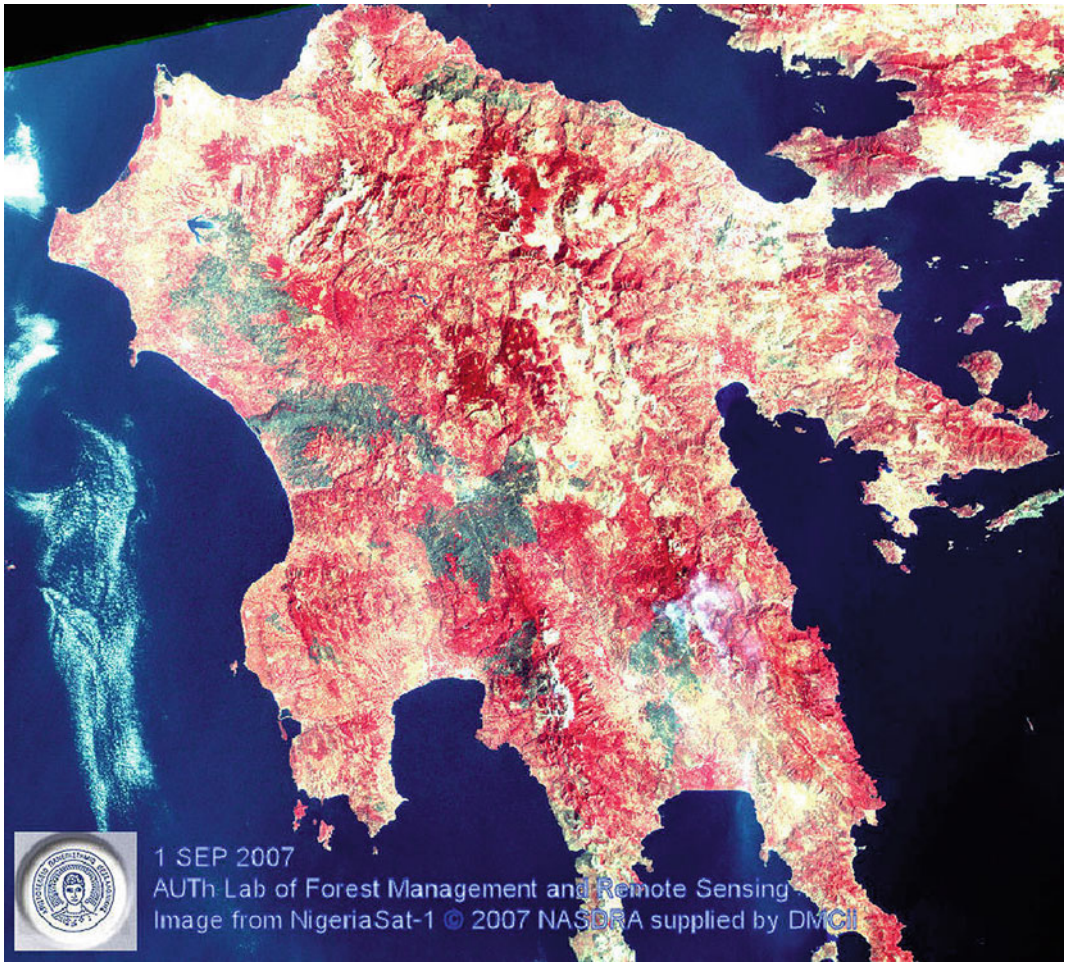
In the search for the underlying causes of the 2007 Greek forest fires, discussions most often lead to weaknesses in Greek physical planning and development regulations, which inadvertently encourage criminal actions such as arson.

Greek officers concluded that at least some of the fires of 2007 could be attributed to arson. In the Peloponnese, suspicions of arson were reinforced by the fact that dozens of fire episodes started at the same time. Evidence suggests that the 2007 fires broke out due to a combination of criminal intent, carelessness, and accidents. In addition to arson, the lack of maintenance of the electricity pylon network; carelessness of local farmers, villagers, and forest visitors who started fires on hot days; illegal landfills left unguarded; and the inability of elderly farmers to control fires they started to maintain grazing land are frequent cited causes of fires (Xanthopoulos, 2007).

Despite significant investments and an increase of the fire suppression budget since 1998, the Greek forests suffered record-setting forest fires in which the death toll, costs, losses, and damages involved have been staggering.

However, a "successful" 6-year period of firefighting in Greece, which was due to a number of factors, was interpreted as efficiency of the fire management system based on fire suppression. Thus, the fire problem was considered finally solved or at least under control. Vegetation management programs have been ignored, and the forests were left to accumulate billions of tonnes of biomass. In addition, the high temperatures, even during the winter months, extended the growth period of the vegetation and increased the production of biomass. Due to the alternating moist and dry periods, increased volumes of cured vegetation accumulated in the forests (Eftichidis, 2007).

Given the change in the live and dead fuel moisture conditions, the fires moved to sites that in the past were less dry and where the fire used to burn surface fuels with low intensity. Currently, fires in these sites burn intensively and develop large dimensions due to high accumulation of dead vegetative material. Furthermore, the fires tend to invade areas occupied by forest species that have become more flammable and less fire-adapted in the face of worsening climatic conditions. Fir and black pine forests are good examples of this situation in Greece.



The above-mentioned conditions eventually led to a series of mega-fires in south and southwestern Greece that burned 250,000 ha, 72% of which burned during the last week of August 2007 in five adjacent fires in the region of Peloponnese (Eftichidis, 2007).

The year of 2007 was particularly dry for Greece. Measurements from the National Observatory of Athens show that high temperatures are recorded not only in the summer but during the winter months as well. A report by the National Technical University of Athens describes the winter of 2007 as the warmest in 100 years of collected data. The summer was affected by three heat waves with continuous temperatures as high as 42–45°C for several days at a time.

During the first heat wave, in the eastern part of Greece, the weather station of the city of Pyrgos, one of the most affected areas in Peloponnese, recorded for the first time in its history maximum temperatures of 38.5°C and 41.1°C, respectively, for the 24th and 25th of June. The second heat wave was worse and lasted 10 days from July 17–26, with two peaks according to the Pyrgos meteo station data, first the 18/7 (39.7°C) and second the 25/7 (43.4°C which was also a historical record for the last 50 years). The last heat wave (22–25 August with temperatures ranging from 38°C up to 42.3°C) occurred just before the firestorm started. These persistent heat waves dehydrated the forest vegetation and prepared the environment for the mega-fire that followed (Eftichidis, 2007).

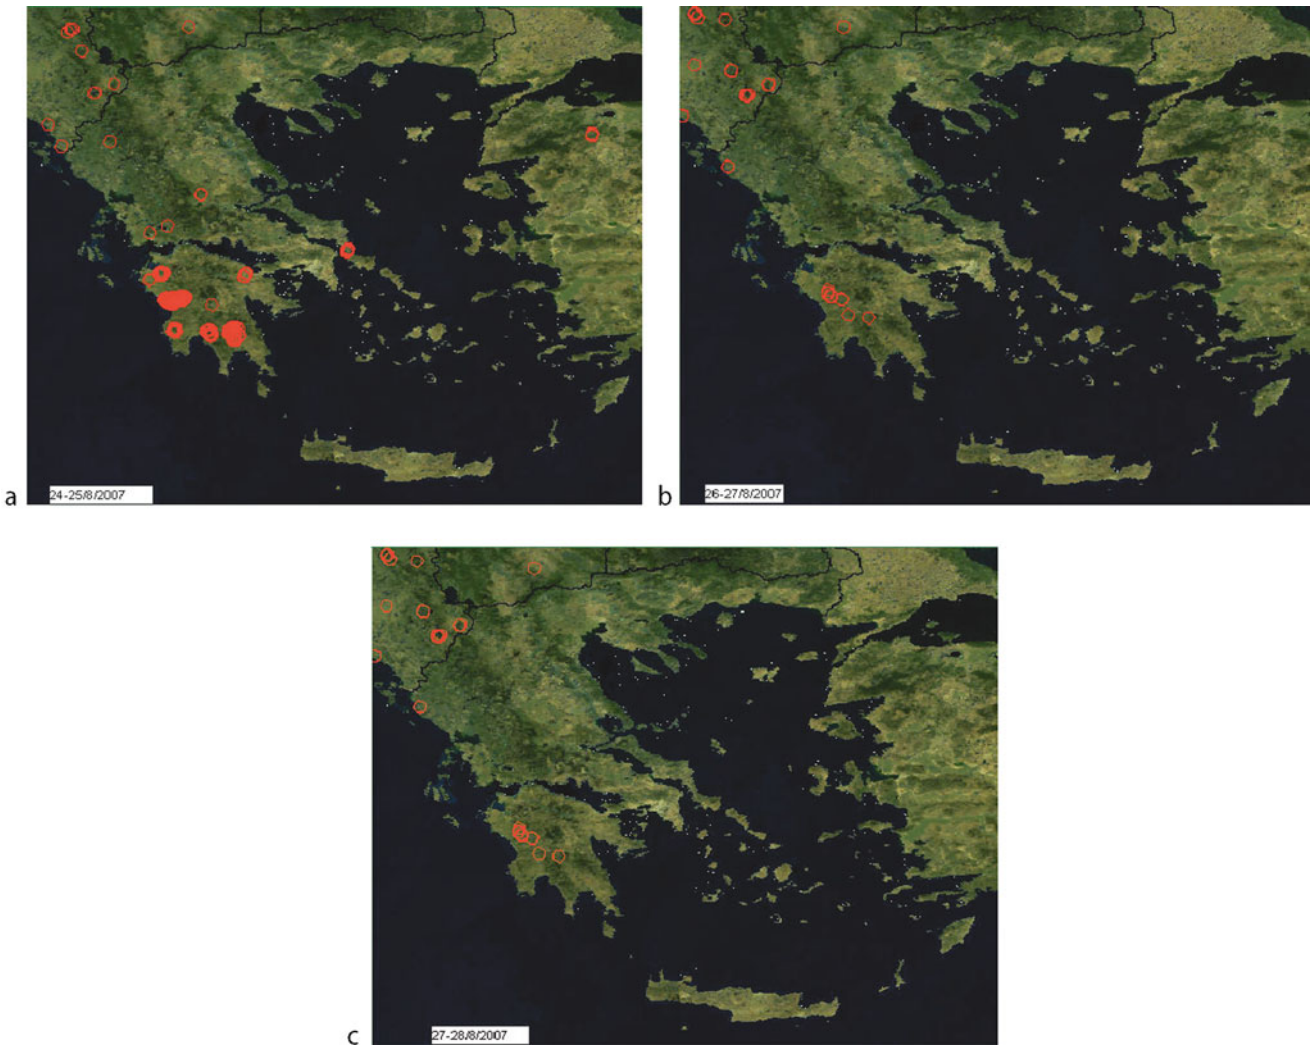
The wind speed in the area of Pyrgos during the dates of the fire (24–27 August) reached 30.6 km/h, whereas day temperature was constantly above 40°C. The humidity of the air fell below 12% during the warmer hours of the day, reaching 40% after midnight.

The majority of the fires in Peloponnese started the night of 23 August and involved several parts of south and west Peloponnese, including the regions of Messinia, Arcadia, Laconia, Ilia, and Achaia. The 24th of August was the 80th day without rain in the area of Pyrgos. On the 25th of August, a state of emergency was declared, and international assistance was requested to fight the fires. On the 29th of August, due to the change of the weather, the fires began to die, and the fire brigades succeeded to contain most of them within the next 2 days. A distribution of the burned areas in the region of Peloponnese is shown in Figure 3. According to the calculations made by the Remote Sensing Laboratory of the

Mega-Fires in Greece (2007), Figure 3 Footprint of the areas burnt in Peloponnese during August 2007 (Source: Remote sensing Laboratory of the Aristotelian University of Thessaloniki).

Aristotelian University of Thessaloniki using satellite data of resolution 30 × 30 m, the total burned area is 177,265 ha. An area of 78,104 ha was agricultural land, whereas 1,634 ha corresponded to structures and infrastructures (villages, roads, installations, etc.).

The evolution of the fire ignitions during this period is shown in Figure 4. It is evident that most of the fire ignitions occurred in the first 2 days of the firestorm (24 and 25 August), whereas significant new fires continued to start until 28 August (Eftichidis, 2007). The situation far exceeded the capabilities of the Greek firefighting forces. Reinforcements and help provided by several other countries for the firefighting operations was not able to control the high-intensity fires in progress.



The data of the mega-fires of Peloponnese are shown in the next table (Table 1).

The fires burned hundreds of square kilometers of pine and fir forests, open forested areas, shrublands, olive groves, vineyards, as well as vast number of isolated residences, installations, and houses in the villages. Several regions faced breakdowns in telecommunications, electricity, and water supplies.

As can be seen from the data in Table 1, the fires of Megalopoli, Zacharo, and Pyrgos and the fires in dry sites were more extensive than the fires that burned in higher altitudes and more humid sites such as the mountains of Taygetos and Parnon. The extent of the fires is also related to the forest species of the regions. In Taygetos and Parnon, stands of fir trees burned more slowly than pine stands that burned elsewhere.

The extent of the 2007 situation was completely new in comparison to the historic forest fire patterns. The extreme intensity of these fires made their control impossible even when they reached areas that are normally used as fire control points.

Damages were unprecedented and of extreme severity. Many people evacuated their homes to move to safer places. Unfortunately, most of the inhabitants of the villages, in particular aged people, refused to leave their houses and belongings, and a number of individuals died as a consequence.

Mega-Fires in Greece (2007), Figure 4 Fire ignitions in Peloponnese during the dates 24–28/8/2007 (Source NASA).

Mega-Fires in Greece (2007), Table 1 Burned areas by mega-fires in Greece, summer 2007 (Source: MODIS burned area products)

Fire name	Burned area (ha)	Growth duration
Mnt. Taygetos	11,357	24–27/8/2007
Mnt. Parnon	20,681	23–30/8/2007
Megalopoli	42,350	24–27/8/2007
Zacharo	45,809	24–30/8/2007
Pyrgos	42,652	24–30/8/2007
Total	*162,849*	

There were also cases of people who did not evacuate in a timely manner, due to the unpredictable speed of the fire propagation as well as due to lack of coordination of the evacuation operations during the first days of the fires. Some of these people were trapped and killed in car accidents while trying to escape from the burning villages. The death toll of the mega-fires of the summer 2007 in southern Greece was more than 70 people, which is a high number of victims in worldwide wildfire history.

Flames engulfed the archeological site of Olympia, home of the first Olympic Games, and the temple of Apollo Epikourios, a 2,500-year-old monument near the town of Andritsaina in southwestern Peloponnese. Thus, the situation was made extremely complex, requiring the authorities to evacuate villages, save archeological sites, and protect human property rather than just extinguishing the flames.

Effects of the 2007 fires

The mega-fires of the summer 2007 in Greece had significant environmental impact due to the large extent and the erratic behavior of the fire. Biodiversity in several protected areas belonging to the Natura 2000 network

covering some 30,132 ha (WWF Hellas, 2007) was affected. On the Peloponnese, WWF recorded impacts at seven important Sites of Community Importance and significant impacts to the biotopes of certain species of special ecological importance, for example, the golden jackal (70% of its population lived in these protected areas of the Peloponnese), 4 out of 5 species of endemic lizards, land turtles, and other animals. The potential for recovery of these biotopes depends on the effective protection of these areas from any future change in land use (WWF Hellas, 2007).

Another notable ecological impact of the 2007 forest fires occurred in the National Park of Mount Parnitha near Athens. A significant part of the nucleus of the National Park and of the Parnitha true -fir (*Abies cephalonica*) forest was burned. The destruction in much of the Parnitha National Park is irreversible in the midterm since true-fir forests are not adapted to fire events. The forest fire in Parnitha also caused damage to the populations of several protected birds, mammals (especially deer – the National Park of Parnitha hosted the most important population of *Cervus elaphus* in the country), and other vertebrates and invertebrates (WWF Hellas, 2007).

The 2007 forest fires influenced the local climate of the fire-afflicted areas in Greece. These impacts consisted of a rise of average local temperatures, extension of the summer period, and a reduction of the volume and at the same time increased intensity of rainfall.

Following the catastrophic fires on the Peloponnese and Evia in August 2007, the Greek government declared a state of emergency and allocated about €300 million for emergency relief. However, the final cost of the fires is likely to have been higher. Tourism and agriculture were hard-hit, and the regeneration of forests will take many years. An independent estimate by the international assessment firm Standard & Poor's evaluated the damage in the range of €3–€5 billion, corresponding to 1.4–2.4% of the country's GDP (Xanthopoulos, 2007).

Especially on the Peloponnese, the impacts of forest fires to the local economy are considered to have been very high. The on-site inspections recorded extensive damage to entire villages, thousands of houses, livestock, the road network, and to telecommunications, electricity, and irrigation networks.

The tourism sector is also expected to have been affected significantly. Tourism on the Peloponnese was almost exclusively based on the natural environment and the traditional human settlements as primary attractions for the thousands of foreign and Greek visitors. If unplanned development of the human settlements and encroachment on natural areas is not effectively prevented during the reconstruction phase, the region is expected to experience a degradation of its tourism potential (WWF Hellas, 2007).

As concerns the agricultural sector, it should be kept in mind that the Peloponnese hosted 35% of the country's livestock and 30% of the country's olive groves (Bassi and Kettunen, 2007).

Indeed, the 78,043 ha of agricultural land ruined on the Peloponnese were primarily olive groves. In the prefecture of Ilia alone, 50% of the olive production potential was totally incinerated (WWF Hellas, 2007). Such damage should be seen in relation to the main source of income in this area. In this prefecture, 50% of the workforce was in the primary sector. At the same time, this prefecture has the lowest GDP/capita of all prefectures affected by the August fires (approximately half of the national average GDP/capita).

The extensive damage to olive trees and livestock is bound to change the agricultural production balance on a national level and will require extensive compensation for agricultural damage. Indeed, many farmers will have to live on European subsidies and national compensation for several years. For many, there will not be full compensation for damages, and they will be called upon to decide whether to make a new start or abandon their way of life (Bassi and Kettunen, 2007).

The most significant social impact of the 2007 fires was the deaths of 76 people (Xanthopoulos, 2007). The fires also left thousands of people homeless and unemployed (WWF Hellas, 2007).

The quality of life of the inhabitants in fire-affected areas will also be undermined by damage to the landscape. It is estimated that the destruction of the natural vegetation cover will be followed by a disturbance of the soil and water balance and, most likely, by floods and landslides in the future (WWF Hellas, 2007).

Conclusions

The mega-fire phenomenon appears to be increasing in frequency and destruction worldwide. The potential influence of the climate change in the future on the rate of fuel accumulation is of concern. The increase in temperatures and the decrease in rainfall shall contribute to the growing forest fuel load that will be available for future fires. In particular, the problem will be exacerbated in cases where human activity mixes with forest vegetation. There is no question that the forest fire season of summer 2007 was very difficult for Greece. However, the circumstances cannot be considered unique, and it would be overly simplistic to solely attribute the disaster to extreme weather conditions resulting from climate change (Xanthopoulos, 2007). Scientific study indicates that the main underlying causes lie in the lack of appropriate preventive forest management and of a fire prevention policy, the weakness of state mechanisms for effective forest fire suppression, and the lack of organized hazard management plans in the event of mega-fires. Above all, the perception that protection from forest fires is equivalent to forest fire suppression is to blame for the tragic fire events of 2007.

There are several reasons that the mega-fire phenomenon has been growing during the last few decades. For instance, the management of the vegetation in noncommercial forests and the impact of climate change

on the accumulation of biomass and to the moisture status of the forest vegetation. These two factors are reinforced by uncontrolled urban growth in the wildland urban interface and the relative large investments in fire suppression infrastructure and policies. In addition, public expectations for the land discourage or exclude activities that might reduce fuel loadings (Williams, 2007)

Fire suppression can be successful during years of mild fire seasons, contributing thus to the accumulation of flammable biomass that will be available to the fire in the dry years that will follow with extreme weather conditions. This leads to the paradox of increasing the risk while investing in mitigation. Mega-fires are not occurring due to a lack in funding. The worst fires on record in the USA coincide with the highest preparedness budgets ever seen (Williams, 2007).

Sustainable management of the vegetation is a key issue in addressing the problem of accumulation of biomass and the artificial structure of the tree stands due to human-centered forest protection plans. These facts lie behind the intensity and the size of mega-fires and define the chances for control. Therefore, the wise management of the fire problem should be reinforced through sustainable forest management for mitigation purposes (Eftichidis, 2007).

Mega-fires have to be addressed as a hybrid of civil protection and environmental issues since they impact natural resources, but at the same time, they threaten the lives of citizens, consume agricultural production, destroy properties, and create severe postfire social problems.

Land planning organizations have to find ways for reducing exposure and improving the coping capacity of rural population to forest fire, in order to limit the disastrous consequences of mega-fires.

MERCALLI, GIUSEPPE (1850–1914)

Valerio Comerci
ISPRA – Institute for Environmental Protection and Research, Roma, Italy

Giuseppe Mercalli was born in Milan, Italy, on May 20, 1850. In 1872, he was ordained a Roman Catholic priest and in 1874 became a professor of Natural Sciences. He devoted his life to the study of *volcanoes* and *earthquakes* and, at the same time, was a dedicated schoolteacher for over 35 years, writing several natural science handbooks. Until he became director of the Vesuvius Observatory in 1911, he taught at the Catholic seminary of Monza and at the Lyceums of Reggio Calabria (1888) and Naples (1892). He was lecturer at the Universities of Catania and Naples.

A pupil of the geologist Antonio Stoppani, he started his scientific activity by studying Quaternary Alpine glacial deposits, but soon expanded his interests to volcanological and seismological research that made him famous. In 1883, his monograph "Vulcani e fenomeni vulcanici" was published, concerning Italian *volcanoes* and related phenomena. In this work he presented his observations and studies on the Eolian Islands, the Phlegrean Fields, Etna and *Vesuvius*, and also on Italian *earthquakes*, and their correlation with *volcanoes*. He compiled a catalog of Italian *earthquakes* from 1450 BC to 1881, highlighting the existence of *seismic districts*, where seismic activity is more frequent and characteristic. He drew four seismic maps, representing the first scientific synthesis of Italian seismicity. This work was a milestone for seismologists of that time, like Mercalli's monographs on the Ischia (1883), Liguria (1887), Ponza (1892), and Andalusia (1881) *earthquakes*. Other geological and seismic monographs were published in 1897 on Piemonte and Liguria and on Calabria and Messina, followed by the studies on the 1905, 1907, and 1908 Calabrian *earthquakes*.

He revised the De Rossi-Forel *intensity scale* and in 1900 the ten degree Mercalli scale was officially adopted in Italy. In the course of time it was modified by several

seismologists but Mercalli's name was maintained: the *Modified Mercalli scale* is today used worldwide.

Mercalli studied some Etna eruptions and the Eolian islands, in particular Stromboli and Vulcano, but the main subject of his investigations was certainly *Vesuvius*, to which he dedicated over 20 years of his life. Moreover, he summed up his ponderous studies on active *volcanoes* of the world in the volume "I vulcani attivi della Terra", printed in 1907, which actually represents the first Italian treatise on volcanology. He not only provided a precise description of the observed phenomena but also introduced classifications, stating the specific characteristics of the different eruptive apparatus and their manifestations.

During the night of March 18–19, 1914, a fire put an end to Mercalli's life, one that had been entirely dedicated to science.

METEORITE

Jay Melosh
Purdue University, West Lafayette, IN, USA

Synonyms

Asteroid; Bolide; Meteor; Meteoroid

Definition

A meteorite is a mass of solid material (either stony or metallic) on the surface of the Earth that came from space.

Discussion

The word meteorite is used for such an object on the surface of the Earth. In space, it is called a meteoroid if small or an asteroid if large (there is no strict dividing line between a meteoroid and an asteroid: typically, a diameter of about 1 km is used, but usage varies within wide limits). A meteor is the bright streak in the sky that accompanies the entry of a meteoroid into the Earth's atmosphere. A meteor that exhibits one or more bright explosions is called a bolide.

Most meteorites originate in the asteroid belt between Mars and Jupiter, but a few come from the surfaces of larger planets, such as Mars or the Moon. Some volatile-rich types may come from comets. Meteorites are classified as stony, iron (metallic), and stony-iron. Stony meteorites, which are about 40 times more abundant in space than irons, are further classified as either chondrites (the most abundant type, with many subclasses of chondrite) or as achondrites. Chondrites contain small, mm to cm diameter, spherical inclusions that are more or less distinct in the body of the meteorite. Freshly fallen meteorites are enclosed in a glassy crust of melted material, the fusion crust, which forms by friction with the air as the meteoroid enters the Earth's atmosphere at high speed.

Meteorites are described as either finds or falls, depending upon the circumstances of their discovery. They are conventionally named after the post office nearest to the point at which they are recovered, such as Allende (fell in 1969 near the town of Allende, Chihuahua, Mexico). In the case of the recently discovered meteorites in Antarctica, names are given that refer to the location, year, and order in which they were cataloged, such as ALH84001 (found near the Allen Hills Moraine in 1984 and the first to be cataloged).

METHANE RELEASE FROM HYDRATE

Graham Westbrook
University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Climate-induced dissociation of methane hydrate; Release of methane from hydrate caused by global warming

Definition

The release of methane gas from methane hydrate, which is a clathrate (a solid in which water molecules form a cage enclosing methane molecules), occurs when an increase in pressure or a decrease in pressure create conditions that cause hydrate to break down into its separate constituents of water and gas. A natural increase in temperature can be caused by a warming climate, and reduction in pressure, for hydrate beneath the seabed, by a fall in sea level.

Discussion

Methane hydrate is stable under conditions of low temperature and high pressure such as those found on land in regions of permafrost or under the ocean in water deeper than 300–600 m, depending on the water temperature. The concentration of methane in the ocean is usually far too low for hydrate to form, but in the sediment and rocks beneath the seabed, methane concentration can be high enough to form hydrate. The thickness of the gas hydrate stability zone (GHSZ), in which hydrate can form and exist stably, is limited by the increase of temperature with depth within the Earth. Methane from deeper hydrocarbon reservoirs or generated by bacteria from the organic material in the sediment migrates upward, as free gas or dissolved in water, into the GHSZ, where it forms hydrate. The amount of carbon in hydrate beneath the seabed is probably equal to the carbon in all other sources of natural gas and petroleum in the Earth.

An increase in seabed temperature reduces the extent of the GHSZ. In deep water, the seabed remains in the GHSZ, whereas the downward propagation of the temperature increase causes the base of the GHSZ to migrate upward, releasing methane, which may reenter the GHSZ and form hydrate again, limiting the amount that may escape into the ocean. Where the GHSZ in shallower water is removed completely by warming, the methane released is free to migrate through the sediment to the seabed. The upper continental slope is most prone to methane release by this mechanism, because temperature change is greatest in the upper water column. Although hydrate is absent from most continental shelves, because they are too shallow for the GHSZ to occur, it exists in rocks and sediment beneath the shelf in the Arctic because of the low temperature caused by the presence of permafrost created during the last glacial period when large parts of the shelf were subaerial. There, sea-level rise reinforces the effect of increasing water temperature by flooding low-lying land with water that is warmer than the average temperature of the land surface. Permafrost retards the escape of methane released from hydrate, because the extra heat required to melt the ice slows down the increase of temperature, and because ice impedes the flow of gas. This can impose time lags of hundreds of years between the onset of warming and methane escape.

Over recent years, there has been increasing evidence that methane released from hydrate as a consequence of warming enters the ocean, but little evidence that much of it enters the atmosphere to contribute to global warming. It appears that the rate of release of methane is generally too slow to overcome its solution in the ocean, where, after oxidation, it contributes to ocean acidification. Catastrophic gas venting or submarine landslides of hydrate-rich sediment might, however, be effective in releasing large amounts of methane over short periods of time. Submarine slides have been widely cited as an agent of ancient increases in atmospheric methane but their potency has still to be proven. It has been proposed that the release of gas from rapid dissociation of hydrate creates zones of over-pressured gas in sediment beneath continental slopes, reducing sediment strength and increasing the likelihood of submarine slides, which can cause tsunamis.

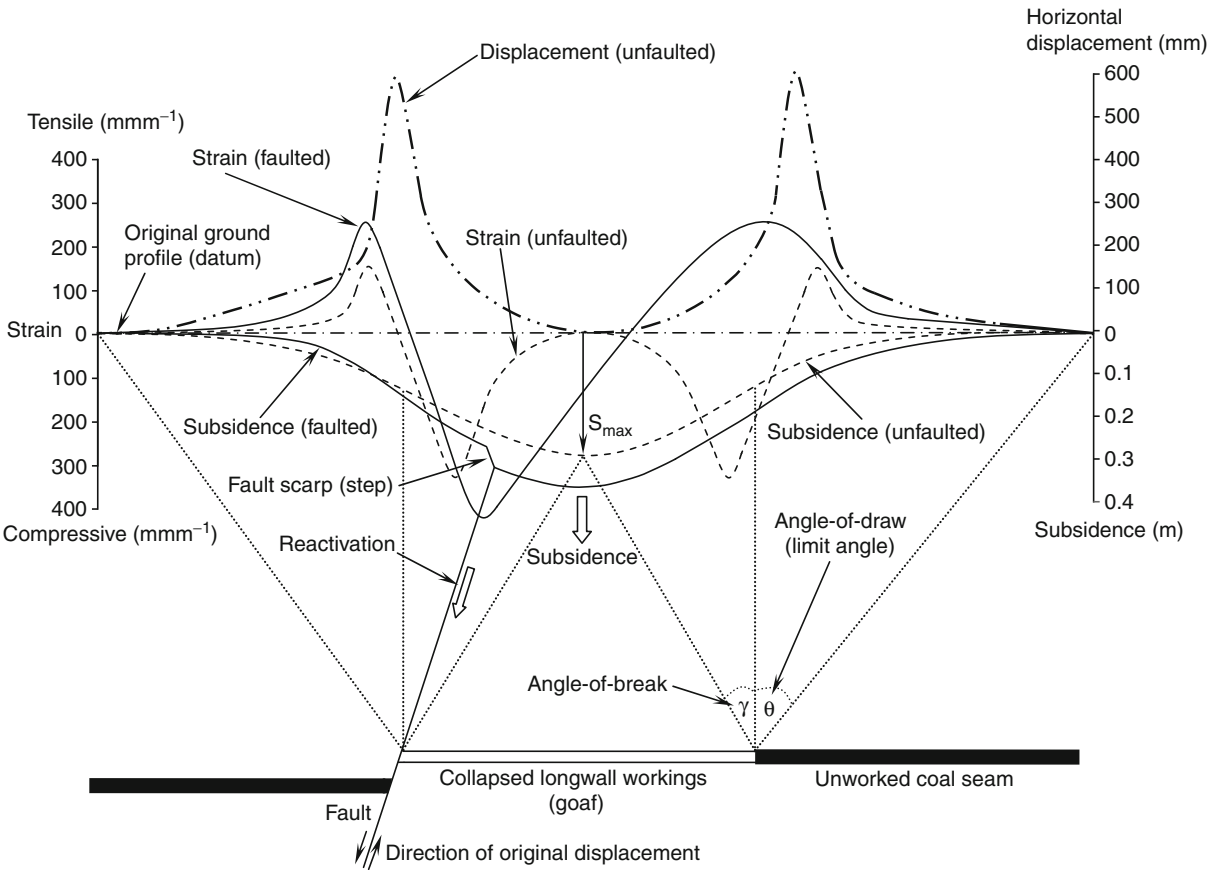
MINING SUBSIDENCE INDUCED FAULT REACTIVATION

Laurance Donnelly
Wardell Armstrong LLP, Greater Manchester, UK

Synonyms

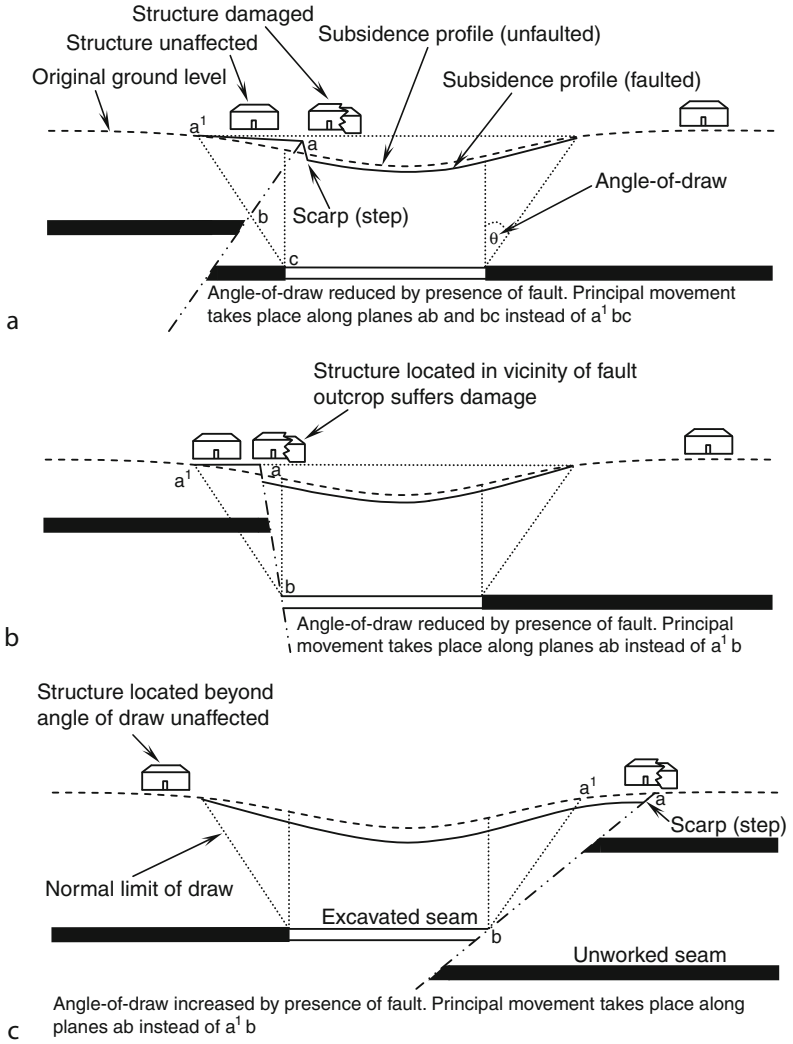
Break lines; Fault steps

Definition



Faults are naturally occurring discontinuities in rock or soil where there has been observable and measurable displacement by shearing and/or dilation. Faults located in areas prone to mining subsidence, caused by the longwall extraction of coal, are susceptible to reactivation. This may result in the generation of a fault scarp along the ground surface (also referred to by some mining and subsidence engineers as a "step" or "break line").

Summary



Mining subsidence-induced fault reactivation may generate a scarp, graben, fissure, or zone of compression along the ground surface (Figures 1 and 2). This is significant because it may cause physical damage to structures (buildings, houses, industrial premises, bridges, dams, pylons, and towers), services and utilities (sewers, water conveyances, gas mains, pipelines, and communications cables), and transport networks (tracks, roads, motorways, railways, rivers, and canals) (Figures 3–6).

The topographic expression of reactivated faults may vary considerably from subtle deflections and flexures barely recognizable across agricultural land or road side verges, to distinct, high-angled fault scarp walls, upto approximately 3–4 m high and 4 km long. In areas of high relief, reactivated faults may influence the first time failure of slopes and the reactivation of landslides (Figures 7–9). More commonly, fault scarps are less than a meter high, less than a meter wide, and vary in length from just a few meters to a few hundreds of meters long.

Reactivated faults do not always appear at their expected outcrop position as inferred on geological maps. This may be attributed to the acceptable mapping tolerances (since geological maps provide an estimate of their likely outcrop position on the ground surface). This is often complicated by the variable nature of the strata, surficial deposits, or made ground, which a fault displaces. Greater thicknesses of surficial

Mining Subsidence Induced Fault Reactivation, Figure 1 Schematic model to illustrate fault reactivation during the mining of a horizontal coal seam by the longwall-mining method. Fault reactivation generates a fault scarp (or step) in the subsidence profile (trough) and disrupts the distribution of the horizontal displacements and strains. High compressive ground strains tend to occur at the fault scarp (but not always, these may also be tensile, generating a fissure) (After Donnelly, 2009).

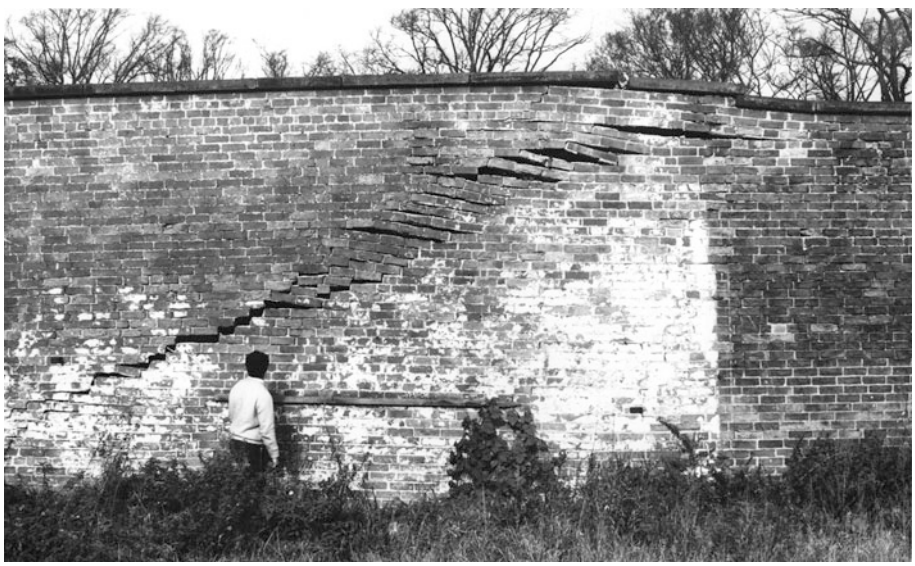
Mining Subsidence Induced Fault Reactivation, Figure 2 The influence of faults on mining subsidence and the angle-of-draw. (**a** and **b**) Any structures located in the vicinity of fault outcrops during their reactivation will almost certainly physical damage. When workings are located in the footwall of the fault, any structure located in the hanging wall may be safeguarded as the fault absorbs most of the ground strains (although this is not always the case). In examples (**a** and **b**), the presence of the fault has reduced the angle-of-draw (and therefore area-of-influence) in the hanging wall. (**c**) Faults may also extend the angle-of-draw, beyond that which would otherwise prevail in the absence of any faults (After Donnelly, 2009).

deposits tend to reduce the severity of a fault scarp, but influence a much broader area. Where the cover is thin or absent a distinct, high-angled fault scarp may develop, but where these are thicker a less distinct, broad, open flexure will be generated. Fault scarps are normally temporary features of the ground surface and may be destroyed soon after their generation by, for example, repairs to roads and structures, the ploughing of agricultural land, or by processes of weathering and erosion. In some instances, reactivated faults have reduced the amount of subsidence on the unworked side of a fault by absorbing ground strains and safeguarding houses, structures, and land that may have been otherwise damaged.

Faults are capable of several phases of reactivation each time they are influenced during longwall coal mining operations, separated by periods of relative stability. Fault reactivation has been documented since the middle part of the nineteenth century throughout the United Kingdom and in many other coal mining regions around the world.

Although fault reactivation, in certain circumstances, may continue for periods of time (weeks to several years) after "normal" subsidence has been completed,

movements along most faults does eventually stop in the majority of cases investigated.



The mechanisms of mining subsidence-induced fault reactivation are only partially understood. Since ground movements along faults have been observed and recorded to take place over weeks, months, and years, aseismic creep appears to be the dominant mechanism. However, brittle shear failure may be possible where the fault displaces strong sandstone or limestone. There is currently no strong evidence to suggest that coal mining-induced fault reactivation induces seismicity (earthquakes), although this is difficult to prove.

Mining Subsidence Induced Fault Reactivation, Figure 8 The 3–4 m high and 4 km long Tableland Fault scarp, which has influenced the Darren Goch landslide and displaced stream valleys, South Wales Coalfield (Photograph © Laurance Donnelly).

Mining Subsidence Induced Fault Reactivation, Figure 9 A typical South Wales fault scarp representing several phases of reactivation, probably initiated by valley deglaciation and exacerbated by mining subsidence. These form distinct, extensive topographic features, which may reach at least 4 m high and 3–4 km long. These influence surface drainage and groundwater flow and landsliding (including first time failures and reactivation of existing landslides) (Photograph © Laurance Donnelly).

It would be prudent on all engineering sites containing geological faults in active and former mining areas to investigate their potential effects on ground stability, mine gas emissions, or groundwater/mine water discharges, before development and construction is carried out. It is recommended that this be undertaken at the desk study and ground investigation stage of a project to reduce the risks for unforeseen ground conditions. The ground may then be suitably treated, or appropriate foundations designed, prior to any construction or developments taking place. Further information on mining-induced fault reactivation is present in Donnelly,

MISCONCEPTIONS ABOUT NATURAL DISASTERS

Timothy R. H. Davies
University of Canterbury, Christchurch, New Zealand

Definitions

Adaptability. The ability to adapt – in this context, to unexpected or altered behavior of natural systems.
Mitigation. Measures taken by society to reduce the consequences of a disaster.
Natural disaster. An event in which the behavior of part of Earth's natural systems causes severe consequences to society, usually greater than local in scale.
Natural hazard. A natural system with the potential to damage society; alternatively, any natural process with the ability to damage society *even if society is not yet present in the area*.
Resilience. The ability to resume normal functioning after a disaster.
Risk. (noun) Probability; probability multiplied by consequence; (verb) to take a chance.
Sustainability. The ability to be sustained – requires specification of *what* is to be sustained, at what *level of intensity*, for what specified *time period*, and what are the *indicators of unsustainability*. Needless to say, these requirements are usually ignored.
Vulnerability. The degree to which society can be affected by disasters.

Introduction

As a result of many years of thinking about natural disasters, teaching students about natural disasters and trying to help communities avert natural disasters, I have come to a number of realizations about the nature and causes of hazards and disasters. These can be summarized as follows:

(a) People cause natural disasters by behaving in ways that make society vulnerable to infrequent high-magnitude natural events.
(b) More people and more development means more and bigger natural disasters.
(c) "Natural hazards" can usefully be defined as processes of nature with the potential to cause damage to society.
(d) Altering the behavior of natural systems usually results in increasing the probability of a natural disaster.
(e) Maintaining altered behavior of natural systems creates significant long-term costs to society.
(f) People behave according to their world views.
(g) Scientists are often poor communicators, especially with nonscientists.
(h) Whatever can happen, will happen one day; that could be today.
(i) Scientists should do what they are good at – science.
(j) Communities must make their own disaster-management decisions.

These realizations sometimes conflict with more conventional thinking about disaster mitigation, among both scientists ("experts") and lay people. I make no claim whatsoever that my views are "right" for anyone else – but I do think that, even if they are wrong, they are at the very least a useful set of discussion points to stimulate fundamental thinking about how to better reduce the impacts of natural disasters. The following list of "misconceptions" – perhaps better thought of as challenges – sets my realizations (which are at present "true" for me) against the background of conventional or traditional practices and thinking.

Misconceptions

That we know what we are talking about

Discussions about natural disasters are frequently plagued by the different meanings that different people attach to words such as "hazard," "disaster," "risk," and so on. The word "hazard" is particularly broadly interpreted; to some, hazard is synonymous with risk as the numerical probability of a specific event

happening in a specified time interval; to others, it is synonymous with "natural process," such as a landslide occurring on an uninhabited island. Many other interpretations occur between (and even beyond) these extreme examples. Again, "risk" is sometimes defined as the product of probability and consequence, whereas to others it is simply numerical probability as noted above. Similar confusion is possible with the terms "vulnerability," "catastrophe," "disaster," "resilience," and many others.

This is not the place to propose specific meanings for words (with the exception of two examples suggested below); it is, however, appropriate to note that in order to make substantial progress in mitigating inevitable future natural disasters, the meanings of words used either in print or orally must be made completely clear by the user. If this is not done, audiences should ask for it to be done. Experience has shown that such requests are often a complete surprise to the user of the words, and indeed may be treated as an insult; this probably indicates that the user is not clear about the meaning. In any case, continued discussion in the presence of unresolved conflicting interpretations of word meanings is usually unproductive and thus a waste of time.

As examples of how it is possible to unequivocally define potentially confusing words, I offer the following:

"Sustainable" – a specified activity is sustainable at a specified level for a specified time if it does not result in unacceptable consequences (to whom?).

"Natural hazard" – a natural process that currently has the potential to be deleterious to society.

That natural disasters are caused by misbehavior of nature

Natural disaster is a term commonly used to describe severe damage and/or deaths in communities affected by events such as tornadoes, earthquakes, tsunami, volcanic eruptions, storms, etc. It is important to understand that the *events* are simply part of the normal behavior of the Earth's natural systems; they were going on for billions of years before humans evolved, and will continue for billions of years into the future. There is no element of natural misbehavior involved. Events that cause natural disasters are usually somewhat rare on the timescales commonly considered by communities, and are therefore sometimes unexpected, but the only element of misbehavior that can be identified is that the communities did not expect the event to occur and were therefore unprepared – i.e., human misbehavior.

That natural disasters can be prevented by altering the behavior of nature

This misconception arises from the idea that nature misbehaves; if it does then its behavior can be corrected. It is telling to note that the German language term for river engineering is "*Flußkorrektion*" – literally "river correction," implying that the form of the river prior to engineering was incorrect. This is undoubtedly a consequence of the definition of Civil Engineering up until the 1970s: "Harnessing the great powers of nature for the benefit of man," reflecting the idea that "man" has dominion over nature.

Certainly engineering has been vital in developing resources for (hu)mans' use, and modification to the everyday behavior of natural systems can be sustainable. To modify the infrequent events that are the usual trigger for natural disasters, though, is a much more challenging task for a number of reasons:

(a) Data describing infrequent events are usually sparse, so those events are poorly known and understood and the design of control measures to that extent is unreliable.
(b) These infrequent events are characterized by greater magnitude and power than the more frequent, lower-intensity events to which communities are accustomed, so control is correspondingly more difficult.
(c) Fiscal constraints commonly limit the magnitude of event that is able to be "controlled"; but a greater (superdesign) event can occur at any time, and when it does occur it will cause a natural disaster in spite of engineering controls.
(d) Implementation of works to alter the behavior of nature inevitably generates the public perception that there can be no more disasters in that place, so development accelerates, leading to greater costs when the inevitable superdesign event occurs.

Natural disasters cannot be prevented; given Earth's ever-increasing population and occupancy of available land, natural disasters will increase in frequency. The impacts of future natural disasters can be reduced only by better knowledge of their trigger events and careful preparation by communities to reduce their own vulnerability.

That humans are powerless against nature

This is a more recent misconception than most of the others. It is a reaction to the realization that, in many places where geological activity is intense, the forces involved are simply too large for humans to counter. It appears to follow that there is nothing we can do to prevent natural disasters.

It is certainly true that little or nothing can be done to alter the behavior of earthquakes, volcanoes, glaciers, and other large-scale physical processes, and, as outlined elsewhere in this entry, *reliable* modification of infrequent, intense natural process is not achievable. The natural processes that trigger disasters will therefore continue to occur. This does not make society powerless

to reduce the impacts of disasters, however. A disaster occurs when a community is affected by an extreme natural process; but there is nothing to prevent the community from modifying *its own* behavior so as to become less vulnerable to the disaster. What is required is that society becomes aware of the likely consequences of the trigger event, and is prepared to adapt its own behavior in the light of those effects. We may in principle be unable to control nature, but we are in principle able to control ourselves.

The increase in meteorological disasters is caused by climate change

There seems to be a general awareness that natural disasters triggered by storms are increasing in frequency and magnitude (e.g., Hurricane Katrina, recent storms in Japan and the Philippines). This has been cited as evidence that anthropogenic climate change is both real and rapid, and is causing extreme meteorological events to increase in intensity. The hard factual evidence for this is pretty much nonexistent; the storm sequences of recent years lie within the natural event variability that would be expected with a stable climate, even if they may be unusual in that context. Recent storminess is not yet evidence for climate change.

What is clearly evident is the exponential increase in damage costs of weather-related disasters from the 1960s to the present day, as evidenced in many reports. This coincides with the dramatic rise in human population and investment value over the same period – the more there is to lose, the greater will be the losses.

Statistical data on natural behavior can be used to design reliable disaster countermeasures based on cost-benefit analysis

This is the classical natural hazard management concept; if we design to manage the most likely event, then over time net benefit will be maximized. There are a number of flaws in this concept. For example, the probability of the most likely event is much less than the sum of the probabilities of the other events, so the most likely event is in fact *un*likely to occur – it is much more likely that some other event will occur. For example, in 1,000 throws of a six-sided die, the most likely number of sixes is 166.7 (1,000/6). This is of course impossible, because 0.7 of a "six" cannot occur; the most likely possible number (167) of sixes is also much less likely to occur than some other result. Many of these flaws result from the fact that in dealing with disaster-triggering events, we are always dealing with a small sample. This is not only a small dataset describing the infrequent (and therefore few) recorded trigger events, but also the small number of events that will occur in the future in the timescale of relevance.

Events capable of causing disasters are by definition infrequent; if they were frequent, humans would alter their behavior so that the natural hazards were not disastrous. Thus, if we are planning to mitigate disasters at a given site over, say, the next hundred years, we can expect a small number of trigger events – certainly fewer than five, possibly none at all. Here is the point: *Statistical predictions about a small sample of events are intrinsically imprecise*. If a dice is rolled 6,000 times, we expect close to 1,000 sixes; say between 950 and 1,050, which is 1,000 $\pm$ 5%. If the same dice is rolled six times, however, we expect close to 1 six; so the best-case scenario is 1 $\pm$ 1 or 1 $\pm$ 100%. Even if we have a million years of event data from the past, the fact that we are predicting *into* a small sample space makes the prediction intrinsically imprecise.

The other fact that makes cost-benefit analysis of doubtful value is that net benefit equals unmitigated damage cost minus mitigated damage cost. Now both unmitigated and mitigated damage costs are large and imprecise numbers; this means that subtracting one from the other to get net benefit gives a much smaller and much more imprecise number – so imprecise in fact that using it as a design discriminator is often unrealistic.

Natural disasters are always big

The word "disaster" intrinsically implies something big – bigger than an "incident," say, or a "mishap" (but smaller than a "cataclysm" or a "catastrophe"). As with much terminology, however, its meaning depends on one's point of view. A minor mudslide that kills an unemployed peasant is completely unworthy of notice to the vast majority of a population, but to the close relatives of the dead man it is clearly an event that will change their lives, and could realistically be called catastrophic; for the local community in which the man had lived for many years it is a disaster.

People resist hazard mitigation because they are ignorant

It is a common experience among hazard managers that persuading people to take sensible precautions against disasters is difficult. Even persuading them to accept the fact of the existence of a hazard of which they were previously unaware can be tremendously difficult. In such cases an easy solution to the problem is to label the people stupid; but this is both untrue and unproductive.

People usually behave according to what they think is the right thing to do; their view of the right thing to do

may be the result of ignorance or prejudice, but it is not the result of stupidity. Ignorance and prejudice can be altered by good communication; but by definition, stupidity cannot.

At another level, peoples' behavior aligns with their view of how the world operates. Hence, before they have experienced a natural disaster, people will resist being required to carry out hazard assessments and mitigation measures – whereas after the disaster they may blame the authorities who failed to protect them. This is not stupidity, it is the result of a change of world view.

The point of this is that informing people about potential natural disasters is always unwelcome, and the information will be resisted. In order to communicate it effectively, the "expert" needs to understand the world view of the people, and to be overtly empathetic about the psychological impact the information can have. Such empathy is not possible with people one has (even to oneself) labeled "stupid."

Worst-case scenarios are scaremongering and problematic

It is not uncommon for natural hazards scientists to be accused of scaremongering when outlining the potential impacts of extreme natural events on communities, together with the comment that this is not a constructive way to go about communicating science to society. It is indeed the case that simply stating that a community has a 1% per year chance of being devastated by a landslide is likely to create a situation where further communication is difficult; nevertheless, if that information is correct then it needs to be made available so that the community can make decisions about how to manage the situation. The reality is that

(a) Every worst-case scenario can occur, and given long enough will occur.
(b) The worst-case scenario can occur tomorrow.

Thus any disaster-management planner who does not convey such information to a community is not carrying out their duty – in fact any official whose estimate of the likely disaster magnitude is exceeded has failed.

How, then, can such information be conveyed without engendering a non-constructive reaction? This needs forethought – it is too late when standing before the microphone in the Community Hall. It is necessary to establish mutual trust between the community and the official before real communication can occur, so considerable groundwork is required. The whole topic of effectively communicating hazards science to communities and their leaders, so that it can be useful in decision making, is being seriously addressed nowadays (e.g., http://www.usgs.gov/science_impact/index.html) and is possibly one of the most important factors in advancing disaster management worldwide.

A useful aspect of considering a worst-case scenario is that any action a community takes to mitigate its impact will be much more effective against any (much more likely) lesser event. It also has the effect of making a community actively aware of the nature of the landscape they use.

Scientists know best

Reducing the impact of a potential disaster is a task that requires knowledge of the physical aspects of the disaster and knowledge of the social functioning of the community it impacts. Scientists acquire the former through research, but they do not have the latter; I would even venture to suggest that the people with the best potential knowledge of how the community functions are not sociologists or social scientists, but *the community itself*. It is not uncommon, especially where less-developed communities are receiving aid to reduce disasters, to find that scientists exceed their brief of understanding and communicating science, and carry on to state what actions the community should take to mitigate disasters.

I submit that this is not the best way to operate. Especially in dealing with communities of people whose culture is not that of science, or even that of the land of origin of the scientists, all that scientists can usefully do is make information easily available; how that information is used by the community is a decision that can only be made by the community. In doing this, the community accepts responsibility for its resilience to disaster. The community may choose to seek further advice from the scientists, but the latter group should, in my opinion, refrain at all times from trying to influence decision making (difficult though this may be).

This is not just cultural correctness: It is a pragmatic way of ensuring that the disaster-management decisions made are acceptable to the community, and therefore are carried out. There is a long list of situations where solutions have been imposed on communities, found not to be acceptable by the communities and simply not implemented; or, if implementation was part of the job, the works or procedures put in place were not maintained and lapsed through neglect. Rarely does the agency responsible for the solution return to assess its effectiveness. By contrast, when the community is the decision maker, the community will ensure implementation goes ahead and that maintenance occurs.

Conclusions

As noted at the outset, these "misconceptions" are both personal to myself and intended for discussion; however, the purpose is very serious. Of all the

tertiary programs I have been involved in, disaster management is the one with far and away the greatest potential to benefit society – and, if it is done poorly, to do the opposite. *Disaster mismanagement kills people*. Natural processes do not obey the theories of scientists; if the theories are sound, they more or less represent natural processes. In disaster management the best possible information is always required; nature cannot be influenced by theory, policy, or blind faith. Hence, it is imperative that we think deeply about the behavior of nature and of communities; we take nothing on trust, however eminent the source; and we are open to admitting that our present ideas might be wrong.

Synonym

Risk reduction

Definition

Mitigation is the planning and execution of measures designed to reduce the risk to acceptable or tolerable levels.

Introduction

Risk mitigation is an important component of risk management. To develop effective risk mitigation measures, one should understand the key determinants of risk; that is hazard and vulnerability.

Risk mitigation strategies

Risk mitigation strategies for natural hazards aim at either reducing the hazard, or reducing the vulnerability and exposure of the population, infrastructure, and other elements at risk. They can broadly be categorized into the following groups:

- Physical measures to reduce the frequency and/or severity of the hazard
- Land-use planning
- Early warning systems (and emergency evacuation plans) (*early warning systems*)
- Risk communication (*risk perception/communication*) and public awareness campaigns
- Legislation and enforcement of building codes
- Measures to pool and transfer the risks such as natural hazard insurance

Public awareness campaigns are effective in reducing the vulnerability of the exposed population for all types of natural hazards.

Physical measures may be used to stop, delay, or reduce the impact of certain types of natural hazards such as debris flow, flash flood, river flood (*flood protection*), storm surge, and tsunami. On land, these may include "soft" measures in the form of drainage, erosion protection, vegetation, ground improvement; or "hard" structures like dikes, embankments, and vertical concrete or stone block wall. Offshore, the man-made physical barriers like jetties, moles or breakwaters, or even submerged embankments could be constructed to reduce the impact of cyclone, storm surge, and tsunami.

A well functioning and efficient early warning system, including well-designed escape routes and safe areas, is probably the best way to prevent loss of life due to tsunami, flood, storm surge, cyclone, volcanic eruption, and certain classes of landslides. To develop a reliable early warning system, the physical processes and mechanisms need to be understood and methods need to be developed for measuring, modeling, and predicting the natural hazard of concern, for example, landslide or tsunami. Design of functional networks of

escape routes and safe places is strongly dependent on the local context.

The most effective method for mitigating the earthquake risk is to construct buildings and other infrastructure to withstand the earthquake-induced load effects. In seismically active regions, important structures should not be placed in areas that are exposed to earthquake-induced landslides and ground failure, unless measures to improve the ground and/or stabilize the slope(s) are implemented. Obviously relevant legislation and enforcement of building codes must be in place for this mitigation strategy to be successful.

Identification of appropriate mitigation strategy

For a given hazard and element at risk, a number of viable mitigation measures may be available. The identification of the optimal risk mitigation strategy involves:

1. Identification of possible hazard scenarios and hazard levels
2. Analysis of possible consequences (loss of life, monetary losses, damage to the environment, etc.) for the different scenarios (*risk assessment*)
3. Assessment of possible measures to reduce the hazard
4. Assessment of possible measures to reduce or eliminate the potential adverse consequences
5. Recommendation of specific measure(s) on the basis of technical evaluations and discussions with the stakeholders
6. Transfer of knowledge and communication with authorities and society

Any mitigation strategy needs to be part of a community's integrated land-use planning and subjected to analyses that assess and circumvent its potential negative environmental impacts. The optimal risk mitigation strategy is not always the most appropriate one. The exposed population and other stakeholders must be involved in the decision-making process that leads to the choice of the most appropriate risk mitigation strategy.

Summary

Mitigation is an important component of risk management and it refers to the planning and execution of measures designed to reduce the risk. Risk mitigation strategies for natural hazards may focus on reducing the hazard, or on reducing the vulnerability and exposure of the population, infrastructure, and other elements at risk. To identify the most appropriate risk mitigation strategy, the exposed population and other stakeholders must be involved in the decision-making process.

MODIFIED MERCALLI (MM) SCALE

Valerio Comerci
Geological Survey of Italy, Rome, Italy

Definition

The Modified Mercalli Scale is one of the several scales used in the world to estimate the intensity of earthquakes (see entry *Intensity Scales*). It is a tool to evaluate the severity of historical earthquakes in many regions of the world, and it is currently adopted in the USA and other countries for *macroseismic surveys*. Note that there are different versions of MM Scale, all with 12 degrees. The first one was devised by Wood and Neumann in 1931 (see Table 1), modifying and condensing the Mercalli-Cancani scale, as formulated by Sieberg in 1923. This scale is a hierarchical classification of observed effects; the diagnostic effects for the lower degrees are essentially those on people, for the intermediate and higher degrees those on objects and buildings, and for the highest degrees (XI and XII) those on the environment.

Afterward, *Richter* proposed a new version, the MM Scale of 1956 (Richter, 1958), which takes into account four different classes of masonry, defined according to quality of workmanship, construction materials employed, and resistance against lateral forces. Later on, other MM scales have been produced, such as the versions by Brazee (1979) and Stover and Coffman (1993), the variant by Dengler and McPherson (1993) addressed to sparsely populated areas, or the revisions carried out by Dowrick (1996) and Hancox et al. (2002) for New Zealand, etc.

Therefore, when using MM intensity values, it is necessary to specify the scale version.

Modified Mercalli (MM) Scale, Table 1 Modified Mercalli intensity scale of 1931 (From Wood and Neumann 1931)

I	*Not felt* – or, except rarely under especially favorable circumstances Under certain conditions, at and outside the boundary of the area in which a great shock is felt: Sometimes birds, animals, reported uneasy or disturbed; Sometimes dizziness or nausea experienced; Sometimes trees, structures, liquids, bodies of water, may sway –doors may swing, very slowly
II	*Felt indoors by few, especially on upper floors*, or by sensitive, or nervous persons Also, as in grade I, but often more noticeably: Sometimes *hanging objects may swing*, especially when delicately suspended; Sometimes trees, structures, liquids, bodies of water, may sway; doors may swing, very slowly; Sometimes birds, animals, reported uneasy or disturbed; Sometimes dizziness or nausea experienced
III	*Felt indoors by several, motion usually rapid vibration* Sometimes not recognized to be an earthquake at first *Duration estimated* in some cases Vibration like that due to passing of light, or lightly loaded trucks, or heavy trucks some distance away *Hanging objects may swing slightly* Movements may be appreciable on upper levels of tall structures. Rocked standing motor cars slightly
IV	*Felt indoors by many, outdoors by few* *Awakened few*, especially light sleepers *Frightened no one*, unless apprehensive from previous experience. Vibration like that due to passing of heavy, or heavily loaded trucks. Sensation like heavy body striking building, or falling of heavy objects inside *Rattling of dishes, windows, doors*; glassware and crockery clink and clash *Creaking of walls, frame*, especially in the upper range of this grade *Hanging objects swung*, in numerous instances Disturbed liquids in open vessels *slightly* Rocked standing motor cars noticeably
V	*Felt indoors by practically all, outdoors by many or most: outdoors direction estimated* *Awakened many* or most *Frightened few* – slight excitement, a few ran outdoors Buildings trembled throughout *Broke dishes*, glassware, to some extent *Cracked windows* – in some cases, but not generally *Overturned vases, small or unstable objects*, in many instances, with occasional fall *Hanging objects, doors, swing* generally or considerably Knocked pictures against walls, or swung them out of place. Opened, or closed, doors, shutters, abruptly *Pendulum clocks stopped*, started or ran fast, or slow *Moved small objects, furnishings*, the latter to slight extent. *Spilled liquids* in small amounts from well-filled open containers. *Trees, bushes, shaken slightly*
VI	*Felt by all*, indoors and outdoors *Frightened many*, excitement general, some alarm, many ran outdoors. *Awakened all* Persons made to move unsteadily *Trees, bushes, shaken slightly to moderately* Liquid set in strong motion Small bells rang – church, chapel, school, etc *Damage slight* in poorly built buildings *Fall of plaster* in small amount *Cracked plaster* somewhat, especially fine cracks in *chimneys* in some instances *Broke dishes*, glassware, in considerable quantity, also some windows *Fall of knickknacks, books, pictures* *Overturned furniture* in many instances *Moved furnishings* of moderately heavy kind
VII	*Frightened all* – general alarm, all ran outdoors Some, or many, found it difficult to stand Noticed by persons driving motor cars *Trees and bushes shaken moderately to strongly* Waves on ponds, lakes, and running water Water turbid from mud stirred up Incaving to some extent of sand or gravel stream banks Rang large church bells, etc Suspended objects made to quiver *Damage negligible* in buildings of good design and construction, *slight* to moderate in well-built ordinary buildings, *considerable* in poorly built or badly designed buildings, adobe houses, old walls (especially where laid up without mortar), spires, etc *Cracked chimneys* to considerable extent, *walls* to some extent. *Fall of plaster* in considerable to large amount, also some stucco. *Broke numerous windows, furniture* to some extent

Modified Mercalli (MM) Scale, Table 1 (Continued)

	Shook down loosened brickwork and tiles
	Broke weak chimneys at the roofline (sometimes damaging roofs). *Fall of cornices* from towers and high buildings
	Dislodged bricks and stones
	Overturned heavy furniture, with damage from breaking
	Damage considerable to concrete irrigation ditches
VIII	*Fright general* – alarm approaches panic
	Disturbed persons driving motor cars
	Trees shaken strongly – branches, trunks, broken off, especially palm trees
	Ejected sand and mud in small amounts
	Changes: temporary, permanent; in flow of springs and wells; dry wells renewed flow; in temperature of spring and well waters
	Damage slight in structures (brick) built especially to withstand earthquakes
	Considerable in ordinary substantial buildings, partial collapse: racked, tumbled down, wooden houses in some cases; threw out panel walls in frame structures, broke off decayed piling
	Fall of walls
	Cracked, broke, solid stone walls seriously
	Wet ground to some extent, also ground on steep slopes
	Twisting, fall of chimneys, columns, monuments also factory stacks, towers
	Moved conspicuously, overturned, very heavy furniture
IX	Panic general
	Cracked ground conspicuously
	Damage considerable in (masonry) structures built especially to withstand earthquakes:
	Threw out of plumb some wood-frame houses built especially to withstand earthquakes;
	Great in substantial (masonry) buildings, some collapse in large part; or wholly shifted frame buildings off foundations, racked frames; serious to reservoirs; underground pipes sometimes broken
X	*Cracked ground*, especially where loose and wet, up to widths of several inches; fissures up to a yard in width ran parallel to canal and stream banks
	Landslides considerable from river banks and steep coasts
	Shifted sand and mud horizontally on beaches and flat land
	Changed level of water in wells
	Threw water on banks of canals, lakes, rivers, etc
	Damage serious to dams, dikes, embankments
	Severe to well-built wooden structures and bridges, some destroyed
	Developed dangerous cracks in excellent brick walls
	Destroyed most masonry and frame structures, also their foundations
	Bent railroad rails slightly
	Tore apart, or crushed endwise, pipe lines buried in earth
	Open cracks and broad wavy folds in cement pavements and asphalt road surfaces
XI	Disturbances in ground many and widespread, varying with ground material
	Broad fissures, earth slumps, and land slips in soft, wet ground. Ejected water in large amounts charged with sand and mud
	Caused sea waves (“tidal” waves) of significant magnitude
	Damage severe to wood-frame structures, especially near shock centers
	Great to dams, dikes, embankments, often for long distances
	Few, if any (masonry), structures remained standing
	Destroyed large well-built bridges by the wrecking of supporting piers, or pillars
	Affected yielding wooden bridges less
	Bent railroad rails greatly, and thrust them endwise
	Put pipe lines buried in earth completely out of service
XII	*Damage total* – practically all works of construction damaged greatly or destroyed
	Disturbances in ground great and varied, numerous shearing cracks. Landslides, falls of rock of significant character, slumping of river banks, etc., numerous and extensive
	Wrenched loose, tore off, large rock masses
	Fault slips in firm rock, with notable horizontal and vertical offset displacements
	Water channels, surface and underground, disturbed and modified greatly
	Dammed lakes, produced waterfalls, deflected rivers, etc
	Waves seen on ground surfaces (actually seen, probably, in some cases). Distorted lines of sight and level
	Threw objects upward into the air

MONITORING NATURAL HAZARDS

Michel Jaboyedoff, Pascal Horton, Marc-Henri Derron, Céline Longchamp, Clément Michoud
University of Lausanne, Lausanne, Switzerland

Synonyms

Observation; Surveillance; Watching

Definition

The verb "to monitor" comes from the Latin "monere" which means to warn. In geosciences, it means to watch carefully at a hazardous situation and to observe its evolution and changes over a period of time. It is also used to define the activity of a device that measures periodically or continuously sensitive states and specific parameters.

Introduction

Hazard monitoring is based on the acquisition and the interpretation of a signal indicating changes in behavior or properties of a hazardous phenomenon or the occurrence of events. This ranges from acquiring basic meteorological data to advanced ground movement measurements. Hazards monitoring began sometime ago, when the Babylonians first tried to forecast weather. When Aristotle wrote his treatise *Meteorologica*, the Chinese were also aware of weather observations (NASA, 2012a). Pliny the Elder studied in details the eruption of the Vesuvius in August 79 AD, providing one of the first scientific observations of a natural catastrophe. Presently, the evolution and the precision of monitoring are closely linked to the development of new technologies. A very interesting example highlighting the importance of technological development is provided by hurricane statistics. The number of hurricanes had often been underestimated because of the lack of information prior to the appearance of satellite imagery: many hurricanes that did not reach the coasts were simply not registered (Landsea, 2007). Today, the development of telecommunications and electronics has made easier the adoption of monitoring systems. In addition, satellite remote sensing has improved greatly the detection of changes at Earth surface. Nevertheless, monitoring remains a costly activity, implying that actually only few hazard types and locations are monitored. Moreover, as dangerous phenomena are usually complex, several parameters have to be monitored, and in most cases one single variable is not a sufficient criterion to provide reliable warnings.

Monitoring can be either linked to an early warning system, leading to act directly within the society, or used to record hazardous events to provide data for hazard assessment and a better understanding of the phenomenon. Some of the monitoring results are public and accessible at no cost, such as earthquake data, whereas meteorological data are often sold because they are profitable due to their direct impact on society (such as agriculture, air traffic, news, and tourism). In any case, with the boom of Internet, more and more free data is accessible in many countries.

In the following, we describe briefly the most common sensor types used for monitoring several hazards and further discuss monitoring aspects.

Instruments and measured variables

Originally, monitoring was mainly done by simple human observations or with limited devices, and some were performed manually, such as the first rain gauges. Now, even if some monitoring is still based on observations, as for snow avalanches, it is mainly instrumented, and many sensors are also used for remote-sensing techniques. The great advance in computer sciences and communication technologies has increased the accessibility to instruments, by improving technology and reducing costs.

Climatic variables are monitored by satellite and meteorological stations. According to the World Meteorological Organization (WMO, 2012a), the global observing system (GOS) acquires *"meteorological, climatological,*

hydrological and marine and oceanographic data from more than 15 satellites, 100 moored buoys, 600 drifting buoys, 3,000 aircraft, 7,300 ships and some 10,000 land-based stations."

Hazard monitoring consists primarily of treating a signal in order to obtain information about movement, moisture, temperature, pressure, or physical properties (Table 1). A monitoring sensor is local when it records properties at its own location (thermometer, rain gauge, etc.). Remote sensors are used to collect properties of distant objects. Remote-sensing techniques can be active (a signal is sent and received) or passive (only receiving). For instance, InSAR (interferometric synthetic aperture radar) is an active remote-sensing method to detect ground movement, whether Earth surface temperatures can be measured from satellites by passive remote sensing analyzing specific bands of the electromagnetic spectrum (Jensen, 2007). Currently, satellites using microwaves or bands in the visible and infrared spectra permit one to quantify environmental variables such as rainfall, CO_2, water vapor, cloud fraction, and land temperature (NASA, 2012b).

Two important advances in the last 20 years now allow one to measure ground movements, one key factor for many natural hazards: (1) the GNSS (Global Navigation Satellite System), which allows measuring 3D displacements, and (2) the satellite and terrestrial InSAR techniques that permit one to map very accurate displacements using two successive radar images by comparing the phase signal. Of course, local direct measurements of displacements such as extensometers, tide float gauges, or inclinometers are still very much used and complement these recent techniques.

The final goal of hazard monitoring is to provide information about physical parameters directly or indirectly interpreted in order to evaluate the level of risk. The following presents some of the most current methods used to monitor the main hazards affecting human activities.

Meteorological monitoring

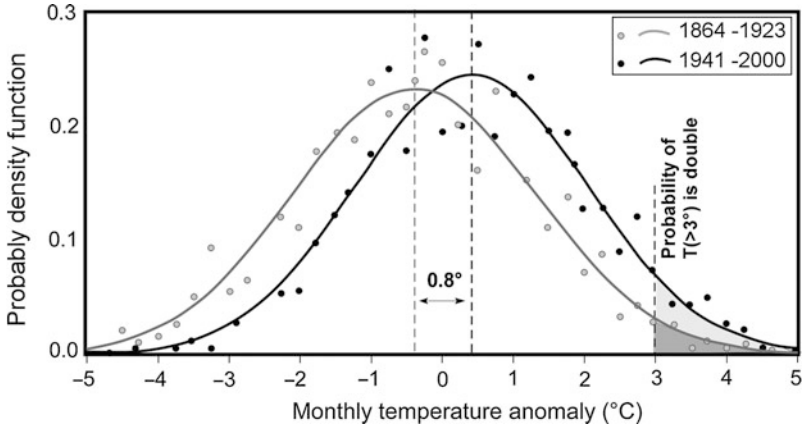
Monitoring meteorological variables is mainly dedicated to weather forecasting but also to the understanding of climate change. It covers phenomena from local to global scale. Spatial and temporal scales of the phenomena are linked. Local and extreme events, such as tornadoes, hail, or thunderstorms, last only a few minutes to hours, and their location and intensity cannot be forecasted in advance. These kind of events are the topics of short-range forecasting, or nowcasting, that rely on observations and measurements of the phenomena after its initiation, as, for instance, by means of satellite or ground-based radar data. Regional events, such as heavy precipitation over a mountain range, strong winds over a country, or hurricanes, can usually be foreseen a few days in advance. These are forecasted at medium range by numerical weather forecast models that rely on the actual state of the atmosphere, assessed by radiosounding balloons, meteorological stations, or satellite images. The global scale is related to climate changes and is monitored by temperature measurements (Figure 1), sea level rise tracking, and various other indices.

Weather monitoring is thus dedicated to forecasting but also to increase the knowledge about the phenomena. Most of the data acquired during an event are then used by the scientific community for various applications, such as statistical analyses, improvement of the understanding of the processes, or development of more reliable models.

Monitoring of local extreme events

The short-range forecasting, often referred to as nowcasting, focuses on the pending few hours and the local scale. It strongly relies on monitoring to anticipate the displacements of the occurring hazard.

Thunderstorms with intense precipitation or hail are usually tracked by means of ground-based precipitation radars. The returning radar pulses provide the spatial distribution of the hydrometeors and so the intensity of the precipitation. The diameter of the raindrops or the hail may be approximated based on the reflectivity factor or the signal attenuation. The main advantage of radar measurements is that it provides real-time precipitation information on a large area, but there are several issues for precipitation estimation. The first one is that the drops are detected on a wide range of altitudes and the calculated intensity may not match ground observations due to wind or evaporation (Shuttleworth, 2012). Another issue is for mountainous regions, as mountain ranges are responsible for beam shielding (Germann et al., 2006). However, various algorithms and correction methods exist to make the radar data valuable for nowcasting. The goal of such forecasting is to assess the motion and the evolution of precipitation patterns (Austin and Bellon, 1974). While it was initially just an extrapolation of the patterns, it is becoming more sophisticated by use of numerical forecasting models that are initialized with radar data (Wilson et al., 1998).



Tornado detection is possible using a Doppler radar, which uses the Doppler effect on the reflected pulse to assess the velocity of hydrometeors, according to the radial axis. By displaying the motion within a storm, it becomes possible to identify a tornado vortex signature (Donaldson, 1970; Brown et al., 1978), which is characterized by an intense and concentrated rotation. With this approach, the presence of tornado genesis can be identified before a tornado touches the ground. The US government deployed a network of 158 Doppler radars for tornadoes monitoring between 1990 and 1997 (NOAA website).

Monitoring of regional meteorological variables

Today's weather forecasts are mainly based on numerical weather prediction (NWP) models. However, these models rely on data assimilation, which is a statistical

Monitoring Natural Hazards, Table 1 Description of the most common sensors used to monitor natural hazards

Sensors	Monitored variables	Principles	Monitored phenomenon
Pressure measurement	Pressure (air, water), in situ stress measurement	Barometer: used a height of fluid in vacuum to compensate the atmospheric pressure Pressure transducer: convert a material deformation electrical signal	Atmospheric circulation, water table, Earth crust deformations
Radar (RAdio Detecting And Ranging)	Distance to a hard object and velocity	Reflection of an emitted microwave by an object and received by an antenna. The Doppler effect permits to estimate the speed of an object	Precipitation imaging, river discharge (velocity), sea level rise, tornadoes
Laser (Light Amplification by Stimulated Emission of Radiation) and *Lidar* (Light Detection And Ranging)	Distance to a surface and orientation	The Laser consists in amplifying coherent light by using the principle of stimulated emission, creating a narrow beam that can be reflected by surfaces. The Lidar uses the principle of range finder by evaluation of the distance by the time of flight or the phase comparison. The direction of the beam is recorder in order to obtain the 3D coordinates. Information on the reflectivity can be also obtained	Landslides movements and characterization, local atmospheric circulations
Thermometer	Temperature	The measurement is realized using changes of the properties of materials under temperature variations such as volume (mercury), or the electric resistance such as thermistors or thermocouple which produce a current proportional to the temperature between two different materials	Climate, weather forecasts, volcano
Accelerometer and seismometer	Acceleration, velocity, displacement	Measurement of ground acceleration using transforming movement into electrical signal	Earthquake, surface deformation (landslides)
Wind sensor	Wind speed and direction	Anemometer is a rotating device entrained by wind such as cup. Anemometers usually use three half spheres like rotating along a vertical axe. The windvanes is a device which is orientated parallel to the wind. Measurement of ultrasonic wave by several sensors permits to obtain the wind velocity and direction	Weather, hurricanes, tornadoes
Rain gauge	Amount of precipitation throughout time	The traditional rain gauges are tipping-bucket, like a container that is emptied each time the unitary volume that can be measured is reached. Precipitations can also be measured using rain drop impact counts	Weather, bad weather
InSAR (interferometric synthetic aperture radar)	Topography, small surface displacement using radar	By using ground-based or satellite InSAR images, it is possible to extract a distance to the ground and a very accurate changes between two images down to millimeter resolution in the direction of line of site. This is based on microwave interference	Earth surface deformation: Earthquakes, volcanoes, landslides, subsidence
GNSS (Global Navigation Satellite System)	Ground position	The principle is to acquire several highly precise travel times of microwaves from at least two satellites (with highly precise positions) and to compute the distance and location to calculate the best position (can be improved include the phase information). Highest accuracy is obtained by using differential GNSS method which computes difference with a well-known GNSS position. This remove several error such atmospheric and ionosphere one. The position resolution reaches a few millimeters	Earthquakes, volcanoes, landslides, subsidence

Monitoring Natural Hazards, Figure 1 Statistics of Swiss monthly temperature differences to the average over the whole period. This shows a shift of 0.8°C. The probability to get a monthly temperature 3°C greater than the average temperature is at least twice for the period 1941–2000 compare to 1864–1923 (Modified from Schär et al., 2004).

combination of observations and short-range forecasts, to adjust the initial conditions to the current state of the atmosphere (Daley, 1993; Kalnay, 2003). Data such as temperature, pressure, humidity, and wind are acquired by weather stations, or radiosounding balloons to get a profile of the troposphere (Malardel, 2005).

Air temperature, barometric pressure, wind speed, and direction are commonly measured at weather stations, but also with costal or drifting weather buoys. Some boats and aircrafts are also equipped with sensors acquiring various atmospheric variables.

Rain gauge stations provide point precipitation measurement. It is the first and most common way to measure precipitation, and so it has the advantage that long time series exist. However, these are subject to systematic errors (values lower by about 5–10%) related to the wind and to the choice of the gauge site (over exposure to the wind in open area or shade effect from obstacles around) and gauge design (Shuttleworth, 2012). The height of the gauge is a defined parameter and balances the effect of the wind that decreases closer to the ground, and of the splash-in that increases nearer to the ground. The rain gauges evolved to reduce errors linked to the wind, to evaporation, and to condensation, and changed from manual measurements toward automatic recording.

Weather station networks are organized at a national or regional scale. In 1995, the World Meteorological Organization proposed a resolution (Resolution 40) to "facilitate worldwide co-operation in the establishment of observing networks and to promote the exchange of meteorological and related information in the interest of all nations" (WMO, 2012b). This database contains time series from all over the world.

Precipitation assessment by remote sensing is not as accurate as ground-based measurements, but it provides information in area where no or few observations exist. It is likely to be the only way for precipitation measurement to be possible at a global scale (Shuttleworth, 2012). The Tropical Rainfall Measuring Mission (TRMM) satellite with precipitation radar onboard allows measuring the vertical structure of precipitation (Iguchi et al., 2000; Kawanishi et al., 2000). Precipitation can also be derived from visible and infrared satellite data (Griffith et al., 1978; Vicente et al., 1998).

In addition, the meteorological satellites such as meteosat-9 (www.eumetsat.int) deliver images in visible or infrared spectra providing important data to the meteorologist. It is also a very important source of information in case of the development of severe hazards, such as hurricanes.

Monitoring of climate and climate change

Climate studies rely on long series of high-quality climate records (Figure 1). The most analyzed parameter is the air temperature. Scientists use data recorded at weather stations over decades and employ different methods to reconstruct past data before the beginning of the measurements. Data reconstruction, rescue, and homogenization are still important topics today.

Some satellites have radiometers on board to monitor clouds and thermal emissions from the Earth and Sea Surface Temperature (SST) (NASA, 2012a). For instance, SST can be measured using the calibrated infrared Moderate Resolution Imaging Spectroradiometer (MODIS) installed on Observing System satellites Terra (Minnett et al., 2002). The sea level can be measured using a Radar altimeter of the Jason-2 satellite, which permits one to provide inputs for El Niño or hurricane monitoring. Sea level rise is mainly caused

by climate change and is currently about 3.4 ± 0.4 mm/year (Nerem et al., 2010).

Floods monitoring

Floods have several origins often linked to intense precipitation, massive snowmelt, tsunamis, hurricanes, or storm surges, but several are related to other hazards like landslides and rockfalls. The main instrumental setups to forecast floods are weather stations, with a particular emphasis on the rain gauge, weather radars, and meteorological models.

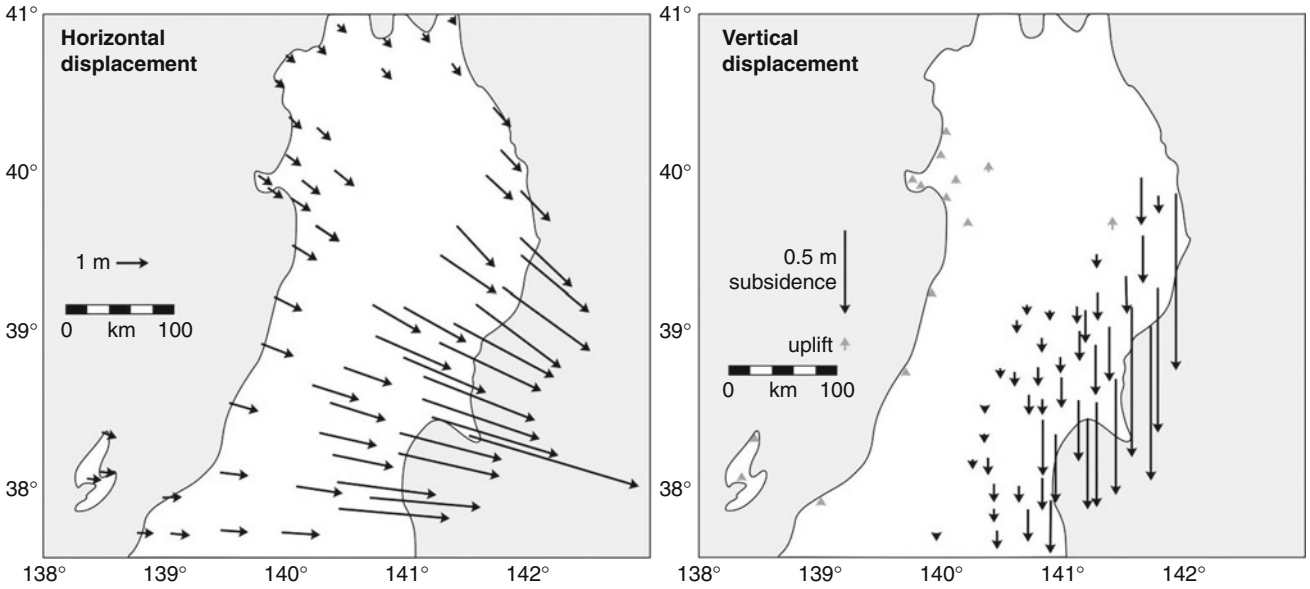
The direct monitoring of floods is done by measuring rivers discharge and/or lakes and sea level. The river discharge is linked to the measurement of the stage (or level), which is the water height above a defined elevation, by a stage-discharge relation. The stages of rivers or lakes are measured by float, ultrasonic, or pressure gauges (Olson and Norris, 2007; Shaw, 1994). The stage-discharge relation has to be updated frequently because of erosion and deposition problems. This relationship is established using current-meters based on rotor or acoustic Doppler velocimeter which establishes the velocity contours of the river section (Olson and Norris, 2007; Shaw, 1994). Radars are also used and seem to be a promising way to obtain discharge (Costa et al., 2006), by using ground-penetrating radar (GPR; the echo of emitted microwave permit to get the river bed profile) coupled with a Doppler velocimeter in order to get the discharge estimation.

In several lowland areas, flood monitoring includes the embankment monitoring that means stability analysis as for landslides. The survey of affected flood area is performed by man-made mapping, aerial photography, or satellite imaging when the flood area is wide, as in Bihar (India) in August 2008 (UNOSAT, 2012).

Earthquake monitoring

Earthquakes monitoring has two objectives: one to provide data for hazard assessment and the other to develop some aspects for prediction. The main recent technologic advances are GNSS and InSAR techniques that allow one to observe the deformation of the Earth's crust before (interseismic), during (coseismic), and after (post-seismic) an earthquake (Figure 2). This permits, for instance, to expect large earthquakes like in the Cascadia Subduction Zone (Hyndman and Wang, 1995), California, and Turkey (Stein et al., 1997).

The displacements recorded by several seismometers provide the necessary information to estimate the location of an earthquake, its magnitude or the energy released. The statistics of the magnitude for defined zones lead to define the Guntherber-Richter law which may be used to obtain the probability of occurrence for earthquakes of a magnitude larger than a given value. In addition, fine analysis using inversion methods of wave signal provides information to characterize the surface of failure (Ji et al., 2002).



The use of monitoring to predict events within a few days or hours is not yet possible because of the variability of geodynamical contexts. For example, a monitored variable may display opposite signals depending on the context, such as radon which can increase before earthquakes as in Kobe in 1995 (Igarashi et al., 1995) but which can also decrease (Kuo et al., 2006). The amplitude of the signal is thus not significant. The observation of an enhanced activity close to a fault (foreshocks) can be used as signal, but this activity increase does not necessarily lead to earthquakes.

The forecast is still not accurate, but observed ground deformations coupled with history of earthquakes permit one to estimate the probability that large earthquakes occur at a location within a period of time (Stein et al., 1997). The two most promising methods are the following: (1) The first is to characterize the ground mechanical properties using ambient seismic noise. The post-seismic period leads to significant seismic velocity changes (Brenguier et al., 2008), indicating most probably stress field modification, but it seems from recent results that it can also be observed before the earthquake. (2) The second is to analyze ionospheric anomalies of the total electron content that are detected before earthquakes by GNSS systems (Heki, 2011).

Tsunamis monitoring

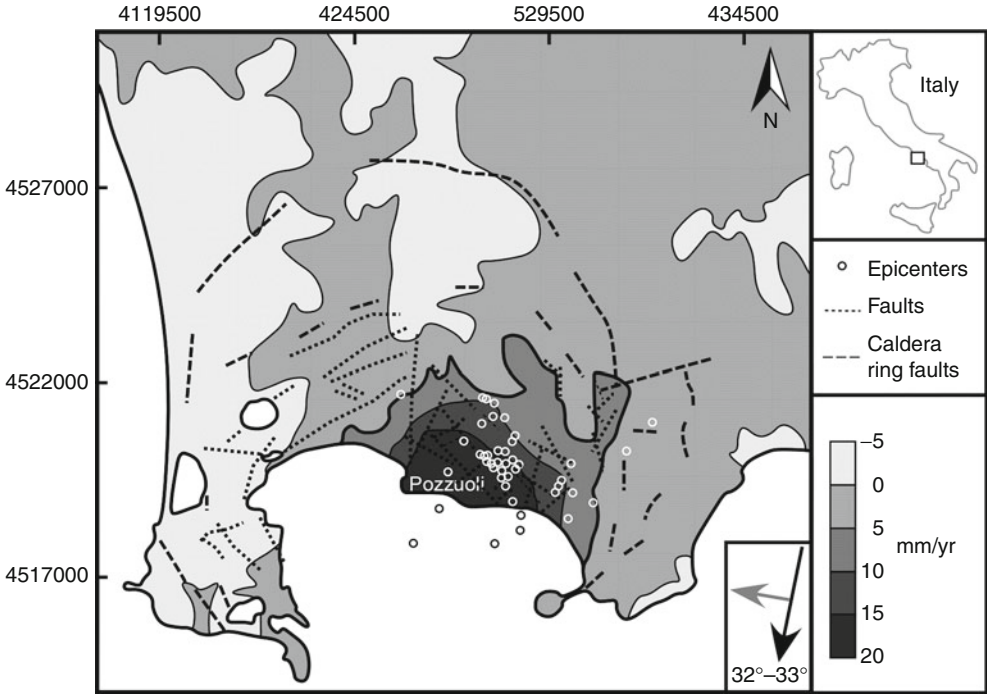
Tsunamis can have different origins including earthquakes, large volcanic eruptions, submarine landslides, rock falling into water, etc. The indirect monitoring is related to the triggering factors of the phenomenon, which are mainly earthquakes or landslides. The Åknes rockslide in Norway is an example of indirect monitoring applied to mountainside instability of significant volume that can fall into a fjord and generate a tsunami. The monitoring of the instability is part of a full early warning system including the evacuation of villages located on the coast within a few minutes (Blikra, 2008).

The direct monitoring of tsunamis is the record of the wave propagation and can be fundamental for different reasons: a large earthquake does not lead necessarily to a tsunami, then the alarm should be canceled if the closest gauges do not indicate any wave (Joseph, 2011); the wave can occur later than expected; the occurrence of landslides (submarines or not) are not always detected. In addition to tide gauges, several seafloor sensors (pressure) are located near the coastal areas of continents and islands, but also in the middle of the ocean (Joseph, 2011). The most advanced monitoring system is the Deep-Ocean Assessment and Reporting of Tsunamis (DART II), and it consists of a surface buoy localized by GNSS and communicating the pressure recorded at the bottom of the ocean by a pressure sensor. The communication with a satellite is bidirectional (Meinig et al., 2005). Such devices are being deployed all over the world (NOAA, 2012) showing great results, like the satellite altimeters that

Monitoring Natural Hazards, Figure 2 Coseismic crustal deformation of the Tohoku Earthquake. Horizontal and vertical displacement. These displacements are defined by the difference between the positions on the day before the mainshock (March 10) and those after the mainshock, March 11 (Modified and simplified after RCPEVE, 2012).

recorded accurately the 2004 Sumatra tsunami wave all around the world (Smith et al., 2005).

Volcanoes monitoring



Volcanoes are one of the most spectacular natural hazards on Earth and can be the most disastrous. As an example, the eruption of the Krakatau (Indonesia) in 1883 killed some 30,000 people, releasing a significant volume of ash that briefly affected climate (Durant et al., 2010) and generated a large tsunami wave (Gleckler et al., 2006). As eruption types are so diverse, their monitoring is not easy. Several activities can provide precursory signs, linked to magma movements which change the properties of the ground. The first activity signs that are usually monitored by seismographs are tremors indicating stress adjustments. These stress changes induce ground deformations that can be observed by high precision tiltmeters, indicating changes in slope of the surface. Currently, GNSS are commonly used (Figure 3); they can provide continuous 3D displacements and have partially replaced the electronic distance meter (EDM) laser beam. In addition, since the early works of Massonnet et al. (1995), the InSAR technique allows one to observe deformation of volcanoes, providing information on their behaviors. Any change in the ground can influence measurable parameters such as gravity, temperature, and magnetic field. All those variables can be monitored. The change in gas composition in fumaroles is frequently reported, especially an increase in CO_2 content or a change in the ration F/Cl. Nevertheless, it is quite difficult to monitor gases because they follow preferential paths up to the surface that can change during a precursory period (McNutt et al., 2000). At Etna volcano, ambient seismic noise signature has been recognized as a potential precursor that can be monitored in order to forecast an eruption (Brenguier et al., 2008).

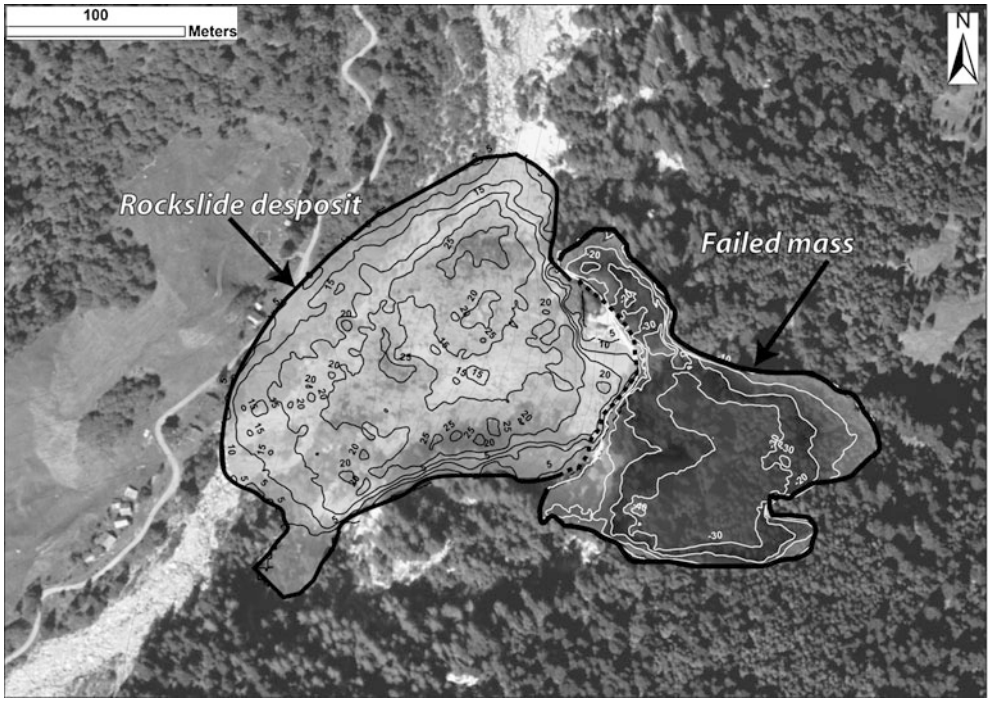
The monitoring of volcanoes does not only involve the volcano itself, but also ash that can disturb aerial traffic or have an impact on the agriculture. Sulfur dioxide, ash, and aerosols (sulfuric acid) are mostly monitored by satellite imaging (ultraviolet and infrared sensors) which is not designed directly for that purpose (Prata, 2009). As those processes are closely linked to atmosphere movements, many of the monitoring techniques of weather forecasting are also used.

Landslides monitoring

Landslides are easily observed because they are moving masses affecting and deforming the relief. As a consequence, the main variables to monitor are the movement and parameters that are modifying the stress or the properties of the material that is under deformation (SafeLand, 2010). Except in the case of earthquakes or exceptional precipitation, the displacement is the main parameter to monitor. In most of the cases, the failure is preceded by an acceleration of movements. Depending on the material geometry and the volume involved, the failure may be forecasted (Crosta and Agliardi, 2003), and this acceleration can sometime be directly correlated with groundwater level using a mechanical model (Corominas et al., 2005).

Two types of landslides must be distinguished: shallow and deep-seated landslides. The first are too small and too localized to be easily monitored, but today several

Monitoring Natural Hazards, Figure 3 PS-InSAR™ showing uplift along the line of sight with data from descending orbit on October 2005–November 2006. Observe the correlation between uplifts, structures, and seismic activity (Modified and synthetized after Vilardo et al., 2010).



attempts are made to create early warnings for shallow landslides (Sassa et al. 2009). The deep-seated failures are usually sufficiently large to display significant movements before catastrophic failure.

Large landslides monitoring

The main instruments used to monitor large landslides are dedicated to movements. Physically, extensometers can be used to measure displacements and crack meters can be used to observe the opening of cracks. When boreholes are available, manual inclinometer or permanent inclinometer columns may be used, providing the deformation profiles and often the failure surface where most of the deformation concentrates. These devices are often used for early warning system, as for the site of Åknes (Norway) (Blikra, 2008). As water plays an important role in controlling movements of a landslide, boreholes can be used to measure the level of the water table (manually or by measuring the groundwater pressure).

Surface movements can be followed using targets and total station (laser distance meter), but today, if the required conditions of visibility are appropriate, permanent GNSS can be used for a permanent monitoring of the movements (Gili et al., 2000). The disadvantage of these methods is that they are point measurements only. By using advanced satellite InSAR techniques (PS-InSAR, SBAS, etc.), a significant percentage of landslides can be imaged and monitored. In addition, time series of displacement of ground reflectors can be obtained. One of the last evolutions of the InSAR is the SqueeSAR™ method that enhances significantly the capability of tracking ground displacement (Ferretti et al., 2011). Unfortunately, satellite InSAR is not suitable for early warning because satellites take several days to pass over an area a second time. If no appropriate reflective object exists on the monitored surface (for instance due to forest cover), the InSAR method can be applied only if corner reflectors are installed on the ground, providing movements on selected points only (Singhroy et al., 2011). With ground-based InSAR (GB-InSAR), it is possible to follow the movements of the surface of a landslide or rockslide, when it is visible in the direction of the line of sight. This is very useful to observe the deformation evolution of the front of landslides (Tarchi et al., 2003).

The Lidar technique provides full 3D point clouds in the case of terrestrial Laser scanner (TLS), which allows characterizing rock slopes and landslides (Safeland, 2010; Jaboyedoff et al., 2012). It permits one to monitor and to follow the full evolution of a landslide surface that is moving, to understand mechanisms of failure (Oppikofer et al., 2008) and also to monitor rock fall by comparison of successive acquisitions (Figure 4). The airborne Laser scanner (ALS) is less accurate but

Monitoring Natural Hazards, Figure 4 Map of the deposit and failed mass thickness of the of the Val Canaria rockslide (Ticino, Southern Swiss Alps). This map based on the comparison of the airborne and terrestrial Lidar digital elevation model taken before and after the 27.10.2009 rockslide event (modified after Pedrazzini et al., 2011; the aerial picture and airborne Lidar are provided by swisstopo).

permits one to estimate differences between digital elevation models.

For most landslides, several different sensors are required to establish an early warning system (Blikra, 2008; Froese and Moreno, 2011). Since a few years ago, photogrammetry and image correlation have developed, leading to very promising results (Travelletti et al., 2012). Geophysics methods are also improving their capabilities to image the underground. One of the most interesting recent developments is ambient seismic noise analysis. For a rock mass, it indicates a decrease of the natural frequency before failures and for landslides, a decrease of the surface wave velocity (Mainsant et al., 2012).

Debris flow and shallow-landslides monitoring

Shallow landslides and debris flow landslides are mostly dependent on precipitation. As a consequence, the main monitored variables are precipitation intensity, and duration (Baum and Godt, 2010; Jakob et al., 2011). Saturation, soil moisture, and antecedent precipitation are variables that are also often monitored. In the case of shallow landslides, the exact location cannot be determined, thus the entire area is considered as hazardous if some thresholds are exceeded. It must be noted that an early warning system designed for rainfall-induced landslides is operational in Hong Kong and has been continuously improved since 1977 (Chan et al., 2003; Sassa et al., 2009).

In the case of debris flows, sensitive catchments can be equipped in order to issue warnings. The seismic sensors and ultrasonic gauges permit one to deduce velocity and peak discharge (Marchi et al., 2002).

Monitoring shallow landslides and debris flows is still a topic of research under development because the triggering and the localization of such phenomena are not yet well understood.

Snow avalanche monitoring

Snow avalanches are seasonal events and depend strongly on climate variables such as previous precipitation, snowpack depth and strength, and temperatures. As a consequence, snow avalanches monitoring concentrates essentially on hazard level quantification. This is mainly performed using human observations (SLF, 2012) and weather stations equipped by ultrasonic snow depth sensors. Observed variables are strongly dependant on local physiographic conditions. In addition to monitored data, the observers perform snow hardness tests in order to detect the potential mechanical weakness in the snowpack (Pielmeier and Schneebeli, 2002). The conditions for avalanches are

so diverse (wet snow, large amount of fresh snow, etc.), that up to now, human intervention in the monitoring remains the main method to monitor and forecast this hazard.

Other monitoring

There are other hazards to monitor. Some require the integration of meteorological data in the monitoring design. For instance, a drought corresponds to a period of abnormally dry weather leading to a deficit of water in the hydrologic cycle and finally leading to problems (but the definition of drought is not unique). Forest fires are consequences of dryness, with origins that are often not natural, but anthropogenic. Hail storms are also hazardous phenomenon that can lead to serious damage; hail monitoring is mainly based on human observation and meteorological radar. Lightnings are monitored using an electromagnetic sensors network. All the sensors detecting one specific lightning provide the distance to it. The location is then deduced by searching the best agreement between all the detected distances to sensors.

Future of monitoring as a demand of the society

The monitoring of natural hazards is often a tedious task because if the physics well describes the single phenomenon, in natural environments, the occurrence of an event is controlled by several simultaneous phenomena. It implies that, for the analysis and prediction of events, a number of different variables are required to be able to describe all possible cases.

The power of computer science, communication technologies, and the improving quality of sensors, combined with decreasing prices, make the monitoring of environmental data more precise and easy. This leads to new understanding of natural hazards and also to the implementation of early warning systems that will permit one to manage territories in a safer way. In addition, nowcasting, as proposed by World Meteorological Organization, is now an objective of this organization to provide forecasts in less than 6 h. Such developments are mainly possible because of computer power available almost everywhere and a generalized ability to communicate rapidly by anybody with the "smartphone" technology.

MONSOONS

Song Yang, Viviane Silva, Wayne Higgins
Climate Prediction Center, NCEP/NWS/NOAA, Camp Springs, MD, USA

Synonyms

Mausam; Rainy season; Wet season

Definition

The term "monsoon" is derived from the Arabic word "mausam," which means season. Halley (1686) defined monsoon as the seasonal reversal of steady and sustained surface winds, which blow from the northeast during winter and from the southwest during summer. In spite of this original definition rooted in atmospheric circulation, rainfall is another variable that has been widely used to define monsoon.

Discussion

Although there is no universal definition, monsoons are atmospheric systems with certain well-defined characteristics (Webster 1987). All monsoons have a life cycle characterized by distinct onset, maintenance, and demise phases. They feature abundant rainfall during summer and dry conditions during winter. The strongest monsoon, the Asian summer monsoon (Ramage 1971), affects about half of the world's population. Monsoons are also found in other tropical–subtropical land areas, including Australia, Africa, South America, and North America (Webster 1987; Nogues-Paegle et al., 2002; Sultan et al., 2003; Higgins et al., 2006).

Monsoon variability is influenced by various weather and climate phenomena, including synoptic-scale disturbances, tropical waves and cyclones, and tropical intraseasonal variations that contribute to active and break periods. Interannual and longer variations of monsoons are due to both internal dynamics of the coupled atmosphere–ocean–land system and interactions of monsoons with other climate phenomena such as El Niño-Southern Oscillation, snow cover, and the Pacific Decadal Oscillation.

Although the major cause of monsoons is the thermal contrast between land and ocean, the discernable features of monsoons vary from region to region. The monsoon climate over many Asian countries is characterized by wet and hot conditions in summer but dry and cold conditions in winter, corresponding to a pronounced seasonal reversal of surface winds. However, regions close to the equator usually experience two rainy seasons. Over eastern Africa, the monsoon rainfall is characterized by "long rain" in March–May and "short rain" in October–December. The North American monsoon is characterized by distinct rainfall maxima over western Mexico and the southwestern United States and by an accompanying upper-level anticyclone over the higher terrain of northwestern Mexico. The South American monsoon features a pronounced wet season (November–March) and a dry season (April–September) over central Brazil. An intense upper-tropospheric anticyclonic circulation, located over eastern Bolivia, appears during the wet season.

Monsoon variability is often related to floods, drought, and other hazardous extreme weather and climate events. Excessive monsoon rainfall causes floods and landslides and hence considerable social and economic impacts. Alternately, insufficient monsoon rainfall leads to drought, and therefore scarcer fresh water supplies. Monsoon depressions and tropical storms with high winds and tidal surges are often embedded within the large-scale monsoon circulation, posing threats to human lives and property. Monsoon behavior, such as the intensity and duration, influences

economic planning and development, water resource management, agriculture (planting and harvesting), and emergency response. Because of the significant societal and economic impacts of monsoons, it is important to continue to improve understanding towards more realistic simulation and prediction of monsoons.

CASE STUDY

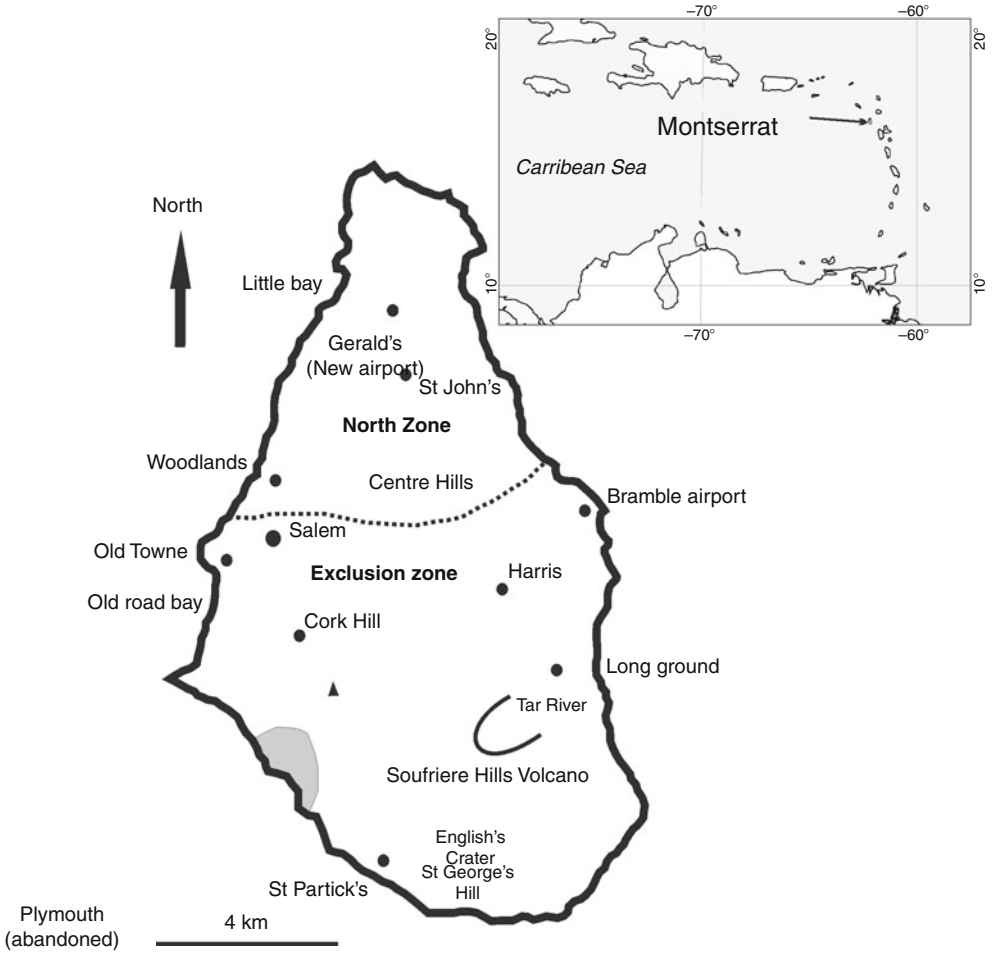
MONTSERRAT ERUPTIONS

Katherine Donovan
University of Oxford, Oxford, Oxfordshire, UK

Montserrat is a small volcanically active island in the Caribbean situated on the Lesser Antilles island arc. The island's main volcano is called the Soufrière Hills and this volcano has been erupting since 1995.

1995–1998

In 1995 after 40 years of quiescence a relatively small lava dome was extruded. This dome grew at 4 m^3/s until 1997 when the dome collapsed producing multiple pyroclastic flows. These burning clouds of ash destroyed the previously evacuated capital city of Plymouth in March 1997 and killed 19 people in June 1997. The volcano continued to erupt until 1998 showing a cyclic seismic and dome growth behavior that was used by scientists at the newly established Montserrat Volcano Observatory (MVO) to provide short-term forecasts (McNutt et al., 2000). This initial period of activity changed Montserrat dramatically, destroying the prosperous south and forcing residents to relocate to the rugged and difficult north (Figure 1). In 1998 the pre-eruption population of 11,000 had reduced to just 4,000 as long-term evacuations, loss of livelihoods, and personal danger forced the people of Montserrat to transmigrate, mainly to the United Kingdom (Aspinall and Cooke, 1998).



1998–2003

As the people gradually abandoned hope the volcano continued to erupt. Between 1998 and 2003, Andesitic lava domes continued to grow and collapse, for example, in 2000 a 29 million m^3 dome collapsed generating a magmatic eruption and over 40 pyroclastic flows (Carn et al., 2004). In 2003, the volcano produced the largest dome collapse ever recorded in historical time with 210 million m^3 of material giving way, and 170 million m^3 collapsing in just 2 hours of activity (Herd et al., 2005). Figure 2 shows the smoking crater that was left behind. This major collapse followed 2 years of dome growth, caused a tsunami, a previously unrecorded pressure wave, a shock wave, and tephra fall that caused extensive damage on Montserrat and neighboring islands (Herd et al., 2005).

2003-Onwards

The Soufriere Hills is now the best monitored volcano complex in the Caribbean with an array of technologically advanced monitoring equipment and a permanent scientific team. But recent changes in seismicity, which previously aided eruption forecasts, have led to changes of procedure at the MVO and increased pressure to find more accurate precursors (Luckett et al., 2008).

As the physical monitoring of the volcano continues, so does the struggle of the Montserrat people (Figure 3). Relocation to the northern regions caused long term social issues, including a lack of cultural building considerations and inferior agricultural land causing residents to return to the dangerous regions to farm. Transmigration also caused multiple stresses and unanticipated concerns, for example, there was a lower standard of schooling in the UK compared with pre-eruption standards on the island (Kelman and Mather, 2008). As the eruption continues the future of the remaining Montserratians is unclear, they require a sustainable livelihood in order to remain on the island but with limited space and imminent danger this may be difficult to achieve. Scientists and local authorities are under extreme pressure to protect the remaining Montserratians from further suffering.

Montserrat Eruptions, Figure 1 Location of Montserrat Island and the Soufriere Hills Volcano. This map also marks the exclusion zone that covers the majority of the southern island.

Montserrat Eruptions, Figure 2 A view of the crater taken in December 2004 (*Catherine Lowe*).

Montserrat Eruptions, Figure 3 A minibus used for tourism is caught in a lahar in November 2004. This image demonstrates the difficulties in maintaining a sustainable livelihood on an active volcanic island (*Catherine Lowe*).

MORTALITY AND INJURY IN NATURAL DISASTERS

Shannon Doocy
Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Synonyms

Casualties; Fatalities

Definition

Disaster. An event that causes significant damage, destruction, or loss of life where local response capacity is overwhelmed and outside assistance is required.

Natural disaster. Disasters resulting from the effects of naturally occurring hazards such as earthquakes, volcanoes, floods, or extreme climatic events.

Natural disaster mortality. Deaths resulting from a natural disaster, most often those that are immediate and directly attributable to the event.

Natural disaster injury. Physical damage or harm to the body caused by a natural disaster.

Natural disaster mortality and injury in the twentieth century and beyond

Since the beginning of the twentieth century, natural disasters have resulted in over 22.6 million deaths and 6.6 million injuries, and have affected the lives of more than 5.4 billion people (CRED, 2010). While the number of natural disasters reported and the size of populations affected have followed an increasing trend, fatalities have declined as a result of advances in early warning systems, disaster preparedness, and improvements in emergency management and response. However, human vulnerability to natural hazards is escalating, primarily due to the increasing population density and land use change which suggests that the human toll of future natural disasters will rise (Huppert and Sparks, 2006; United Nations, 1988). Poverty is a major risk factor for mortality and injury in natural disasters, and the size of impoverished populations in high-risk areas is likely to increase in future years (Eshghi and Larson, 2008).

A rapid-onset natural disaster is an event that is triggered by an instant shock. Most natural disasters are classified as rapid-onset events though it is important to note that in some cases there is enough warning time to allow for evacuation and other mitigation measures. In contrast, a slow-onset natural disaster unfolds over a longer time period where the hazard is felt as an ongoing stress over days, months, or even years (UNDP, 2004). Natural disaster impacts on human populations from 1900 to date are summarized in Table 1. More than half (52%) of reported deaths in natural disasters since the beginning of the twentieth century are attributable to drought. The significance of drought-related deaths is historically underappreciated where many casualties are secondary or indirect and are uncounted. Floods and earthquakes are also large contributors to natural disaster mortality, accounting for 31% and 10% of deaths, respectively. Natural disaster injuries were overwhelmingly caused by three types of events: earthquakes (33%), extreme temperature events (28%), and floods (20%).

Drought

More than half of disaster-related deaths since the beginning of the twentieth century are attributed to drought, a slow-onset natural disaster that has devastating long-term effects on communities. Drought is a frequent phenomenon that is sometimes associated with famine; however, famines are rare, complex, and often the result of multiple underlying causes including chronic poverty, economic inequalities, and conflicts (Sen, 1982).

Some of the worst famines in the recent history include the 1943 Bengal famine, the Great Leap Forward famine in China from 1958 to 1961, the 1974 famine in Bangladesh, and regional famines in the Sahel during the mid-1970s and mid-1980s (CRED, 2006). In recent decades, drought-related mortality has been concentrated in Africa where in many cases drought-related impacts are exacerbated by conflict and other preexisting cultural and political tensions. Both starvation and disease epidemics are primary causes of drought mortality; however, many secondary deaths where drought is a causal factor go unreported (CRED, 2010). While drought-related mortality is complex, multicausal, and likely to be underestimated, numerous methodologies and long-term development strategies exist that seek to reduce the impacts of drought (Dreze and Sen, 1990; FEWS, 2010). Compared to other types of natural disasters, droughts clearly resulted in the greatest number of deaths in the past century, however, drought-related mortality has substantially decreased in recent history where between 1990 and 2009, there were 37 droughts with a total of 4,472 deaths reported (CRED, 2010).

[a]Includes mortality and injury from earthquake-induced tsunamis

Mortality and injury in rapid-onset natural disasters, 1980–2009

Rapid population growth and changing trends in natural disasters over time suggest that earthquakes and storms will have the greatest impacts on human populations in the coming decades. Rapid-onset natural disasters, including earthquakes, volcanoes, meteorological events, floods, mass movements, and wildfires, caused over 1.4 million deaths and 5.0 million injuries within the past three decades. Deaths and injuries in rapid-onset natural disasters in the past 30 years are summarized in Figure 1 and Table 2. Earthquakes, which accounted for only 10% of events, resulted in 43% of deaths and 28% of injuries. Storms, including cyclones and hurricanes, comprised 33% of events and were the cause of 30% of deaths and 12% injuries. The most common event, floods, was associated with 16% of mortality and 23% of injuries. Extreme temperature events, which accounted for 5% of rapid-onset natural disaster events, resulted in 7% of deaths and 37% of injuries. Injury reporting is likely more complete in extreme temperature events than other types of disasters, particularly those in the middle- and low-income countries where the majority of mortality and injury occur, because the vast majority of extreme temperature events are in high-income countries where better health information systems ensure more accurate reporting. Other disaster types, including volcanic eruptions, mass movements, and wildfires, accounted for 12% of events collectively but contributed only 4% of mortality and <1% of reported injuries (CRED, 2010).

Earthquakes

Earthquakes are concentrated in Asia which is the most populous continent with approximately 60% of the world's population (UN, 2010). Over the past century,

Mortality and Injury in Natural Disasters, Figure 1 *Rapid-onset natural disasters and their impact on human populations, 1980–2009* (Source CRED, 2010. **Others include volcanoes, wet and dry mass movements, and wildfires*).

[a]Include volcanoes, wet and dry mass movements, and wildfires

53% of earthquakes and 75% of earthquake mortality were in Asia, and their impact in this region has been increasing in the recent decades in parallel with rapid population growth and industrialization. In the past 30 years, 86% of earthquake deaths were in Asia. An average of 827 deaths and 1893 injuries were reported per earthquake disaster between 1980 and 2009. Earthquake-induced tsunamis, which were reported in 3% of earthquakes in the past 30 years, contributed 60% of all earthquake-related fatalities, primarily due to the catastrophic Indian Ocean tsunami in 2004 which resulted in 227,000 deaths and affected over 2.4 million people in the coastal areas of Indonesia, Sri Lanka, India, and Thailand (CRED, 2010). Other recent devastating earthquakes include the 2008 Sichuan earthquake which killed an estimated 87,476 Chinese and the 2010 Haiti earthquake where mortality estimates range from 45,000 to above 300,000 with CRED reporting 22,570 deaths (CRED, 2010; BBC, 2011). The primary cause of death in earthquakes is building collapse, and direct mortality is both rapid, occurring within hours, and delayed where deaths occur within several days of the earthquake (Kunii et al., 1995). Instantaneous deaths are caused by severe crush injuries or trauma-induced hemorrhage; other causes of rapid death include asphyxia from dust inhalation or chest compression, hypovolemic shock, or drowning in earthquake-induced tsunamis. Delayed deaths can be caused by hypothermia, hyperthermia, dehydration, crush syndrome, and sepsis (Safar et al., 1988). In the aftermath of most earthquakes, the majority of people requiring medical assistance have minor injuries including superficial lacerations, sprains, and bruises; fractures and injuries requiring surgery and hospitalization are less common (Noji, 1997). The greatest demand for emergency medical services is within the day following the earthquake, and most of the injured can be treated on an outpatient basis; within 3–5 days, the demand for medical attention at hospital emergency departments usually returns to normal (Schultz et al., 1996; Oda et al., 1997).

Storms

Meteorological events, which include hurricanes, tropical cyclones, local storms, and winter storms, occurred predominantly in Asia (39% of events) and the Americas (32% of events) over the past 30 years; however, their impact is concentrated in Asia where 90% of deaths were reported. An average of 174 deaths and 247 injuries were reported due to meteorological events between 1980 and 2009. Tropical cyclones are by far the most deadly type of meteorological event and accounted for 94% of storm fatalities, or an estimated 428,734 deaths, in the past 30 years. There were an average of 342 deaths per tropical cyclone, and mortality was concentrated in Asia where more than 91% of tropical cyclone deaths were reported. The most devastating recent tropical cyclones include the 1991 Bangladesh cyclone which killed 138,866 people and cyclone Nargis which resulted in an estimated 138,366 deaths in Myanmar in 2008 (CRED, 2010). The majority of storm-related deaths are drownings associated with storm surges; other causes of mortality and injury include burial in collapsed structures, blunt trauma, and storm-induced mudslides (French, 1989; Noji, 2000). Most care seekers after floods suffer from lacerations and can be treated on an outpatient basis; closed fracture and other penetrating injuries are also common (Noji, 1993, 2000).

Floods

Geographically, floods in the past 30 years have been concentrated in Asia (42%), the Americas (23%), Africa (21%), and Europe (14%). However, flood mortality occurred predominantly in Asia and the Americas, which accounted for 65% and 25% of flood deaths, respectively; India and Bangladesh have particularly high levels of flood mortality (NRC, 1987; CRED, 2010). The average flood between 1980 and 2009 resulted in 66 deaths and 380 injuries. General floods accounted for 59% of floods and 48% of flood mortality. Flash floods, which comprised 14% of flood events, were the most deadly type of flood, and accounted for 27% of flood mortality (50,764 deaths) with an average of 121 deaths per flash flood. The deadliest recent flash flood in Venezuela killed an estimated 30,000 people in 1999. Other recent high-mortality floods were in China (3,656 deaths in 1998 and 2,755 deaths in 1996), Haiti (2,665 deaths in 2004), Somalia (2,311 deaths in 1997), and India (1,811 deaths in 1998 and 2001 deaths in 1994) (CRED, 2010). Flood deaths and injuries are primarily the result of fast-flowing water that is laden with debris. The main cause of deaths is drowning, followed by combinations of trauma, hypothermia, and drowning (Beinin, 1985). Among flood survivors, a very low proportion of victims require emergency medical care (Noji, 2000). Injuries from floods are generally minor and include lacerations, infection of wounds, skin rashes, and ulcers (PAHO, 1981).

Extreme temperature events

Extreme temperature events which include heat waves and also extreme winter conditions and cold waves are mostly

frequently reported in Europe (45%), Asia (31%), and the Americas (20%). The average extreme temperature event during the past 30 years resulted in 307 deaths and 5,496 injuries. Extreme heat events, which accounted for 36% of extreme temperature events, accounted for 89,046 deaths (87%), while more common extreme cold events (64% of events) resulted in 13,755 deaths (13%). There were an average of 707 deaths per extreme heat event and 62 deaths per extreme cold event over the past 30 years. Overall, 87% of heat wave fatalities were concentrated in Europe, while cold wave deaths were prevalent in both Asia (53%) and Europe (32%). It is important to consider that reporting of deaths and injuries may be more complete in extreme temperature events because extreme temperature events are predominantly reported in more developed countries with better information systems; furthermore as compared to other types of rapid-onset natural disasters, they do not cause infrastructure damage and widespread societal disruption. In extreme temperature events, hyperthermia (heat) and hypothermia (cold) deaths are either direct or indirect causes of mortality and injury. Hyperthermia cases are likely to be underreported because heat-related illness can exacerbate the existing medical conditions and can be difficult to identify; in addition there is variation in criteria used to identify heat-related deaths (MMWR, 2006). In heat waves, where risk of mortality is greater, numerous underlying demographic and physiological characteristics have been identified as risk factors for death, and risk of respiratory death is increased (Davido et al., 2006; Hertel et al., 2009).

Conclusion

One of the difficulties in assessing natural disaster injury and mortality is that information for many events is unreported or casualty estimates are inaccurate; this is particularly true for injuries that are undocumented for a majority of events. As a result, the true impact of natural disasters on human populations is likely to be substantially greater than the recorded impact, especially in events that occurred before substantial improvements in natural disaster reporting that were observed in the 1970s (CRED, 2010; Ehsghi and Larson, 2008). Understanding the causes of death and injury in natural disasters is important for planning disaster response. Morbidity and mortality patterns for certain types of natural disasters have been identified and can be used to plan the type of relief supplies, equipment, and personnel that will be required in the early stages of disaster response (Noji, 2000). Many factors contribute to the outcome of a natural hazard, including if the hazard evolves into a disaster and the resulting level of impact on human populations. While all natural disasters are unique and require a response that is tailored to the specific event, mortality and injury patterns can be anticipated and used to inform emergency medical relief and the planning and management of the ensuing humanitarian response.

CASE STUDY

MT PINATUBO

Katherine Donovan
University of Oxford, Oxford, Oxfordshire, UK

Mt Pinatubo is an active stratovolcano located in Central Luzon, Philippines, that has had significant global impacts.

The 1991 eruption

Mt Pinatubo had been quiescent for 500 years until 1990 when a nun working with traditional Aetas people living high on the volcano reported unusual activity, such as steaming cracks in the ground, to the Philippine Institute of Volcanology and Seismology (PHILVOLCS). Once these and other volcanic precursors were confirmed, PHILVOLCS in collaboration with a team from the US Geological Survey (USGS) started to monitor the activity and collate all existing geological data on previous activity.

Mt Pinatubo, Figure 1 The pre-climactic eruption column of Mt Pinatubo taken on 12 June 1991 from Clark Air Base (This photograph has been reproduced courtesy of the Philippine Institute of Volcanology and Seismology).

Previous eruptions had been recorded in local oral histories and warned of caldera forming eruptions lasting up to 3 days (Rodolfo and Umbal, 2008), yet geological surveys for the volcano were scarce and the international team of volcanologists had very little time to estimate potential eruption size and impact. Despite this, a 5-level warning system was implemented and evacuation zones were delineated (Newhall 2000). Fortunately, because of the quick actions of the scientists and government some 85,000 people were evacuated just before one of the most powerful eruptions of the twentieth century took place on 15 June 1991 (Leone and Gaillard, 1999; Gaillard, 2008) (Figure 1).

The eruption caused widespread destruction ejecting 5 km^3 of magmatic material and leaving behind a 2.5 km wide caldera (see Table 1). This eruption affected 2.1 million people and despite the added danger from a coinciding typhoon, approximately, only 300 people were directly killed and the management of this eruption was considered a success. The eruption was recorded in detail within the text *Fire and Mud: Eruptions and lahars of Mount Pinatubo* edited by C. Newhall and R.S Punongbayan (1996).

The secondary hazard and long-term social impact

The combination of widespread volcanic deposits and seasonal rains caused a secondary hazard known as lahars

Mt Pinatubo, Table 1 A statistical summary of the main products produced by the 1991 Mt Pinatubo eruption (Source: Wolfe and Hoblitt, 1996)

Hazard type	In detail	Size	Impact area
Tephra	Thickness deposited	1 cm < thick	75,000 km^2
		10 cm < thick	2,000 km^2
	Total bulk volume	3.4–4.4 km^3	
Pyroclastic flows	Distance traveled from source	12–16 km	5–6 km^2
Magma	Total volume	5 km^3	
Total ejecta	Total bulk volume	8.4–10.4 km^3	
Gas	SO_2	17 Mt	

Mt Pinatubo, Figure 2 The top image shows a lahar watch point in the Sacobia-Bamban River on Mt Pinatubo in 1991 and the image below was taken from the same position in 1992. In the lower image, only the roof of the watch point can be seen amongst the lahar deposits (These photographs have been reproduced courtesy of the Philippine Institute of Volcanology and Seismology).

(or volcanic mudflows) that annually threatened an area of 770 km^2 (Figure 2). This dangerous long-term hazard is responsible for killing nearly twice as many people than the actual eruption (Gaillard, 2008). Despite efforts to relocate residents out of lahar-prone regions some people still remain. Gaillard (2008) discusses the push and pull factors that motivate these at-risk communities to live in potentially dangerous regions on Mt Pinatubo. Push factors include victims having to pay for their new homes and services despite having no means of income in the long term evacuation centers. Pull factors include historical and cultural attachments, some declaring, "we are dead and drowned but we will never leave" (Gaillard, 2008, 323). Social and political issues caused increased difficulties in the management of lahars and relocation of evacuees, but the scale of recovery efforts indicate the difficulties faced by disaster managers. By 1997, 42,396 families had been re-homed in 23 centers around the volcano. This required 6,000 ha of land in addition to over 300 km of roads and electrical networks (Leone and Gaillard, 1999).

The economic costs of the eruption and lahar activities over the ensuing 2 years has been estimated at 11 billion pesos with 600,000 people losing their sources of income (Tayag and Punongbayan, 1994). This event demonstrates the potential physical and social impacts of such a large eruption and highlights the need for long-term disaster management in volcanic regions.

Definition

Mud volcano was defined by Kopf (2002) as a surface expression of mud that originated from depth. Depending on the geometry of the conduit and the physical properties of the extrusive, the feature may be a dome or a pie with low topographic relief (Figure 1). Mud volcanoes may be the result of a piercing structure created by a pressurized mud diapir, which breaches the Earth's surface or ocean bottom.

Discussion

The connotations relate to formations created by geo-excreted liquids and gases; from extruded mud, and liquid. The parent material is rapidly deposited, overpressured, commonly thick argillaceous sequences of mostly Tertiary age.

The depositional environment includes ridges, plains, and intermountain falls and hollows occupied with temporary salty lakes, and plateaus with an abundance of mud domes and cones extruding mud and rock fragments (gryphons), and water-dominated pools with gas seeps (salses); offshore mud volcanoes form islands and banks on the sea floor that alter the topography and shape of the coastline.

In terms of origin, mud volcanoes are mainly present all over subduction zones and orogenic belts, where rapidly buried sediment overthrusts deeper stratum. With an increase of burial stress and temperature, a decrease in porosity and maturation of organic material are favored (Hedberg, 1974). In these conditions, trapped pore water and forming hydrocarbon gas may cause overpressure of the mud at depth (Judd and Hovland, 1997). The mud, depending on the magnitude of the buoyancy, either slowly ascends through the overburdened rock and forms mud diapirs or extrudes vigorously along zones of structural weakness such as faults and fractures and forms mud volcanoes (Brown, 1990). During rapid ascent, self-ignition of emanating methane may cause flaming eruptions and a societal hazard (Bagirov and Lerche, 1998; Ismail-Zadeh, 2006).

Mud volcanoes are used as source of natural gas. Clay from volcanoes can be used as raw material for production of ceramics and bricks. Mud from volcanoes contains medical qualities and is widely used in local spas and perfumery.

Debris flows; Lahars; Mudslides

Definition

There is a wide spectrum of natural processes that take the form of a rapid mass movement of saturated soil or sediment under the action of gravitational acceleration; here the adjective "rapid" means that the typical velocity is within the 1–25 m/s range (Iverson, 1997). These mass movements are often referred to as "debris flows." Mudflows constitute an end-member of this large family: when the sediment is rich in clayey materials and poor in coarse particles (note that there is no consensus in literature on classification and the definition of mudflows may vary depending on the authors), the sediment looks like a muddy fluid (Coussot and Meunier, 1996).

Discussion

In most cases, mudflows are initiated after long or heavy rainfalls over mountain slopes or result from the acceleration of a landsliding mass. Bank and bed erosion may also result in mudflows, in particular in rivers whose channel incises soils made up of loose soils (e.g., loess or volcanic-ash deposits). Once set in motion, mudflows can travel large distances (mostly in the 1–100 km range) and spread over gentle slopes; the mean slope gradient for observing mudflows is usually in excess of 10%, but on some occasions, mudflows were observed on shallow slopes (less than 1%).

The capacity of mudflows to travel large distance has been ascribed to their viscous behavior. There is still a vivid debate on the origins of mudflow fluidity (Ancey, 2007). Some authors provided evidence that the mud behaves like a viscoplastic fluid, that is, like a solid when the shear-stress level is low and like a viscous fluid for shear stresses in excess of a critical value (called the *yield stress*) (Coussot and Meunier, 1996). Other authors consider mud as a liquefied soil, that is, a soil within which pore pressure is sufficiently high to reduce shear strength resulting from particle friction (Iverson, 1997, 2005). Both theories have been implemented in generalized hydraulic models; a set of equations that describe flow evolution in terms of flow-depth and velocity (Huang and García, 1998).

Mudflows are a major threat in mountainous and volcanic areas, claiming thousands of lives and millions of dollars in lost property each year (e.g., Sarno and Quindici in southern Italy in May 1998, where approximately 200 people were killed).

MYTHS AND MISCONCEPTIONS IN DISASTERS

Alejandro López Carresi
Centre of Studies on Disasters and Emergencies,
Madrid, Spain

Definition and introduction

Humankind has always relied on myths to provide an answer for the unknown. Fact and imagination are interwoven to account for uncertainties. Disasters are

prototypical representations of uncertain situations that must be dealt with. What is real in a myth can play its role in coping with a disaster. Equally important, though, is to separate what is imaginary about myths in disaster management. The debate on disaster myths and misconceptions has been a recurrent issue among scholars, practitioners, and other actors involved. This entry does not intend to be a comprehensive account and explanation of all myths in disaster management. This is just an introduction to a few of those myths: epidemics, looting and antisocial behavior, massive population movements, and goods donations.

One of the most popular lists of myths and misconceptions was first published by the Pan-American Health Organization in the 1980s and has been widely used, modified, and adapted ever since (Table 1).

The first 18 items were used by Alexander (2007) in a survey about disaster myths among disaster management students in Italy and USA. Despite the differences in the country of origin, background, training, and field experience, the students gave similar answers. This is illustrative of how deeply rooted some of these wrong assumptions are and how persistent in time they prove to be.

Dead bodies, epidemics and disease: always predicted, hardly ever materialized

Shortly after nearly every disaster, the news headlines alert people to the risk of major epidemics of communicable diseases. For example, after the 2004 Asia tsunami, there were widespread fears that a second wave of deaths was to be expected, and that disease and epidemics may cause as many casualties as the tsunami itself. The forecasted disease mortality and epidemics, as in most previous similar occasions, failed to materialize.

Despite the widespread idea that dead bodies can generate epidemics after disasters, there is no evidence to support that myth (Morgan and de Ville de Goyet, 2005). The health risks of dead bodies resulting from natural hazards are very few because the immediate cause of death is trauma, not infectious disease. Dead bodies can transmit a number of diseases for a limited period of time (Morgan, 2004), and only if those diseases were already present in the host *before* death takes place.

The overrated risk of major epidemics after disasters does not imply that all health concerns in disaster response are irrelevant. Frequently, local health services are affected or destroyed, interrupting the provision of adequate community care. Also, some common diseases are frequent, but rarely in epidemic proportions. What can be expected is an increase in gastrointestinal diseases, respiratory diseases, and some vector-borne diseases such as malaria. There are no indications of massive mortality increases or large epidemic outbreaks in any of those cases. Besides, the lack of crucial data about the number of previous cases of the detected disease prevents any comparison and the determination of the trend as increasing or decreasing.

Myths and Misconceptions in Disasters, Table 1 List of myths and misconceptions from PAHO, 2000

Myth: Disasters are truly exceptional events
Reality: They are a normal part of daily life and in very many cases are repetitive events
Myth: Disasters kill people without respect for social class or economic status
Reality: The poor and marginalized are more at risk of death than are rich people or the middle classes
Myth: Earthquakes are commonly responsible for very high death tolls
Reality: Collapsing buildings are responsible for the majority of deaths in seismic disasters. Whereas, it is not possible to stop earthquakes, it is possible to construct anti-seismic buildings and to organize human activities in such a way as to minimize the risk of death. In addition, the majority of earthquakes do not cause high death tolls
Myth: People can survive for many days when trapped under the rubble of a collapsed building
Reality: The vast majority of people brought out alive from the rubble are saved within 24 or perhaps even 12 h of impact
Myth: When disaster strikes panic is a common reaction
Reality: Most people behave rationally in disaster. While panic is not to be ruled out entirely, it is of such limited importance that some leading disaster sociologists regard it as insignificant or unlikely
Myth: People will flee in large numbers from a disaster area
Reality: Usually, there is a "convergence reaction" and the area fills up with people. Few of the survivors will leave and even obligatory evacuations will be short-lived
Myth: After disaster has struck survivors tend to be dazed and apathetic
Reality: Survivors rapidly start reconstruction. Activism is much more common than fatalism (this is the so-called therapeutic community). Even in the worst scenarios, only 15–30% of victims show passive or dazed reactions
Myth: Looting is a common and serious problem after disasters
Reality: Looting is rare and limited in scope. It mainly occurs when there are strong preconditions, as when a community is already deeply divided
Myth: Disease epidemics are an almost inevitable result of the disruption and poor health caused by major disasters
Reality: Generally, the level of epidemiological surveillance and health care in the disaster area is sufficient to stop any possible disease epidemic from occurring. However, the rate of diagnosis of diseases may increase as a result of improved health care
Myth: Disasters cause a great deal of chaos and cannot possibly be managed systematically
Reality: There are excellent theoretical models of how disasters function and how to manage them. After >75 years of research in the field, the general elements of disaster are well-known, and they tend to repeat themselves from one disaster to the next
Myth: Any kind of aid and relief is useful after disaster provided it is supplied quickly enough
Reality: Hasty and ill-considered relief initiatives tend to create chaos. Only certain types of assistance, goods, and services will be required. Not all useful resources that existed in the area before the disaster will be destroyed. Donation of unusable materials or manpower consumes resources of organization and accommodation that could more profitably be used to reduce the toll of the disaster
Myth: In order to manage a disaster well it is necessary to accept all forms of aid that are offered
Reality: It is better to limit acceptance of donations to goods and services that are actually needed in the disaster area

Myths and Misconceptions in Disasters, Table 1 (Continued)

Myth: Unburied dead bodies constitute a health hazard
Reality: Not even advanced decomposition causes a significant health hazard. Hasty burial demoralizes survivors and upsets arrangements for death certification, funeral rites, and, where needed, autopsy
Myth: Disasters usually give rise to widespread, spontaneous manifestations of antisocial behavior
Reality: Generally, they are characterized by great social solidarity, generosity, and self-sacrifice, perhaps even heroism
Myth: One should donate used clothes to the victims of disasters
Reality: This often leads to accumulations of huge quantities of useless garments that victims cannot or will not wear
Myth: Great quantities and assortments of medicines should be sent to disaster areas
Reality: The only medicines that are needed are those used to treat specific pathologies, have not reached their sell-by date, can be properly conserved in the disaster area, and can be properly identified in terms of their pharmacological constituents. Any other medicines are not only useless, but potentially dangerous
Myth: Companies, corporations, associations, and governments are always very generous when invited to send aid and relief to disaster areas
Reality: They may be, but in the past disaster areas have been used as dumping grounds for outdated medicines, obsolete equipment, and unusable goods, all under the cloak of apparent generosity
Myth: Technology will save the world from disaster
Reality: The problem of disasters is largely a social one. Technological resources are poorly distributed and often ineffectively used. In addition, technology is a potential source of vulnerability as well as a means of reducing it
Myth: There is usually a shortage of resources when disaster occurs, and this prevents them from being managed effectively
Reality: The shortage, if it occurs, is almost always very temporary. There is more of a problem in deploying resources well and using them efficiently than in acquiring them. Often, there is also a problem of coping with a superabundance of certain types of resources

As rare as they may be, it is still worth commenting on the occasional outbreaks of disease after disasters caused by natural hazard. According to the Center for Disease Control and Prevention (CDC), an epidemic is the occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time. Floret and colleagues found that in only 3 out of more than 600 geophysical disasters recorded worldwide from 1984 to 2004, there were epidemic outbreaks: measles after the Pinatubo eruption in Philippines in 1991, coccidioidomycosis (a fungal infection caused by inhalation of spores) after an earthquake in California in 1994, and malaria after earthquake and heavy rains in Costa Rica in 1991 (Floret et al., 2006).

The cholera epidemic which developed in the aftermath of the devastating January 12, 2010 Haiti earthquake is instructive. Although perceptually linked with the disaster, it is clear that the epidemic itself was the product of a set of unusual circumstances more closely aligned with an external input and preexisting sanitary conditions (Piarroux et al., 2011).

Decision makers should keep in mind that infectious disease epidemics after disasters are very rare and that massive and indiscriminate actions to prevent unfounded health risks are not recommended. Health and disease after disasters are a major issue, and undoubtedly some illnesses increase and public health deteriorates (Noji, 1997). But the presence of infectious diseases does not justify unfounded fears of major epidemics (WHO, 2006).

Looting and social unrest: the augmented perception of exceptional events

According to the most widespread expectation, looting is frequent after disasters, and preventative measures must be taken immediately. This perception is based on the idea that disasters change societies and communities, triggering negative actions and antisocial collective behavior. But the reality is that looting is the exception and not the norm (Auf der Heide, 2004), and when it does happen, it follows different patterns than looting associated with riots and civil unrest crises. Pro-social adaptive behavior and the willingness to help others is generally the collective reaction to be expected.

First of all, a distinction needs to be made between looting and taking essential items for survival. While looting may be considered the illicit taking of nonessential items with the sole purpose of obtaining personal profit, many researchers use the term "appropriation" when the goods taken are used to cover basic needs, such as the need for food, water, and shelter (Quarantelli, 1994). However, most of these actions are perceived and reported by media, law enforcement, or casual observers as examples of social disorder, violent behavior, and looting. Unconfirmed rumors are also assumed as proof of looting.

When actual looting occurs in disasters, it is commonly undertaken by people from outside the community, frequently by people usually involved in criminal activities, individually or in small groups, taking advantage of the sudden opportunity (Quarantelli, 1994). By contrast, looting in riots and situations of civil unrest is enacted by normally law-abiding people from the community, in a collective manner and openly undertaken with wide social support. Most of those who loot and steal after disasters also do it before disasters. The disaster itself does not act as a social transformer that triggers deep changes or significantly increases antisocial behavior.

In summary, while detailed observation of disasters and the vast majority of the scientific literature indicate that widespread looting and social disorder is a myth and actual looting is truly exceptional, the number of disasters with actual looting and its precise extent remains unclear.

Displacement and disaster-stricken populations: the unexisting exodus

After disaster, the myth perception is that a massive displacement of those affected will follow. However, massive

population displacements are not a common feature after disasters caused by natural hazards. It is in wars and armed conflicts where it is possible to find this type of exodus, with thousands or even hundreds of thousands of people painfully walking roads and paths, carrying their scarce belongings by any possible means. These displaced people will travel long distances, usually up to the first secure place they may find, and settle in quite large camps for extended periods of time.

The situation in disasters caused by natural hazards is quite otherwise. Some people may seek help from relatives outside the affected areas or in assistance camps, but most will not leave the area, or at least they will not be displaced very far away. In disasters, people will try to stay as close as possible to their homes, their neighborhoods, their villages, etc. In fact, the typical population movement more frequently observed is toward the disaster area. As early as the 1950s, this feature was identified and named "convergence behavior" (Fritz and Mathewson, 1957). People going toward the disaster-stricken zones will include concerned relatives seeking news about missing family members or aid workers. As an example, the Haiti earthquake in 2010 produced plenty of news headlines reporting massive population exodus from the capital toward the Dominican Republic by road and the USA by boats. While indeed some people attempted to reach those destinations, these actions were already commonplace in Haiti before the earthquake. And even though the difficult situation in some cities in the aftermath of the disaster may have increased attempts to leave, the reality was far from the massive exodus many predicted.

Donations: received versus needed

Donation of all kind of commodities is indeed a very typical image after disasters. All kind of goods are donated, boxed and shipped to disaster areas. But the reality is that most such donations cause significant problems. First, there are costs linked to the logistics involved in the process: reception, classification, boxing, handling, transportation, distribution, and other related logistical elements.

Second, many donated items are inappropriate or unusable: expired medicines, unpaired shoes, extremely dirty clothes, culturally unacceptable food, winter clothes to tropical areas (or the opposite), etc. All of these situations and many others have been observed regarding donations to disaster-affected countries. The consequence is that despite the intention to help, these donations compound the situation by forcing the diversion of human resources from other essential tasks into the classification and storage of the donations.

In most occasions, the mere cost of transportation will exceed by far the value of the donated goods. Although a donated blanket seems free of charge, by the time that blanket reaches the target beneficiary, particularly if it is shipped from a long distance, the final costs will be far higher than purchasing that blanket locally. The farther the donation travels from the destination country, the higher the costs will be. Besides, massive influx of external goods, if that keeps happening beyond the first days of the disaster response, may affect local markets negatively. No one will purchase in local markets goods that the aid agencies distribute for free. Even in disasters with high levels of destruction, there will be always less-affected or unaffected neighboring areas with available sellers of basic products such as clothes, blankets, and cooking items. Certainly, price inflation may affect certain local products in disaster areas in the initial stages of an emergency. But aid organizations must strive to reject unwanted donations in kind and encourage individual donors and institutions to donate cash to well-established and recognized organizations involved in the response; the cash will be used to purchase locally as many products as possible to support the recovery of the area.

Conclusions

Education about disasters for the public, the media, and above all, the professionals is critical for increasing our awareness about the consequences of distorted information.

Also, a new approach may be needed. Just denouncing the inappropriateness of mass burials will not solve the problem faced by authorities when they have many thousands of bodies to bury. There is a need to obtain basic data from the bodies (estimated age, clothes, old scars, taking digital pictures, etc.) and to keep records for future possible identification by relatives, or addressing the cultural and religious sensitivities through mass funerals or rituals. After these or other palliative measures have been taken, mass burials may still be hard to avoid. But certainly, authorities are better served by concentrating their efforts on activities that reduce fear, which could eventually bring some closure for the survivors.

Finally, better organized relief operations would contribute to reduce social problems caused by unsatisfied basic needs. Social unrest caused by poor access to essential items has been recorded in post-hurricane Katrina in New Orleans in 2006 and post-earthquake Haiti in 2010. Better disaster response and better organized relief distribution, which is based on better disaster preparedness, may contribute to solve this problem.

The struggle to debunk disaster myths was initiated long ago and it will not be won in the short-term. The final objective is not to destroy the myth itself but a reduction in human suffering. Myths persist because they give answers in uncertain situations. If disaster responders and societies learn to better provide certainties, explanations, and an organized response in a disaster situation, the myths will go back to being just imaginary stories.

Acknowledgment

The author would like to acknowledge the invaluable help of Marta Cabarcos-Traseira, Deputy Director of CEDEM, in writing this entry.

N

NATURAL HAZARD

Anita Bokwa
Jagiellonian University, Kraków, Poland

Definition

Natural hazard is an unexpected and/or uncontrollable natural event of unusual magnitude that might threaten people.

The concept of natural hazard

A *hazard* is a source of potential harm or a situation with a potential to cause loss. It may also be referred to as a potential or existing condition that may cause harm to people or damage to property or the environment (Middelmann, 2007). A *natural hazard* is associated with geophysical processes that are an integral part of the environment and involves the potential for damage or loss that exists in the presence of a vulnerable human community (Stillwell, 1992); it is an unexpected threat to humans and/or their property (Mayhew, 1997). These definitions indicate that natural hazards have not only natural, but also social, technological, and political aspects. Natural hazards include geophysical hazards, i.e., hazards where the principal causal agent is climatic and meteorological (e.g., floods, hurricanes, and droughts) or natural hazards where the principle causal agent is geological and geomorphological (e.g., landslides, tsunamis, and earthquakes). They do not include biological hazards, both floral and faunal, such as fungal diseases, poisonous plants, viral diseases, and infestations or locusts (Geophysical hazard, 2010).

Classification of natural hazards

Natural hazards are usually grouped according to the causative element of the Earth's geosystem (Graniczny and Mizerski, 2007, modified; Karst as Geologic Hazard, 2006; Glacier Hazards, 2010):

1. Meteorological hazards: for example, thunderstorm, tornado, tropical cyclone (hurricane, typhoon), cold and heat waves, fog, hail, drought, dust storm
2. Hydrological hazards: for example, flood, snow avalanche, glacier hazards (e.g., ice avalanches or debris flows from outbursts of subglacial water reservoirs and periglacial lakes)
3. Oceanographical hazards: for example, storm surge, sea-level change
4. Geological hazards: for example earthquake, volcanism, mass movements (e.g., landslide, rock fall, debris avalanche), karst hazards (e.g., cover-collapse sinkholes and sinkhole flooding), tsunami
5. Hazards connected with vegetation: for example, wildfire, bushfire
6. Extraterrestrial hazards: for example, meteorite strike

This classification is a simplification and only one of many possible schemes used to organize the complicated issue of natural hazards. For example, within the SHIELD Project (SHIELD, 2009), natural hazards are divided into only two groups: geological hazards (earthquakes, volcanoes, floods, slope failures, tsunamis) and atmospheric hazards (fires, thunderstorms, snow and ice, fog). In fact, most natural hazards are the result of several contributing processes, for example, floods are caused by prolonged rainfalls; tsunami waves follow earthquakes; bushfires are one of the outcomes of drought. Likewise, Stillwell (1992) classified natural hazards on the basis of their origin: within the Earth, such as earthquakes and volcanoes; on the Earth's surface, such as landslides and subsidence; and above the Earth, such as violent storms and fog. The author additionally points to the fact that multiple causes also involve a human element, which is of particular importance in developing nations. The conditions of poor

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

people living on dangerous ground, in unsafe buildings, and with fragile lifelines can magnify the impact of disasters.

Natural hazards may be also classified by:

1. Time of occurrence: Some have the potential to occur at any time of year (e.g., tsunami), whereas others are often seasonal (e.g., thunderstorm).
2. Impact: From frequent moderate impacts (e.g., bushfire) through to rare but potentially catastrophic impacts (e.g., earthquake).
3. Predictability: Some hazards may occur suddenly (e.g., rockfall), whereas in the case of others, the threat may be identified in advance and a warning provided (e.g., flood).

The spatial distribution of natural hazards is influenced by region and topography, and they also vary in the size of the geographical area affected (Middelmann, 2007). Additionally, apart from "traditional" natural hazards, new items are added to the list as the human civilization develops. For example, Beer (2001) argues that air pollution should be viewed as a natural hazard of meteorological origin, because it is caused by meteorological factors that are sporadic in nature and has the potential to cause damage to life or property, or both. Omitting important natural hazards, for example, heat waves or frosts, in some classifications is another issue.

As presented by Wilhite (1996), it is common also for droughts to be omitted from various assessment figures because they differ from other natural hazards by their slow onset, and because they seldom result in structural damage or loss of life. Drought is also one of the most underreported natural disasters, because the sources of most of the statistics are international aid or donor organizations. Unless the countries afflicted by drought request assistance from the international community or donor governments, droughts are not reported. Thus, severe droughts such as those that occurred in Australia, Uruguay, Brazil, Canada, Spain, Italy, and the United States in 1990s are not included in these statistics. Drought is considered by many to be the most complex, but the least understood of all natural hazards, affecting more people than any other hazard. For example, the droughts of the early 1980s to mid-1980s in sub-Saharan Africa are reported to have adversely affected more than 40 million persons. Drought differs from other natural hazards in several ways. Firstly, it is a "creeping phenomenon," making its onset and end difficult to determine. The effects of drought accumulate slowly over a considerable period of time, and may linger for years after the termination of the event. Secondly, the absence of a precise and universally accepted definition of drought adds to the confusion about whether a drought exists or not and, if it does, what is its severity. Thirdly, drought impacts are less obvious and spread over a larger geographical area than are damages that result from other natural hazards. Drought seldom results in structural damage.

For these reasons, the quantification of impacts and the provision of disaster relief is a far more difficult task for drought than it is for other natural hazards. Because drought affects so many economic and social sectors, scores of definitions have been developed by a variety of disciplines. In addition, because drought occurs with varying frequency in nearly all regions of the globe, in all types of economic systems, and in developing and developed countries alike, the approaches taken to define it should be impact and region specific.

Effects of natural hazards

Natural hazards have the potential to cause a number of primary and secondary phenomena. The secondary phenomena produced by a natural hazard vary with event, as does their severity. Tropical cyclones bring strong winds and heavy rains which cause secondary hazards such as floods, storm tides, landslides, and water pollution. Floods inundate areas, which in turn may trigger landslides, erosion, water quality deterioration, or turbidity, as well as sediment deposition. Severe storms range from isolated thunderstorms to intense low-pressure systems producing phenomena such as severe winds, heavy rain, lightning, floods, storm tides, hail, and coastal erosion. Secondary effects of bushfires include water pollution, erosion, and reduced water catchment yield. A landslide may block a watercourse, leading to flooding and debris flows upstream. Earthquakes may also bring fire, flooding, water pollution, landslides, tsunamis, and soil liquefaction that can be as devastating as the primary hazard. Each of these phenomena may produce physical, social, and economic effects.

Physical effects on the built infrastructure may involve structural and nonstructural damage and/or progressive infrastructure deterioration. They may also result in the release of hazardous materials such as chemicals which are usually stored in a safe environment. Social effects may include fatalities, injuries, homelessness, or loss of income, or secondary effects such as psychological impact, disease, or loss of social cohesion. Economic effects may include business disruption; disruption to the supply of power, water, and telecommunications; and the cost of response and relief operations. Secondary economic impacts, such as insurance losses and rising premiums, loss of investor confidence, and costs of providing welfare and medical assistance, may also result. However, a natural hazard is not inherently negative, as hazards produce a disaster only when they impact adversely on communities. Natural hazards can bring positive environmental and social benefits. Bushfires, for example, can stimulate growth and regenerate forest ecology, as the heat from fire is required for some seeds to germinate. Floodplains are picturesque places for recreational activity, and floods can bring welcome relief for people and ecosystems suffering from prolonged drought (Middelmann, 2007).

Natural hazard and natural disaster

A key distinction exists between what is termed a "natural hazard" and what is referred to as a "natural

disaster." A natural hazard is a serious disruption to a community or region caused by the impact of a naturally occurring process, occurring as a rapid onset event that threatens or causes death, injury, or damage to property or the environment, and which requires significant and coordinated multi-agency and community response. Such serious disruption can be caused by one, or a combination, of natural hazards (Middelmann, 2007; Newton, 1997). So hazards might lead to disasters; a disaster is the impact of a hazard on a community/society: For example, a tornado is an example of a natural hazard; a tornado disaster occurs when a severe tornado destroys part of a town, causing significant loss of life and property, often beyond the ability of the local community to recover from, without assistance (White and Etkin, 1997). Scheidegger (1997) points to an important cognitive aspect, already mentioned above: What one calls a "disaster" is in any case only an anthropocentric valuation: If there are many *human* casualties, one speaks of a disaster, otherwise merely of a natural event (cf. the impact of the Tunguska meteorite in 1908, which would have been a catastrophic disaster if the object had hit Tokyo, St. Petersburg, Berlin, London, or New York).

Economical aspects of natural hazards and natural disasters

An economic framework is often used to calculate the cost of natural disasters. Each decade, property damage from natural hazards events doubles or triples. Japan and the United States are the countries where economic damages resulting from natural disasters are the highest in the world (Natural Hazards – A National Threat, 2007). In the period 1970–1990, almost 3 million lives were lost, 820 million people were affected, and up to U.S.$100 billion worth of property was damaged by various natural catastrophes worldwide (Stillwell, 1992). From 1991 to 2000, some 1.5 billion people were affected by floods alone (Natural Hazard, 2010). In 2001–2010, every year on average almost 107, 000 people were killed due to various disasters and almost 232, 000, 000 were affected (Disasters in numbers, 2011). However, the difficulty of measuring the actual impact of a natural disaster on the community continues to be a major challenge because of the complexities in assessing loss. Intangible losses, such as the destruction of personal memorabilia and the effects of post-disaster stress, are particularly difficult to measure. Though insured losses are the most easily captured, they represent only a small proportion of the total loss. These complexities need to be kept in mind when measuring and communicating the concept of "impact" (Middelmann, 2007).

The effects of urbanization and increasing population growth and density, most notable in big cities and coastal regions, have led to greater demand for and concentration of infrastructure and a higher potential exposure to natural hazards (Middelmann, 2007). White and Etkin (1997) distinguished four human-induced reasons of growing natural hazards risk:

1. Fast global population growth
2. Continued growth of material possessions by households
3. Urbanization
4. Coastalization

Nearly100 million people per year are born, mostly in developing countries. Inevitably this leads to greater population density and hence more people exposed to perils in any particular area. Despite entrenched poverty in some countries and intermittent recession in many others, the global economy is still growing, and one result of this growth is that households and companies acquire more goods – especially expensive and fragile consumer durables. In addition to the single radio a Western middle class family might have possessed 50 years ago, we have added two or three automobiles, many radios, several televisions, a refrigerator and a freezer, cameras, mobile phones, and several computers. This Western pattern of material acquisition is now spreading rapidly to the emerging economies of Latin America, East and South Asia, and to the economies in transition in central Europe. As agriculture reduces its need for labor, and as the coal mines lose their attraction for manufacturing enterprises, there are fewer and fewer reasons for people to inhabit the interiors of continents.

The coastal movement began in the United States and Western Europe early in twentieth century, and the same trend is now gathering momentum in China and Southeast Asia. Thus, it is a phenomenon which is prevalent in both the richest and the poorest countries. Coasts are areas of a relatively high risk for natural hazards because of their vulnerability to storms, tsunamis, and flooding (as well as earthquakes). If sea-level rise continues (as is predicted by greenhouse climate models), this will further increase the risk. Canada is something of an exception to this global trend in that the Atlantic coast is not a magnet for population. In terms of economic opportunity, the draw in central and eastern Canada is the St. Lawrence Valley, focused on the Greater Toronto Area, and this is not an area which is particularly susceptible to natural hazards. However, the same dangers of concentration of insured wealth exist, given the high rate or urbanization and the concentration of Canada's population in just three urban areas. The Pacific Northwest is a classic case of concentrated coastal risk: The Greater Vancouver area is situated in an active fault zone and at risk from earthquakes, volcanic eruptions, landslides, liquefaction, tsunamis, and sea-level change. In search of recreation and retirement, Canadians conform to the global trend in seeking coastal zones with a warmer climate, especially Florida, the Caribbean Islands, and Mexico. These trends are producing a greater number of affluent people living in coastal cities and other built-up areas, and to a large extent account for the fact that billion dollar losses have become commonplace in recent years. To some extent, this trend

could be reversed through land-use planning (by not allowing people to live in harm's way), or by ensuring that people assume their own risk. Although a great deal has been written on the problems of managing such huge urban agglomerations, very little has been produced specifically on the management of urban risks. The professions of "risk management and insurance" and "urban management" have yet to form any significant partnerships.

Risk, vulnerability, and mitigation of natural hazards

Natural hazards are closely linked to risk and vulnerability issues. Risk refers to the chance of something happening that will have an impact on objectives, whereas vulnerability is the degree of susceptibility and resilience of the community and environment to hazards. A risk is often specified in terms of an event or circumstance and the consequences that may stem from it. Risk is measured in terms of a combination of the consequences of an event and their likelihood (Middelmann, 2007). Overpopulation, unemployment, poverty, decreasing self-reliance through urbanization, as well as misuse of capital and natural resources, all contribute to vulnerability (Stillwell, 1992). A good understanding of hazard, exposure, and vulnerability is fundamental in any rigorous analysis of the risk posed by natural hazards, as the assessment of risk is only as good as the data used. Knowledge of the elements likely to be exposed to the impact of the hazard phenomena is vital in determining the potential impact or consequence of any hazard on a community or society. This includes information on the people, buildings, and infrastructure potentially exposed to a hazard impact. Such data are fundamental to any analysis of risk, regardless of the hazard. It is also important to consider the potential impacts of climate change on the future risk. The study of prehistoric impacts of natural hazards can also be useful in extending historical knowledge for application today (Middelmann, 2007).

Climate change scenarios indicate that the risk of natural hazards are supposed to increase. According to the IPCC Fourth Assessment Report of 2007 (IPCC, 2007), observed global climate changes have already caused increasing ground instability in permafrost regions and rock avalanches in mountain regions. In the twenty-first century, it is very likely that hot extremes, heat waves, and heavy precipitation events will become more frequent. Based on a range of models, it is likely that future tropical cyclones (typhoons and hurricanes) will become more intense, with larger peak wind speeds and heavier precipitation associated with ongoing increases of tropical sea-surface temperatures. There is less confidence in projections of a global decrease in numbers of tropical cyclones. The apparent increase in the proportion of very intense storms since 1970 in some regions is much larger than simulated by current models for that period. Extratropical storm tracks are projected to move poleward, with consequent changes in wind, precipitation, and temperature patterns.

By the 2080s, many millions more people than today who live in coastal areas are projected to experience floods every year due to sea-level rise. The numbers affected will be largest in the densely populated and low-lying megadeltas of Asia and Africa and small islands are especially vulnerable. Available research suggests a significant future increase in heavy rainfall events in many regions, including some in which the mean rainfall is projected to decrease. The resulting increased flood risk poses challenges to society, physical infrastructure, and water quality. It is likely that up to 20% of the world population will live in areas where river flood potential could increase by the 2080s. Increases in the frequency and severity of floods and droughts are projected to adversely affect sustainable development. Some regions of the world are predicted to be especially endangered by the possible future changes. Coastal areas, especially heavily populated megadelta regions in South, East, and Southeast Asia, will be at the greatest risk due to increased flooding from the sea and, in some megadeltas, flooding from the rivers.

By 2050, ongoing coastal development and population growth in some areas of Australia and New Zealand are projected to exacerbate risks from a sea-level rise and increases in the severity and frequency of storms and coastal flooding. Climate change is expected to magnify regional differences in Europe's natural resources and assets. Negative impacts will include an increased risk of inland flash floods and more frequent coastal flooding and increased erosion (due to storminess and sea-level rise). In southern Europe, climate change is projected to worsen conditions (high temperatures and drought) in a region already vulnerable to climate variability, and to reduce water availability, hydropower potential, summer tourism, and, in general, crop productivity. Climate change is also projected to increase the health risks due to heat waves and the frequency of wildfires. Cities of North America that currently experience heat waves are expected to be further challenged by an increased number, intensity, and duration of heat waves during the course of the century, with a potential for adverse health impacts.

As many natural hazards are connected with the atmospheric processes, the World Meteorological Organization (WMO) undertakes many disaster risk reduction activities. They are integrated and coordinated with other international, regional, and national organizations. WMO coordinates the efforts of national meteorological and hydrological services to mitigate human and property losses through improved forecast services and early warnings, as well as risk assessments, and to raise public awareness. Emphasis is on disaster risk reduction: One dollar invested in disaster preparedness can prevent seven dollars' worth of disaster-related economic losses – a considerable return on investment. WMO's objective is to reduce by 50%, by 2019, the associated 10-year average

fatality of the period 1994–2003 for weather, climate and water-related natural disasters (Natural hazard, 2010).

Natural disasters have a significant economic, social, environmental, and political impact on societies. While some of the impact of natural disasters can be mitigated, the risk cannot be completely eliminated. Growing economic and technological advances may assist in managing disasters, but they also make communities more vulnerable to potential impacts of hazards. This occurs through the increase in numbers and concentration of people and other assets exposed to hazards, and greater reliance on infrastructure such as power and water supplies (Middelmann, 2007). As far as management strategies are concerned, for example, satellite surveillance and monitoring shows a great promise in identifying hazards and assessing damage from disasters. Brazil is using satellite imagery to follow drought developments and deforestation. An early warning system offers the chance to prepare for a disaster such as a hurricane, although it has little use against earthquakes or volcanic eruptions. In 1988, early warning minimized loss of life during Hurricane Hugo. Some regions are prepared for disaster with hazard zone maps and evacuation plans, but these measures may not always work. For example, even though hazard zone maps had been prepared for the area around Nevado del Ruiz, Colombia, residents failed to respond and were caught by the eruption of 1985. Behind much of the loss from mass movement and flooding lies overuse or deforestation of land. These are critical problems in much of Latin America which land-use regulations could help to reduce. Recognizing vulnerability to a natural hazard and avoiding settlement on hazardous sites can also reduce the effects of natural disasters. Slope of active volcanoes and floodplains of major rivers are fertile sites for crop production, but they hold latent danger (Stillwell, 1992).

According to Quarantelli (Newton, 1997), the implications of rethinking "natural" disasters as having social causation are fourfold:

1. Mitigation of disasters must stress social rather than physical approaches.
2. These approaches must place emphasis on proactive rather than reactive actions.
3. Such actions need to focus on internal flaws in society rather than external forces.
4. Reduction of vulnerability to disasters must be integrated as part of ongoing policies and programs of societal development.

If we accept that full prevention is unattainable, then our rethinking of disasters leads us toward a policy of long-term loss reduction – mitigation. Local institutional involvement is crucial for the adoption and implementation of hazard mitigation. Factors such as local leadership, locally devised rules and strategies, adaptation to dynamic conditions, recognition of local rights, monitoring and compliance, and linkage help local governments to promote recovery and mitigation efforts (Reddy, 2000).

Public perception of natural hazards

The concept of natural hazard involves assignation of values (e.g., dangerous, harmful, and bad) to natural phenomena, depending on their potential impact on humans. That anthropocentric perspective, predominantly exploited by mass media, is one of the reasons of flawed public understanding of the Earth's geosystem functioning. The term "natural hazard" refers to one of the aspects of human perception of the natural environment. The relations between human beings and environment began about 5 million years ago and from the beginning people have attempted to become as independent from the environment as possible. Nature is generous and a friendly source of food, building materials, energy, etc., but also a hostile and mysterious power bringing earthquakes, floods, tornadoes, etc.

Natural hazards have impacted humans since they first walked on the Earth, influencing, shaping, and modifying human behavior, gradually or catastrophically changing the way people live with and respond to the environment (Middelmann, 2007). Milestones in civilization development were marked by inventions of new technologies of energy production, first from biomass and later from various kinds of fuels. One of the consequences was changing public attitude to the environment. The most recent trend is based on the idea of individual and collective responsibility for the environment, followed by actions aimed to mitigate negative environmental changes (Mannion, 1997). The technological achievements of the last 200 years, followed by significant social transformations on a global scale, have created an illusion of the potential independence of humans from the environment. About 50% of the world population lives in cities, but the figures vary from over 80% in USA and Australia to 38% in Africa (United Nations, 2008). In USA, people spend over 90% of their lifetime in closed spaces, for example, homes, office buildings, cars, shopping centers (Jacobson, 2002).

Although significantly affected by humans, the environment is still ruled by the same natural processes that have operated since before the dawn of the human existence (e.g., plate tectonics, water cycle). The Earth's ecosystem remains in a dynamic equilibrium and extreme events, potentially dangerous for humans, are regular elements of this state (e.g., earthquakes or tornadoes). Scheidegger (1997) goes further and says that a landscape is, in fact, an open, nonlinear, dynamic system where tectonic uplift and seismic activity represent the input: mass wastage and relief degradation, the output. The apparent "stability" is due to the fact that open, nonlinear dynamic systems tend to develop into relatively stable, self-organized ordered states "at the edge of chaos." Short of complete breakdown, such systems reestablish order in steps of various magnitudes.

Over time, attribution of natural hazards and disasters has shifted from supernatural or mystical forces, to nature (physical forces in natural systems), and with some

reluctance, to humans who have made changes to natural systems. In this transition of thinking, we have added to the list of causation, but never fully abandoned the earlier sources. Quarantelli notes the inherent danger in this approach when he observes, "the distinction often drawn between so called Acts of God (or Nature) and Acts of Men and Women is both a useless and false one. There also lurks in the distinction a supposition that one kind of disaster is more directly controllable than other ones" (Newton, 1997, p. 222). Moreover, a natural hazard or disaster, in a pure sense, does not exist; rather there is an interaction of changes in physical systems with existent social conditions. Hazards and disasters are therefore more accurately seen as social phenomena. Additionally, natural hazards are not always initiated through only natural means, and human activity can sometimes exacerbate their occurrence. For example, deforestation in mountainous areas contributes to flood occurrence by diminishing the natural water absorption. In Australia, arson is a common source of ignition for bushfires. Still, the potential impact of a hazard is the same regardless of its origin (Middelmann, 2007). Natural hazard can also depend upon the organization and values of society that control the degree to which risk may be reduced (Stillwell, 1992).

At present, two major approaches seem to dominate in the public attitude to the causes of natural hazards. One approach, called "the dominant view," emphasizes the geophysical processes underlying natural disasters. It involves monitoring and predicting, risk assessment and zoning, and emergency planning and relief. Expertise is provided by the physical sciences and engineering, such as work of Scheidegger (1997). This approach assumes that technology can solve most hazard/disaster problems, but it is restricted mainly to the developed countries. Another approach emphasizes the human/environment relation of natural disasters as seen by cultural geographers and other social scientists. It is based on the assumption that a natural hazard can only exist in the presence of a vulnerable human community and that natural disasters are characteristic rather than accidental features of places and societies. This approach also recognizes that recent disasters occur in conjunction with major social change and environmental impact, and therefore it is most applicable to the developing countries (Stillwell, 1992).

Communicating natural hazards

Information on natural hazards can often be seen as controversial or having the potential to cause panic if not adequately communicated. Natural hazards and disasters have been recently receiving much attention in books, periodicals, and the news media. This may be due to improved monitoring and communications rather than to an increase in natural phenomena. A growing concern over this problem prompted the United Nations General Assembly to designate the 1990s as the International Decade for Natural Disaster Reduction. Since 1965, the International Geographical Union's Commission on Man and Environment has been playing a central role in stimulating and coordinating natural hazard and disaster research activities of geographers worldwide (Stillwell, 1992). But as shown by Nicholls (2001), even if the forecaster-media interactions work well, there may still be problems with the understanding of forecast information. Australian experiences during the 1997/98 El Niño indicated that many users had difficulties interpreting the uncertainties inherent in a climate forecast.

There is considerable evidence in the psychological literature that people do *not* handle uncertainty and probabilities at all well. A group of psychological factors called cognitive illusions confound the attempts to communicate and understand uncertainties. Slovic summarizes the nature and effects of these illusions: "...research on basic perceptions and cognitions has shown that difficulties in understanding probabilistic processes, biased media coverage, misleading personal experiences, and the anxieties generated by life's gambles causes uncertainty to be denied, risks to be misjudged (sometimes overestimated and sometimes underestimated), and judgements of fact to be held with unwarranted confidence. Experts' judgments appear to be prone to many of the same biases as those of the general public, particularly when experts are forced to go beyond the limits of available data and rely on intuition. Strong initial views are resistant to change because they influence the way that subsequent information is interpreted. New evidence appears reliable and informative if it is consistent with one's initial beliefs; contrary evidence tends to be dismissed as unreliable, erroneous, or unrepresentative. When people lack strong prior opinions, the opposite situation exists – they are at the mercy of the problem formulation. Presenting the same information about risk in different ways (for example, mortality rates as opposed to survival rates) alters people's perspectives and actions" (Nicholls, 2001, p. 149).

The difficulties people have in dealing with probabilities and uncertainties, as summarized by Slovic, have clear implications to attempts to have climate predictions (which are inherently uncertain and probabilistic) used in an optimal fashion. Since climate forecasts must be delivered in terms of probabilities because of the chaotic nature of the climate, scientists must also learn how people interpret and misinterpret these probabilities. Cognitive biases affected the way El Niño forecasts were received and interpreted in Australia during 1997. For instance, two biases are "availability" and "anchoring." During 1997 many press articles on the El Niño described the severe impacts of the 1982/83 event. Users then had a great difficulty adjusting their expectations of the impacts of the 1997 El Niño away from what they had experienced during 1982. This occurred even when they were reminded that the 1982 impacts were very extreme, compared with historical impacts of the El Niño on Australia. The "availability" of the reports about the 1982/83 impacts led users to "anchor" to the 1982 impacts, and they subsequently could not "adjust" away

from that anchor sufficiently. Nicholls (2001) discusses the ways of avoiding these cognitive biases – the "anchoring" problem, for instance, could be reduced by ensuring that a variety of El Niño events, with varying degrees of impact, are discussed in the context of a forecast based on El Niño. Scientists need to work on, not just improving our monitoring and predicting of the next El Niño and other climate and weather hazards, but on innovative ways to present these predictions to the public.

There appears to have been somewhat more attention paid to the difficulties of communication in short-range predictions; but even here, much could be gained from increased communication between atmospheric scientists and those dealing with other forms of disasters. The development of appropriate policies and communication strategies to deal with sensitive situations is therefore essential. Equally important is instilling a culture of safety and local participation in the community. The preparedness of a community for a natural hazard can reduce the impact of an event of natural disaster and allow for more rapid recovery. Therefore, a key to reducing the overall risk of natural disasters is for those who play a role in the management of natural disasters to work closely with the wider community (Middelmann, 2007). One of the obstacles that must be overcome is the communication strategy.

Creating closer links between policy, research, and practice is central to reducing the impact of natural hazards and natural disasters. Communication across these domains provides an appreciation, understanding, and involvement across interrelated areas and is of high importance in reducing risk. However, for science and research to effectively influence policy development, information must be clearly communicated to government in a timely and understandable manner. This is vital in ensuring scientific research reaches its full potential and assists policy makers to make informed and relevant decisions using the best information available. As the Centre for European Flood Research observes: "If scientists really want to influence policy more, researchers need to become more visible, and clearer about the kind of changes they are aiming for, and are able to achieve" (Middelmann, 2007, p. 61). Practitioners need to communicate effectively to those whose role is to develop a policy. Similarly, any policy which is developed needs to be coherent in "whole-of-government" terms. It is also vital that those involved in policy development seek the expertise of those working "on the ground." Researchers need to liaise with practitioners to find out what their needs are, and work toward developing relevant methodologies and techniques which can be easily applied and communicated to effectively inform policy makers. Successful linking of policy and research requires an open and continuous dialogue. Where this relationship is effective and natural hazard impacts are minimized, the benefit is felt by politicians, policy makers, researchers, practitioners, and the community (Middelmann, 2007).

Apart from uncertainty, the lack of a precise and objective definition of a phenomenon may be a serious obstacle to understanding it. A good example is the case of drought. It must be accepted that the importance of drought lies in its impacts. Institutional, political, budgetary, and human resource constraints often make drought planning difficult. One major constraint that exists worldwide is a lack of understanding of drought by politicians, policy makers, technical staff, and the general public. Lack of communication and cooperation among scientists and inadequate communication between scientists and policy makers on the significance of drought planning also complicates efforts to initiate steps toward preparedness. Because drought occurs infrequently in some regions, governments may ignore the problem or give it low priority. Inadequate financial resources to provide assistance and competing institutional jurisdictions between and within levels of government may also serve to discourage governments from undertaking planning.

Other constraints include technological limits (such as difficulties in predicting and detecting drought), insufficient databases, and inappropriate mitigation technologies. Policy makers and bureaucrats need to understand that droughts, like floods, are a normal feature of the climate. Their recurrence is inevitable. Although we cannot influence the occurrence of the natural event (i.e., meteorological drought), we can lessen vulnerability through more reliable forecasts, improved early warning systems, as well as appropriate and timely mitigation and preparedness measures. Drought manifests itself in ways that span the jurisdiction of numerous bureaucratic organizations (e.g., agricultural, water resources, health, and so forth) and levels of government (e.g., national, state, and local). Competing interests, institutional rivalry, and the desire to protect their agency missions (i.e., "turf protection") impede the development of concise drought assessment and response initiatives. To solve these problems, policy makers and bureaucrats, as well as the general public, must be educated about the consequences of drought and the advantages of preparedness. Drought is an example of an interdisciplinary problem that requires input by many disciplines and policy makers (Wilhite, 1996).

Summary

Natural hazards are phenomena resulting from the geophysical processes that are an integral part of the environment. People cannot control natural hazards, but can be significantly affected by them if a natural disaster (i.e., the concrete realization of a hazard in a populated area) occurs. There are many direct and indirect effects of natural hazards, but most of them are associated with great economic and nonmaterial losses. Therefore, those phenomena are characterized not only by natural but also social, economic, and political aspects. As the climate change scenarios indicate that the risk of natural hazard is supposed to increase, it is of utmost importance to improve the mitigation strategies. The basic problem to be solved is better communication together with better information and knowledge transfer from the scientific community to

societies and politicians. That goal can be achieved by permanent environmental education programs realized both at the international and regional level.

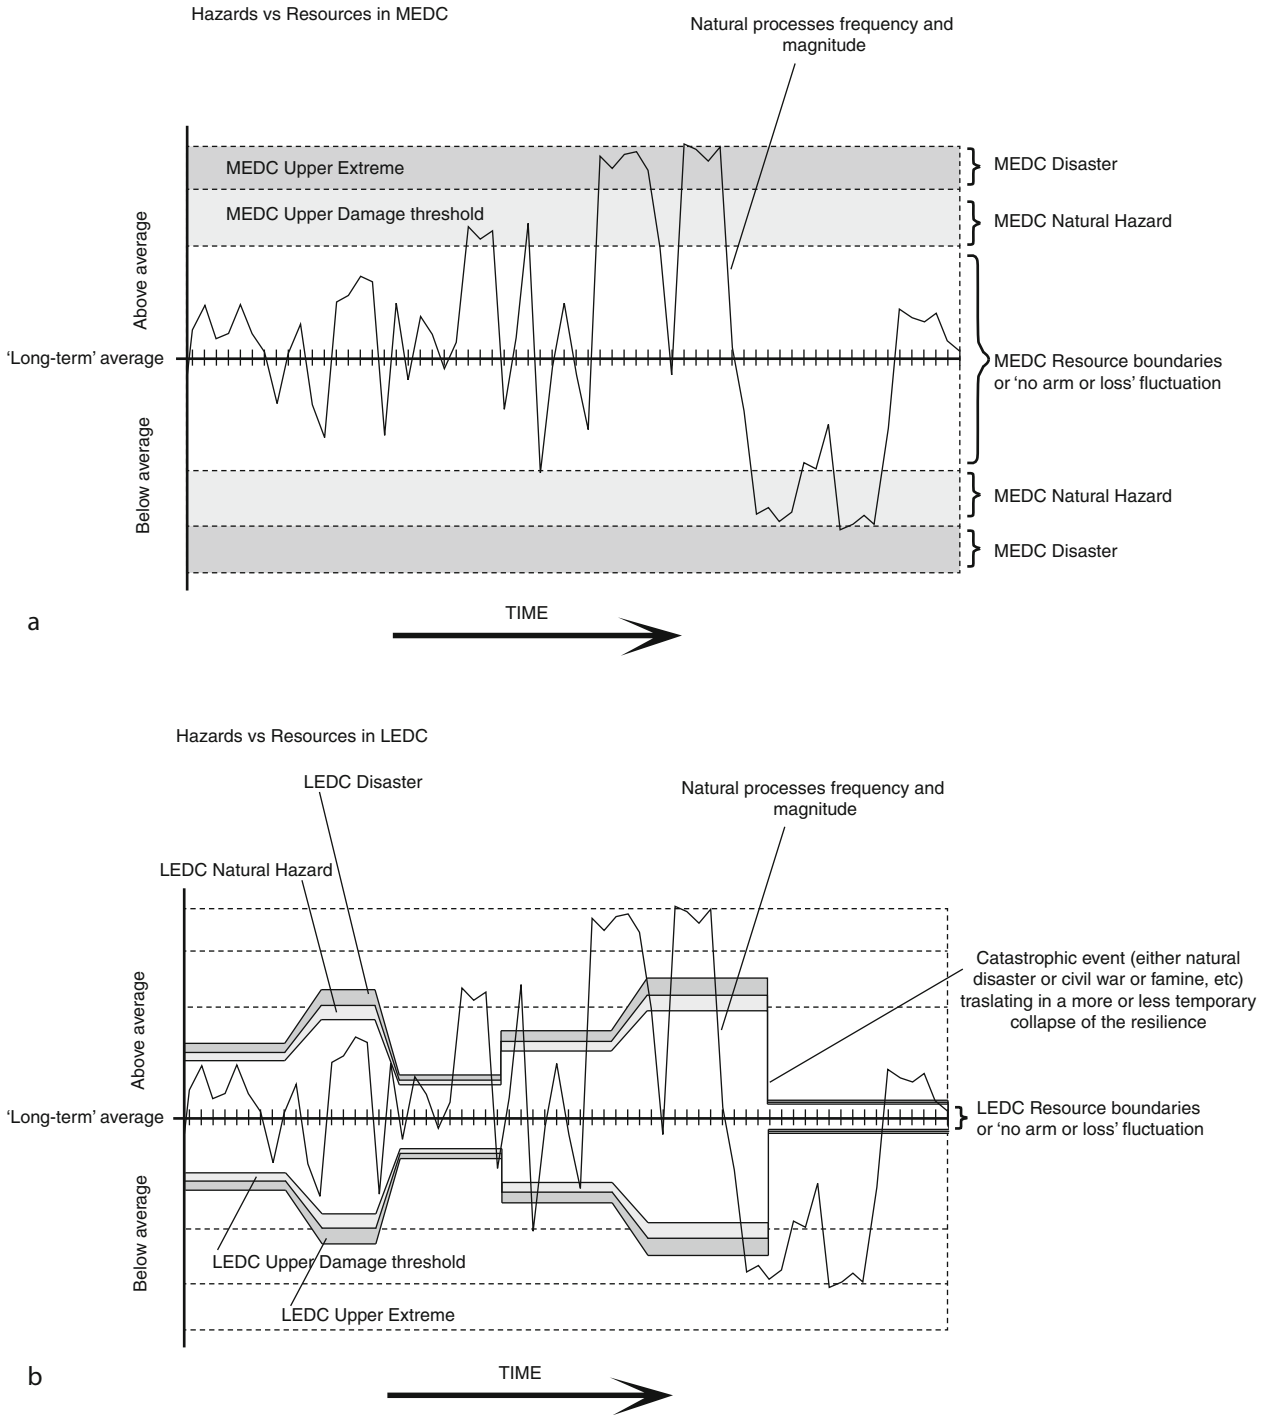
Introduction

This entry deals mainly with geophysical hazards (geological, geomorphological, and atmospheric) in developing countries. A brief mention of the role of international agencies in LEDC is also given. First of all, though, some definitions of natural hazards and of developing countries are required.

Definitions

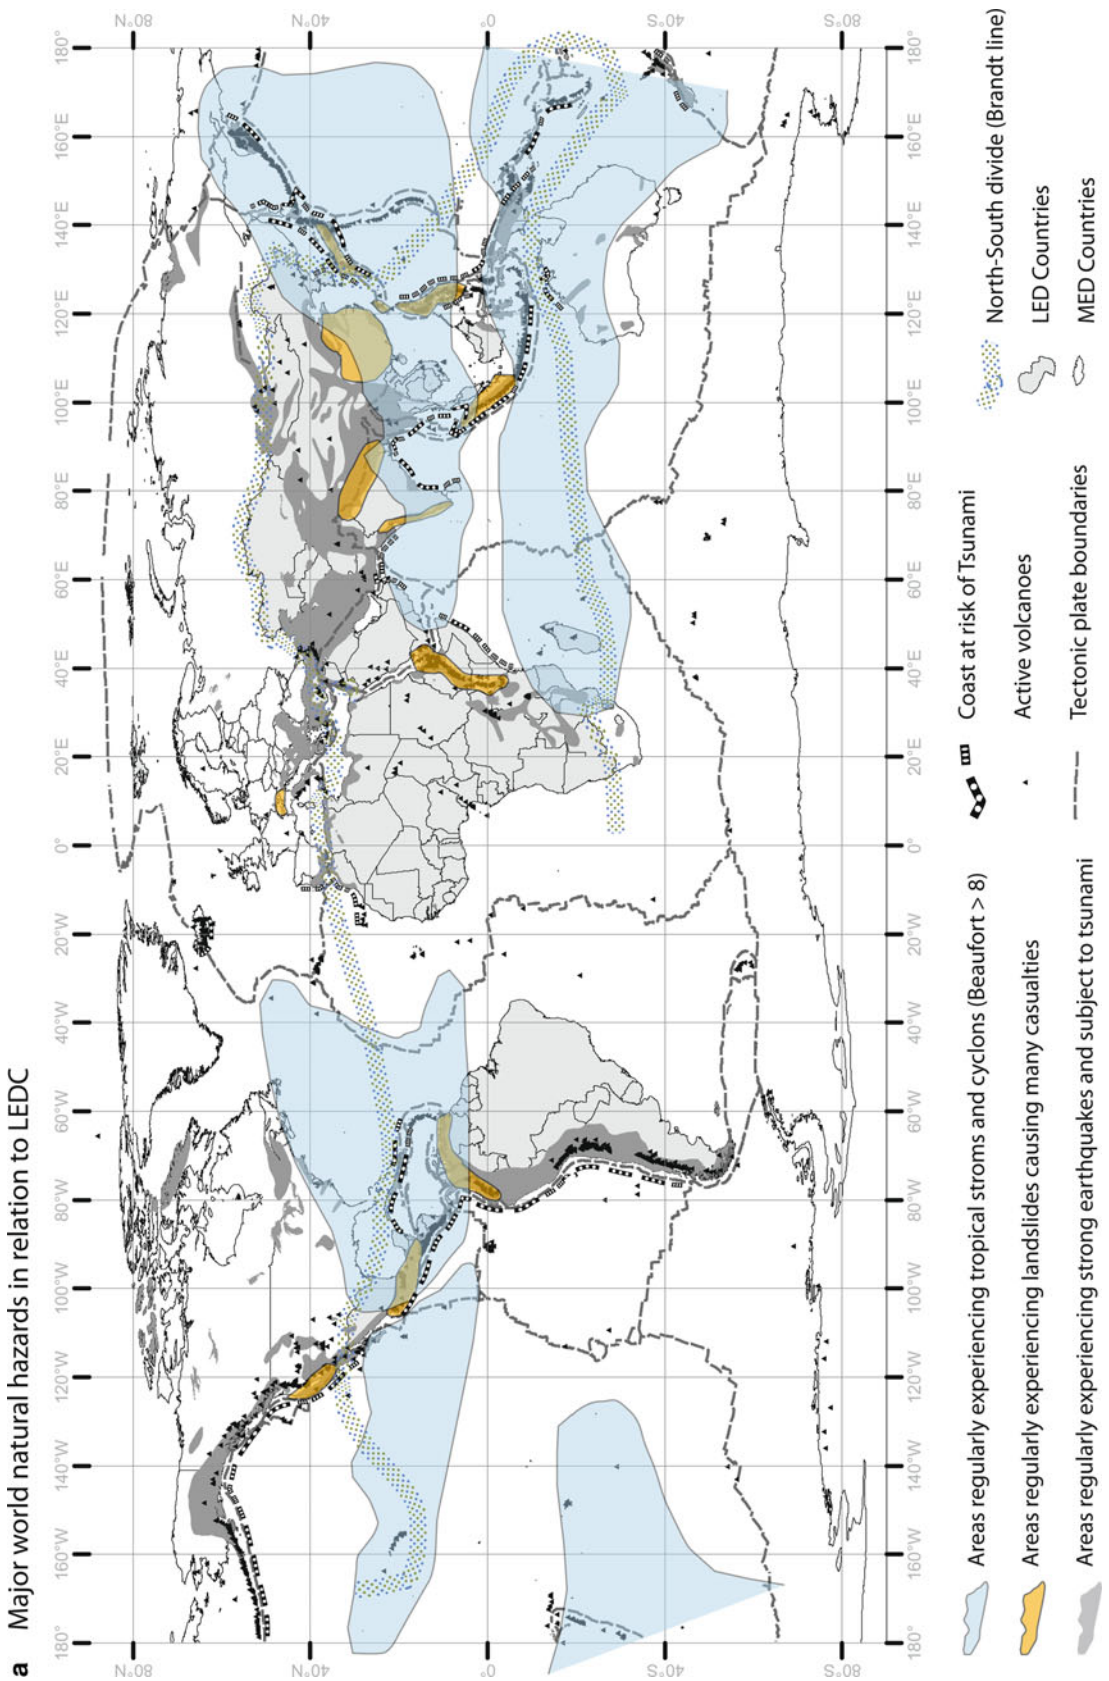
The word "hazard" derives from the Arabic az-zhar, a composed word meaning literally "gaming die" (Concise Oxford English Dictionary, 2002). The first English meaning is "*a dice game in which the chances are complicated by arbitrary rules*" (Concise Oxford English Dictionary, 2002) and only in its second definition there is a mention to what is here addressed, that is, "*risk of loss or harm*" (Concise Oxford English Dictionary, 2002). These definitions highlight how the term "hazard" is highly anthropocentric in nature, and could not be differently so. In fact, it describes an interaction between biophysical processes (occurring on planet Earth forever) acting on a territory where at a specific time there is human occupancy. Hence, some natural events can cause harm or loss of human life or to valued goods, and so they are perceived as hazards. Without the human presence, there would not be such a perception, as for instance, when a strong earthquake strikes in an uninhabited area of the planet or when very extreme events happen on other planets where humans are not present, for instance, global atmospheric perturbation on planet Mars with wind velocity of some hundred kilometers/hour that we do not define as hazard but simply observe and describe.

The term "hazard" is also quantitatively defined within the geophysical community using the formula: $R_s = H \times E \times V$ (here specifically defined for landslide risk by Varnes, 1984)
where



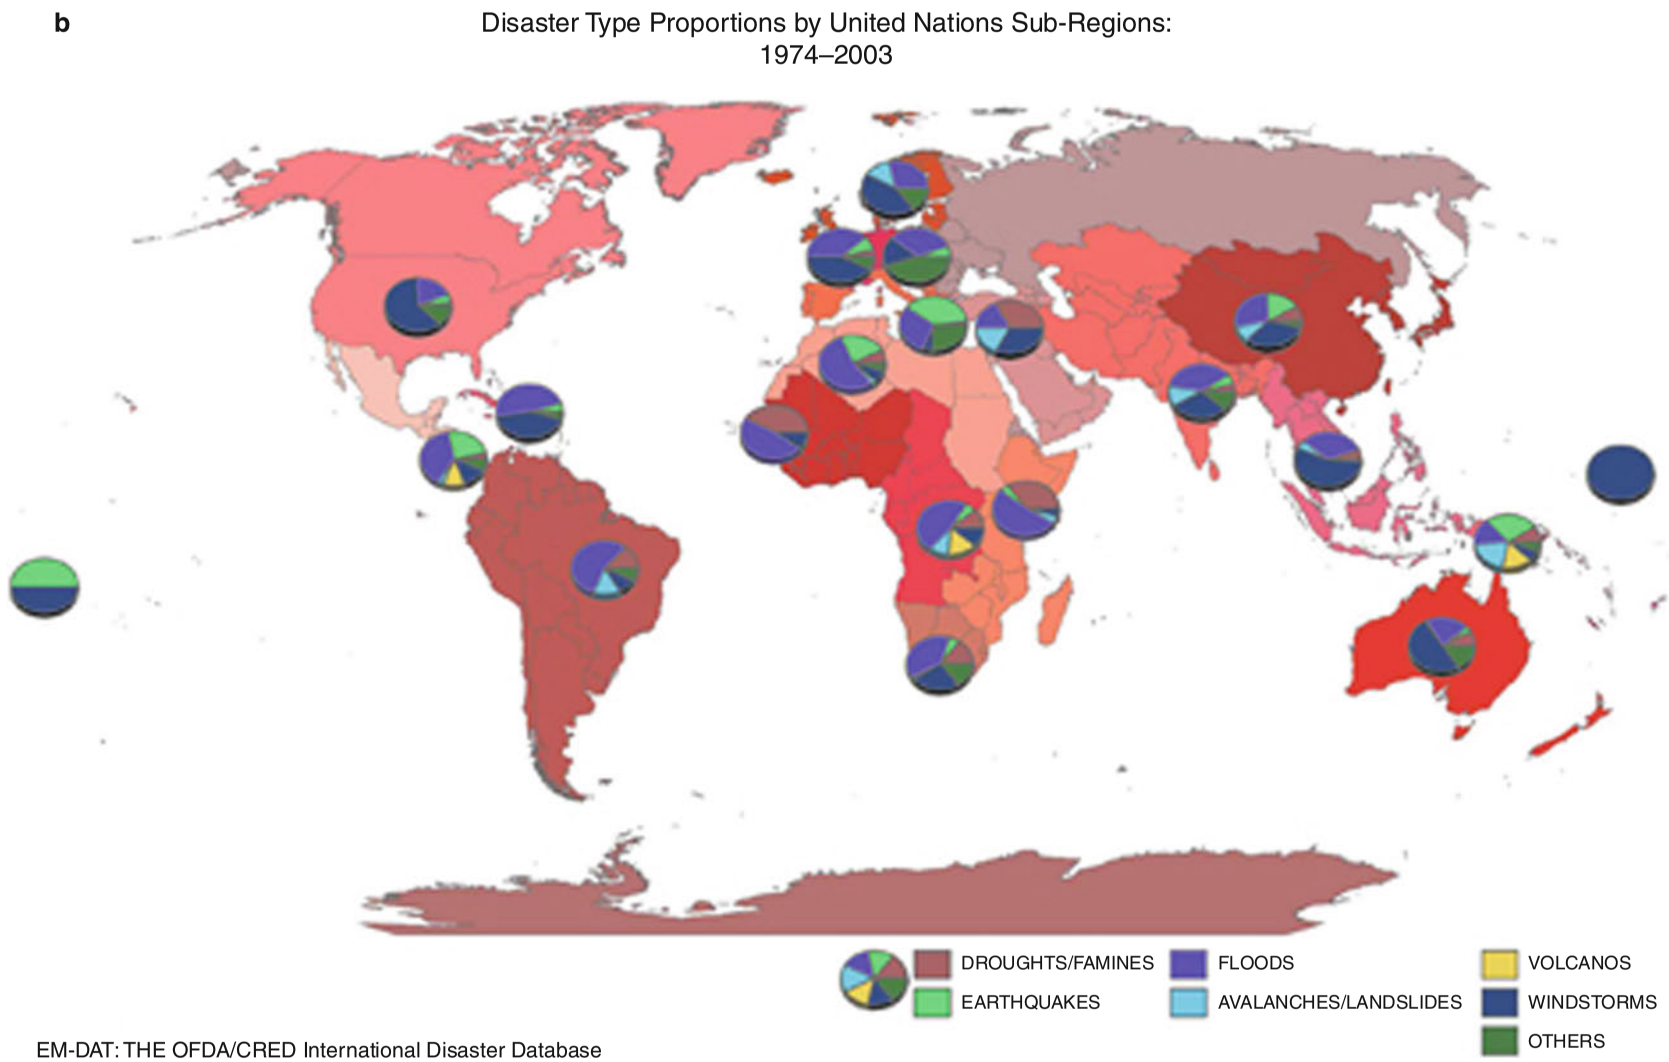
R_s = specific risk, or the expected degree of loss due to a particular magnitude of natural phenomenon within a specified area over a given period of time
H = *hazard*, or the probability of occurrence of a particular magnitude of natural phenomenon within a specified area over a given period of time
E = elements at risk, or the total economic value of population, properties, artifacts, infrastructures, amenity, etc. within the specified area under consideration
V = vulnerability, or the proportion of elements at risk or likely to be affected detrimentally by the hazard, that is, the significance of loss represented either as a percentage of E or on the scale 0 to 1.

The term "natural hazards" also relates vastly with the concept of time as both perceived by humans and as a natural factor. In relation to the human perception of time, well explained by Smith (2009) and shown in Figure 1, humans retain a sort of long-term average knowledge of natural environmental processes they live in. Here "long term" is related to an individual life span or his/her few generations back in time, depending on the degree of link with the cultural roots in each culture. In this way, for instance, the long-term climatic fluctuations experienced on the planet in the last tens of thousands years are far beyond the human temporal panorama and thus cannot easily be incorporated into a culture if not with quite a certain degree of intellectual effort. In some cases events with even shorter return periods (in the range of 100 years) are not recognized by human beings. Different cultures retain different temporal panoramas as well exemplified in the case of Australian aborigines who retain very old knowledge of their landscape through oral tradition. In relation to time as a natural factor in natural hazards, the concept of magnitude and frequency, or return period, is crucial (Alcantara-Ayala, 2002) and combined with socioeconomic resilience they define the resource boundaries, upper damage threshold, and upper extreme of Figure 1.



In conclusion, a natural hazard is a physical and/or biological event that can cause harm to human beings and their goods above a certain "acceptable" threshold, in a specific place at a certain time. The most controversial issue in this definition is to quantify the "acceptable threshold" in terms of both human life and economic damage. Such a foggy definition is also reflected in the discrepancy between the few global databases of natural hazards: Munich Re Geo-Risk (http://sustainability.munichre.com/en/ts/geo_risks/default.aspx), Swiss Re National Catastrophe (http://www.swissre.com/pws/about%20us/knowledge_expertise/top%20topics/natural%20catastrophes/natural%20catastrophes.html), CRED EM-DAT (www.em-dat.net). Although these datasets converge on the overall figures, they are in disaccord when counting each specific event and its tolls, as also highlighted by Mosquera-Machado and Dilley (2009).

The term "developing countries" has even more uncertainties in its definition. The United Nations Statistical Division (http://unstats.un.org/unsd/methods/m49/m49regin.htm#developed) defines it on the basis of the Human Development Index (HDI) which accounts for life expectancy at birth, literacy rate and gross enrolment ratio, and standard of living expressed by the GDP per capita. Using these indicators, the UN groups the world into Regions (developed and developing) and Countries (developed and developing). Following this classification, the Developing Regions are composed of: Africa, Caribbean, Central America, South America, Asia (excluding Japan), and Oceania (excluding Australia and New Zealand). The Developed Regions are formed by the rest of the world, namely Northern America, Europe, Japan, Australia, and New Zealand. To the developed macro regions is usually added also South Africa and Israel. A number of other definitions include emerging economies (Jain, 2006), BRIC countries (Brazil, Russia, India, China; Goldman Sachs, 2003) and so forth.



The World Bank uses purely economic indicators such as the GNI (Gross National Income per capita) and sets

Natural Hazards in Developing Countries, Figure 1 Comparison between MEDC and LEDC thresholds for the onset of Natural Hazard and Disaster. The thin lined curve in both diagrams indicates a natural process, for example, rainfall, with its frequency and magnitude in time. The midline stands for the long-term average. (**a**) In the MEDC thresholds are quite stable through time if not becoming wider with time. Also they show a quite wide range of tolerance or resilience that defines the resource boundaries. A natural hazard impacts on society only when the MEDC Upper Damage threshold is surpassed (Modified after Smith and Petley, 2009). (**b**) In LEDC, on the other hand, all boundaries and thresholds are highly variable in time depending on socioeconomic instability of these countries. The resource boundaries are in general smaller than the one of MEDC. Furthermore in LEDC, the thresholds for Upper Damage and Upper Extreme are not very far one from the other, while in MEDC, they are more widely spaced.

Natural Hazards in Developing Countries, Figure 2 (Continued)

Natural Hazards in Developing Countries, Figure 2 (**a**) Location of the LEDC and of some of the main natural hazards in the world. The LEDC regions are: Central and South America, Africa (excluding South Africa), Asia (Mid, Central, South East, Far, excluding Japan South Korea, Taiwan, and Russia). (**b**) Disaster type proportion by UN macro regions 1974–2003 (From CRED database).

Natural Hazards in Developing Countries, Table 1 Environments and their main locations in the LEDC regions

Environment	Occurrence
Monsoonal	Indian Ocean realm
Humid tropic	Central America, South of Mexico; Amazon basin; Central-West Africa,
Arid and semiarid (cold and hot)	Mexico; parts of South America; North, Central, East and Southern Africa; Asia and Middle East (excluding South East Asia)
Deserts	Mexico; parts of South America; North Africa (Saharan region), East and South Africa; Asia and Middle East (excluding South East Asia)
Mountain (including high mountain and associated Plateau)	Central and South America (Andes); Asia (Alpine-Himalayan mountains)
Coastal	All regions
Islands	Mainly South East Asia and Pacific realm
Glacial and periglacial	Western and Southern part of South America (Andes); Asia (Alpine-Himalayan mountains)
Technoscapes or anthropic environments (megacities)	All regions, mainly on coastal environments

thresholds of GNI each year on the first of July. With this classification, the bank defines the following category of countries: Low-Income, with $975 or less per capita/year; Lower-Middle Income, $976–$3,855 per capita/year; Upper-Middle Income, $3,856–$11,905 per capita/year; and High Income, $11,906 or more. The first two groups are usually referred to as developing countries, but the bank also specifies that this system is not always related to the degree of development of a nation (http://go.worldbank.org/K2CKM78CC0).

An alternative to these definitions is given by the term Less Economically Developed Countries (LEDC), as opposed to More Economically Developed Countries (MEDC). LEDC have high birth rates (>20%), death rates (>30%), and infant mortality (>30%); more than half of their workforce are involved in agriculture and have a low level of nutrition, secondary schooling, literacy, electricity consumption per head and GDP is usually less than 1,000 USD/capita/year (Mayhew, 2009).

Visually, the so-called North–south divide, separating MEDC and LEDC countries, is also shown in Figure 2 with "South" countries in gray and "North" countries in white (Brandt, 1980).

Type of natural hazards in developing countries

Natural hazards are zonal phenomena (Green, 2007) and as such they are not evenly distributed on the entire planet. Figure 2 shows the distribution of several hazards and it emerges how much more LEDC are exposed to natural hazards than MEDC.

Natural Hazards in Developing Countries, Table 2 Examples of natural hazards, their rapidity, and the environment they mainly occur in, with reference to Table 1

Type of natural hazard	Rapid	Slow	Environment
Avalanches	X		Mountain, glacial, periglacial
Epidemics diseases		X	All (with much less influence on the glacial and periglacial)
Coast = erosion		X	Coastal, technoscapes
Desertification		X	Arid and semiarid
Drought		X	Arid and semiarid
Dust storm	X		Arid and semiarid (with global effects)
Dzud (also spelled Zud)		X	Arid and semiarid (cold, especially Mongolia plains)
Earthquakes	X		All
Coastal Floods	X	X	Coastal, technoscapes
Floods	X	X	All (excluding glacial and periglacial)
Flash floods	X		Arid and semiarid
Fog		X	Mountain
Glacier surges		X	Glacial
Hail	X		Mountain, desert (coastal)
Hurricanes/ typhoons	X		Coastal, islands (mainly between +20° and −20° of latitude)
Plant and livestock pests		X	All (with much less influence on the glacial and periglacial)
Sea level rise		X	Coastal, technoscapes
Sinkholes (karst)		X	All (if limestone or dolomite or evaporitic rocks are present)
Slope instability	X	X	Mountain, humid tropics, monsoonal
Soil erosion (including gully erosion)		X	Most, especially with human interference
Storms	X		All
Thermokarst		X	Glacial and periglacial
Tornadoes	X		Arid and semiarid, mountain
Tsunamis	X		Coastal, technoscapes
Volcanic	X		All
Wildfires	X		Arid and semiarid

Derived from Alexander (1993), Whittow (1996), Alcantara-Ayala (2002), Goudie (2002), and Smith and Petley 2009

The environments found in the LEDC countries are summarized in the following Table 1, where under the field Occurrence is listed the main geographical distribution within the LEDC.

Each of the environments of Table 1 has its own specific type of geophysical and biological processes. Table 2 presents most of the natural hazards occurring by environment, that is far from being exhaustive.

Some geophysical hazards are not following the same zonation of Table 1; instead they are located at tectonic plates boundaries (see Figure 2). Notably earthquakes, tsunamis, and volcanic activity are mainly found in the so-called circum Pacific fire belt, encompassing all the continental areas facing the

Natural Hazards in Developing Countries, Table 3 Examples of complex interaction between natural and anthropic causes of some natural hazards

Natural hazard	Anthropic component	Natural component
Desertification in semiarid area	Clearing, overgrazing, wood collection, charcoal burning, etc.	Drought and climate change
Soil erosion in a valley bottom	Runoff from new roads, removal of protective vegetation for overgrazing, increased cropping areas, plowing perpendicular to the contour lines, etc.	Change in climate or in base level
Coastal erosion	Side effect of groynes up the coast, or of a reduced sediment supply due to damming of the rivers	Higher intensity and/or frequency of storms, increase in sea level
Flooding (river)	Removal of natural vegetation, urbanization, overgrazing, mismanaged dam regulation, land encroachment	Higher intensity and may be amount of rainfall

Adapted from Goudie (2002), p. 507

Pacific Ocean, the Caribbean Sea, the East Indian Ocean and the Philippine Sea, as well as onshore Central and South Asia.

Traditionally, natural hazards are defined as a "sudden release of energy and/or matter in that specific system" (Smith and Petley, 2009), with an accent on their velocity of development. This is true for the most striking processes like earthquakes, tsunamis, volcanic eruptions, rapid landslides, and flash floods, but in fact the release of energy and/or matter can also be slowly onsetting instead of rapid. Drought, dzud (or zud), soil erosion, dust storms, desertification, coastal erosion, and salinization are some of the slow developing processes. Table 2 distinguishes between the different velocities of each natural hazard in LEDC. Although it could be noticed that most of the events are rapid in their final expression, it is important to identify the development processes of any specific natural hazard in order to be able to identify the most appropriate type of monitoring and early warning systems as well as preparedness plans that should be adopted for each specific hazard.

Most of the biological hazards are slowly on setting if not chronically endemic and in most cases it is difficult to identify them as purely natural. In countries where the human population is below the average nutritional and health status like, for example, in the bottom billion population (Collier, 2008), the impact of a virus/infection could be devastating, while in better-off countries the impacts of the same infection would be much lower. An example is given by malaria infection that is weakening most of African population but not its richer tiny percentage, because they have access to better health care, sanitation, and nutrition. Similarly some geomorphological hazards are the result of interplay between human and natural causes, as shown in Table 3.

The global death toll due to natural disasters in the developing countries can be as high as 95% of the total (Alexander, 1993). There are three indicators usually adopted for defining the magnitude of a natural hazard or disaster: number of deaths; number of people affected; and economic loss (CRED database). It has been shown (Pielke and Pielke, 2000) that there is an inverse correlation between the economic loss and the death toll: The more economic loss is suffered the less death is registered. This means that when high income countries are hit, they lose mainly economically while when a low income country is hit, the death rates are higher.

For this reason in LEDC, the most accepted indicator for magnitude of natural hazard is mortality and using this indicator it results that the top 25 countries affected by multi-hazard mortality are all in the LEDC (Mosquera-Machado and Dilley, 2009).

Vulnerability has been recognized as the most important factor in calculating risk, both to population and goods (Wisner et al., 2004). Nevertheless vulnerability is calculated in many different ways and still there is no standard practice (Alexander, 1993; Wisner et al., 2004; Mosquera-Machado and Dilley, 2009). Despite the variability in assessing vulnerability in LEDC, some factors leading to lower resilience are common: Lack of institutional organization, lack of sound early warning systems, low preventive capacity at both structural and cultural levels, low awareness and education of the population at risk, absence of effective civil protection are some of the causes of higher exposure to risk, not to mention the more general –but still relevant to the issue – poverty trap (Alexander, 1993; Smith, 2009; Wisner et al., 2004, among others).

Role of international agencies dealing with natural hazards in developing countries

The international community, led by a move of the United Nations in early 1990s, started addressing these issues especially for LEDC. The International Decade for Natural Disaster Reduction (IDNDR), which then evolved into the ISNDR (International Strategy for Natural Disaster Reduction, http://www.unisdr.org/) started with a strong engineering paradigm, top-bottom approach (Hamilton, 2000; Smith, 2009; Chester, 2002), and then, with the ISNDR, evolved into a more development/complexity type of approach.

Following the 1994 devastating famine in sub-Saharan Africa, a group of humanitarian agencies launched the

Sphere Project, with the aim of coordinating and improving the professionalism, effectiveness, and accountability of the aid actions in disaster contexts. The Sphere Humanitarian Charter and Minimum Standards in Disaster Response sets out for the first time what people affected by disasters have a right to expect from humanitarian assistance. The aim of the Project is to improve the quality of assistance provided to people affected by disasters, and to enhance the accountability of the humanitarian system in disaster response (http://www.sphereproject.org/content/view/27/84/lang,english/). Sphere standards set a new paradigm in humanitarian emergencies: Despite being a nonmandatory set of standards, most agencies/organization comply with them. Sphere standard undergoes also periodical participatory review.

Conclusions

Despite a great deal of studies concerned with the explanation and forecast of global atmospheric and volcanic hazards, addressing also the developing countries, there is still a desperate need for detailed identification of natural hazards in developing countries (especially the more complex, slow developing ones). Capacity building at academic and professional level should be supported and strengthened by the international community. There is a big opportunity here also for philanthropic donations by wealthy Africans, South Americans, and Asians who can probably better select and direct their generous efforts to deserving compatriots/research centers.

One of the biggest challenges to reduce natural hazard vulnerability especially in LEDC for policy makers, land planners, international and local community leaders is well spelled out by Smith and Pedley (2009, p. 339) "Any improvement in the connectivity between people and their environment depends on assisting all community exposed to risk to develop their own hazard-reducing capabilities and local self-reliance following disasters. This is not always an easy task because it depends, to some extent, on external inputs. For example, the construction of rural roads in landslide-prone terrain is doomed to failure if no provision is made for the use of appropriate engineering measures. Once again there is a need for integrated approaches in which sensitive external assistance is deployed to help build community skills for the anticipation of hazards and the mitigation of their impacts."

NATURAL RADIOACTIVITY*

Cathy Scheib
British Geological Survey, Nottingham, UK

Definition

Natural radioactivity originates from two primary sources: cosmic radiation and radioactive elements in the earth's crust. All the elements from polonium (atomic number 84) to uranium (atomic number 92) are radioactive. Radioisotopes of some lighter elements are also found in nature (e.g., ^{40}K).

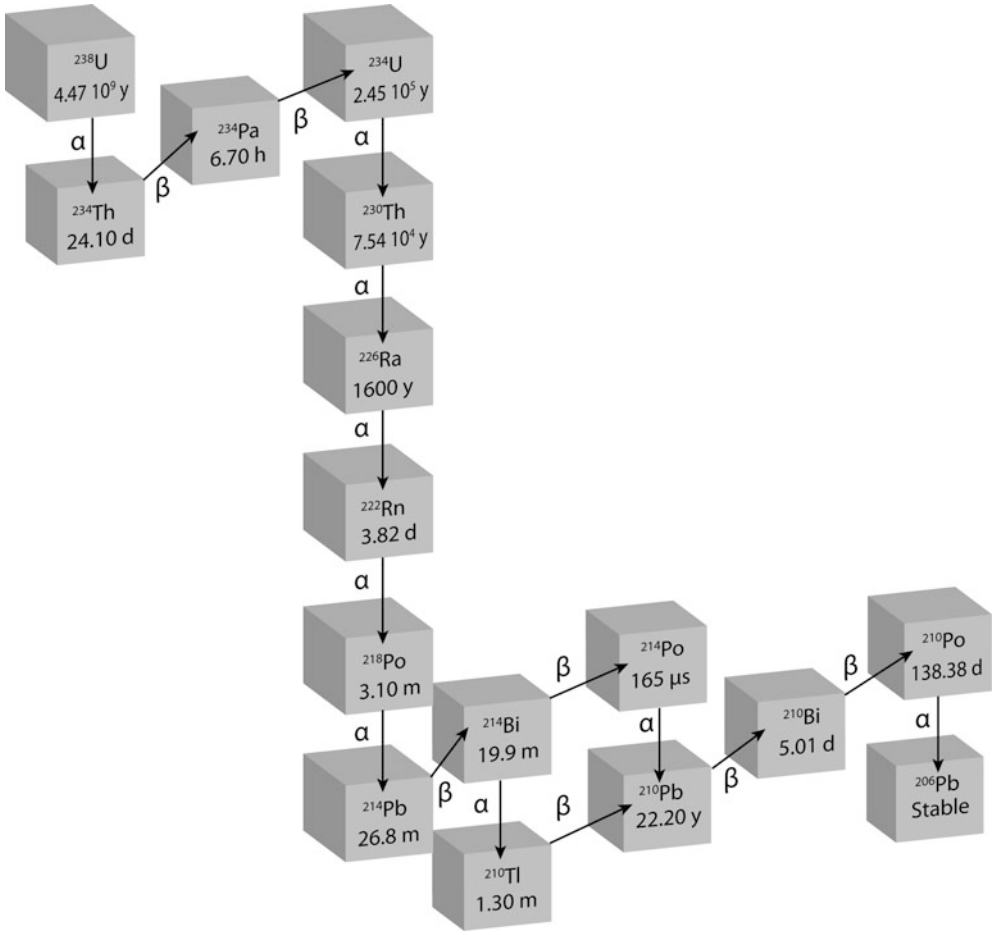
Introduction

Many atoms are unstable and will change quite naturally into atoms of another element accompanied by the emission of ionizing radiation. Unstable atoms that change through radioactive decay to form other nuclides are said to be radioactive and are referred to as radionuclides or radioisotopes. The rate of change or decay of an unstable radionuclide is indicated by its half-life, which is the period of time during which half the original number of atoms would have decayed. The radioactivity of the earth includes three major categories: *primordial radionuclides*, which have very long half-lives, were created in stellar processes before the earth was formed and are still present in the earth's crust; *secondary radionuclides*, which are decay products of primordial radionuclides that are themselves radioactive and will decay to other secondary radionuclides or to stable isotopes; and *cosmogenic radionuclides* which are continuously produced by bombardment of stable nuclides by cosmic rays, primarily in the atmosphere. Natural radionuclides are ubiquitous in the environment and make a major contribution to background radiation (see *Dose Rate*).

Cosmic radiation

The atmosphere is continuously exposed to primary cosmic radiation that originates in outer space. This cosmic radiation comprises predominantly protons (about 87%) and alpha-particles (about 11%), with a smaller fraction of nuclei and very high energy electrons comprising the remainder. The interactions of these primary particles with atmospheric nuclei produce electrons, gamma rays, neutrons, and mesons.

The amount of cosmic radiation increases with altitude and with polar latitudes. The annual cosmic-ray dose equivalent is about 0.3 mSv at sea level. In Leadville, Colorado (altitude 3,200 m), for example, the residents receive around 1.25 mSv year^{-1}, which is more than four times the annual dose from cosmic radiation at sea level (Eisenbud and Gesell, 1997). Because of this effect of altitude, passengers and crew of high-flying aircraft are subject to additional dose from cosmic rays. Solar activity affects the effective dose from cosmic radiation received during aviation; the amount of cosmic radiation produced by the sun varies with an approximately 11-year cycle (see *Solar Flares*). Years with increased levels of solar activity translate to a higher frequency of solar flares, some of which increase the amount of cosmic radiation in the earth's atmosphere resulting in higher annual effective doses to aircrews during those years (UNSCEAR, 2000).



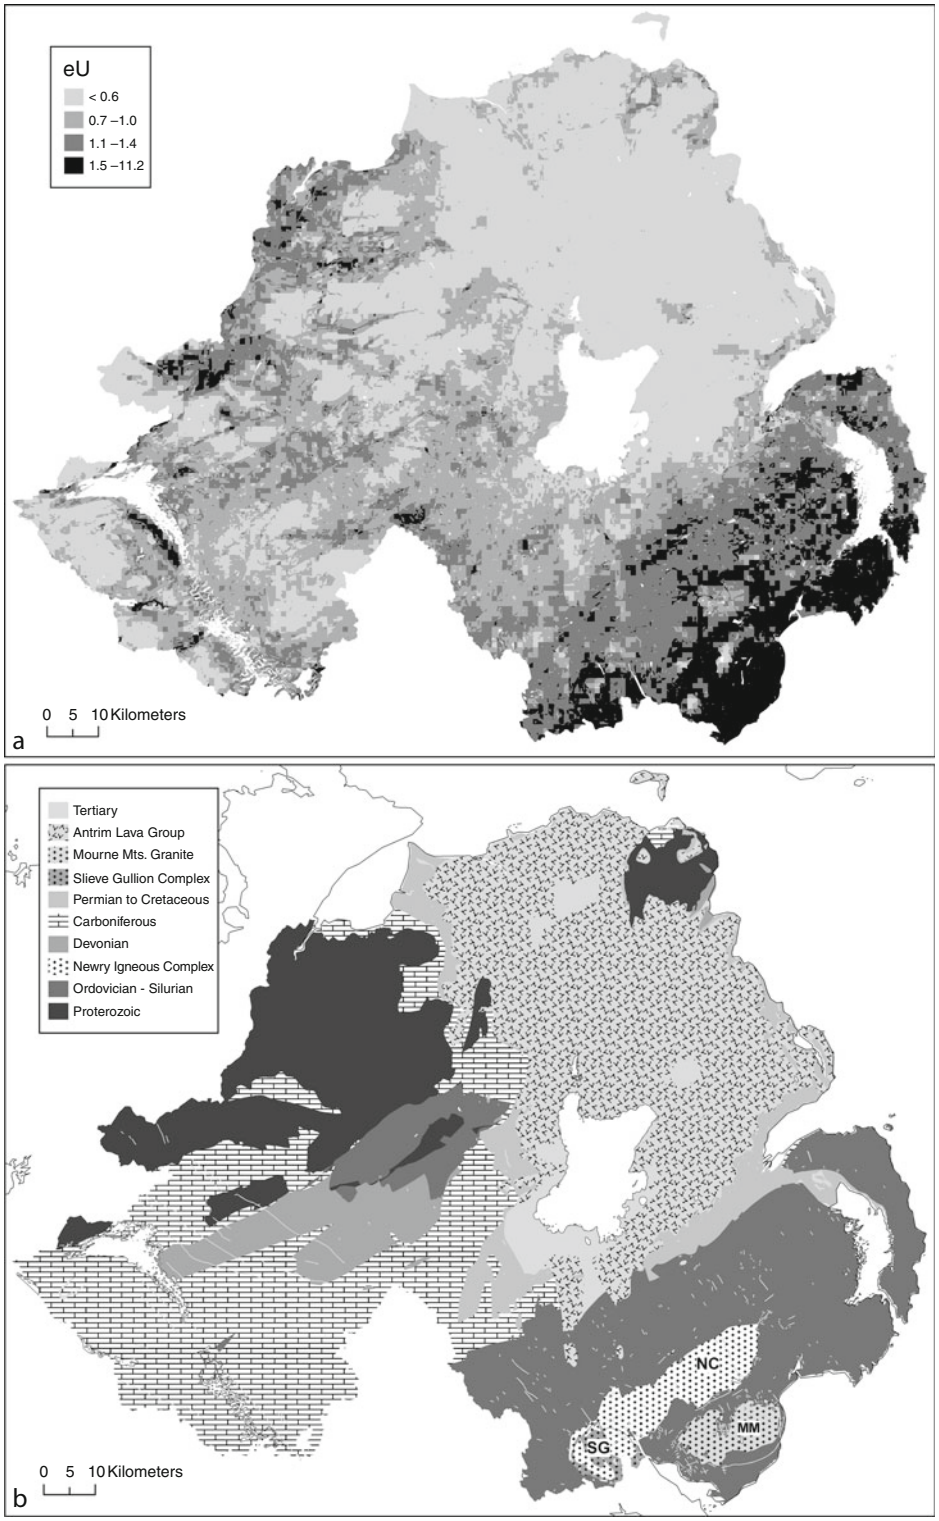
The nuclear reactions initiated by cosmic particles in the atmosphere give rise to a number of cosmogenic radionuclides, such as ^{14}C, which is used to date relics containing naturally carbonaceous material.

Terrestrial natural radioactivity

The naturally occurring primordial radionuclides of the earth can be divided into those that occur singly and those that are the components of three decay chains. The uranium series originates with the most abundant uranium isotope, ^{238}U (Figure 1), and accounts for the largest proportion of human exposure to ionizing radiation due to radon gas (^{222}Rn). The actinide series begins with ^{235}U, which comprises only 0.72% of total uranium, and the thorium series originates with ^{232}Th.

In a closed system, the daughter nuclides produced by radioactive decay in each series eventually achieve a state called secular equilibrium with their parent radionuclide. This state is achieved when the half-life of the parent nuclide is much longer than those of the succeeding species, such that there is no significant change in the concentration of the parent during the time interval over which its shorter-lived descendants attain equilibrium. When this state is achieved, all nuclides within a given decay chain decay at the same rate. The ^{232}Th series comes to equilibrium in about 70 years, in contrast to the ^{238}U chain, which takes longer than 10^6 years to reach equilibrium. This state of secular equilibrium only occurs in a truly closed system, so disequilibrium can occur if the system changes and is no longer "closed." For example, if the members of the decay chain are being transported by ground water, the differing physicochemical behavior of each element in the chain may lead to differing migration rates or the precipitation or dissolution of the different decay chain members, thus leading to disequilibrium. As ^{226}Ra is chemically very different from ^{238}U, it is possible

*©British Geological Survey



Natural Radioactivity, Figure 1 The uranium series. Half-lives and major decay radiation (α – alpha decay; β – decay (National Nuclear Data Centre, Brookhaven Laboratory). Often the transitions are accompanied by the emission of gamma radiation. y = years, d = days, h = hours, m = minutes.

in natural processes for the two to become separated so that the ^{226}Ra and its daughter products are unsupported by the parent ^{238}U. Thus, there may not be a simple relationship between measurements of secondary radionuclides beyond ^{226}Ra in the uranium series and ^{238}U. Decay series disequilibria can be used as an investigatory tool in earth and environmental sciences.

An example of a non-series primordial radionuclide is ^{40}K. Potassium-40 comprises only 0.0119% of total K and undergoes branched decay producing ^{40}Ca and ^{40}Ar, the latter producing high-energy gamma rays. The K-Ar ratio is often used in geochronology. Potassium-40 is easily the predominant radioactive component in normal foods and human tissue.

Terrestrial gamma rays originate chiefly from the radioactive decay of the natural K, U, and Th which are widely distributed in terrestrial materials including rocks, soils, and building materials extracted from the earth. In general, the gamma radiation dose at any location is proportional to the amount of K, U, and Th in the ground and in building materials. ^{214}Bi contributes most of the gamma activity of the uranium decay series (Figure 1) and ^{208}Tl is the main gamma active daughter product derived from the ^{232}Th series. In airborne gamma-ray surveying, a technique which provides spatially integrated gamma-ray data over large areas, these daughter products are used to estimate equivalent uranium (eU) and equivalent thorium (eTh), respectively. Estimates of eU (Figure 2), in addition to K, eTh, and dose rate determined by a national-scale aerogeophysical survey across Northern Ireland, showed that gamma-emitting radionuclide distribution was closely related to bedrock (Figure 2) and surficial geology and, to a lesser extent, to technological enhancement of naturally occurring materials, for example, by power production (Appleton et al., 2008; Beamish and Young, 2009).

Soils developed over radioactive rocks generally have a much lower gamma radioactivity than the rock substrate. Radioactive elements in the rock fragments and derived minerals in the weathered overburden are diluted with

Natural Radioactivity, Figure 2 (**a**) Distribution of average eU (mg kg^{-1}) by airborne gamma-ray survey, grouped by 1-km grid squares and geology combination (bedrock and superficial geology type) for Northern Ireland, UK; and (**b**) Simplified bedrock geology of Northern Ireland. Natural Radioactivity, Table 1 Ranges and averages of the concentrations of ^{40}K, ^{232}Th, and ^{238}U in typical rocks and soil (Eisenbud and Gesell, 1997)

Material	Potassium-40		Thorium-232		Uranium-238	
	% total K	Bq Kg^{-1}	mg kg^{-1}	Bq Kg^{-1}	mg kg^{-1}	Bq Kg^{-1}
Basalt (crustal average)	0.8	300	3–4	10–15	0.5–1	7–10
Granite (crustal average)	>4	>1,000	17	70	3	40
Shale sandstone	2.7	800	12	50	3.7	40
Carbonate rocks	0.3	70	2	8	2	25
Continental crust (average)	2.8	850	10.7	44	2.8	36
Soil (average)	1.5	400	9	37	1.8	22

organic matter and water. Average concentrations of ^{40}K, ^{232}Th, and ^{238}U in typical rocks and soil are given in Table 1.

Areas of high natural radioactivity

The level of natural background radiation varies depending on location, and in some areas, the level is significantly higher than average. Areas of high natural radioactivity include: Ramsar in Iran due to hot-springs containing high levels of ^{226}Ra and ^{222}Rn; areas of thorium-bearing monazite sands in Brazil, China, Egypt, and India; volcanic rocks in Brazil and Italy; uranium mineralization in France, the UK, and the United States; and radium enriched karst soils developed over limestones in Switzerland, the UK, and the United states (UNSCEAR, 2000).

Technologically enhanced naturally occurring radioactive materials (TENORM)

Human activity may lead to what is known as "technologically enhanced naturally occurring radioactive materials" (TENORM). TENORM industries may release significant amounts of radioactive material into the environment resulting in the potential for extra or enhanced exposure to ionizing radiation. These industries include mining, phosphate processing, metal ore processing, heavy mineral sand processing, titanium pigment production, fossil fuel extraction and combustion, manufacture of building materials, aviation, and scrap metal processing (Vearrier et al., 2009). Workers in TENORM-producing industries may be occupationally exposed to ionizing radiation (UNSCEAR, 2000).

Oklo natural nuclear reactor

Fossil remains of a 2-billion-year-old nuclear "reactor" were discovered in 1972 in Oklo, Gabon. The percentage of ^{235}U present in the environment was much greater 2 billion years ago than it is now, and along with oxidizing conditions which allowed the uranium to dissolve, be transported, and preferentially concentrated, a "critical mass" was attained. Criticality was sustained for on the order of 10, 000 years, during which time an estimated 15, 000 MW-years of energy was released by the consumption of ~6,000 kg of ^{235}U (Eisenbud and Gesell, 1997). Studies of the migration of the fission products from the Oklo reactors provide a natural analogue for radioactive waste management (Brookins, 1990).

Summary

Natural radioactivity originates from two primary sources: cosmic radiation and radioactive elements in the earth's crust. Natural radionuclides are ubiquitous in the environment and make a major contribution to background radiation. The level of natural background radiation varies depending on location. ^{238}U is the most abundant uranium isotope and its decay products account for the largest proportion of human exposure to ionizing radiation, primarily due to radon gas (^{222}Rn). Terrestrial gamma rays originate chiefly from the radioactive decay of natural K, U, and Th which are widely distributed in terrestrial materials including rocks, soils, and building materials extracted from the earth. In general, the gamma radiation dose at any location is proportional to the amount of K, U, and Th in the ground and in building materials. Industrial processes can concentrate naturally occurring radioactive materials, which can enhance the ionizing radiation exposure to workers or exposed populations.

NEOTECTONICS

James P. McCalpin
GEO-HAZ Consulting Inc., Crestone, CO, USA

Definition

Neotectonics. Any Earth movements or deformations of the geodetic reference level, their mechanisms, their geological origin, and their implications for various practical purposes and their future extrapolations (Mörner, 1978).

The study of young tectonic events (deformation of upper crust), which have occurred or are still occurring in a given region after its final orogeny (at least for recent orogenies) or more precisely after its last significant reorganization (Pavlides, 1989).

The study of the post-Miocene structures and structural history of the Earth's crust (AGI, 2009).

Introduction

From the three definitions given above, it is clear that neotectonics is the study of "young" tectonic movements, but there is disagreement on exactly how young they must be to qualify as "neotectonic." Hancock and Williams (1986), following Blenkinsop, suggested that neotectonics commenced "when the contemporary stress field of a region was established." The age of this establishment differs in various regions of the world, but is generally between the Oligocene and Miocene periods. Such an initiation time conforms to Vita-Finzi's (1986) succinct definition of neotectonics as "late Cainozoic tectonics."

Neotectonics has a broad spatial extent as well as broad temporal extent. At the macroscale, it describes the current and geologically recent movements of the Earth's tectonic plates (see *Plate Tectonics*). At the mesoscale, it describes vertical and lateral movements of mountain chains such as the Himalaya, and vertical isostatic movements. At the microscale, it deals with the movement on individual faults (see *Fault*) and folds, with dimensions as small as a few km.

Detecting areas of neotectonic deformation

Neotectonic movements are commonly associated with areas of active seismicity and active faulting, such as plate margins (see *Plate Tectonics*). For example, linear bands or belts of earthquakes (see *Earthquake*) typically indicate zones of active faulting and folding. However, some late Cainozoic (neotectonic) structures have not generated significant seismicity in historic time, because they have either become inactive, or because the recurrence interval (see *Recurrence Interval*) between earthquakes is longer than the period of historic record. To locate these more subtle neotectonic faults/folds, geologists look for traces of their deformation expressed as tectonic landforms, a field of study known as tectonic geomorphology. Examples of tectonic landforms are faceted spurs on mountain fronts, created by young normal and reverse faulting; deflected drainages, shutter ridges, sag ponds, and other disrupted topography along strike-slip faults (see *San Andreas Fault*; *North Anatolian Fault*); and raised marine terraces or drowned coastal forests along actively subducting coasts (see *Subduction*). At regional scales such landforms are identified by satellite imagery (Landsat, ASTER, Google Earth, synthetic aperture radar), whereas at local scales, they are normally recognized on aerial photographs or in the field. In many cases, detailed field studies may yield the number, displacement, and timing of prehistoric earthquakes from such landforms (see *Paleoseismology*).

Neotectonic movements are not limited to individual faults and folds, but may also affect broader areas of the crust via post-earthquake crustal warping, isostatic rebound, or epeirogenic uplift. In coastal zones regional uplift and subsidence create geomorphic evidence such as emergent or submergent shorelines (respectively), or stratigraphic evidence such as recent coastal, lacustrine, or colluvial deposits (e.g., Bertrand et al., 2011). In continental areas, regional uplift may be reflected by rejuvenation of drainage networks, tilting of drainage networks creating asymmetry, or tilting of lake basins. Neotectonic structures are also associated with young geologic basins (onshore or offshore), that contain Neogene and Quaternary sediments. Neotectonic faults and folds are normally located at the margins of such basins, but they may also lie hidden beneath the basin fill, in which case geophysical surveys are required to locate and characterize them.

Finally, neotectonic movements affect areas of active volcanism, including vertical deformation due to loading by volcanic eruptions, magma movements (inflation, deflation, bulging); movement on volcano-tectonic faults; rifting; and crustal-scale landsliding, and volcano flank collapse.

Measuring neotectonic motions (slip amount, slip rate)

Neotectonic studies seek to measure the rate and direction of crustal movement at all scales, either as relative or absolute motions. Prior to the 1970s, almost all measurements were of relative motion. An example is using the offsets of landforms across faults or folds to measure the fault slip amount and rate (see *Paleoseismology*). Such offsets measure the motion of the two fault blocks relative to each other, rather than the absolute motion of either block compared to some larger reference frame. In coastal areas, it is possible to measure neotectonic vertical slip amounts and rates in relation to sea level, an absolute measure, but lateral offsets across

faults are only measured as relative motions. After large historic earthquakes, first-order level lines were often surveyed into the epicentral area from 50–100 km away, so at sites within 50–100 km of the coast the vertical motions could be related to sea level. Beyond 100 km, vertical motions could only be measured as relative.

With the advent of radio astronomy, satellite geodesy, and laser altimetry in the 1980s, it became possible to measure neotectonic motions relative to fixed points on the Earth's surface, to the geoid, or to any external reference frame (Vita-Finzi, 2002). The first real-time, absolute measurement of horizontal plate motions was made using VLBI (very long baseline interferometry), which measures the time difference between the arrival at two Earth-based antennas of a radio wavefront emitted by a distant quasar (see http: //cddis.nasa.gov/vlbi_summary.html). At present the VLBI method has been replaced by global positioning satellites (GPS), which measure horizontal motions in relation to an Earth centric reference frame.

Although vertical neotectonic motions can also be measured via GPS, the accuracy and precision is lower than for horizontal measurements. Fortunately, vertical crustal motions can also be measured via laser altimetry (satellite laser ranging) and by interferometry of synthetic aperture radar (InSAR). The latter technique has revealed patterns of cm-scale uplift and subsidence over hundreds to thousands of square kilometers associated with large earthquakes, with non-tectonic mechanisms such as fluid withdrawal, and also vertical movements of unknown origin. Like many new tools developed in science, InSAR is demonstrating that deformation of the Earth's surface is more complex, subtle, and widespread than previously thought.

Modeling neotectonic motions

Neotectonic motions can be modeled qualitatively or quantitatively. The qualitative models aim at establishing a region's stress regime, that is, the orientation of the horizontal maximum and least principal stresses responsible for neotectonic deformation. This type of "stress inversion analysis" can be performed on static geological data, such as the orientation and slip sense of faults. For example, a system of parallel normal faults indicates an extensional stress regime with the least principal horizontal stress perpendicular to fault strike. Neotectonic stress regimes have also been inferred from the orientation of joints. The key to inferring a neotectonic stress regime from "static" geologic fault or joint data is to measure only neotectonic faults and joints, rather than older faults and joints produced by earlier stress regimes.

Stress regimes can also be inverted from more direct data such as focal plane mechanisms of earthquakes; paleomagnetic rotations of Neogene deposits; and well-bore breakouts and other direct measurements of contemporary stress fields.

More refined, quantitative neotectonic models rely on finite-element simulations of plate or microplate motion (e.g., the NeoKinema model of Liu and Bird, 2008). Such models attempt to reproduce the observed plate motions as measured from GPS surveys, by specifying in the model an arrangement of crustal layers of a given shape/thickness/rheology, and by assigning stresses to them. These models may also include simulated erosion and the isostatic effect of that erosion, inasmuch as the isostatic effect perturbs the evolving stress field, and thus may conceivably control the locations, styles, and rates of tectonic deformation (feedback).

Distinguishing between seismogenic and non-seismogenic neotectonic deformation

It is important from a hazards viewpoint to know whether the observed, measured, or modeled neotectonic deformation is being produced by seismogenic or non-seismogenic processes. As explained elsewhere (see *Tectonic and Tectono-Seismic Hazards*), most hazards to human life and property arise from tectono-seismic (earthquake-related) processes. However, not all neotectonic deformation is associated with earthquakes. For example, some tectonic fault types produce surface deformation but do not generate earthquakes, such as bending-moment faults and flexural-slip faults. Likewise, processes such as fault creep, deep-seated gravitational spreading (sackung), gravity sliding, evaporate-related faulting and folding, karst, glacio-isostatic faulting, and dike-related faulting can deform the geoid and are thus neotectonic, but are non-seismogenic. Because these structures/processes do not produce earthquakes, they pose much less of a hazard than seismogenic structures.

In practice, it is sometimes difficult to distinguish neotectonic deformation from seismogenic sources versus non-seismogenic sources, because the surface manifestations are very similar. This dilemma has become more acute now that systems such as GPS and InSAR are able to measure hitherto-undetectable patterns and rates of surface deformation. Hanson et al. (1999) provide a treatise for specialists on how to distinguish these fault types.

Summary

Neotectonics is the study of "young" tectonic movements, subsequent to the establishment of the contemporary stress (or seismotectonic) regime in the area of study. This means that neotectonics covers the tectonics of currently active structures, as well as some Neogene structures that may no longer be active. At the macroscale, neotectonics describes the Neogene movements of the Earth's tectonic plates (see *Plate Tectonics*). At the mesoscale, it describes vertical and lateral movements of mountain chains such as the Himalaya, and vertical isostatic movements. At the microscale, it deals with the movement on individual faults (see *Fault*) and folds, with dimensions as small as a few kilometers.

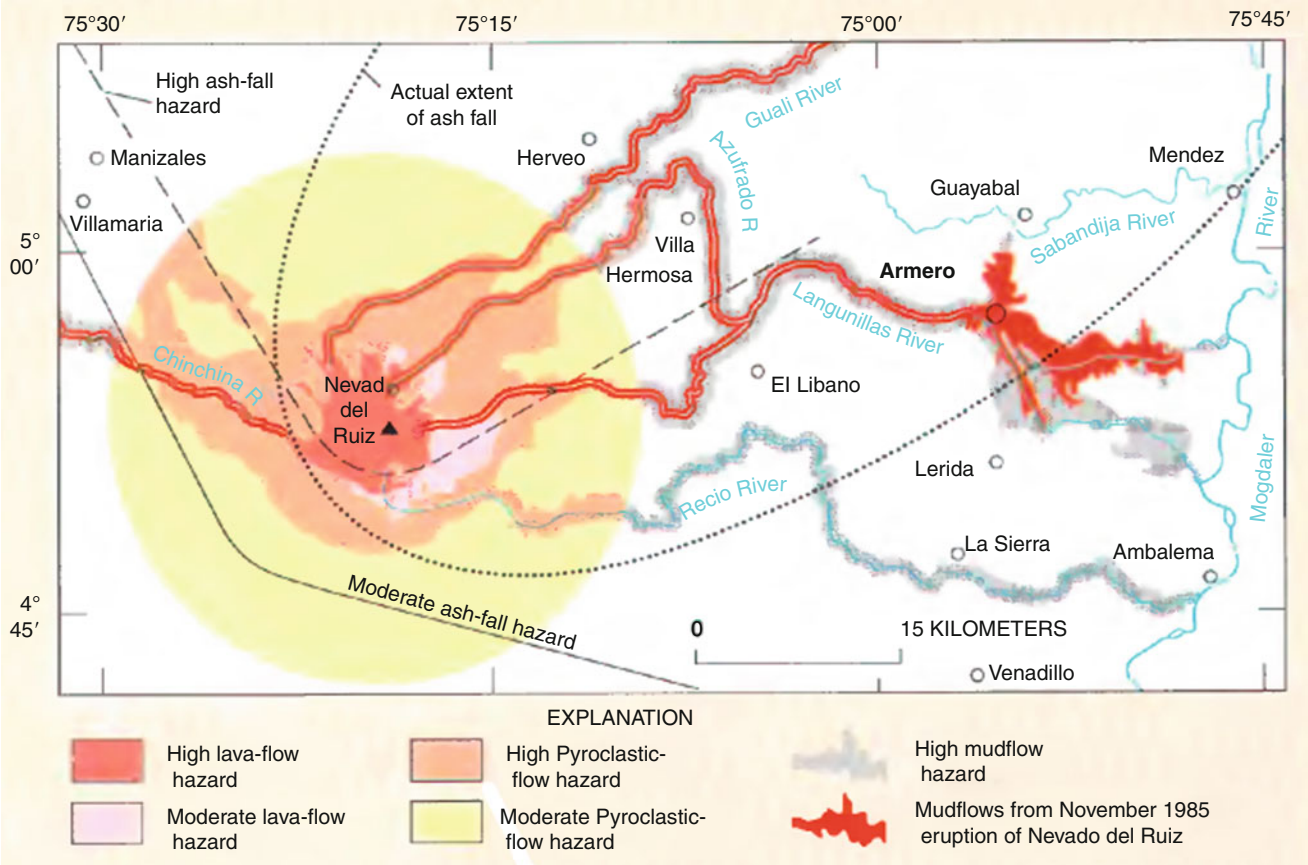
Definition and facts

- Modest eruption on summit ice pack generates lethal lahar.
- 23,000 killed in second-worst volcano disaster of the twentieth century.
- Factors include delayed hazard map, inadequately prepared local authorities, unprepared populace, and refusal to accept false alarm.
- *Lessons from Armero* provide many guidelines for future emergencies.

Introduction

Nevado del Ruiz Volcano, 5,370-m high, is located near Manizales in the Central Cordillera of Colombia between the Magdalena Valley to the East and the Cauca Valley to the West (Figure 1). Although Colombia has several active volcanoes, prior to the eruption of Ruiz in 1985, the country had virtually no first-hand experience in dealing with active volcanoes, nor were Colombian scientists specialized in volcanology. For most Colombians, tales by grandparents about minor eruptions at Galeras and Puracé volcanoes in the south of the country provided the only vague impressions of active volcanism. This inexperience played a major role in the events described. The impressions of Colombians changed on November 13, 1985, when a minor magmatic eruption at Ruiz generated the worst volcanic debris-flow (lahar) disaster in recorded history worldwide, and the second-worst volcanic disaster of the twentieth century.



The small but explosive eruption at the summit crater produced pyroclastic (mixed pumice and gas) currents that scoured and melted much of the summit's snow and ice cap (Figure 2), sending torrents of meltwater and pyroclastic debris down the volcano's flanks, where they coalesced in channels and entrained additional debris and water to form large *lahars*. On the western slope, overbank flooding by lahars caused some 1,900 fatalities and destroyed 200 houses. On the eastern slope, successive lahar waves obliterated 5,000 buildings and killed over 21,000 people in the town of Armero, located 50 km east of the volcano's summit (Figures 1 and 3). The death toll ranks fourth in history, behind only Tambora in 1815 and Krakatau in 1883, both in Indonesia, and Mount Pelee, Martinique, in 1902.

Yet the eruption was not a surprise, and neither were its effects. Persistent fumarolic, seismic, and phreatic activity had served as precursors for almost a year. Colombian workers were assisted by international specialists from the USA, Switzerland, Ecuador, France, Italy, New Zealand, and Costa Rica.

Despite these circumstances, the emergency management system failed to avert catastrophe. The consensus of those who have carefully studied the case history is that many of the casualties could have been prevented by improved hazards management practices (Voight, 1988, 1990, 1996a, b; Hall, 1990, 1992; Giesecke et al., 1990; Barberi et al., 1990; Miletti et al., 1991). There are important lessons to be learned from the Ruiz disaster pertinent to the scientific and public responses and adjustments to volcanic hazards – lessons that will provide valuable guidelines for future emergencies.

The re-awakening of Nevado del Ruiz

The Nevado del Ruiz complex has a 1.8 million year eruptive history, but most relevant is its behavior over the past 11,000 years. That history had been studied sufficiently to establish that voluminous and hazardous lahars were generated during relatively small eruptive events that

Nevado del Ruiz Volcano, Colombia 1985, Figure 1 Map of Nevado del Ruiz and surrounding region, showing volcanic hazards, and river valleys affected by lahars (mudflows) in the November 13, 1985, eruption (*red*) (Hazard map data from Parra and Cepeda (1990), redrafted by USGS).

melted only part of the summit icecap (Figure 2). The historical eruptions of 1595 A.D. and 1845 A.D., both of which produced voluminous lahars, are described by Fray Pedro Simón (in Acosta, 1850). The eruption of 1595 A.D. caused 636 fatalities (Simón 1625, as cited in Acosta, 1850), and about 1,000 were killed in the eruption of 1845 A.D. (Arboleda, 1918), during a time when the region was much less densely populated than in 1985.

The first signs of unrest at Ruiz related to the 1985 catastrophe were detected in November and December 1984. What happened next is summarized in the timeline below (Voight, 1990; Hall, 1990):

Time line

November, December 1984. Unusual fumarolic activity within the crater and earthquakes near summit.

January 6, 1985. Geologists visit summit crater, notice a new small crater within and conclude monitoring needed.

February, March 1985. Fumarolic activity at crater, felt earthquakes. Civic committee formed in Caldas Province and feature article with photographs appears in key newspaper.

April 1985. Strong fumarolic activity, felt earthquakes; UNESCO nominates an expert team in anticipation of assisting Colombians.

May 1985. Visiting UNDRO scientist recommends hazard map, civil defense planning, monitoring.

Colombian geology-mines bureau INGEOMINAS requests USGS for expertise and geophones.

June 1985. USGS supplies hardware but declines to send expert. UNESCO offers expert team and equipment to Colombian Foreign Affairs Minister, but letter is “lost” for 2 months.

July 1985. Continued fumarolic activity and earthquakes. Caldas Province, concerned by lack of progress at national level, forms risk committee and requests foreign assistance. Meanwhile INGEOMINAS installs provisional array of four portable seismographs, although initial array is unsuitable, and analysis is delayed. First long-period event recorded on July 23.

Nevado del Ruiz Volcano, Colombia 1985, Figure 2 The town of Armero at the mouth of the Lagunillas River, after impact by the lahar generated by the November 13, 1985, eruption. Lahar deposits in *brown* to *gray* color, reflectant where wet (R.J. Janda (USGS) photo).

Nevado del Ruiz Volcano, Colombia 1985, Figure 3 Nevado del Ruiz and its summit glacier ice cap, overlain by a veneer of brown pyroclastic current deposits. The pyroclastic currents rapidly eroded snow and ice at the summit, creating a deluge of water that resulted in lahars in several river systems surrounding the volcano (J. Marso (USGS) photo).

August 1985. Swiss seismologist arrives to aid Caldas Province and installs three-component short-period seismometer. Two independent groups are now operating seismometers.

September 6, 1985. Intense seismicity with tremor begins, with small ash emissions on September 8.

September 11, 1985. Strong phreatic explosion generates ash rain in population centers and 27 km-long

lahar in Azufrado river. Concerns and emergency work set in motion, although provinces decide to manage emergency plans independently.

September 18, 1985. Work on a hazard map begins by local geologists. USGS and UNDRO send scientists to support efforts. Ash emissions on September 23, 24, and 29; fumarole samples taken.

October 1985. UNESCO scientist guides combining the two seismic networks.

October 7, 1985. Preliminary hazard map and report presented to government; first INGEOMINAS seismic report issued (despite operation since 20 July).

October 9, 1985. UNDRO reports ashfalls and lahars most likely and within "very near future, the necessary measures will have been taken to protect the population." Reporter's version of hazard map published with errors.

October 21, 1985. Deformation studies began at Nevado del Ruiz, too late to detect signal.

November 1985. Public presentation of revised hazard map postponed from November 12 to 15.

Meeting of mayors to review emergency plans scheduled for November 15. Nevertheless, plans to remove seismic network discussed, due to operational costs. Gas analyses suggest magmatic signature, and on November 10, 3 days of tremor began, less pronounced that in September.

November 13, 1985. Phreatic eruption begins 15:06 h. Regional emergency committee, in Tolima Province at prescheduled planning meeting, issued preliminary warnings but conditions returned to normal. Magmatic eruption begins 21:08 h; *23,000 die in Armero and Chinchiná.*

Slow progress in managing the volcanic *unrest*

Monitoring and planning activities had only gradually developed and were not merged in a coherent effort. Notably lacking was a resident scientist with significant volcanic eruption experience. A preliminary hazard map and report was released October 7. The report noted the very high probability for lahars, "with great danger for Armero, Mariquita, Honda, Ambalema, and the lower part of the Rio Chinchina." But "the government, skeptical of an impending eruption and worried more about the consequences of the map itself" (Hall, 1992), ordered that it be rechecked and resubmitted by November 12. Meanwhile, Civil Defense compiled field counts of the population-at-risk along the river systems, and scheduled meetings at national, provincial, and local levels to disseminate risk and preparedness information. The information transfer to the local level was coordinated by the emergency committees in each province with variable success.

On October 22, 1985, an advisory team representing the National Volcanological Group of Italy emphasized the lahar risk and need for a place of refuge for the populace in river towns (Barberi et al., 1990). The Caldas Emergency Committee met again in Manizales on November 12, 1985. They noted that gas analyses suggested a magmatic origin, the hazard map revision was still incomplete, and seismic analyses had not been issued since October 10. Tremors had been occurring for several days, but less pronounced than in early September. Visual observations yielded no signs of an impending eruption. But on November 13, a phreatic eruption began at 15:06 h that resulted in a light ashfall in Armero. The Tolima Provincial Emergency Committee at a prescheduled planning meeting issued preliminary warnings from its distant capitol, but conditions appeared to return to normal. During the evening, heavy rains and an international soccer game kept most Armerians inside at home. Then a magmatic eruption began 21:08 h, creating collapsing currents of hot pumice-gas mixtures that melted the snowpack and generated a flood of water and debris. The latter breached a landslide-blocked drainage and lake that had formed upriver from Armero during 1984–1985, exacerbating the subsequent lahar impact.

The day Armero died

The eruption-generated lahars raced down three of the volcano's major drainage systems. Around 22:40 h, the riverbank village of Chinchiná on the western slope was struck. Hundreds of homes had been evacuated because of the general alert by Civil Defense, but still 1,927 persons died (Gueri and Perez, 1986).

From 21:45 h to 22:00 h, officials in Tolima attempted to inform Armero of the situation, but power and communication difficulties were experienced. No evacuation orders, neither specific nor systematic, were issued, although some representatives of various agencies took individual action (Voight, 1988, 1990, 1996a, b). Disgorged from the Lagunillas canyon at 23:35 h as a wave nearly 40 m high (Figure 2), the muddy boulder-laden torrent crushed Armero (Pierson et al., 1990). A second major pulse struck at 23:50 h, followed by a number of smaller and finer-grained pulses, the last at 01:00 h. Many survivors took flight only after the first flood waves struck the town, and although many escaped, over 21,000 people perished. Thousands had managed to reach islands of high ground, but many experienced difficulty in extracting themselves from, or crossing, the soft mud of the final lahar pulses. A national TV station had broadcast news of the eruption, although many remember the message as advising no cause for alarm – a message singularly inappropriate for Chinchiná or Armero.

Analysis of a catastrophe

In early 1985, risk evaluations by UNDRO found a receptive audience in Manizales and Caldas Province near the volcano, but not in distant Tolima Province which marginally included the high-risk area of Armero. National agencies were not fully committed to the task, partly because of limited funds, experience, and equipment, but also from a lack of conviction that the threat was real. USGS managers were reluctant to send

volcanologists and equipment to Ruiz beforehand, largely "because of skepticism (particularly before September 1985) that the crisis would actually culminate in significant activity." With the perception of disinterest at the national level, the Caldas group sought international assistance, creating rivalries that developed between seismic groups. The volcano hazard map requested as early as March 1985 had not been worked on until September, with the result that the existing management plans lacked the necessary understanding and focus toward areas targeted for high risk.

With the September 11, 1985, phreatic eruption and ashfall in Manizales, the gap of credibility closed especially in Caldas Province, and regional agencies accelerated their efforts and requested national assistance. By October, the management structure appeared to be gaining effectiveness, but when put to the test a month later – the system failed. Some of the factors included:

1. Although the risks were becoming known, provincial and national government made the conscious decision not to evacuate the villages until and unless the danger could be *guaranteed*. Evacuation before the event would have caused economic, political, and law-enforcement problems, and no official was willing to accept this responsibility. *Thus, the authorities on the whole acted rationally in the short term but were unwilling to bear the economic or political costs of early evacuation or a false alarm. Scientific studies accurately foresaw the hazards but were insufficiently precise to provide a reliable prediction of an uncertain but possibly devastating event. Therefore, catastrophe had to be accepted as a calculated risk, and this combination – the limitations of prediction/detection, the refusal to accept a false alarm, and the lack of will to act on the uncertain information available – provided the immediate and most obvious cause of the catastrophe"* (Voight, 1996a).
2. Under the above circumstances, mitigation would have required a supremely efficient and tested disaster-prevention system, with unerring detection (with around-the-clock well-instrumented monitoring) and data interpretation, followed by instantaneous decision making, effective alert communications, and a swift response by a thoroughly prepared population. Such elements did not exist.
3. The local authorities at Armero were inadequately prepared and equipped, and had insufficient information of what the eruption might hold for the town. "What-to-do, where-to-go" information had not been communicated to the population. The situation was different at Chinchiná in Caldas Province, where officials had made an effort to educate the population, and where an alarm was given as early as 21:30 h. Nevertheless, casualties here were also high, due to the shorter lead time and the difficulty in spreading a night-time warning to the riverbank community.
4. The response of civil defense could not be prioritized due to the lack of specific hazard maps prior to October 7.
5. A tragic aspect of this catastrophe was the fidelity of the hazard maps in relation to the events of 1985 (Parra and Cepeda, 1990; Voight, 1990). The written descriptions of the 1845 lahar (Acosta, 1850) precisely mirror those of 1985. Further, had this information been utilized earlier for city planning, catastrophe could have been wholly averted.
6. Communication breakdowns are common during volcanic emergencies. However, a review of the communications carried out on November 13, 1985, reveals that the system for information transfer had redundant elements and worked reasonably well (Voight, 1988, 1990). However, the system was not organized to make rapid decisions nor give alerts. It had been decided earlier that only the President of Colombia could authorize the needed evacuations, a situation that required more than 2 h (at the inconvenient time, 21:00–23:00 h) of ascending and subsequent descending approvals along the bureaucratic chain-of-command, in order to permit the local authorities to give the alarm. A local authority should have been charged with this responsibility. The primary problem was not information dissemination, but of lack of readiness and the will to act decisively.
7. The media played an important role (Hall, 1992), and its impact reflected the culture and socioeconomic conditions in the two affected provinces. Due to isolation from Bogota, Caldas boasted a strong local newspaper in Manizales that gave commendable coverage of the developing crisis. Tolima, on the other hand, depended on Bogota's daily newspapers which carried fewer and shorter volcano articles. As a result, Caldas' authorities and population were better prepared and more effective in instigating government action.
8. What was the role of technology? Would telemetered seismographs and real-time analysis have prevented disaster? The data suggest that there were no definitive short-term warnings of the November eruption (Martinelli, 1990, 1991). To offset the lack of telemetry, the scientific staff visually monitoring the volcano, and tending to a seismometer 9 km from the crater observed the onset of the eruption and so advised Manizales by radio with sufficient time to save most lives, *if appropriate further communication transfer and decisions had followed and the population-at -risk had been prepared.* Neither Armero nor Chinchiná directly received this early warning. And what of lahar detectors? Farmers living along the probable lahar paths were instructed to be watchful; with the eruption, they heard the approaching lahars but had no means of communicating a warning downstream to Armero. At the time lahar detectors were not off-the-shelf items, but as a result of Ruiz, acoustic debris-flow detectors with telemetry are now standard equipment and have been deployed at numerous sites worldwide.

Lessons from Armero

The *Lessons from Armero* (Voight, 1988, 1990, 1996a, 1996b) are fundamental and have aided the management of volcanic emergencies in other regions.

Recognize and document the hazards. Hazard maps play a crucial role in identifying the likely types of volcanic phenomena and the areas of high risk. The maps should also indicate areas that are safe, in order to assist emergency managers to define refuge for evacuation planning. Of course, hazard maps must not only be made, they need to be *used*. A very early priority is therefore *to produce a timely and well-distributed map and document that will allow mitigation planning to proceed effectively and without delay.*

Rank site vulnerability. Hazards and vulnerability have different degrees of severity, whereas mitigation planning and response is time consuming. Thus, the most vulnerable sites should be mitigated first. This procedure was not followed at Armero. *The lesson is that systematic attention must be given to identifying and resolving local problems of the most threatened communities at a very early stage*.

Modern volcano monitoring techniques (seismic, geodetic, infrasound, chemical), installed on the high hazard volcanoes long before any crisis, have the ability to provide timely warnings of changing activity and pre-eruption events. In parallel fashion, fixed and portable communications nets must be established in order to assure the effectiveness and diffusion of such warnings.

Accept the social responsibility to communicate the risk to the public. There are two categories. The first is public awareness and education, in which the authorities, citizens, and communities are informed about the character of volcanic risk and appropriate responses. The second is the warning, in which an endangered public is alerted to the problem and the relevant protective actions. Armero revealed failures in both categories. In regard to the first, volcanologists have produced compelling videos of volcanic hazards, and social scientists have developed risk communication guidelines. In regard to the second, scientists should try to make sure their warnings reach the affected people. S*cientists, who have the best appreciation of the true hazard, can often do more by taking on the social responsibility as well as a technical one, and can be a strong and persistent voice within the hazard management structure to ensure that the mitigation process truly reaches the affected people.*

Time is the most important variable. At Armero, an important contribution to the failure was to wait (either delay or postponement) until the last possible minute. One cannot expect that emergency management and public response operate efficiently on an extremely short time scale. Delays in hazard recognition and mitigation can reflect also the reluctance of a national government to invest time, money, and foreign expertise toward assessment of an uncertain hazard.

Plan critical decisions in advance. In moments of crisis, complex decision-making processes that involve a bureaucratic chain-of-command, or hours of committee discussion, or that assume rapid, unstressed communications linkages are not effective nor dependable. The decision-making process associated with warnings should be simplified by advanced consideration and agreement of the decision criteria.

Is the warning system tested and is it reliable? It is possible to design a risk communication and emergency warning system that maximizes the probability of sound public advice and also minimizes the potential negative impact of some personal characteristics of the public (see Voight, 1996a). The system should be tested by drills in advance of crisis.

Anticipate warning communications problems. Satellite and radio telemetry, microwave radio systems, cellular phones, standby power sources, and redundancy, all have a place in volcano emergency management.

Attention to the media is not a casual responsibility, but ranks in importance to the scientific work. Media reporting powerfully interacts with the public and officials with printed messages that are superior in providing detailed information essential for preparedness, whereas the electronic media are superior in *conveying alarms* to the public. Conflicting coverage and some distortions are inevitable, personal and commercial interests may use the media to aid mitigation efforts, or retard them, and the attention of the media to hazards may depend less on whether the underlying issues have been resolved than on whether they unfold in newsworthy fashion. In some cases, adversarial relations can develop between scientists and media producers, and such situations are clearly not helpful but can be difficult to resolve. Scientists dealing with risk and safety issues have to cope with strong uncertainty and ignorance, and yet are called upon to express judgments on ambiguous facts. Scientists have the obligation to supply balanced, reliable information to the population in a timely manner and in a form that can be widely understood, to further the mitigation process.

Do not underestimate lahar hazards. The public and decision makers need to know that lahars are not just muddy water but can include fast boulder-laden flows capable of demolishing concrete steel-reinforced buildings.

Conclusions

At Ruiz most of the elements desirable for successful hazards management had been in place. The youthful geology and geochronology of the cone had been studied, and postglacial flowage deposits had been mapped. Key historical events were studied. Advice was available from foreign experts, equipment had been provided, a hazards map was produced a month before the crucial event, and national, provincial, and local governments showed concern. The magmatic eruption was small and its effects had precedents. Thus, the catastrophe was not produced by technological defectiveness, nor by an overpowering eruption, nor by overwhelming bad luck. Instead Armero

was created by cumulative human error, indecision, and shortsightedness in response to uncertainty. In the event the authorities were unwilling to bear the economic or political costs of early evacuation or a false alarm, and they delayed action to the last possible minute. Catastrophe was the calculated risk, and Nature cast the die.

And so the lessons of Armero are not new lessons; they are old lessons forged in human behavior that once again required the force of catastrophe to drive them home.

Acknowledgments

We thank our colleagues on the Comité de Estudios Volcanologicos in Manizales. Special mention is due to Bruno Martinelli, the Swiss seismologist in our paper, and the Colombians H. Cepeda, P. Medina, E. Parra, F. Munoz, A. Nieto, and N. Garcia, later killed at Galeras. We also acknowledge our USGS colleagues, particularly Dick Janda, D. Harlow, N. Banks, R. Norris, J. Lockwood, and J. Zollweg. Andinista Bis, who was killed on Ruiz, and Oscar Ospina, both made great contributions.

NORTH ANATOLIAN FAULT

Thomas Rockwell
San Diego State University, San Diego, California, CA, USA

Definition

The North Anatolian Fault in Turkey is a major, continental transform system that connects the compressional system of faults in eastern Turkey, the Caucasus and the Zagros to the extensional regime in the Aegean Sea region. This fault zone, which extends 1,400 km from its juncture with the East Anatolian fault near Karliova east of Erzincan westward into the Gulf of Saros in the Aegean Sea, has a long and complex history, with the modern trace superposed on a Jurassic Neothethyan suture zone. The modern North Anatolian fault was reactivated in late Miocene time as a strike-slip zone to accommodate the westward extrusion of the Anatolian Plate resulting from the northward collision of the Arabian Plate with Asia.

Geodetic studies indicate that the fault is loading at a rate of about 25 mm/year along its entire trace. Several geologic studies suggest a lower rate of 15–20 mm/year from dating of offset late Quaternary geologic markers, and this lower rate is consistent with the production rate of large earthquakes for the length of the fault for the past 1500 years, as determined from paleoseismic and historical data. The geologic rates may not account for off-fault deformation, whereas the geodetic rates may not account for a persistent transient or visco-elastic relaxation after

rupture of nearly the entire plate boundary. Consequently, the actual loading rate for large earthquake production along the North Anatolian fault remains controversial.

The fault has experienced a remarkable westward progression of large earthquakes during the past century, beginning with the great 1939 M7.9 Erzincan earthquake, which resulted in 360 km of surface rupture and right-lateral displacements of up to 10 m. Subsequent earthquakes in 1942 (M7.1; 50 km of rupture), 1943 (M7.7; 280 km of rupture), 1944 (M7.4; 165 km of rupture), 1951 (6.8; 30 km of rupture), 1957 (M7; 30–50 km of rupture), 1967 (M7.2; 80 km of rupture), 1999 (M7.5; 130 km of rupture), and 1999 (M7.1; 50 km of rupture) essentially unzipped the fault westward for over 1,000 km, nearly to the Marmara Sea, which has been attributed to progressive failure due to Coulomb stress loading.

The long historical record of earthquakes in Turkey, along with extensive paleoseismic work at various sites along the fault, has led to an understanding of prior earthquake sequences, and an assessment of local and regional seismic risk. The previous earthquake sequence played out over the period of a century, and initiated with a very large earthquake in 1668 along the same faults that ruptured in 1943 and 1944. This was followed by large earthquakes in 1719, 1754, 1766, and 1766, the last two of which ruptured through the Marmara Sea and the Gallipoli peninsula. A major concern is that the current sequence has not played itself out and that another earthquake may occur in the Marmara Sea next to Istanbul, one of the great cities of the World with a population of over 13 million people.

Pyroclastic flow

Definition

Nuée Ardente is a "glowing cloud" of superheated (often incandescent) particles and gases formed by the collapse of an explosive eruption column.

Discussion

Nuée Ardente is an old term that has been largely replaced by "pyroclastic flow" or more recently "pyroclastic density current" (PDC) (cf. Sulpizio et al., 2008). The name *Nuée Ardente* is derived from observations of Mount Pelée in 1902 (cf. Fisher and Heiken, 1982). Pyroclastic flows (and surges) are extremely hazardous and destructive processes that can have a number of origins (Nakada, 2000). The most well known are those that originate from the collapse of a rising eruption column. This collapse is usually instigated by a change in the eruption velocity caused by changing vapor/particle concentrations at the vent. If the expansion of the gas content of the erupting column can no longer support the lower ballistically expelled parts of the column, it will collapse. The collapse produces a density current of hot gases and particles. The heat is sufficient enough that during flowage, the cloud of particles and gas glows, hence the French name for a glowing cloud, "Nuée Ardente." The particles range from fine grained ash size to blocks tens of centimeters in diameter, depending on the disaggregation of the magma in the vent. Mixed with the clasts and being expelled from them, are hot gases that help fluidize the pyroclastic flow. Depending on the size of the eruption, height of the collapsing column, and topography, pyroclastic flows can travel tens to hundreds of kilometers from the vent. They also vary significantly in characteristics depending on the magma type and size of the eruption. The most common pyroclastic flows involve dacitic to rhyolitic ejecta erupted during Peléan, sub-plinian to plinian eruptions, but basaltic pyroclastic flows such as at Villarrica (Witter et al., 2004:305) and Kilauea (Fiske et al., 2009) have also been reported, though they are rare.

OVERGRAZING

Norm Catto
Memorial University of Newfoundland,
St. John's, NL, Canada

Definition

Overgrazing is the excessive consumption of vegetation by livestock.

Discussion

Overgrazing, and the consequent food shortage for livestock, represents a hazard directly for human populations dependent on the livestock. It also is a contributing cause to soil and sediment erosion, as material unprotected by vegetation is subject to removal by wind, running water, and mass movements.

Overgrazing can be a major contributing cause of desertification, where formerly arable land or pasture is converted to unproductive terrain. Overgrazing may result in desertification, even though there has been no significant change in the amount of rainfall or the temperature. However, desertification is a complex process resulting from the interplay of numerous factors, and many instances of desertification are not directly linked to overgrazing.

Human populations that have increased rapidly due to increased livestock production may be at risk if overgrazing reduces food supply. Overgrazing is a significant risk in areas subject to drought or strong winds, particularly steppes and areas adjacent to deserts, including Australia, Patagonia, northern China, India, Pakistan, the prairies of North America, and drier regions of northern and southern Africa.

As overgrazing and its effects can be very localized, detailed vegetation cover and land use assessments should be conducted, and local and regional factors considered prior to the implementation of changes in agricultural policy. Effective management of a potential overgrazing problem requires careful consideration of the human cultural factors, in addition to physical analysis.

OZONE

Tom Beer
Centre for Australian Weather and Climate Research,
Energy Transformed Flagship, Aspendale, VIC, Australia

Definition

Ozone (O_3) is a tri-atomic form of oxygen that constitutes a minor and variable constituent of the atmosphere. Most of the ozone is found in the stratosphere (which is the

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

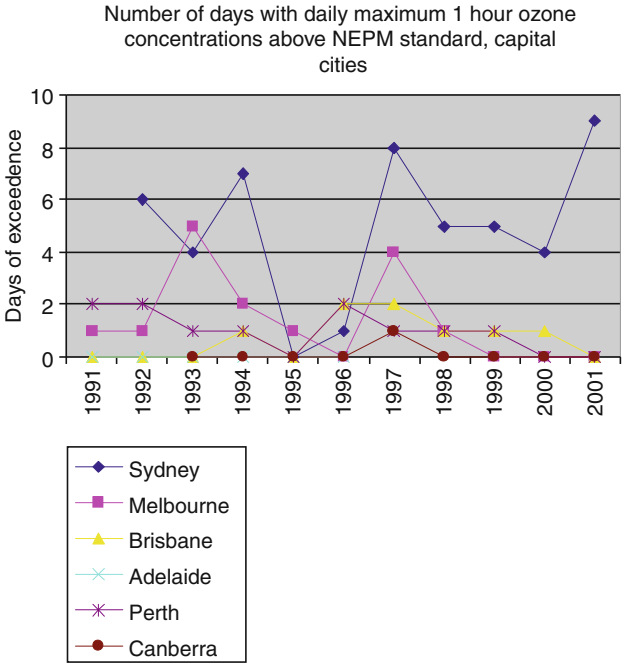
region from approximately 15 to 45 km altitude). It can also be found at ground level.

Discussion

In the lower part of the atmosphere, ozone is formed by chemical reactions between the hydrocarbons and oxides of nitrogen in industrial and automotive emissions that are initiated by sunlight. High ozone concentrations at ground level are an indicator of a type of air pollution called photochemical smog. Air pollution, as noted by Beer (2001), constitutes a meteorological hazard.

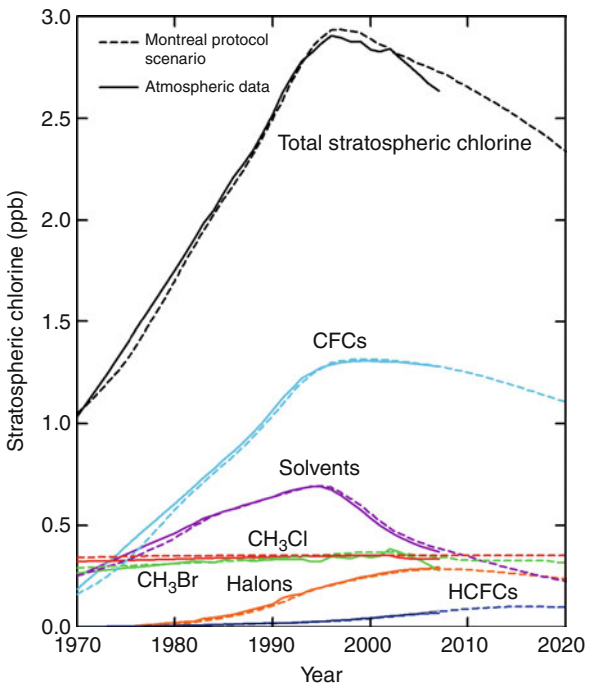
In the stratosphere, ozone is concentrated in a layer centered at approximately 35 km altitude. It is an efficient absorber of ultraviolet radiation and thus acts to protect living systems from the harmful effects of such radiation.

Certain anthropogenic chemicals containing chlorine and bromine, known as ozone depleting substances (ODS), react with ozone and contribute to the destruction of the ozone layer. These chemicals are able to diffuse into the stratosphere and produce a hole in the ozone layer in the polar regions at certain times (especially during spring). The Montreal Protocol was introduced to ban emissions of ozone depleting substances.



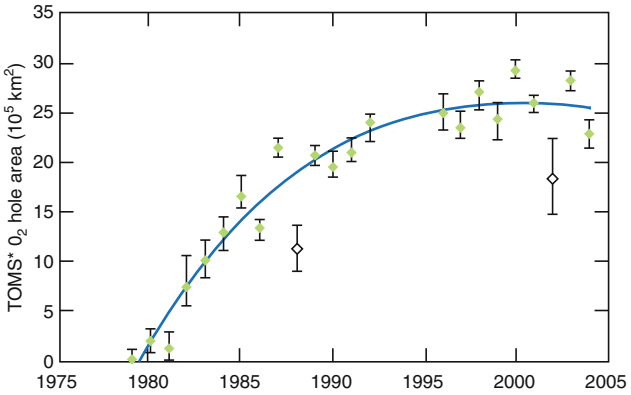
The ozone hole and global warming are separate atmospheric issues that are not necessarily related to each other.

Urban air quality



High ozone concentrations and the resulting photochemical smog are of particular concern in localities with plentiful sunshine that do not control their automobile and industrial emissions. Ozone shows average concentrations that exceed guideline values in cities on all continents, demonstrating that it is a global problem (Baldasano et al., 2003). In particular, megacities in the developing world have high ozone concentrations resulting from unregulated emissions and large numbers of emitters (industries and automobiles). For instance, Mexico City in 1999 is believed to have recorded the highest ever one-hourly ozone concentration (491 $\mu g\,m^{-3}$). For comparison, the EU has an alert threshold of 240 $\mu g\,m^{-3}$ for a 1-h ozone concentration, whereas Canada has a maximum desirable concentration of 100 $\mu g\,m^{-3}$. Australia has a maximum 1-h allowed concentration of 211 $\mu g\,m^{-3}$ (0.10 ppm), but as shown in Figure 1 the city of Sydney regularly exceeds this concentration.

Stratospheric ozone



The total amount of ozone-depleting gases in the stratosphere is measured by a variable known as Total Stratospheric Chlorine. Accumulation of Total Stratospheric Chlorine slowed during the early 1990s and levels are now declining slowly (Figure 2). Although there is no evidence of a significant reduction in the Antarctic ozone hole in recent years (e.g., the 2006 ozone hole was close to or possibly the largest ever), it stopped increasing significantly in the mid-to-late 1990s and a polynomial fit (shown in blue in Figure 3) indicates that the size of the

Ozone, Figure 1 Changes in lower-atmosphere ozone concentrations in Australia vary substantially from city to city and from year to year (From Beeton et al., 2006).

Ozone, Figure 2 Stratospheric "chlorine" from the worldwide use of major ozone depleting substances. Solid lines are data collected at Cape Grim, Tasmania; dashed lines are model calculations based on past and future emissions of ODS (Montzka and Fraser, 2003).

Ozone, Figure 3 The area of the Antarctic ozone hole as measured by the TOMS satellite sensor has, since 2000, started to reduce (Beeton et al., 2006).

Antarctic ozone hole started to lessen around the turn of the millennium.

The ozone hole has been linked to increased ultraviolet radiation and this in turn results in increased incidence of skin cancer. This link has become more widely known and public action in avoiding excessive ultraviolet radiation has increased significantly. Unfortunately, all other factors being equal, skin cancer incidence may be expected to continue to increase until about 2050, even though ozone levels in the stratosphere have started to recover. The reason for this is that, even though exposure to ultraviolet radiation (as a result of ozone depletion) causes skin cancer, there is about a 50-year time lag between the two.

OZONE LOSS

Mary J. Thornbush
University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

(Stratospheric) Ozone depletion; (Stratospheric) Ozone hole

Definition

Involving the depletion of ozone (O_3) in the stratosphere (located 10–50 km in the atmosphere above the Earth's surface), where it protects organisms living on the Earth's surface. This is caused by chlorine molecules in ozone-depleting substances that react catalytically with ozone, destroying it (Tsai, 2002).

Background to risks

Whereas the accumulation of ground-level (tropospheric) ozone can be harmful to human health, stratospheric ozone protects human health and the environment from ultraviolet (UV) radiation. The ozone layer acts as a shield by filtering out ultraviolet B (UVB), which is linked to increased skin cancer and reduced immunity in humans, DNA damage in other animals, and impacts crop productivity (Roscoe, 2001).

Chlorofluorocarbons

Ozone depletion is caused by reactive chlorine and bromine compounds that are derived from human-made ozone-depleting substances, such as chlorofluorocarbons (CFCs) and halons (volatile bromine-containing organic substances) (Roscoe, 2001). Concern for the destruction of stratospheric ozone due to CFCs in the atmosphere developed toward the middle of the 1970s. CFCs were mainly used as refrigerants, cleaning solvents, foam-blowing agents, and aerosol propellants (Tsai, 2005). They were banned in the USA in 1978 as propellants in most aerosol uses.

Clean Air Act

More than 190 countries signed the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer to protect the ozone layer. Developed countries, including the USA, committed to limiting the production and use of chemicals (such as chlorinated and brominated compounds) that are

harmful to stratospheric ozone. The Montreal Protocol reduced chlorine loading, which is expected to reach 2 ppbv in 2050 – the amount above which the Antarctic ozone hole was noted (Roscoe, 2001). US Congress added provisions to the Clean Air Act of 1970 for the protection of the stratospheric ozone layer since 1990; for instance, terminating the production of harmful chemicals (such as CFCs, halons, and methyl chloroform) in 1996. Other steps are needed to protect the ozone layer, including the development of "ozone-friendly" substitutes for ozone-destroying chemicals, and the reformulation of products and processes to be more "ozone-friendly" (such as refrigerators that no longer rely on the use of CFCs). However, some substitutes are still harmful, including the use of methyl bromide (MeBr) as a pesticide in the absence of an alternative. MeBr is increasingly used in the treatment or prevention of pest infestation at international borders (Norman et al., 2008).

Scientific monitoring

Satellite data have been obtained from the Total Ozone Mapping Spectrometer (TOMS), but ground-based data derived from Dobson spectrophotometric measurements have demonstrated more long-term stability (Straehelin et al., 2002). Using a Dobson spectrophotometer, for example, it was possible to observe an elongation and splitting into two of the ozone hole over Antarctica in late September 2002 probably due to a polar stratospheric major warming (Varotsos, 2004). Ozone loss has also been observed during winter and spring months in mid-latitudes since the beginning of the 1970s, when a large fleet of civil airplanes were planned to fly in the lower stratosphere (Straehelin et al., 2002). Only later in 1985, was an "ozone hole" confirmed over Antarctica, where ozone depletion was evident that could pose a potential health and ecological threat from increased solar UV radiation onto the Earth's surface. According to the National Oceanic and Atmospheric Administration's (NOAA's) Earth System Research Laboratory (Global Monitoring Division), three gases significantly contribute to stratospheric ozone depletion, including CFC-11, CFC-12, and nitrous oxide (N_2O). Since the Montreal Protocol and its Amendments, there has been a peak in Equivalent Effective Stratospheric Chlorine (EESC) around 2000 (Straehelin et al., 2002). National Aeronautics and Space Administration's (NASA's) Laboratory for Atmospheres maintains an Ozone Hole Watch, conveying the largest ozone hole ever was observed over the South Pole on September 24, 2006. An image-based comparison of total ozone in January 2010 of images displayed by the Climate Prediction Center of NOAA's National Weather Service shows greater concentrations in the Northern Hemisphere over the Arctic than in the Southern Hemisphere over Antarctica. This is linked to the heterogeneous activation of ozone-depleting substances on surfaces (such as polar stratospheric clouds or PSCs), occurring at very low temperatures during winter in the polar stratosphere (Straehelin et al., 2002). A planetary-scale comparison of weather systems over Antarctica on September 23, 2002 with September 23, 1999 shows small losses in the 2002 event of a smaller ozone hole, with warmer temperatures, as well as a distorted shape with splitting that could be attributed to planetary waves (Varotsos, 2003). According to this author, the smaller size of the ozone hole over Antarctica in 2002 is similar to 1988, when a strong sudden stratospheric warming occurred. The Antarctic stratosphere has been warming since 1979, particularly in September and October, when most ozone-hole recovery is expected with the reduction of PSCs and a weakened Antarctic polar vortex with increased wave activity in the Southern Hemisphere (Hu and Fu, 2009).

Ozone repair

The Montreal Protocol brought about international cooperation that successfully addressed ozone depletion as a serious global environmental hazard (Norman et al., 2008). The success of the Montreal Protocol is evident in reductions in the use of ozone-destroying substances worldwide since 1986. A more recent meeting in September 2007 has led to the accelerated phaseout of hydrochlorofluorocarbons (HCFCs), which are used especially in cleaning solvents, completely by 2030 (Norman et al., 2008). Like CFCs, HCFCs share the potential for stratospheric ozone depletion and, together with hydrofluorocarbons (HFCs), they also contribute to global warming (Restrepo et al., 2008). HFCs are replacing CFCs and HCFCs, which cause considerably more stratospheric ozone depletion and global warming (Tsai, 2005). Commercial uses of HFCs are as cleaning solvents in electronic components, blowing agents in foamed plastics, refrigerants (in refrigerators and air conditioners), fire suppression agents, propellant in metered dose inhalers, and dry-etching agents in the manufacture of semiconductors (Tsai, 2005). HCFCs still contain chlorine, but release less atomic chlorine into the atmosphere compared to CFCs; also, HCFCs have a short atmospheric lifetime and relatively less potential for ozone depletion than CFCs (Tsai, 2002). It will be decades, however, before the stratospheric ozone layer heals due to the presence of ozone-destroying chemicals already implanted, which are stable compounds (such as chlorine) that can remain in the atmosphere for many years until they decay or are precipitated out of the atmosphere. For example, the Antarctic ozone hole was of record size for 3 months in 2006 (Norman et al., 2008). There are implications for significant amounts of BrO and Cl-atoms found outside the Arctic and Antarctic boundary layer, and that MeBr is ubiquitous in the troposphere at all latitudes (Platt and Hönninger, 2003).

Summary

The problem of ozone thinning has been observed since the finding in 1985 over Antarctica of an "ozone hole." This is an established connection of the disappearance of ozone in cold (polar) regions with airborne CFCs, which are concentrated in the atmosphere by the human use of

refrigerants, foam products, and so on. The 1987 Montreal Protocol established strict regulations on the use of CFCs that has lessened this air pollutant in developed countries. Reductions of CFC use have resulted in ozone recovery in the stratosphere, which helps to protect humans from exposure to UV radiation that is harmful to cells in the human body (such as the skin). Other biological life is also affected by ozone loss, including other animals and plant tissues.

PACIFIC TSUNAMI WARNING AND MITIGATION SYSTEM (PTWS)

Laura S. L. Kong
UNESCO/IOC-NOAA International Tsunami Information Center, Honolulu, HI, USA

Definition

The Intergovernmental Coordination Group for the Pacific Tsunami Warning and Mitigation System (ICG/PTWS) was started in 1965 as a subsidiary body of the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific, and Cultural Organization (UNESCO/IOC). It is comprised of Member States bordering and within the Pacific Ocean, and other interested Member States**.** The ICG/PTWS acts to coordinate international tsunami warning and mitigation activities. One of its most important activities is to ensure the timely issuance of tsunami warnings in the Pacific. This requires cooperation in sea level and seismic networks and data sharing, standardization and understanding of tsunami threat criteria, and effective dissemination of useful tsunami information. Comprehensive tsunami mitigation programs require complementary and sustained activities in tsunami hazard risk assessment, tsunami warning and emergency response, and preparedness. Stakeholder involvement and coordination is essential, and community-based, people-centered mitigation activities will help to build tsunami resiliency. The IOC (Paris, France) serves as the PTWS Secretariat, and coordinates the overall implementation of the global tsunami warning and mitigation system. After the devastating 2004 Indian Ocean Tsunami, the PTWS played a large role in guiding the development of regional systems in the Indian Ocean, Caribbean, and Mediterranean.

The International Tsunami Information Centre (ITIC, Hawaii, USA, started in 1965), a partnership of UNESCO/IOC and the USA National Oceanic and Atmospheric Administration (NOAA), serves as a technical and capacity building resource. The Director is provided by USA and since 1998, the Associate Director by Chile. The ITIC monitors the PTWS's effectiveness in order to recommend and facilitate improvements in the timeliness and accuracy of tsunami advisories, works closely with the international tsunami warning centers to enhance PTWS operations and directly with Member States to strengthen their national systems, facilitates technology transfer through training, workshops, and other capacity building, and acts as an information resource on historical tsunamis, education, and awareness.

NOAA's Pacific Tsunami Warning Center (PTWC, Hawaii, USA, started in 1949 after the 1946 Aleutian Islands tsunami) serves as the operational headquarters of the tsunami warning system. The Northwest Pacific Tsunami Advisory Center operated by the Japan Meteorological Agency (JMA, started in 1952 as a national center and as NWPTAC in 2005) and NOAA's West Coast/Alaska Tsunami Warning Center (WC/ATWC, started in 1967 after the 1964 Alaska tsunami) work with PTWC to provide international tsunami alerts for the Pacific and its marginal seas. The messages are advisory to designated national authorities, as each country is individually responsible for issuing warnings and public safety information to its population. National Tsunami Warning Centres are active in a number of countries. The oldest are in the Russian Federation (Sakhalin and Kamchatka Tsunami Warning Centres started after 1952 Kamchatka tsunami), in Chile (Servicio Hidrográfico y Oceanográfico de la Armada de Chile (SHOA) Sistema Nacional de Alarma de Maremotos (SNAM), started in 1964 after 1960 Chilean tsunami), and in Tahiti, France (Centre Polynésien de Prévention des Tsunamis (CPPT) started in 1965 after 1964 Alaska tsunami). For more information, visit http://ioc-tsunami.org/. For general information on tsunamis, visit http://www.tsunamiwave.info.

PAHOEHOE LAVA

Robert Buchwaldt
Massachusetts Institute of Technology, Cambridge, MA, USA

Synonyms

Ropy lava; Shelly lava; Slabby lava

Definition

Pahoehoe (the word is Hawaiian for ropy) lava is the term for cooling textures of a highly fluid, gas-charged lava flows and was introduced as a technical term by Clarance Dutton, 1883. The surface of Pahoehoe lava is usually smooth, undulant, or ropy (Figure 1). These textures are created by deformation of the flow. As the lava cools, the molten rock becomes more viscous (resistant to flow) and behaves more like a plastic. The moving flow cools from the outside toward the inside and a skin is created at the atmosphere-lava interface, whereas the center is still moving and flowing and tries to escape the surrounding skin. Due to this behavioral difference between the center and the skin, the skin can bunch upward or create wrinkles which can sometimes look like ropes and therefore is called *ropy pahoehoe*. In cases where the surface is creating more shelly textures the pahoehoe is called *Shelly pahoehoe* and where the surface is broken with closely spaced slabs, it is called *Slabby pahoehoe*.

Due to the intrinsic relationship between viscosity and temperature (the higher the temperature the lower the viscosity) the pahoehoe lavas are usually the first to erupt from a vent. The higher the volume of lava emitted the faster the current. Pahoehoe flows move forward in tongues or lobes and are characterized by a glassy, plastic skin. They may embrace obstacles at a rate of about 50 m/h.

Because of the cooling, gas loss, and crystallization of minerals Pahoehoe lava changes its viscosity over time and converts into an Aa lava flow. This conversion only occurs in this direction and it is impossible to convert lava flow occurrences from Aa to Pahoehoe (Peterson and Tilling, 1980).

PALEOFLOOD HYDROLOGY

Gerardo Benito
CSIC-Centro de Ciencias Medioambientales, Madrid, Spain

Synonyms

Ancient floods

Definition

Paleoflood hydrology is the reconstruction of the magnitude and frequency of recent, past, or ancient floods using geological evidence (Kochel and Baker, 1982).

Discussion

Paleoflood hydrology is a multidisciplinary research field that involves expertise from geomorphology, sedimentology, hydrology, modeling, and statistics. The primary goal of paleoflood hydrology is to extend flood records over periods of time ranging from decades to millennia. Past flood data are derived from the lasting traces left by physical indicators such as sediments (e.g., slack water flood deposits, coarse clasts), erosional landforms (stripped soils, flood scarps, high-flow secondary channels), high-water marks (drift wood), tree impact scarps, and damage to vegetation (dendrogeomorphological paleoflood evidence).

The most successful paleoflood hydrology approach is based on paleostage indicators from flood-induced erosion or deposition near maximum water levels of large floods (Baker, 2008). In bedrock canyon margins and during flood stages, eddies, back-flooding and water stagnation occur, significantly reducing flow velocities and favoring the deposition of suspended clay, silt, and sand, known as slack water flood deposits (SWD). Successive layers, or sedimentary units, record a sequence of individual floods over periods of centuries to millennia. Flood timing can be derived from a variety of geochronological procedures including: (1) radiocarbon dating and (2) optically stimulated luminescence from quartz and feldspar grains (OSL).

Water stages derived from elevations of flood layers (paleostages) can be converted into flood discharge. Flood discharge is obtained by a trial-and-error procedure using a hydraulic model, and comparing and contrasting the observed water levels with the simulated ones. The estimated discharges correspond to minimum discharge values since the maximum water depth at the deposition site is unknown. Common one-dimension discharge calculation from a known water surface elevation includes: (1) slope-conveyance, (2) slope-area, (3) step-backwater, and (4) critical-depth methods.

Flood frequency analysis (FFA) may incorporate paleoflood information (non-systematic data) together with systematic (annual maximum discharge) data. It is assumed that the number of k observations exceeding an arbitrary discharge threshold (X_T) in M years is known (censored data as an analogue to partial-duration series). Maximum likelihood estimators, expected moment algorithm, and fully Bayesian approach have been shown to be efficient in the estimation of statistical parameters of traditional flood distribution functions (e.g., Gumbel, LP3, Generalized Extreme Value, Benito and Thorndycraft, 2005).

Paleoflood hydrology has been applied in many regions of the world in: (1) flood-risk estimation; (2) determination of the maximum limit of flood magnitude and non-accedences as a check of the probable maximum flood (PMF); (3) flood response to climatic variability; and (4) assessing sustainability of water resources in dryland environments where floods are an important source of water to alluvial aquifers (Benito and Thorndycraft, 2005).

PALEOSEISMOLOGY

Alan R. Nelson
U.S. Geological Survey, Golden, CO, USA

Synonyms

Ancient earthquakes; Prehistoric earthquakes

Definition

Paleoseismology is the study of the location, timing, and size (magnitude) of past, usually prehistoric, earthquakes.

Discussion

Paleoseismology is a subdiscipline of the broader fields of neotectonics, active tectonics, and earthquake geology (Yeats et al., 1997; Burbank and Anderson, 2001; Keller and Pinter, 2002; Bull, 2007; McCalpin and Nelson, 2009). Paleoseismology differs from these more general studies of the deformation of Earth's crust during the past few million years in its focus on the almost instantaneous deformation of landforms and sediments during earthquakes. Paleoseismology adapts many concepts from seismology, structural geology, and tectonics, but its field methods and techniques are derived from Quaternary geology (the past 2 million years of Earth history) and related disciplines, such as geomorphology, sedimentology, archeology, paleoecology, soil science, soil mechanics, imagery analysis, and age dating. Most paleoseismic field studies require extensive training or experience in Quaternary geology, itself a highly interdisciplinary field.

Generally, paleoseismic evidence records only large (magnitude > 6.7) earthquakes because evidence of lower magnitude earthquakes is rarely created at the surface. Even where evidence of past earthquakes is preserved, much is eroded or obscured within tens to hundreds of years of an earthquake. Evidence includes rupture or warping of the ground surface along a fault, (e.g., a vertical fault scarp or a laterally offset stream valley),

landforms showing sudden uplift or subsidence of large regions above a tectonic plate-boundary fault (broadly warped river terraces or uplifted or subsided shorelines), and features recording the effects of strong ground shaking or tsunamis tens to thousands of kilometers from the fault on which a large earthquake occurred (unusual landslides, liquefaction structures, or tsunami deposits).

Historical records of large earthquakes are short compared to the complete geologic history of most active faults. Even in parts of China and the Middle East where earthquake catalogs extend back 1000s of years, written records of earthquakes do not identify all faults capable of generating large earthquakes. Archeology helps document the history of large earthquakes in some regions, but much of the earthquake history of most major faults is accessible only through the techniques of paleoseismology. Paleoseismic records may extend over tens of thousands of years particularly in regions where earthquakes are infrequent or where earthquake evidence is unusually well preserved. Understanding regional patterns of large earthquakes in space and the earthquake histories of individual faults are critical in defining regional earthquake hazard, forecasting future damaging earthquakes, and mitigating their effects.

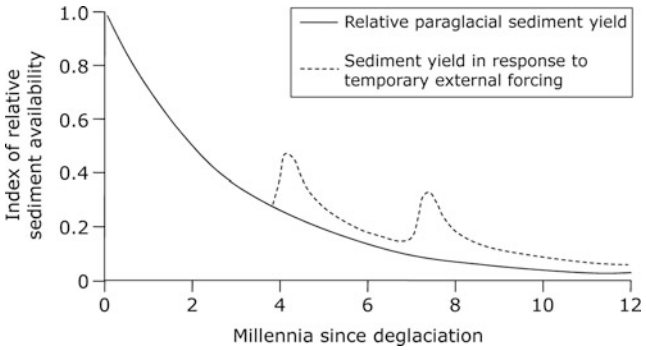
PARAGLACIAL

Jasper Knight
University of the Witwatersrand, Johannesburg, South Africa

Definition

Paraglacial. "Nonglacial processes that are directly influenced by glaciation" (Church and Ryder 1972, p. 3059).



Paraglaciation. (1) (v.) The geomorphological regime under which landscapes undergo modification by paraglacial processes. (2) (n.) The time period during which paraglacial processes operate in a given area, starting from the time of land surface exposure upon deglaciation, to the time at which regional sediment yield reaches average interglacial background values. At this point, the effects of paraglacial processes are indistinguishable from background, and the period of paraglaciation has ceased.

Introduction and development of the paraglacial concept

The term "paraglacial" was first used by Ryder (1971) and Church and Ryder (1972) to refer to the changes in sediment yield that take place as a result of the presence, and then retreat, of glaciers in a landscape. Specifically, Church and Ryder (1972) looked at changes in fluvial sediment yield during late Pleistocene and present-day glacier retreat in Baffin Island and in British Columbia, Canada. In this paper, they argued that loose, surficial glacigenic sediment, deposited during ice retreat, was actively reworked by outflowing rivers and led to a period of enhanced sediment yield from such glaciated catchments. Ballantyne (2002a) describes this as "glacially conditioned sediment availability." Following glacier retreat, sediment yield decreases exponentially over time as the glacial sediment store is progressively reworked, reaching background interglacial values over a period of anything up to 10,000 years following initial ice retreat (Figure 1).

In the development of the paraglacial concept since the 1970s, the term has been used to include other earth surface processes including slope and periglacial weathering processes; mass movements; and lacustrine, coastal, and nearshore processes (Ballantyne, 2002a). As such, therefore, the paraglacial concept has gained wider currency as an umbrella term for all those processes that are enhanced or modified by the climatic disturbance associated with the presence, or development, of glaciers (see *Glacier Hazards*). Paraglacial processes and sediment yield should be distinguished from periglacial processes (sensu stricto), which merely imply the operation of a cold climate, not necessarily the presence of glaciers themselves (Slaymaker, 2009). Also implicit in this broader definition is the relationship between paraglacial processes and the wider glacial context within which these processes are found: "It refers both to proglacial processes, and to those occurring around and within the margins of a former glacier" (Church and Ryder, 1972, p. 3059).

From this broad definition of the term *paraglacial*, therefore, it is logical to make two key inferences. First, that the domain within which paraglacial processes operate waxes and wanes in location and size and changes in tempo with glacier extent, in particular over large spatial scales and on long, glacial-interglacial timescales (see *Climate Change*). Second, that a wide range of earth

Paraglacial, Figure 1 Schematic graph showing the exponential decrease in sediment yield typical of paraglacial environments, and temporary changes in sediment yield in response to external forcing by events such as changes in base level or landsliding into valley floors (After Slaymaker, 2009).

processes that typically change when in the presence of glaciers (including subaerial and subsurface weathering, groundwater flow, geochemical pathways, and far-field effects on coastal sediment supply and sea level) should also be included under the paraglacial umbrella (Knight and Harrison, 2009a). This is a somewhat wider definition than that proposed by Ballantyne (2002a), but follows on from well-established principles of equilibrium-disturbance models in ecosystems and in systems theory (e.g., Seneviratne et al., 2006; Lenton et al., 2008). This theme of landscape disturbance highlights the important role that paraglacial processes exert, during major phases of ice retreat, on the types, locations, frequency, magnitude, and landscape impact of earth surface processes, particularly in landscapes where physical environments are changing rapidly because of glacier retreat (see *Geohazards*). It is in these environments, therefore, where a range of natural hazards occur. Typical paraglacial processes and the natural hazards that are associated with them are now examined in detail.

Evidence for paraglacial processes in past and present landscapes

Because the processes associated with paraglaciation are not exclusive to that setting, the landforms resulting from these processes are also not unique (Whalley, 2009). Some landforms that result from the paraglacial enhancement of these processes, however, can be linked morphogenetically and by radiometric dating to periods of glacier retreat and glacigenic sediment release, particularly in mountain environments which are sensitive to climate-driven changes in glacier extent (see *Climate Change*). Examples of specific physical processes and environments that respond to paraglaciation are now described. These correspond to both late Pleistocene and present-day glaciers, and in mountain and lowland glacial settings.

River responses to ice retreat

Glacier retreat is associated with the release into the proglacial environment of both loose glacigenic sediment and meltwater (Orwin and Smart, 2004). As such, glacier retreat is genetically associated with invigoration of river discharge and changes in river geomorphology, and therefore with periods of river system instability (Church and Ryder, 1972; Juen et al., 2007; Huss et al., 2008). Many rivers in alpine and mountain settings exhibit these characteristic paraglacial properties, even if these rivers are not specifically termed "paraglacial" (see *Flood Deposits*). Over short (decadal to centennial) timescales when glaciers are in retreat, increased sediment supply leads to river gravel aggradation within mountain and piedmont mid and upper-catchments, nearest to where sediment is being released (Wilkie and Clague, 2009). Sediment supply into valley bottoms can also take place from steep, unstable, glaciated slopes, particularly those that comprise glacial sediment rather than bare rock (Figure 2). Slope failure associated with slope collapse contributes a "slug" of loose sediment into these river systems, which has implications for sediment budgets and processes by which this sediment is transferred downstream (Bartsch et al., 2009). Paraglacial river responses are also spatially complex, in which barriers to downstream sediment transport (such as overdeepened, glacially scoured valleys) inhibit sediment yield to lowland floodplains. Worldwide, many paraglacial sediments today are trapped within rock-bounded upland basins and within enclosed mountain blocks, and may be unlikely to contribute to downstream sediment supply (Hewitt, 2006).

Today, meltwater production and sediment release from the margins of lowland outlet glaciers in Iceland are important in the maintenance of fronting outwash plains (sandar) (Marren, 2005). Hydrographic records of outflowing rivers from these glaciers show high temporal variability of river discharge (Old et al., 2005) (see *Flood Hazard and Disaster*). These rivers are also geomorphically unstable, and are characterized by rapid aggradation, avulsion, and bar and channel migration (see *Avulsion*; *Flood Deposits*), particularly when associated with subglacial drainage events (jökulhlaups) (Marren, 2005; Marren et al., 2009) (see *Jökulhlaups*). Several studies from SE Iceland highlight the fact that sediment delivery to the sandar of Vatnajökull has helped shape sediment supply and the dynamics of the paraglacial SE Iceland coast to which these rivers flow (Maria et al., 2000). Future changes in glacier-fed sediment supply have major implications for the maintenance of this fronting coastline (see *Coastal Erosion*).

The presence of snow/ice water sources in glaciated mountains also has implications for the temporal dynamics of outflowing rivers (Messerli et al., 2004). Where glaciers are present, glacier melt dominates mountain hydrographs through the summer period, culminating in the late summer when water from other sources is lowest. By contrast, rivers from areas dominated by winter snow cover are most vigorous during spring snowmelt (freshets)

Paraglacial, Figure 2 Photo of catastrophic rockslide/rockfall event caused by valley side debuttressing following ice retreat, Southern Alps, New Zealand (Photo: Jasper Knight).

(Vanham et al., 2008). Long-term changes in glacier and snow cover extent and duration, caused by climate change, have major implications for the sustenance of these river systems (Viviroli and Weingartner, 2004; Kehrwald et al., 2008) and the timing of consequent flood events (Vanham et al., 2008) (see *Hydrograph, Flood*).

Mass movements

Mass movement processes dominate in areas of high relief where steep slopes relax under gravity as a consequence of debuttressing as valley glaciers retreat (Fischer et al., 2006; Hewitt, 2006; Iturrizaga, 2008). Whilst mass movement processes can take place in many different physical settings, they have a greater frequency and/or higher magnitude in glaciated mountains where, first, the erosive effects of glaciers lead to the creation of high relief by valley overdeepening; second, steep-sided and unvegetated landforms comprised of glacial and periglacial debris accumulate at the margins and termini of valley glaciers; and third, bedrock slopes and glacial landforms are exposed to subaerial processes following ice retreat (Iturrizaga, 2008; Korup and Clague, 2009). Evidence for mass movement processes in glaciated lowlands is more subdued, mainly because shallower slopes mean that these processes work more slowly and the land surface is more easily stabilized by vegetation (see *Mass Movement*).

The mass movement processes and resultant landforms are morphologically diverse and not unique to paraglacial settings, and are controlled by slope, aspect, lithology, sediment supply, water content, and nature of the forcing factor that triggers the event (Korup and Clague, 2009). Specific mass movement types found in paraglacial environments include the following:

Rockslides, rock avalanches, and rock falls

Rockslides and rock avalanches are typical landscape relaxation processes in mountain areas subject to glaciation (Hewitt, 2006). They represent pressure unloading of steep rocky slopes, usually as a result of ice retreat or ice/permafrost melt, but also where overlying rock has been rapidly removed by erosion or catastrophic mass movement (e.g., Figure 2) (see *Rock Avalanche (Sturzstrom)*). There is a strong geologic control on the susceptibility of rock slopes to failure by sliding, falling, or avalanching (Jarman, 2006; Cooper, 2007), dependent on rock type, joint density, and relationship of joints to the land surface. These geologic factors also influence the geomorphological impact of failure events, including block size and runout length (Hewitt, 2006). Rocksliding (where intact slabs of rock fail and move in a coherent fashion), rock falls (where blocks are detached singly), and rock avalanches or sturzstroms (where single blocks interact with each other during movement) are all enhanced in both their frequency and magnitude in paraglacial settings (Hewitt, 2006; Cossart et al., 2008). Where available, radiocarbon and cosmogenic dating shows that high magnitude rockslide events occur most frequently in association with the climatic disturbances of the last deglaciation and Little Ice Age, and in recent times by deforestation and land use change (Curry et al., 2006; Hewitt, 2006; Cooper, 2007). Fischer et al. (2006) show that recent mass movements in the European Alps are triggered by a combination of glacier retreat and permafrost warming, which weakens the internal cohesion of rock layers and encourages failure (see *Permafrost*). These processes are typical of areas subject to increased temperature and/or decreased precipitation and where the zone in which periglacial processes operate migrates to higher-altitude locations with climate warming. Hales and Roering (2005) showed that physical weathering processes, contributing material to scree slopes in the Southern Alps (New Zealand), is strongly controlled by temperature and thus elevation. Here, climate warming results in an elevational shift in the location where rock slope failure hazards are most common, tracking the zone in which glacial and periglacial processes operate. Landslides, rockslides, and other mass movement processes are also important in overall rockwall retreat in mountain areas (Curry and Morris, 2004; Hales and Roering, 2005), which tends toward the development of

equilibrium profiles that represent transient landscape stability (Roering et al., 2005). Rockslides, rockfalls, and rock avalanches are therefore common events in steep, sediment-poor areas around the time of and immediately after ice retreat.

Other slope processes

Incipient slope mass movement, that strongly contributes toward the development of these equilibrium profiles, takes place and is maintained in mountain and paraglacial landscapes by solifluction (Ballantyne and Benn, 1994; Matsuoka, 2001). Solifluction, which refers to the process of accelerated soil or sediment creep that takes place in cool climate settings under gravity, is particularly active where water is present at the ground surface (by seasonal melting of snow or permafrost) and where vegetation cover is low (see *Creep*). Solifluction causes a redistribution of unconsolidated or low-strength material from upper to lower slope positions, thereby extending slope length and decreasing slope angle (Curry, 1999). A number of landforms result from solifluction and related slope processes in paraglacial environments, including debris cones (Ballantyne, 1995; Curry et al., 2006) and alluvial fans (Ryder, 1971; Lian and Hickin, 1996; Owen and Sharma, 1998). Development of these landforms is often episodic, driven by high-magnitude events that may be seasonal (by spring snowmelt or summer rainstorms), or more infrequent and associated with particularly unusual climatic conditions.

An example of the enhancement of paraglacial slope processes under climate forcing is the period August 20–23, 2005, in which unusually heavy summer rainfall was received over the European Alps. This event resulted in extremely high rainfall intensity and volume over mountain catchments, particularly in Switzerland, Austria, and Germany, which in turn led to major river erosion and flooding events in alpine mountain valleys (Beniston, 2006). The rainfall weakened glacial sediment on steep slopes, triggering debris flows, landslides, and rockfalls (Hilker et al., 2009). In Switzerland, 25% of all damage by floods and landslides in the period 1972–2007 took place during the August 2006 event alone (ibid.).

In total, these mass movements are important in supplying material to nourish downslope debris cones and scree slopes (e.g., Ballantyne, 1995; Curry et al., 2006; Hales and Roering, 2005). In constrained valleys, this slope material can coalesce, forming a valley fill that over time stabilizes slopes and decreases available accommodation space in lower parts of mountain valleys (Ballantyne and Benn, 1994; Anderson and Harrison, 2006; Straumann and Korup, 2009) (Figure 3). The sediment yield generated by these slope processes therefore decreases over time through the paraglacial period, with accompanying decrease in frequency and magnitude of their

Paraglacial, Figure 3 Photo of paraglacial valley fill by solifluction processes that has been subsequently downcut and reworked by river rejuvenation during the Holocene, County Donegal, northwest Ireland (Photo: Jasper Knight).

Paraglacial, Table 1 Typical range of natural hazards associated with paraglacial processes that operate over short (seconds to months) and longer (years to centuries) timescales

	Drivers of the process	Associated hazardous processes and events
Short timescale paraglacial processes		
Proglacial lake outburst floods	Ice margin retreat; collapse of supporting moraine dam; landslide into the proglacial lake	Sandur erosion and aggradation; downstream flooding; debris flows; mud flows
Jökulhlaups	Ice margin retreat; subglacial volcanic eruption	Sandur erosion and aggradation; downstream floods; debris flows
Rockfalls, rockslides (sturzstrom)	Rock slope debuttressing; permafrost melt	May transform in a downslope direction into a debris flow
Landslides	High precipitation; river undercutting; slope debuttressing	Often leads to formation of landslide-dammed lakes; increased sediment input into rivers; distal debris flows and mud flows
Debris flows, mass flows, mud flows	High precipitation; permafrost melt	Formation of landslide-dammed lakes; enhanced sediment input into rivers
Longer timescale paraglacial processes		
Solifluction, gravity-driven flows	High precipitation; permafrost melt; sediment availability; steep and unstable slopes. Often results in slope stabilization and formation of valley fill	Land surface instability and movement in permafrost regions; episodic flows downslope
Sediment yield of outflowing rivers	Related to upslope sediment supply by a range of processes. Often results in sediment storage within parts of the river basin	Rapid changes in river geomorphology by erosion and deposition; increased flood frequency; mass flows and mud flows
Coastal sediment supply	Paraglacial rivers transport sediment to coasts, therefore coastal sediment budgets are strongly dependent on this sediment source	Decreased river sediment yield over time leads to sediment starvation along paraglacial coasts, and increased coastal erosion

accompanying natural hazards (Table 1). These variations in different processes and the timescales over which they operate reflect the response time of paraglacial landscapes, also called their relaxation time, to climate change and ice retreat.

Paraglacial response times

The response time of any paraglacial landscape is quite variable, depending on its location, the geomorphological process under consideration, and the baseline value of the process against which its response time to climatic disturbance is measured (Ballantyne, 2002b). The most rapid paraglacial responses will be those that take place nearest to the glaciated area, and also in areas of high relief when unstable slopes are exposed (Table 1). The processes involved here will include large-scale mass movements, in particular landslides and rockslides, which are reported from many paraglacial mountain blocks worldwide, in particular the Himalayan ranges (Hewitt, 1998) (see *Landslide*). Here, large-scale avalanches into overdeepened valleys take place shortly after (within few ka of) major ice retreat, and can often lead to development of landslide-impounded glacial lakes (Hubbard et al., 2005) (see *Landslide Dam*). Development and drainage of these lakes is a major hazard in rapidly changing glaciated landscapes. Similar processes also took place throughout the smaller-scale glaciated landscapes of Scotland (e.g., Jarman, 2006). Dating and other evidence here suggests that many of these events can take place for a long time after initial ice retreat, and sediment yield can be reinvigorated by glacial lake drainage, river flood events, or rapid climate changes (e.g., Ballantyne, 2002b). The response of paraglacial landscapes in their totality, and therefore the nature of the processes and geomorphological hazards that take place during this relaxation time, varies according to geographic setting, landscape relief, process type, and timescale (Table 1).

Outlook: the future of paraglacial environments and hazards under climate change

Today, due to global warming, most mountain glaciers worldwide are in retreat (e.g., Haeberli et al., 2007), meaning that these mountain landscapes are in transition from glacial to paraglacial in terms of the major process domains that operate in those environments. This has important implications in turn for individual geomorphological processes and natural hazards (see *Glacier Hazards*). For example, recent ice retreat in the European Alps has led to increased rockfall and debris flow hazards from surrounding slopes, increased sediment yield to outflowing rivers, and changes in water flow contribution to these rivers by glacier melt and changes in snow cover

depth and duration, giving increased flood frequency in adjacent valleys (Fischer et al., 2006; Stoffel and Beniston, 2006; Fuchs, 2009). These multiple and wide-ranging impacts in the Alps are a preview of what glacier retreat will likely mean for glaciated mountains worldwide in future decades.

This present mountain glacier retreat is causing a renewed phase of enhanced paraglacial sediment delivery to valley bottoms (Knight and Harrison, 2009b). This is associated with increased magnitude and frequency of debris flows, landslides, and rockfalls, which transport sediment into mountain catchments (Stoffel and Beniston, 2006). The increased sediment supply is then available to be reworked downstream during flood events (which are themselves increasing in frequency), resulting in major changes in river geomorphology and generation of mass and mud flows. Monitoring of mountain river systems is only just now starting to identify these trends (Beylich et al., 2006; Warburton, 2007) but such studies are needed in order to identify the strength and longevity of the paraglacial signal. Paraglacial processes are extremely important in understanding contemporary mountain geomorphology, and paraglacial hazards are those that will dominate mountain settings in the next decades to centuries (Knight and Harrison, 2009b).

PERCEPTION OF NATURAL HAZARDS AND DISASTERS

Jaroslaw Dzialek
Jagiellonian University, Krakow, Poland

Definition

Perception of natural hazards and disasters involves intuitive judgments, beliefs, and attitudes adopted by individuals and groups of people about the likelihood of occurrence and course and mechanisms of development of such phenomena. The subjective nature of the understanding of natural hazards influences people's decisions.

Discussion

Risk perception is influenced by many factors, which are, firstly, related to the nature of the hazard itself, and, secondly, to psychological, social, and cultural components and their mutual interactions. In the case of natural hazards, risk perception analysis has to take into account that they vary immensely from sudden events such as flash floods, avalanches, or earthquakes to long lasting phenomena such as heat waves or droughts. Most comparative studies focus on human-induced dangers, whereas risk perception of natural hazards has been researched less often. It is somehow consistent with the fact, that people are usually much less concerned about natural hazards when compared to other health, safety,

environmental, or social risks (Fischer et al., 1991), and that technological threats are often perceived as more dreadful than natural ones (Wachinger and Renn, 2010).

The way an average person perceives and understands natural hazards and disasters is different from that of an expert who uses scientific methods to assess the risks involved (Smith, 2001). A non-expert's knowledge about the natural environment tends to be limited, fragmentary, and uncertain (Slovic, 2000). It must be noted though that over time some indigenous populations inhabiting an area for many generations have gathered valuable knowledge to cope with disasters (Shaw et al., 2008), with an interesting example of the Solomon Islands, where immigrant populations have suffered much higher losses during 2007 tsunami than indigenous inhabitants living in the same areas (McAdoo et al., 2009).

The study of human perception of natural hazards and disasters can bring significant benefits for disaster mitigation policies because people's behavior is largely dependent on their perceptions. Individuals rely on their beliefs, which tend to differ from objective knowledge, in making decisions in the real world, including making choices where to settle, taking measures to prevent a disaster, taking out insurance and determining their behavior during the course of a disaster such as whether to evacuate. The ubiquitous subjective element is there even if an objective risk assessment is undertaken. For this reason it is important to understand factors that bias human perception of such phenomena towards underestimating or overestimating them. Based on this information, risk communication strategies can be devised between experts and non-experts that will bring the beliefs of the latter to the results of the former (Tobin and Burrel, 1997; Smith, 2001).

Experts and non-experts assess similar components of the natural environment, but their outcomes may differ. Both have to answer the same set of questions: (1) Is a certain phenomenon possible at all in a given area? (2) What is the likelihood of an occurrence within the person's lifetime? (3) What might be the scale of the phenomenon? (4) What casualties and damage can it cause? (5) How can one prepare for such an event? An important part of an individual's perception process is understanding how natural phenomena develop and, consequently, how they can be prevented or mitigated.

While assessing a threat some people may tend to overestimate it, whereas others may be prone to underestimate it. Social amplification and attenuation of risk perception are two concepts that try to explain how the initial risk is altered through social interactions in the risk communication process (Wachinger and Renn, 2010). K. Smith (2001, p. 72) and V. Covello (1991, p. 112) presented sets of factors increasing or decreasing the perception of risk associated with various hazards, including environmental hazards. People tend to be more concerned with hazards that produce an immediate and direct impact and involve numerous fatalities in a short span of time and space. According to this view, when considering only natural hazards, people may be less concerned with, for example, a drought, the effects of which are delayed and spread over large areas, than with an earthquake, which can cause catastrophic damage within a limited area. People also tend to be more anxious about phenomena whose origin they understand less (e.g., tsunami), or those that are more complicated (e.g., earthquakes), or that seem less controllable (e.g., hurricanes). Both authors point to the role of the media, which may stoke the sense of danger by increasing attention even if the objective likelihood of an event is relatively low.

Individual perception of hazards is mostly based on past experience. Familiarity with a disaster is one of the very few strong predictors for higher awareness of the possible danger (Wachinger and Renn, 2010). Many case studies show that people who have experienced a certain phenomenon are more likely to take action to mitigate future hazards (Smith, 2001). Some of this attitude may be down to what is known as the crisis effect where preventive activity is intensive immediately after a disaster, but soon dwindles and gives way to a daily routine (Bell et al., 2005). Attitudes may also differ between communities affected by a disaster depending on the nature of the event. For example in areas where minor floods are a frequent experience, people tend to prepare themselves, whereas in areas affected by a single catastrophic flood it may be perceived as something extraordinary and will not contribute to increasing a local community's resourcefulness (Tobin and Burrel, 1997; Biernacki et al., 2008). That was the case of those sites in Germany affected by a "100-year flood," where people believed that a similar event would not be possible during next 100 years, or during their lifetime (Renn, 2008). Other personal factors such as age, gender, or education level are usually tested as less important or insignificant in influencing risk perception of natural hazards (Wachinger and Renn, 2010). However, gender perspective is one of the most promising research areas as women generally rate various risks as more serious than men do (Finucane et al., 2000; Gustafson, 1998).

Some limitations of human risk perception are related to psychological mechanisms. Natural disasters may cause unpleasant feelings of anxiety and a lack of a sense of security. For this reason each individual's emotional and psychological traits have an impact on their perception. This may lead to an effect known as cognitive dissonance whereby a person is confronted by information that undermines the integrity of their beliefs about the world and causes an inner tension. An example of such cost-benefit consideration would be a strong attachment to a home that is located in a hazard zone. Rather than taking preventive action or even moving out, the predominant response to this situation observed in people is a denial of the threat and refraining from taking any active measures.

Past experience may be modified by another psychological phenomenon describing people's beliefs about what causes good and bad events in their lives and is known as the locus of control (Bell et al., 2005). People

with an external locus of control perceive natural disasters as divine retribution or ill fate, whereas individuals with an internal locus of control will tend to take personal responsibility for such events. The former group will have a sense of hopelessness leading to a fatalistic attitude and a complete lack of preparation, despite their past experience of a natural disaster (Tobin and Burrel, 1997; Lin et al., 2008). The latter, on the other hand, espouse a belief that damage and harm can be prevented by active measures (McClure et al., 1999).

When a direct personal experience is not available people have to rely on indirect sources, such as media reports or their previous education. In the case of the media, their potential to contribute to a misperception of a risk mentioned above stems from a certain bias since they normally tend to focus on the news, which increases the sense of anxiety and threat. However, there is no evidence that media shape opinions. On the contrary, people tend to select elements from media coverage that are consistent with their beliefs and confirm them (Breakwell, 2007). Risk communication and risk education policies in the area of natural hazards are more and more often developed and implemented in many countries to exchange information, knowledge, and opinions between risk managers and those who may be affected by the disasters.

Different types of communities, such as rural and urban, may have different views of natural hazards. City-dwellers are further removed from the natural world and may have a lesser awareness of the hazards involved in it. They may also perceive these threats similarly to technology-related hazards, which in their view can be easily mitigated with technical means. Rural populations, on the other hand, may have a better awareness of natural threats because of their closer integration with the natural environment. Additionally, natural disasters may pose a considerable threat to their income if derived from agriculture or tourism, which would provide an additional stimulus to learn more about the topic (White, 1974; Bell et al., 2005).

The attitudes of individuals can, in general, be defined with regard to three aspects: knowledge, emotions, and actions. This can also be applied to attitudes toward natural disasters. The cognitive dimension involves knowledge (not always objective) and awareness of local hazards; the emotional aspect involves feelings (typically concern and anxiety); and finally the instrumental aspect defines actions taken in response to a potential natural disaster using the knowledge and feelings already gained. These are the elements of a decision making process in the context of a hazard in accordance to the perception-adjustment paradigm. An individual "(1) appraises the probability and magnitude of extreme events; (2) canvasses the range of possible alternative actions; (3) evaluates the consequences of selected actions; (4) chooses one or a combination of actions" (Burton et al., 1993, p. 101). A combination of the three dimensions produces various types of perception and behavior toward the perceived hazard (Raaijmakers et al., 2008):

- Ignorance when the local population is unaware of a threat and, therefore, develops no concern and takes no preventive actions
- Safety when the local population is aware of a threat, but regards its level as either low or acceptable and is, therefore, not concerned with the threat and makes no preparations for a disaster
- Risk reduction when a high level of awareness and concern produces the previously described mechanism of reducing the cognitive dissonance and denial of a disaster threat; the local population resigns from taking protective action or passes the responsibility on to the authorities
- Control when an aware population takes preventive action that helps reduce their concern

Smith (2001) proposes a different set of basic perceptions of natural hazards adopted by hazard perceivers:

- Determinate perception is demonstrated by people who, faced with a natural disaster, are trying to rationalize it and look for a pattern of occurrence of the phenomenon (e.g., how often it occurs). They will aim to expand technical measures of protection, which may lead them to be satisfied with their level of preparedness and give them a false sense of security that the hazard has been eliminated (Tobin and Burrel, 1997). This behavior is also known as the "levee effect" (Bell et al., 2005).
- Dissonant perception is typical of people who, when faced with a potential hazard, go into denial. In contrast to the previous type these people believe that previous disasters were exceptional and for this reason will rather not repeat themselves and certainly not within their lifetimes. This perception type represents a psychological adaptation strategy (Bell et al., 2005) to living in high-risk areas where, despite the presence of the hazard, people tend to care more about their daily matters than about phenomena that are largely out of their control (Tobin and Burrel, 1997).
- Probabilistic perception is typical of people who accept both the randomness and the likelihood of a natural disaster within their lifetime. Researchers point to the fact that a tendency to transfer the responsibility for dealing with the hazard on to government agencies and organizations is representative of this type of perception. Such people manifest attitudes typical for an external locus of control, that is, a fatalistic approach toward disasters as acts of God and resignation from preventive measures.

Summary

There are numerous factors influencing the perception of natural hazards and disasters, and these factors can be broken down into situational (physical and socioeconomic environment) and cognitive factors (psychological and attitudinal variables) (Tobin and Burrel, 1997). Perception studies should deal with the characteristics of the

phenomena and communities as proposed by G.F. White (1974): the magnitude and frequency of an event, recency and frequency of personal experience, significance of the hazard to income interest, and personality traits. The range of variables that needs to be taken into account is large and, unfortunately, "their modeling has proved somewhat elusive in that particular variables can sometimes have different effects under different situations" (Tobin and Burrel, 1997, p. 164). Researchers are still looking for increasingly detailed explanatory models for the human perception of natural threats within existing theoretical frameworks.

PERMAFROST

Julian B. Murton
University of Sussex, Brighton, UK

Definition

Permafrost. Permafrost is ground that remains at or below 0°C for 2 years or more.

Active layer. The active layer represents the upper layer of ground subject to annual freezing and thawing in areas underlain by permafrost. The base of the active layer occurs at the depth of maximum seasonal penetration of the 0°C isotherm into the ground.

Ground ice. Ground ice denotes all types of ice contained in freezing and frozen ground.

Thermokarst. Thermokarst denotes the processes, landforms, and sediments associated with ablation – usually by thawing – of ice-rich permafrost.

Yedoma deposits. Ice-rich silts that contain on average 2–5% carbon by weight – often in the form of grass rootlets – that form a layer commonly 10–40-m thick. They underlie a region of more than 1 million km^2, mostly in central and northern Siberia. They represent the buried relict soils of the mammoth steppe-tundra ecosystem that formed during Pleistocene glacial periods.

Introduction

Permafrost on the Earth's crust forms a layer or isolated bodies that range in thickness from centimeters to ~1,500 m, and in temperature from 0°C to about −20°C. In the Northern Hemisphere, the permafrost region occupies up to ~23 × 10^6 km^2 (~24%) of the exposed land area (Zhang et al. 2008). Within this region, permafrost is classified in terms of its spatial extent, varying – in a transect from colder northern areas to warmer southern areas – from *continuous* (where it underlies 90–100% of the land surface), through discontinuous (50–90%), to sporadic (10–50%) or isolated (0–10%).

As a result, the actual area of exposed land in the Northern Hemisphere that is underlain by permafrost is significantly smaller than that of the overall permafrost region, and it is estimated to be ~12 × 10^6 km^2 to 17 × 10^6 km^2 (~13–18%) (Zhang et al. 2000). Geographically, permafrost can be classified into four main types:

1. *Polar permafrost* (e.g., in Arctic and Subarctic lowlands)
2. *Mountain permafrost* (e.g., in the Rocky Mountains of Canada and the USA)
3. *Plateau or montane permafrost* (e.g., the Qinghai-Xizang Plateau of China)
4. *Subsea permafrost* (e.g., within the continental shelves of the Beaufort, Laptev, and East Siberian Seas) (French 2007)

Climatically, permafrost is either in equilibrium with current atmospheric and environmental conditions, or it is adjusting to them. Much of the polar and subsea permafrost in the Arctic developed during glacial periods of the Pleistocene, when climate tended to be colder than present and lower sea levels exposed large areas of continental shelves to atmospheric conditions. Today, such old (relict) permafrost tends to be in various stages of warming or thawing, with some decoupled from the atmosphere by a deepening (residual) thaw layer above the degrading permafrost. A second period of permafrost growth has occurred in the last ~100–200 years, after the Little Ice Age. Such young permafrost is currently forming where sediments are freshly deposited in the Arctic deltas of rivers such as the Lena and Mackenzie, or where lakes drain and the thawed sediments beneath them become directly exposed to cold air temperatures.

Ground ice and carbon

Permafrost often contains ground ice and is a globally significant store of carbon. The ground ice varies from ice cements and ice lenses or veins to bodies of massive ice, meters thick and hundreds of meters or more in lateral extent (Mackay 1972; Murton and French 1994). The ice is often concentrated in the upper few meters of permafrost developed in silt-clay soils (Shur et al. 2005) and fine-grained porous bedrocks (Murton et al. 2006), forming a widespread ice-rich layer in Arctic regions that is susceptible to thaw-related disturbance. The total volume of ground ice in the Northern Hemisphere is estimated at ~11 × 10^3 km^3 to 35 × 10^3 km^3, equivalent to ~3–9 cm of sea-level rise (Zhang et al. 2000). These authors estimate that the area of ice-rich permafrost – ground-ice content >20% by volume – is between ~1.3 × 10^6 km^2 and ~1.6 × 10^6 km^2. The age of the ground ice varies from a few years to perhaps >740,000 years (Froese et al. 2008).

The carbon is stored mainly in Cryosols (permafrost-affected soils), yedoma deposits, and deltaic deposits, primarily in Arctic and Subarctic lowlands. The Cryosols comprise both organic soils (peatlands) and cryoturbated (i.e., frost-churned) mineral soils (Kimble 2004; Margesin 2009). Cryosols are estimated to contain ~1,024 PgC [1 petagram ≡ 1 gigatonne] at a depth of 0–3 m, whereas at depths greater than 3 m, yedoma deposits are estimated to contain 407 PgC, and deltaic deposits 241 PgC (Tarnocai et al. 2009). This gives a total below-ground carbon pool in permafrost regions of ~1,672 PgC, of which 1,466 Pg occurs in perennially frozen soils and deposits. This 1,672 Pg pool of organic carbon is more than double the current amount of carbon in the atmosphere (~730 PgC), about half of the estimated global below-ground carbon pool, and more than three times greater than the total global forest biomass (~450 PgC) (Kuhry et al. 2009). Less is known about the size and distribution of the N pool in permafrost regions, although it is likely that substantial quantities are stored in permafrost peatlands (Repo et al. 2009) and other C-rich deposits.

Organic carbon accumulates in permafrost regions because cold temperatures and impeded drainage retard decomposition of plant materials, and cryoturbation moves some of this carbon into deeper and colder soil layers (Tarnocai 2009). In addition, upward growth of permafrost – as occurs in accumulating peatlands or in steppe-tundra episodically buried by windblown or alluvial sediments (Zimov et al. 2006) – freezes and preserves the carbon. In effect, the permafrost acts as a giant freezer that stores old carbon and nitrogen, sometimes for tens of thousands of years. The freezer, however, is vulnerable to permafrost thaw.

Permafrost thaw and C/N release

As permafrost is a product of climate (Burn 2007), the ice, C, and N within it are sensitive to climate or microclimate change. Thaw of ice-rich permafrost (thermokarst) results from a variety of factors, ranging from regional climate warming to site-specific disturbances (Mackay 1970; Murton 2009). In turn, a variety of permafrost-related hazards arise (Table 1). Of these, the most significant global hazard is that of climate warming and C/N release to the atmosphere. Local and regional permafrost-related hazards are reviewed by Davis (2001), French (2007), and Whiteman (2011).

Current warming and thawing of permafrost soils (ACIA 2004) results in increased rates of microbial decomposition of organic carbon and subsequent release of carbon dioxide or methane. Carbon dioxide tends to be released where the soils are affected by drying, whereas methane release is favored by wet, anaerobic conditions. Methane is also released from thawing yedoma deposits near the edges of growing thaw lakes. In North Siberia, methane bubbling in thaw lakes is estimated to emit ~3.8 teragrams (0.0038 Pg) of methane per year, and lake expansion during the last quarter of the twentieth century increased methane emission by ~58% (Walter et al. 2006). The Pleistocene age of this methane indicates that old carbon previously stored in permafrost is now being released to the atmosphere, where it constitutes

Permafrost, Table 1 Permafrost-related hazards

Scale	Hazard	Example
Global	Carbon release	Thaw of the permafrost carbon pool
		Thaw of permafrost associated with methane hydrates
Local to regional	Thaw subsidence	Subsidence of pipelines, roads, buildings built on ice-rich soil or bedrock
		Land-surface collapse
		Initiation and growth of thaw lakes
		Drowning of forest and conversion to wetland
	Mass movement	Enhanced rockfalls and landslide activity during thaw of ice-rich mountain permafrost
		Enhanced solifluction, active-layer detachment, and thaw slumping during degradation of ice-rich soil
		Bog bursts and mass flows
	Reduced ice strength	Reduced adfreeze strength (bonding) and bearing capacity between piles and surrounding ice as permafrost warms
		Increased velocity of rock glaciers as permafrost warms and ice weakens
	Frost heave	Enhanced frost heave as wet, silty active layers thicken during permafrost thaw
		Enhanced frost heave when chilled gas pipelines are buried in unfrozen ground in discontinuous permafrost terrain
	Erosion	Enhanced erosion as ground ice thaws within bluffs along sea coasts, lakes, and rivers
	Water supply	Contamination of water above permafrost

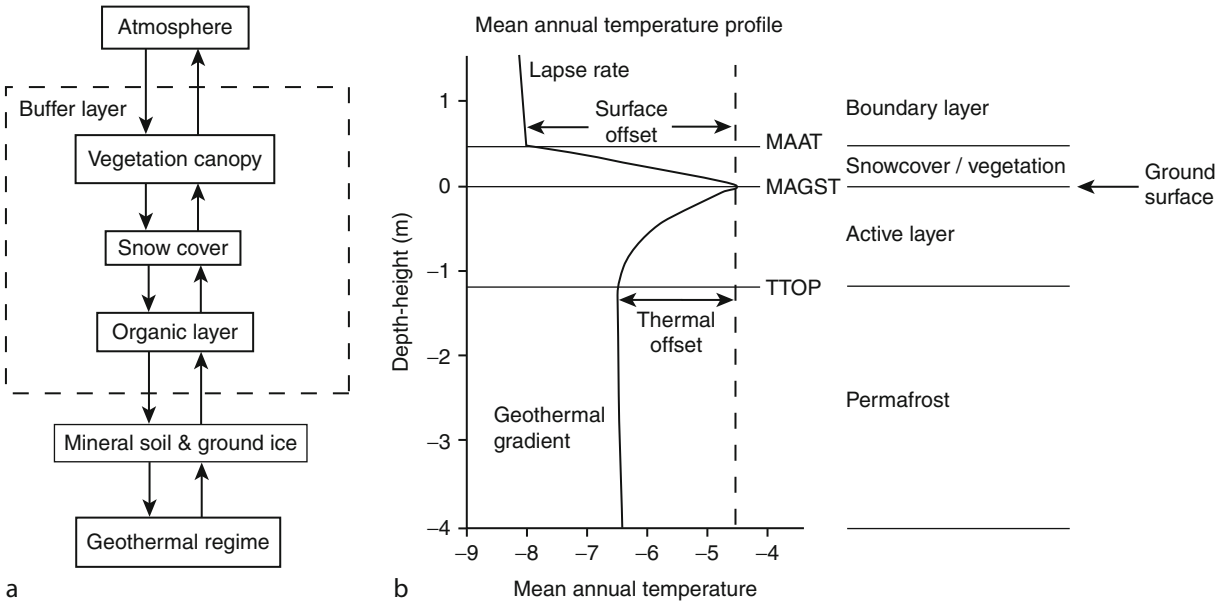
a powerful positive feedback to high-latitude climate warming. Methane bubbling associated with development of thaw lakes may also have contributed significantly to global warming during the Pleistocene-Holocene transition (Walter et al. 2007). N_2O emissions from unvegetated areas of subarctic peaty tundra (Repo et al. 2009) and thawing permafrost (Elberling et al. 2010) may also contribute to atmospheric greenhouse gas (GHG) concentrations, although as yet few data are available on the fluxes and sources.

The strength of the feedback between permafrost C/N and climate change depends on both the amount of organic C/N stored in permafrost and on the rate of C/N release to the atmosphere (Schuur et al. 2008). The rate of release in turn depends on the balance between (a) increased uptake of atmospheric C by enhanced plant growth and (b) increased loss of old permafrost C by increased microbial decomposition (Mack et al. 2004). Consistent with the inferred positive feedback effect, one recent study from an upland thermokarst site in Alaska found that ~15 years after permafrost thaw began, losses of old soil C began to offset increased C uptake by shrubby plants, with the result that this study area became a net source of C to the atmosphere (Schuur et al. 2009). Further studies from other permafrost regions, however, are now needed to quantify the mass balance between C/N in permafrost and the atmosphere. In particular, it is timely and important to focus such studies on C/N-thermokarst terrains that are likely to be hotspots of GHG generation in a warming world.

Thermokarst activity and global warming

Global warming is one of many factors that initiate thermokarst activity. But it is undoubtedly a key factor, based on the abundant evidence in the geological record for pan-Arctic thermokarst activity during the Last Glacial-to-Interglacial Transition (Murton 2001) and the signs of intensifying thermokarst activity in recent decades.

Last 100–150 years: Thermokarst activity during the last 100–150 years has undoubtedly spread and intensified, although not all of it can be attributed to global warming. One of the clearest examples where climate warming has exacerbated thermokarst is an abrupt increase in ice-wedge melting since 1982 in continuous permafrost of northern Alaska (Jorgenson et al. 2006). The melting probably resulted from record high summer temperatures between 1989 and 1998, and was initiated by extreme hot and wet summer weather in 1989, leading to unusually deep thaw of the active layer. This thermokarst activity coincided with a 2–5°C increase in mean annual ground temperature, partially melting ice wedges that had previously been stable for thousands of years.



Farther south, in the warm discontinuous permafrost of Subarctic regions, increased thermokarst activity has taken place since the Little Ice Age (Jorgenson and Osterkamp 2005), but the causes are complex. For example, thermokarst activity in the Tanana Flats, central Alaska, has transformed large area of birch forest into fens and bogs (Jorgenson et al. 2001). Thermokarst here probably began in the mid-1700s, associated with climate warming. But thermokarst activity during the succeeding ~250 years has been enhanced in part by (1) convective heat transfer by movement of relatively warm (2–4°C year-round) groundwater through the fens and underlying outwash gravel, (2) fires, and (3) increased snow depths. Isolating the influence of fire, snow, and climate warming is difficult because an increase in fire frequency may correlate with an increase in summer temperatures (Jorgenson and Osterkamp 2005), and because warmer winter temperatures may correlate with increased snowfall and therefore warmer mean annual ground temperatures (cf. Osterkamp 2007).

In western Siberia, climate warming since the early 1970s is thought to have driven thermokarst activity in two different ways (Smith et al. 2005). In the continuous permafrost zone, the number of lakes has increased substantially, whereas in discontinuous, isolated, and sporadic permafrost zones, it has decreased. This disparity supports a conceptual model in which initial warming of cold, continuous permafrost favors thermokarst activity and lake expansion, followed by lake drainage as permafrost degrades further. In central Siberia, increases in mean annual air temperature and summer air temperatures between 1992 and 2001 at Yakutsk have coincided with (1) thermokarst subsidence beneath stable inter-alas meadows and (2) flooding of young thermokarst basins, enhancing thermokarst activity at a nearby permafrost monitoring site (Fedorov and Konstantinov 2003).

Next 100–150 years: With climate warming predicted to continue during the next century, amplified in Arctic and Subarctic regions (ACIA 2004), thermokarst activity will generally spread and intensify still more. Thawing of permafrost is projected to be concentrated in the current discontinuous permafrost zone during the next 100 years (Delisle 2007). This is of particular concern in Subarctic Alaska, where ~40% of the area may be susceptible to thermokarst (Jorgenson et al. 2007). Thus global warming at high latitudes is putting large areas of ice-rich permafrost at risk of thermokarst subsidence and related disturbances (Nelson et al. 2001). Although projected climate warming in the Twenty-first Century will lead to deeper ground thaw in many permafrost regions, its impacts will be modulated by site-specific conditions. For example, peat and vegetation cover may buffer permafrost from severe degradation, whereas local disturbance of the ground cover or fires in the boreal forest or tundra may accelerate permafrost thaw (Yi et al. 2007). Thus caution is needed in generalizing between projected changes in atmospheric climate and permafrost responses, and modeling of projected responses must consider a buffer layer between the atmosphere and the permafrost.

Buffer layer

A buffer layer of vegetation, snow, and organic material thermally modulates the coupling between atmospheric and permafrost temperatures (Figure 1a). As a result, air temperatures are often offset from ground surface and permafrost temperatures by a few to several degrees °C (Figure 1b). As the buffer layer changes seasonally – for example, with leaf growth in summer, snowfall in winter, and year-round changes in the moisture content of the organic layer – its thermal properties (e.g., albedo, thermal conductivity, latent heat) change. In turn, this alters the surface energy exchanges and ground temperatures. Thus it is essential for permafrost models to parameterize the seasonal contrasts in the different components of the buffer layer. Additionally, models must consider ground ice within permafrost beneath the buffer layer (Figure 1a), because the high latent heat effects of the ice retard permafrost thaw.

Permafrost, Figure 1 Atmosphere-ground thermal coupling in permafrost regions. PIEZOMETER

Sylvi Haldorsen
Norwegian University of Life Sciences, Aas, Norway

Synonyms

Standpipe piezometer; Pneumatic piezometer; Vibrating wire piezometer

Definition

A piezometer is a piece of equipment installed to measure the hydraulic head (pore pressure) in a groundwater aquifer.

Discussion

In an unconfined aquifer the measured hydraulic head is equal to the groundwater level (elevation head) and in a confined aquifer the total hydraulic head is equal to the elevation head plus the pressure head (Fetter, 2001). The piezometers define the hydraulic head at the specific site where it is installed. A number of different piezometers are applied, and the following are the most common:

Standpipe piezometers are cased tube wells with a limited diameter. There is a short screen or only a short slotted section at the lower end of the casing. The tube above the filter acts as a riser pipe. The water level in the riser pipe defines the hydraulic head, and is commonly measured manually. This simple instrument is inexpensive and does not depend on electronic installations.

Pneumatic piezometers record the pore pressure automatically by a pneumatic filter tip. Via a cable, the record is transferred to a pneumatic reader, which may be connected to a readout unit or a data logger. The filter tip may be installed inside a cased tube well or at the end of a separate fitted tube. A pneumatic piezometer facilitates continuous readings and makes readings from remote locations possible.

Vibrating wire piezometers record the hydraulic head by a vibrating wire pressure transducer and signal cable. The wire pressure transducer is commonly installed in a cased tube well. The readings are recorded by a portable readout or a data logger.

Measuring water level underground is an important source of information in hazards studies, especially those involved with landslide monitoring and evaluation.

PIPING HAZARD

Michael James Crozier[1], Nick Preston[1], Thomas Glade[2]
[1]Victoria University of Wellington, Wellington, New Zealand
[2]University of Vienna, Vienna, Austria

Synonyms

Sapping; Seepage Erosion; Tunneling

Definition

Piping and tunneling represent distinct subsurface, linear erosion mechanisms but they are often functionally indistinguishable and generally grouped under the process term *piping* (Bryan, 2000).

Discussion

Essentially *true piping* (referred to as *seepage erosion*, by Dunne (1990)) involves the localized dislodgment and ejection of particles at an outlet in response to seepage forces produced by a positive water potential and high hydraulic gradient, leading to erosion and headward development of a conduit. By contrast, *tunneling* exploits existing macropores such as cracks and root channels, and involves hydraulic entrainment forces and hence is referred to by Dunne (1990) as *tunnel scour*. Both processes may operate in subsurface conduits and the consequent undermining effect and extension of the cavity is referred to as *sapping*.

The criteria for pipe and tunnel development include: a pathway for water entry and concentration of subsurface flow (e.g., cracks, root channels, animal burrows, and other macropores), a decrease in permeability with depth that promotes slope parallel subsurface flow, the presence of erodible material (especially silts and fine sand), space for eroded material to be evacuated (coarse porous

material or an outlet from the slope), and a water supply under positive water potential and high hydraulic gradient. Susceptibility to piping in some regions has also been linked to soil and soil water chemistry.

The development of pipes in an area enhances slope drainage, increases runoff coefficients, decreases concentration time (Anderson and Burt, 1990), limits soil water storage, and consequently increases peak flow during storm events (Jones, 1990).

Pipes may develop into gully systems as a result of conduit enlargement and roof collapse (for a benchmark paper on this process see Laffan and Cutler (1977)) and hence further accelerate storm runoff, leading to localized flooding. Piping and gully development can occur within the space of a few days to years and, as a result, buildings initially thought to be in safe locations can experience flash flooding during storm rainfall. The development of pipes can also affect buildings by undermining foundations and removing structural support, through tunnel enlargement and tunnel roof collapse.

Resistance to landsliding can be affected by piping, through removal of underlying support and changes to subsurface water flow. Although pipes can stabilize slopes through rapid drainage, pipe blockage can allow localized build up of pore water pressures and significantly lower slope resistance (Hardenbicker and Crozier, 2002).

Piping represents a serious potential hazard to dams, particularly earth dams, in some cases leading to serious dam failure (UNEP, 2001). Initiation of pipes can be caused through development of stress cracks but more commonly as a result of the nature of fill material and the integrity of contact between fill and foundations or other structures. A well-known example of the destructive effect of piping is the Teton dam failure, June 5, 1976, which killed 14 people and resulted in millions of dollars of property damage downstream (Independent panel, 1976).

PLANNING MEASURES AND POLITICAL ASPECTS

Brian R. Marker
London, UK

Definitions

Government consists of the bodies (international, national, regional, and local) responsible for administering a state or area including developing policies for, and the regulation of, human activities and resolution of potential disputes between activities and interest groups. The term also applies to the processes of securing outcomes through legislation, regulation, guidance, the coordination of actions, and enforcement of provisions to meet policy objectives.

Land-use planning is the process of identifying the suitability of land for particular uses, setting out policies for land use and determining planning applications in accordance with those policies.

Spatial planning extends the principles of land-use planning by taking account of a full range of spatial factors whether social, economic, or environmental, in order to secure sustainable development.

Emergency planning is the process of identifying potential hazards, coordinating response systems and preparing, practicing and promulgating plans for dealing with the effects of these.

Environmental impact assessment is the process of assembling and interpreting the environmental information that is pertinent to the potential impacts of a proposed development that is considered likely to cause significant adverse environmental effects and to set out

proposals for mitigation of these. The results are presented in an environmental statement.

Sustainability appraisal is a process of assembling the social, economic, and environmental information that is pertinent to assessing the acceptability of alternative policy options intended to secure sustainable development.

Strategic environmental assessment is a process of assembling the environmental information that is pertinent to assessing the acceptability of alternative proposed policy options for sustainable development and forms part of sustainability appraisal.

Introduction

This entry is necessarily generalized because of the great variety of circumstances around the World; but some general principles relevant to natural hazards can be summarized.

Political systems vary from place to place, and time to time, from democratic to centralist and, therefore, from extensive to limited public participation in political, policy, and decision making processes. They also vary in transparency and application. Cultural and other diversity issues also influence actions and outcomes. In general, the scale and complexity of problems is such that the political focus tends to be on current key issues and imperatives rather than all factors that should be taken into account when formulating policies and making decisions. The tendency is to identify short-term tactical "solutions" rather than undertaking strategic actions for the longer term especially where financial resources are limited and governance structures are weak. The result, in relation to natural hazards, is often to carry out work after damaging events rather than taking advance precautions to minimize adverse impacts. The results are higher levels of deaths, injuries, and economic losses than might be the case if societies are, as far as possible, adequately protected and prepared.

Understanding of potential hazards

Most of the World's major populated areas are subject to at least one or two natural hazards and some to several. There is often a lack of widespread appreciation of the potential for these unless damaging events occur frequently. Precautions are not taken unless potential is recognized but all too often precautions are not taken even though the potential has been recognized. Logically, all populated areas should be evaluated for locations, nature, mechanisms, and frequency of all significant potential hazards so that planning and management decisions can be made on an informed basis. In practice, that is often not done until after a damaging event has occurred. If at all, consideration is usually limited to the type of event that has taken place rather than the fuller range of potential hazards. This is partly because of a lack of awareness of potential hazards amongst administrators and decision makers and also because other calls on resources are perceived to be of greater priority. Even where hazards have been identified, problems arise if systems are not developed to provide adequate responses and there is insufficient awareness of provisions.

Government and governance

Government essentially provides the conditions and circumstances required for economic growth, social improvement, and environmental protection and enhancement. Potential conflicts between these aspects are addressed through attempts to secure sustainable development – delivering social, economic, and environmental policies with the least adverse effects for present and future generations (WCED and Commission for the Future, 1987). The extent to which this is done depends on the situation of the nation concerned. In a wealthy developed country it is possible to devote land and resources to environmental protection but in a poor developing country the emphasis is understandably on the immediate economic and social survival of the population. While there is some redistribution of wealth from rich to less rich countries through international aid, this often relates to development of infrastructure, notably water supply, and to health improvement, rather than disaster preparedness and precautionary measures. Also some aid does not reach its intended targets due to inefficiency or corruption.

Governance operates at several levels – international (e.g., the European Union), national, regional, and local. Systems exist at each level for politicians to formulate policies with advice from government officials such as civil servants, and for decision makers to determine planning applications having regard to those policies. All necessarily engage with other sections of society such as industry, commerce, nongovernmental organizations, and the general public. But structures for communication, debate, exchange of ideas and education need to be robust if sound and effective actions are to be secured.

Responsible authorities, at all levels, set out policies that decision makers and other members of society are expected to observe. Implementation depends on legislation to control the development, application of policies and procedures, and behavior of institutions and populations. It provides that certain things must be done at the risk of penalties that are imposed by government bodies or through the legal system. Legislation is usually pitched at a general level with more detailed aspects being contained in secondary regulations that are often administered by government agencies, such as environmental protection agencies, rather than government departments. In addition to the body of law, rights are due, to a greater or lesser extent, to citizens and interest groups. These range from the Universal Declaration of Human Rights, to those of owners of land and property and, in some countries, to the rights of indigenous peoples. Redress for infringements of rights can usually be sought through independent courts. The complexity of systems makes it difficult to secure optimum outcomes. For example, different government departments, levels of government and government agencies have different aims and objectives to meet as

do nongovernmental interest groups. Effective debate and coordination is essential if issues are to be address in a balanced and proportionate manner.

The role of politicians depends on the nature of the political system. Where they are subject to election they must understand public aspirations and persuade people to support their policies. In less democratic systems, the public has no option but to follow government policies but may do so in a half-hearted manner if they are not content with these. In both types of system, however, politicians need to engage with and agree policies with their colleagues and supporters (Hamilton, 2000). But the extent to which those policies are implemented by regulators, decision makers, and the public is also variable.

It has to be accepted that geoscience issues, including hazards, are not key concerns of many politicians, decision makers or the public, until specific damaging events occur. They have to be persuaded to take note. When disaster strikes there may be may be promises about assistance and better future planning and construction and, sometimes, a short-term increase in resources that can detract from preparations for dealing with other relevant hazards. But often the promised aid and planning measures are not implemented (Lewis and Mioch, 2005).

Communication

If natural hazards are to be addressed adequately by politicians, administrators, the media and the public, sound communication with hazard specialists is needed. It is essential to secure adequate attention, resources, and actions before damaging events occur. This is not easy due to a widespread lack of appreciation of the technical issues and because these are often not expressed in terms that can be widely understood. Among many nonscientists there is a weak appreciation of scientific method and of concepts such as hazard, vulnerability, risk, frequency, uncertainty, and probability. Necessary scientific caution may be misinterpreted as meaning that predictions have little value. So can inability to indicate exactly when and where the next damaging event may occur. Also any warning that is not followed by an actual event may cause a loss of confidence. Poor communication can cause under or over-reactions leading to unnecessarily restrictive or excessively lax policies, unwise investment, financial losses, or failure to react. Therefore information is not necessarily received gladly particularly if it raises concerns about hazards and possible associated costs and impacts asset values. It is also difficult to convince stakeholders that hazard and risk assessment needs to be repeated at intervals because of environmental, social, and economic changes.

Overall, scientific conclusions need to be carefully and clearly framed in plain language and dissemination of information needs to be carefully planned and handled. But this is not a one way process. Hazard specialists need to understand: the complexity of administrative structures and procedures; interactions with and between different levels of administration, the wider public and the media; and when and how best to engage with these. They also need to be comfortable collaborating with other relevant disciplines, including sociologists and economists, when addressing hazards (Forster and Freeborough, 2006; Liverman et al., 2008).

Spatial and land-use planning

It is prudent, where possible, to direct development toward the least vulnerable locations. Spatial and land-use planning are systems that control the use of land in the public interest. Developed and many developing countries have systems for regulating the use of land involving the definition of what types of development and conservation might be appropriate in particular locations. Policies are expressed in some form of development planning document. In some systems development plan policies are mandatory – they have to be observed – whereas in others provisions are discretionary – they should be observed unless there are good reasons to do otherwise. Commonly guidance is issued to explain how provisions should be applied but, even so, discretionary responses can be misjudged. Development plan documents provide the opportunity for ensuring that development is undertaken prudently but a key problem is that much existing development is already vulnerable to natural hazards and it is simply impractical to move large settlements to other locations. Also, after damaging events, people usually look to governments to redevelop in the same familiar location, even though they might be safer elsewhere. The extent to which planning policies are complied with depends on the effectiveness of enforcement by the responsible authorities. Enforcement is strong in some countries but weak in others (Greiving and Fleischhauer, 2006; Stallworthy, 2002; Allmendinger, 2009). Spatial and land-use planning therefore play an important part in addressing potential natural hazards (Schmidt-Thomé, 2006) but must be accompanied by appropriate emergency planning procedures.

Evaluation of policy options and development proposals

Policy options are now widely subjected to sustainability appraisal: evaluation of policy options in terms of sustainable development – the economic, social, and environmental implications – to secure the option that will not have unacceptable adverse effects for present and future generations. Within this overall process rests strategic environmental assessment: the process of evaluating the environmental implications of policies and plans (Jones et al., 2005; Helming et al., 2008; Tang, 2008).

Developments that are likely to have adverse environmental effects are widely subjected to environmental impact assessment (EIA). Assessments address the implications of the development for the environment in detail but are often less thorough in considering how the environment might impact on the development. For most significant developments, whether an EIA is required or not, site investigations are required. The results are taken into account, alongside other factors, when determining

planning applications or considering legislation for major infrastructure developments that may fall outside planning systems (Therival et al., 2005; Morris and Therival, 2009).

Site investigations should take full account of natural hazards but there can be a tendency to focus on the characteristics within the site rather than the broader regional context (Weltman and Head, 1983; ASCE, 1996). When an EIA or site investigation is undertaken planning authorities may not be fully equipped to evaluate the quality of the work or the findings, sometimes leading to poor decisions, unless they have access to independent experts.

Emergency planning

When dealing with disasters it is essential to be well prepared with resilient systems and plans. Emergency planning involves preparation of effective responses to likely emergencies, natural and man-made, through civil contingencies procedures. It requires identification of key roles and responsibilities of government, at all levels, emergency services (police, fire, medical, military), utilities and NGOs, as well as public education, assessment of the vulnerability of key services to specific hazards, and training and exercises based on credible scenarios. Key aspects are securing communications and routes that can be kept open during emergencies, safe access to rescue equipment and to supplies and medicine, and, where possible, well understood warning systems (Sinha, 2006; Fleischhauer, 2008; Moore, 2008). The Hyogo Framework of Action was adopted by 168 Member States of the United Nations at the World Disaster Conference in 2005 (UN/ISDR, 2005) to improve performance on disaster reduction and preparedness over the period 2005–2015. This set out five priority actions:

- Ensure that disaster reduction is a national and local priority with a strong institutional basis for implementation.
- Identify, assess, and monitor disaster risks and enhance early warning.
- Use knowledge, innovation, and education to build a culture of safety and resilience at all levels.
- Reduce the underlying risk factors.
- Strengthen disaster preparedness for effective response at all levels.

Conclusions

If potential problems are properly understood and there is a political will to support and fund the necessary actions it is possible to significantly reduce the impacts of hazardous events through planning, coordination, and education. It is useful to consider steps in terms of "the disaster cycle": preparedness, disaster event, relief, restoration and rebuilding, and risk reduction.

Preparedness

Risk can be reduced by:

– Planning for development in the least vulnerable locations and using potentially more hazardous sites for open-space purposes (e.g., wildlife refuges, playing fields), low-density occupation, or space to accommodate effects of hazards (e.g., flood water storage).
– Ensuring, where possible, that precautionary and preventive works are undertaken prior to specific development.
– Ensuring that foundations, constructions, and infrastructure are designed and undertaken so as to minimize the risk of damage and failure.
– Evaluating the location and vulnerability of key services and infrastructure such as power and water supply, communications, access and evacuation roads, fire and police stations, hospitals, and military bases since all have a part to play in bringing aid.
– Ensuring access to supplies through storage or appropriate delivery arrangements that can be drawn on when an event occurs.
– Where appropriate, monitoring potential hazards to give early warning of impending events.
– Developing and practicing emergency responses and warning procedures so that the relevant agencies, including nongovernmental aid organizations, know what to do and are properly coordinated.
– Informing the public of the issue and increasing awareness of early warning signs of hazardous events and of the actions that they should take to minimize risks to themselves and others.

This requires good organization and adequate funding. These are often, but not always, available in developed countries, if the will and understanding is there, but are often uneven in developing countries. Also, the scale and frequency of potential hazards varies greatly. Some cannot be avoided or addressed through preventive work – for instance, a major volcanic eruption, earthquake, or tsunami. For these, adequate design of emergency and relief responses, and, if practicable, monitoring facilities are essential.

During and immediately after the hazard event

Following a hazardous event quick action is needed to:

– Implement search and rescue plans, ensure public security, and, as far as possible, stabilize structures and clear key access routes.
– Deploy national and international aid (food, water, medical supplies, temporary shelter) where it is most urgently needed and to place adequate medical care.

Restoration and rebuilding

As soon as possible thereafter, it is necessary to:

– Undertake remedial work on constructions and infrastructure where possible and to replace it where not.
– Implement plans for clearance and replacement of damaged constructions.

Risk reduction

It is important to learn from the event to identify necessary improvements to reduce future risk and, thus, preparedness. This requires consideration of matters such as:

- The effectiveness of emergency responses.
- The possible need for changes to building codes.
- Improvements to the resilience of infrastructure.
- Changes to land-use planning policies and practices.

However, depending on the severity of the event and the availability of finance and resources recovery may take years.

The development of effective responses requires hazard specialists to understand governance systems, to communicate effectively, and to work closely with experts from other disciplines, for instance, sociologists, economists, and professional communicators. The principal constraint, particularly in developing countries, is the capacity to respond in terms of funds and structures. There is a need for international aid to focus on developing the capacity to respond to emergencies as well as responding to current problems.

PLATE TECTONICS

John Ristau
GNS Science, Avalon, Lower Hutt, New Zealand

Definition

Tectonic Plate: a large slab of rock composed of part of the Earth's crust and upper mantle.

Plate Tectonics: theory which describes the history, motions, and tectonic activity of Earth's tectonic plates.

Introduction

Plate tectonics is a theory which describes the motions of the Earth's tectonic plates over the Earth's surface. The Earth consists of a thin outer shell of solid rock (the crust), a thick viscous layer (the mantle), a liquid outer core, and a solid inner core. The mantle is divided into two layers – a colder and more solid upper mantle and a hotter and more

liquid lower mantle. Together, the crust and upper mantle are called the *lithosphere* which can be thought of as floating on the lower mantle (the *asthenosphere*). The lithosphere is broken into large pieces ~100–200 km thick which make up the Earth's tectonic plates. The plates slowly drift and collide with, pull apart from, and slide past one another.

History

The history of the theory of plate tectonics provides an interesting and important example of a modern scientific revolution where a new theory replaces an existing theory due to the accumulation of new evidence which is not consistent with the existing theory. The history of plate tectonics essentially started in 1915 when Alfred Wegener argued that the fit of the coastlines of the continents, the distribution of coal and glacial deposits, and the distribution of flora and fauna suggested that the continents were once joined as a supercontinent and later drifted apart (*continental drift*). This directly opposed the accepted thinking that the positions of the continents were fixed. At the time, the idea was rejected for a number of reasons with one of the main problems being that there was no acceptable mechanism to explain how the continents moved.

Throughout the first half of the twentieth century, a vast amount of evidence in support of continental drift began to accumulate. Seismic data showed that the spatial distribution of earthquakes is not random but rather that earthquakes mainly occur in the vicinity of what are now known as plate boundaries. Earthquake sources were found to occur in dipping seismic zones around the Pacific, and studies of the transmission of seismic waves showed that the dipping zones were thick mantle slabs with high seismic velocities. These zones mark where one plate is pushing beneath another and led to the concept of *subduction zones*. Studies of the propagation of seismic waves gave important insights into the structure of the Earth's interior.

Paleomagnetism showed strip-like magnetic anomalies related to magnetic reversals along the ocean floor. These strips are offset symmetrically from mid-ocean ridges and increase in age with distance from the ridges with the youngest rocks always having the present-day magnetic polarity. Regular movement of the Earth's magnetic pole (*polar wander*) was found to be different in Europe and North America, suggesting that the two continents had moved relative to one another. The term "seafloor spreading" was introduced in the early 1960s as part of the explanation of how oceanic crust is formed at mid-ocean ridges by volcanic activity and gradually moves away from the ridge. The discoveries of spreading at mid-ocean ridges and subduction at plate boundaries complemented one another perfectly. The concept of upwelling of hot mantle material from the asthenosphere which pushes up through weak parts of the lithosphere provided the driving mechanism for plate tectonics.

By the end of the 1960s, the theory of plate tectonics became firmly established, replacing the fixist paradigm. Confirmation of plate tectonic theory continues through to the present day with modern Global Positioning System (GPS) measurements which measure the current movements of tectonic plates with centimeter scale precision. GPS measurements also show how the edges of the plates deform from collisions between plates while the plate interiors remain relatively undeformed.

How it works

There are three types of boundaries between plates:

1. Divergent boundaries where plates move away from one another
2. Convergent boundaries where plates collide with one another
3. Transform boundaries where plates slide past one another

Divergent boundaries are areas where new lithosphere is formed and provide the driving mechanism for plate tectonics. At places where the lithosphere is thin and weak, hot mantle material from the asthenosphere pushes up and through, forcing the lithosphere apart (Figure 1). It then cools, forming new lithosphere material. Divergent boundaries can occur at either thinner oceanic crust such as mid-ocean ridges, or at thicker continental crust such as the East African Rift Zone.

Convergent boundaries provide the complement to divergent boundaries and are areas where lithosphere material is recycled back into the mantle. Oceanic crust is denser than continental crust, and in regions where oceanic and continental plates collide, the oceanic plate

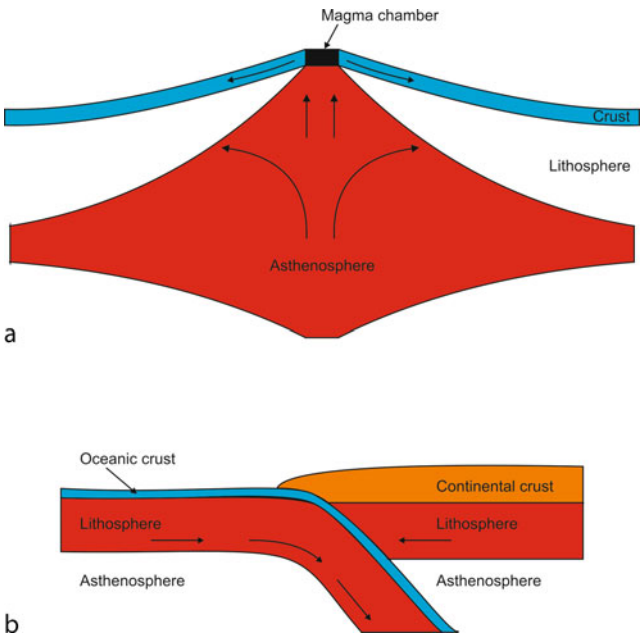

Plate Tectonics, Figure 1 (**a**) Divergent plate boundary formed by mantle material from the asthenosphere pushing through and forcing the lithosphere apart. (**b**) Convergent plate boundary where oceanic crust and lithosphere push beneath continental crust and lithosphere and down into the mantle.

pushes beneath the continental plate and down into the mantle (Figure 1). These areas are known as subduction zones. The world's largest earthquakes are those that occur on the boundary between the subducting and overriding plates such as the 1960 magnitude 9.5 Chilean earthquake or the more recent 2004 magnitude 9.3 Indian Ocean earthquake. The majority of subduction zones are along the boundaries of the Pacific and Indian Oceans and occur beneath the west coasts of North and South America, Japan, the Philippines, Taiwan, Indonesia, New Guinea, Fiji, and New Zealand. In areas where two continental plates collide, neither plate subducts, but instead the lithosphere thickens at the collision zone and has a major effect on topography. The primary example of continent-continent collision is the collision between the Indian and Eurasian plates which produced the Himalayas and the Tibetan Plateau.

Transform boundaries are areas where lithosphere is neither created nor destroyed. These are regions where one plate is sliding past another without convergence or divergence. Examples of transform boundaries include the San Andreas Fault in California and the Queen Charlotte Fault of the west coast of Canada where the Pacific Plate is sliding past the North American Plate, and the Alpine Fault in New Zealand where the Pacific Plate is sliding past the Australian Plate.

Outlook: present day

Over the history of the Earth, the tectonic plates have collided together, forming supercontinents, and moved apart several times. The last supercontinent was known as *Pangaea* which broke apart ~180 million years ago into two smaller supercontinents called *Gondwana* and *Laurasia*. These in turn broke apart into the present-day layout of tectonic plates. There are currently seven or eight major tectonic plates (depending on whether the Indian and Australian plates are considered one plate or separate plates) which cover most of the Earth's surface and a large number of minor plates (Figure 2). Many of the minor plates contribute significantly to seismic hazard in various countries, such as the Philippine plate for Japan, the Nazca plate for the west coast of South America, and the Juan de Fuca plate for the west coast of North America.

PORE-WATER PRESSURE*

Mark E. Reid
U.S. Geological Survey, Menlo Park, CA, USA

Synonyms

Pore pressure; Pore-fluid pressure; Pore-water stress

Definition

Pore-water pressure is the pressure (isotropic normal force per unit area) exerted by the fluid phase in a porous medium (soil or rock) composed of a solid framework and pores filled or partially filled with water or other fluid. Pore-water pressure is averaged over a representative elementary volume containing many pores, rather than an individual pore. SI units of measurement are N/m^2 or Pa (Pascals).

Discussion

Pore-water pressure is commonly measured relative to an ambient atmospheric reference pressure; positive pressures (measured using piezometers) are typically found in saturated materials whereas negative pressures or suctions (measured using tensiometers) are typically found in partially saturated materials. In groundwater systems, the surface of zero pressure (relative to atmospheric) defines a water table.

The distribution and magnitude of pore-water pressures play key roles in the deformation and failure of porous earth materials in a tremendous variety of settings. These pressures can provoke the initiation of rainfall-induced landslides, the liquefaction of sediment during earthquake shaking, the onset of seismic tremor in subduction zones, the displacement of faults, and the hydrofracturing of rock around fluid injection wells. The widespread influence of pore-water pressure arises from several phenomena: (1) porous earth materials typically contain pore fluids as groundwater or soil moisture; (2) mechanical deformation is coupled between the fluid and solid phases (stress and strain in one phase affects the other phase); (3) pore-water pressure can reduce the frictional shear strength of earth materials; and (4) pore-water pressures commonly vary in response to dynamic hydrologic drivers (e.g., infiltration from precipitation, gravity drainage) and geologic events (e.g., earthquake shaking, sedimentary basin compaction, plate subduction, thermal pressurization). Spatial and temporal variations in pore-water pressure, transmitted through groundwater, can provide the trigger to induce deformation or failure.

Pore-water pressure is integral to soil and rock mechanics and geotechnical engineering. Analyses of deformation and failure (such as poro-elastic continuum models or limit-equilibrium approaches) account for the ability of pore water to support normal stress and its inability to resist shear. When earth materials deform more rapidly than induced pore-water pressures can dissipate, they behave quite differently from materials undergoing slower deformation with free drainage. Terzaghi proposed the effective stress principle to separate stress in the solid framework from stress supported by pore water. According to this principle, solid-phase normal stress is reduced as pore-water pressure increases. Thus, the frictional strength of soil or rock (which is proportional to solid-phase normal stress on potential failure surfaces) can be reduced by locally increasing pore-water pressure, thereby inducing failure in landslides or faults. The effective stress principle has been extended to account for fluid suction stress that can strengthen partially saturated earth materials.

POST DISASTER MASS CARE NEEDS

Frank Fiedrich[1], John R. Harrald[2], Theresa Jefferson[3]
[1]Wuppertal University, Wuppertal, Germany
[2]Virginia Tech, Arlington, VA, USA
[3]Loyola University Maryland, Baltimore, MD, USA

Definition

Postdisaster mass care needs include all needs of disaster victims resulting from a disaster. Traditional mass care needs include medical care, sanitation, temporary shelter, food, water, clothing, and other emergency items, as well as collecting and providing information on victims to family members. In a wider sense, further emergency assistance services, housing support, and human services can also be included.

Introduction

According to Smith (1957), traditional mass care needs are concerned with the urgent needs of a large number of displaced and homeless people independent of the cause of displacement. Therefore, typical traditional mass care needs include mainly temporary shelter, clothing, food, as well as medical, nursing, and hospital care. Over the course of time, the concept has been extended, and today, mass care needs can be defined more generally as all needs of disaster victims resulting from a disaster. The mass care annex of the current National Response Framework of the United States (FEMA, 2008b) lists also services and special topics closely related to the traditional mass care needs. Among others, this includes:

- Emergency assistance. This includes family reunification; services and aid for special needs populations, like elderly or handicapped people; medical and special shelters (e.g., pet sheltering); donation management; and volunteer management.
- Housing. Support of the affected population related to housing options, including rental assistance, replace and repair, and loan assistance.
- Human services. These services are related to recovery from nonhousing issues. Examples are programs to replace destroyed personal property and help with disaster loans, and strategies against disaster unemployment.

This chapter focuses on the traditional mass care needs and the major organizations involved in meeting these needs.

International response to mass care events

Once a disaster has affected a country, the local government is responsible for the management of the event. Local laws, plans, and guidelines define the processes and agencies involved in different aspects of response and recovery. Nevertheless, many major events exceed the capability of the local organizations, and international assistance becomes necessary. Among the most important international bodies supporting the response to large-scale disasters are the United Nations (see *United Nations Organizations and Natural Disasters*), the European Union, and the Red Cross and Red Crescent Movement (for Red Cross, see *Red Cross and Red Crescent*). The United Nations and the European Union do not provide mass care assistance themselves, but they provide help in coordinating the international response activities through various programs. In the following sections, the UN and EU mechanisms will be discussed in more detail. Further information about international disaster management can be found, for example, in Coppola (2007).

United Nations (UN)

The UN assists disasters and humanitarian crisis through various programs and funds, specialized organizations, and other bodies. Among the most important organization to meet the initial needs is the Office for the Coordination of Humanitarian Affairs (OCHA). OCHA belongs to the UN Secretariat and has a coordinating role in humanitarian assistance which is then delivered through various local and international organizations. OCHA staffs a United Nations Disaster Assessment and Coordination (UNDAC) standby team which can swiftly be deployed upon request to an affected area. The UNDAC team supports the initial damage assessment and helps to estimate the immediate needs, including mass care needs. OCHA also offers an On-Site Operations Coordination Center (OSOCC) which works closely with the local government and acts as an information hub for the international assistance.

The United Nations' response to the event is based on a cluster system with initially 11 identified sectors. Based on the magnitude of the disaster and the conducted needs assessment, the UN initiates different clusters with predefined organizations – mainly from the UN – as cluster leads. Among the most important clusters related to mass care needs are the camp coordination/management and emergency shelter clusters; health; water, sanitation, and hygiene (WASH); food aid and nutrition; as well as logistics. Important UN organizations in this field include the World Food Program (WFP), the World Health Organization (WHO), the United Nations Children's Fund

(UNICEF), and the Office of the United Nations High Commissioner for Refugees (UNHCR).

European Union (EU)

The two most relevant EU initiatives related to mass care are the Community Civil Protection Mechanism and the Commission Humanitarian Aid department (ECHO).

The Community Civil Protection Mechanism is comparable to UN-OCHA as it plays a major role in coordinating international response efforts provided through the member states of the EU (plus Iceland, Liechtenstein, and Norway). Its Monitoring and Information Centre (MIC) serves as a communication hub for information related to the current situation and the ongoing relief efforts. Once the mechanism is activated through an appeal from the affected country, the MIC facilitates and matches the disaster needs of the affected country with the offers from the participating states. It also offers field experts who can be deployed to support damage and needs assessment. Since the mechanism is typically activated during the most urgent disaster phase, it also provides assistance in the traditional mass care fields.

ECHO's mandate includes to save and preserve life after disasters and to provide assistance to the people in need. ECHO is largely a donor organization and focuses on funding short- and longer term activities and programs. ECHO monitors the progress of the funded activities and promotes the coordination among response organizations. Providing food assistance after disasters has a high priority for ECHO, but ECHO also offers support through other mass care items like toilets, water sanitation equipment, or building materials. For example, in the aftermath of cyclone Nargis in 2008, ECHO provided 10 million euro for food aid and 29 million euro for other humanitarian assistance (EU, 2009).

Estimating mass care needs

In order to provide fast and efficient help to the affected population, it is necessary to have a good understanding of the damages and the resulting mass care needs for goods and services. Until now, the needs estimates are largely based on damage and needs assessment missions after an event, but some comprehensive models to support the development of pre-event plans do also exist.

Post-disaster needs assessment

Based on experiences from past disasters and the setup/operation of camps in conflict zones, a variety of guidelines and estimates are available. The Sphere Project (2004), for example, provides guidelines, estimates, and leading principles for camp management. USAID's Field Operations Guide (OFDA, 2005) and UNDAC's Field Handbook (United Nations, 2000; NRC, 1989; IFRC, 2000; State of Florida, 2005) provide also valuable information related to mass care needs. According to these sources, some important planning figures related to mass care are:

- Total shelter space per person: 480 square feet per person (this includes space for all shelter-related infrastructures).
- Sleeping space: 60 square feet per person.
- Cots and blankets: 1 per person.
- Toilets: 1 toilet per 20–40 persons within a maximum walking distance of 1 min.
- Sinks: 1 sink/tap per 80–200 persons within 2-min walking distance.
- Garbage: 1 30-gallon refuse container for every 50 persons.
- Ice: dependent on the weather eight pounds of ice per person.
- Minimum water requirements: 5 gallons per person per day (1 gallon of drinking water, 2 gallons of water for washing and personal hygiene, 2 gallons of water for other requirements like cooking), for feeding centers approximately 9–10 gallons per inpatient per day, and for hospitals 11–20 gallons per inpatient per day.
- Food: approximately 2,100 calories per person per day. This equals two meals ready to eat (MRE) or approximately three pounds of fresh food (dependent on type of food).
- Shelter staff: it includes staff to run the shelter and to feed people. This number is dependent on the size and the purpose of the shelter.
- Medical supplies: various prepackaged sets exist, like WHO's NEHK 98, which includes medicines, disposables, and instruments, sufficient to support 10,000 people during a 3-month period.
- Clothing needs depend very much on social and cultural factors and the weather.

Scenario-based models for mass care planning

Prior to a disaster, models and scenarios can be used to estimate the impact of a disaster, including estimates for mass care needs. Once realistic scenarios have been identified and calculated, the resulting needs estimates can be included in response plans. During the immediate aftermath of an event, these initial numbers can be used as initial planning figures (Harrald et al., 2007).

While many models and methods exist for different aspects of scenario modeling, not many comprehensive frameworks exist. Among those, HAZUS is probably the most advanced system to date. HAZUS is the *Federal Emergency Management Agency (FEMA)*'s damage and loss estimation methodology for natural disasters. HAZUS is implemented as a software system based on ESRI's *Geographic Information Systems (GIS)* ArcGIS. Originally developed for earthquake risk assessment in the United States, the current release HAZUS-MH4 covers methodologies for earthquakes, hurricanes, and floods. Dependent on the hazard, it includes detailed scientific modules for:

- Hazards (e.g., earthquake hazard)
- Direct damages (e.g., building and infrastructure damages)

- Indirect damages (e.g., fire and hazardous material release)
- Direct losses (e.g., repair costs, casualties, and short-term sheltering needs)
- Indirect losses (e.g., economic losses) (FEMA, 2008a)

HAZUS allows the development of disaster scenarios, and although the focus is on planning and mitigation, it can also be used during response and recovery. While HAZUS is currently only available for the US territories, initiatives like the Global Earthquake Model (GEM) aim to create comparable global scale models and software systems (GEM, 2009).

Of specific interest for mass care planning are the casualty and short-term shelter models since they allow the estimation of scenario-specific mass care needs.

HAZUS's earthquake casualty model estimates casualty numbers due to earthquake damages in four different casualty severity classes: slightly, moderately, severely, and killed/mortally injured. The calculated number and types of casualties are largely based on the time of day of the event, the population distribution, and the estimated structural damages. Although HAZUS does not distinguish between detailed injury types (e.g., blunt trauma), the estimated numbers provide a very good basis for the resulting medical needs. Since HAZUS also calculates damages to hospitals, electricity, and water networks, the scenarios allow the performance of gap analyses to compare the available response capacities with the estimated medical needs.

HAZUS's displaced households and short-term shelter needs model is based on a multi-attribute model originally developed by Harrald et al. (1992) for the American Red Cross. The HAZUS model assumes that displacement is solely based on structural damage to residential buildings. Since a subset of the displaced population may stay with friends and family or rent apartments, the model assumes that only a portion of the displaced households will seek public shelter. While this decision depends on a variety of socioeconomic and demographic variables (Harrald et al., 2000), HAZUS uses ethnicity and income as major determining factors (FEMA, 2008a). The shelter population requires the full range of mass care, but other displaced population may only need a subset of mass care goods and services. On the other side, it must also be noted that severe and long-term damage to water and electricity networks may not allow for timely repair and force people to leave their homes and stay in shelters. Therefore, a recent FEMA-funded study on catastrophic earthquakes in the New Madrid Seismic Zone extended the HAZUS methodology and uses the following population categories for mass care planning (Elnashai et al., 2009, pp 37):

- Shelter-seeking population: this includes the people who are seeking shelter directly after the event. In the days following the event – dependent on socioeconomic and demographic factors – this number is increased by a subset of the population without access to water and electricity. Shelter-seeking population requires water, food, medical care, and shelter-related items and services (blankets, toilets, etc).
- At-risk population: the at-risk population includes the displaced population immediately after the event. During the following days, the people who still live without access to water and electricity can be added.

Once the shelter and at-risk populations are estimated, the post-event expert rules of thumb can be used as an approximation for planning (see section *Post Disaster Mass Care Needs*).

Missing persons registries

Catastrophic incidents often disrupt families. As a consequence, family members do not know the current status and location of their relatives. One of the key problems in mass care is to help people inside and outside the affected area to find information about the status of friends and family members. Shelters often use bulletin boards to publish names and additional information of the people living in the camps. Morgues provide lists of photos and – if available – names of the dead. Additional bulletin boards allow family members to inquire about missing people. Although paper lists are still frequently used, nowadays, a variety of Web-based systems allows searching as well as publishing and requesting status information of missing persons through one single system. The International Committee of the Red Cross (ICRC) provides probably the most widely accepted system. Their "Family Links" Web site helps those separated by conflict or disaster to find information about their loved ones in order to restore contact (ICRC, 2010). In case of a major event, the IRCR sets up a subsite which allows searching and publishing of information related to a specific event. A similar approach is used by Google. Their "Person Finder" Web site setup after the 2010 Haiti earthquake lists more than 55,000 entries (Google, 2010). Google initiates comparable sites for other major events.

Conclusions

Successful response to large-scale and catastrophic events depends very much on how fast professional mass care is available. While the domain of mass care is still dominated by national and international response organizations, field experts, and emergency management professionals, some scientific approaches exist or are currently under development. Reliable damage and loss estimation methodologies provide the framework for the development of mass care-related plans. In addition, the emerging research field of humanitarian logistics seeks to provide methods to improve the distribution of goods during the response to complex disasters.

POSTTRAUMATIC STRESS DISORDER (PTSD)

Fran H. Norris
Dartmouth Medical School, National Center for PTSD, White River Junction, VT, USA

Definition

Posttraumatic stress disorder (PTSD) is a psychiatric condition that occurs following a traumatic event and is characterized by a complex constellation of reexperiencing, avoidance/numbing, and arousal symptoms.

Discussion

Although the term is often used loosely to describe various manifestations of disaster-related distress, PTSD is actually a highly specific anxiety disorder that is diagnosed according to criteria established by the American Psychiatric Association (1994). Criterion A, the trauma criterion, requires that the individual: (1) has experienced, witnessed, or been confronted with an event that involves actual or threatened death or physical injury and (2) responded to the event with intense fear, helplessness, or horror. Whereas all disasters may be stressful, they may not necessarily be traumatic according to this definition. Criterion B, reexperiencing, requires that the person has experienced recurrent and intrusive recollections of the trauma, distressing dreams, subjective feelings of reliving the event, or psychological or physiological distress upon exposure to reminders. Criterion C, avoidance and numbing, requires the presence of at least three of the following: efforts to avoid thoughts or feelings associated with the trauma, efforts to avoid activities, people or places associated with the trauma, inability to recall, diminished interest in activities, estrangement from others, restricted affect, or sense of foreshortened future. Criterion D, arousal, is indicated by difficulty sleeping, irritability, difficulty concentrating, hypervigilance (a feeling of being on-guard), or exaggerated startle response; at least two of these symptoms must be present. In addition, the symptoms must last for at least one month (Criterion E) and result in clinically significant distress or impairment in social, occupational, or other important areas of functioning (Criterion F). Despite the complexity of PTSD, well-validated tools for assessing it exist (Wilson and Keane, 2004).

PTSD is the most commonly studied and observed mental health problem associated with major disasters. Reexperiencing and arousal are very common among disaster survivors, but numbing symptoms and functional impairment are much less so (Norris et al., 2002). The prevalence of PTSD varies widely across disasters depending on the extensiveness of injury, death, and destruction but, on average, it may be experienced by 30–40% of highly exposed individuals, 10–20% of rescue workers and first-responders, and 5–10% of general populations who encompass levels of exposure ranging from modest to severe (Galea et al., 2005). PTSD often

co-occurs with other psychiatric conditions, such as depression and substance abuse.

Disaster-related PTSD often remits on its own. In general, PTSD takes a chronic course in about one third of persons who develop it (Kessler et al., 1995). PTSD can be treated with current evidence favoring cognitive behavioral therapies as the most effective approach (Foa et al., 2009).

PRIMARY WAVE (P-WAVE)

Allison Bent
Natural Resources Canada, Ottawa, ON, Canada

Synonyms

Compressional wave; Longitudinal wave; P Wave

Definition

P waves are compressional elastic waves that travel through the Earth.

Discussion

P waves are seismic body waves meaning that they travel through the Earth's interior. The name primary waves stems from the fact that they are normally the first waves recorded by a seismograph. P waves typically travel at velocities of 6–7 km/s in the Earth's crust and at higher velocities in the mantle. The particle motion associated with P waves is the same as for sound waves in that it consists of a series of compressions and dilatations parallel to the direction of propagation of the wavefront. P waves are recorded by the vertical and radial components of seismographs. They are able to propagate through liquids and gases but at much slower speeds than through solids. P waves are usually small in amplitude relative to S waves and surface waves.

PROBABLE MAXIMUM FLOOD (PMF)

Armand LaRocque
University of New Brunswick, Fredericton, NB, Canada

Synonyms

Extreme Flood; Maximum Flood

Definition

According to the US Federal Energy Regulatory Commission (2001), the Probable Maximum Flood (PMF) is the theoretically largest flood resulting from a combination of the most severe meteorological and hydrologic conditions that could conceivably occur in a given area. PMF is mainly used as a security assessment for existing dams and other impounding structures, and as a design criterion for proposed similar hydraulic structures, in order to avoid dam failures and catastrophic floods.

Discussion

Dams are often built to control floods in areas occupied by people and must be able to store floodwaters, in order to

avoid costly disasters in life and economy. Computer models are used to assess the water storage capabilities of these hydraulic structures, without overtopping under flood conditions. The height of future floods is often predicted in reference with a time interval. For example, a 100-year flood level is considered as the level of a large flood having the chance of occurring once in a period of 100 years. However, historical records of significant floods since one century show that these unusual events may happen more often and cause dam failures and catastrophic destructions in floodplains farther downstream. For this reason, the PMF is currently more frequently used as a design criterion for more important dams, although it is related to a very rare and unlikely occurring event.

The computation method of PMF is based on the integration of the probable maximum precipitation (PMP), or the probable maximum storm (PMS), and the characteristics of the watershed upstream. The PMP is the theoretically largest height of precipitation that may fall on a particular location and for a given duration. The value of PMP can be calculated using rainfall records or estimated from meteorological models. In mountainous areas, the PMS is more frequently used than PMP. PMS is defined as the maximum precipitation that may occur if weather conditions, mainly winds and atmospheric moisture contents, are maximal, for a given location. Other meteorological factors, such as the maximum accumulation of snow and the fastest rate of snow melt, can also be considered. The highest value among PMP or PMS is then used to estimate the maximum water inflow in the drainage area. The hydrograph for PMF can then be compiled, taking into account some important characteristics of the drainage basin, including the soil type, the land use, the size and the shape of the watershed, and the average watershed slope.

PROBABLE MAXIMUM PRECIPITATION (PMP)

Gerd Tetzlaff[1], Janek Zimmer[2]
[1]Universität Leipzig, Leipzig, Germany
[2]GFZ German Research Centre for Geosciences, Potsdam, Germany

Synonyms

Continuous Heavy Rain; Flash Flood; Rainstorm

Definition

The WMO defines Probable Maximum Precipitation (PMP) as "... the greatest depth of precipitation for a given duration meteorologically possible for a given size storm area at a particular location at a particular time of year, with no allowance made for long-time climatic trends." (WMO, 1986).

Discussion

Heavy precipitation and its adverse effects, mostly by floods, are reported from most parts of the world. The reduction of such effects, e.g., through engineering (dams, etc.), requires data on the magnitude and frequency of heavy precipitation events. The information is usually derived from a time series of observed past events. By their nature, such events are infrequent; often a frequency of one such event per 100 years is applied. Observational periods often comprise periods of only a few decades.

Therefore, methods are needed to estimate the probable maximum precipitation occurring in any given set of time-invariant climatic conditions. The approaches to obtain such PMP values comprise two main methods. The first method (WMO, 1986) uses the maximum observed precipitation over a river catchment area and the maximum water vapor content in the same area. The dew point temperature is often extrapolated to an event size with a frequency of one per 100 years. The vertically integrated water vapor content, as deduced from the dew point temperature, is then compared to the value measured during the precipitation event. The resulting adjustment factor is applied to the observed, hitherto maximum, precipitation value. The result is called PMP. The method can only give an estimate, because the processes contributing the second key factor in the formation of precipitation, the vertical velocity, are not considered other than in the nonquantitative method for the observed precipitation event.

To overcome this limitation, it is necessary to extend the concept of PMP to both key factors, which means addressing also the responsible lifting mechanism. By using complex,

state-of-the-art numerical weather prediction models with idealized initial conditions, which should represent the maximum combination of water vapor and a suitable pressure and wind field, it is feasible to estimate the vertical velocity distribution in time and space. This is especially complicated within areas of convection, due to the vast diversity of possible size and organization. Given the 3D-distribution of water vapor and vertical velocity, a diagnostic approach assuming moist-adiabatic ascent yields the maximum rain rates for the given initial conditions (Tetzlaff, 2009).

Among the heaviest precipitation events recorded on Earth, orographic enhancement is frequently the cause. In this case, the maximum precipitation can be deduced quite reliably because of robust estimates of the vertical velocity that originates from forced upslope motion.

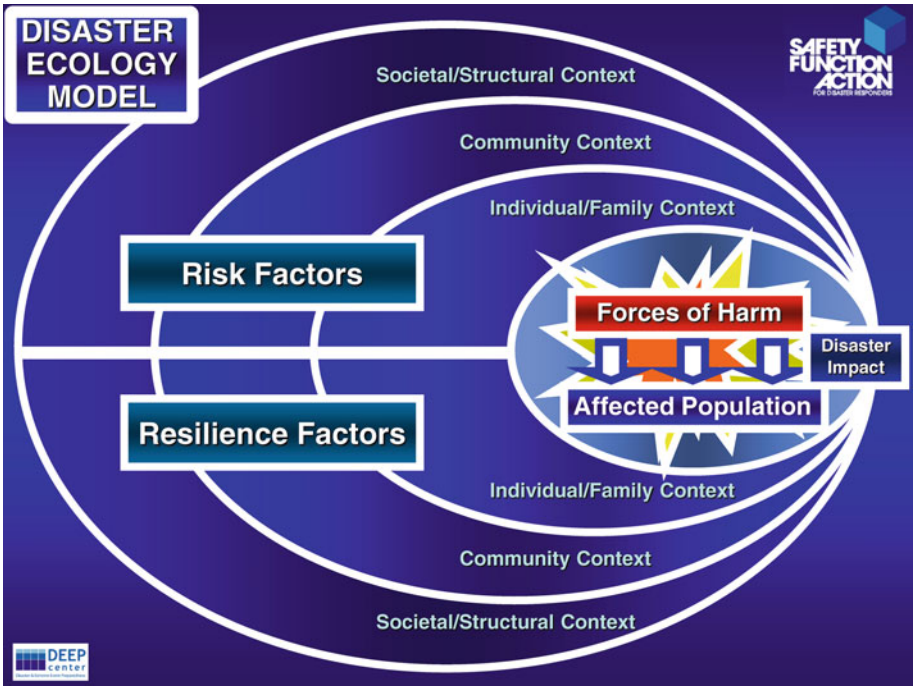
Definition

Disaster Mental and Behavioral Health: Professionals in the rapidly emerging field of *disaster mental and behavioral health*, focus on the interconnected psychological, emotional, cognitive, developmental, and social influences on behavior and mental health and the impact of those factors on preparedness, response, and recovery from disasters and traumatic events.

Introduction

Reverberating mental and behavioral health consequences occur when the physical forces of natural disaster collide with a vulnerable human population. In fact, the psychological impacts are more expansive in scope, more extended in time, and frequently more debilitating in severity than the injurious physical impacts of natural disaster (Shultz et al., 2007b).

The importance of "psychological impacts of natural disasters" becomes immediately apparent by examining four attributes of mental and behavioral health consequences. Aligned with the theme of this *Encyclopedia*, the interconnection between hazards, psychological stress, and mental health outcomes is explored. Next, considering persons "in harm's way," populations at elevated risk for mental health impacts are differentiated by disaster phase. Psychological reactions and psychiatric disorders that may occur following exposure to a disaster are described. Given the significant psychiatric disease burden in the wake of major natural disasters, approaches to behavioral triage, referral, and psychological treatment are presented. The range of possible psychological trajectories for survivors is examined.



Mental and behavioral health consequences in disasters

In the Disaster Ecology Model (Shultz et al., 2007b), "a disaster is characterized as an encounter between forces of harm and a human population in harm's way, influenced by the ecological context, that creates demands exceeding the coping capacity of the affected community." This model serves as the basis for integrating physical and psychological dimensions of natural disaster impact and illustrates the intriguing interplay between hazards and the human population grappling with the rampaging forces of harm (Figure 1).

Psychological consequences of natural disasters can be portrayed across four salient dimensions of scope, severity, duration, and disaster type.

Widespread Scope. Psychosocial consequences of disasters are wide-ranging and pervasive. More persons are affected psychologically than are harmed physically. The "psychological footprint" of disaster is larger than the "medical footprint" (Shultz et al., 2007a).

While many persons in the strike zone will escape physically unharmed from the ravages of a natural disaster, they will nevertheless suffer stress reactions, distress, fear, and possibly bereavement and grief. Persons who are

Psychological Impacts of Natural Disasters, Figure 1 Disaster ecology model: forces of harm and the human population in harm's way.

physically injured will also experience a psychological overlay of "injury-related distress" and elevated risk for subsequent development of posttraumatic stress disorder (PTSD) (Zatzick, 2007). In natural disasters characterized by high mortality, such as the 2004 Southeast Asia tsunami or the 2010 Haiti earthquake, the disaster-affected community will experience prolonged grief, with many survivors dealing with the loss of multiple close friends and family members. Under circumstances of extensive destruction, population-wide distress will arise from population displacement, loss of resources, and scarcity of basic needs.

Spectrum of Severity of Psychological Reactions. Almost all persons exposed to a natural disaster will experience increased levels of fear and distress during times of overt danger (Butler et al., 2003). In fact, the threat of disaster can trigger stress even in the absence of impact. Consider the fear responses and frantic preparatory activities in coastal communities during the warning phase for an approaching hurricane that ultimately remains over water without making landfall (Shultz et al., 2007b). In many cases, these psychological reactions are brief and relatively mild, allowing persons to quickly rebound to full functioning without need for psychological support. In contrast, a subset of disaster-exposed persons will be distressed to the point of making detrimental behavior changes, such as surging the local healthcare system (Ursano et al., 2007). Some individuals may develop psychiatric disorders following encounter with a natural disaster. Best studied is posttraumatic stress disorder (PTSD), but other psychiatric disorders may co-occur with PTSD ("comorbidities"). Among these, major depressive disorder (MDD) and generalized anxiety disorder (GAD) are commonly observed among disaster survivors.

The proportion of disaster-affected persons at each point along this spectrum of severity – from disaster stress to behavior change to psychiatric disorder – generally corresponds to the intensity of exposure to the "forces of harm" in a natural disaster.

Range of Duration. Psychological stress reactions and fear-driven behavioral responses ramp up during the disaster warning phase and escalate during disaster impact, the period of overt danger when destructive forces of harm are operating. However, in the aftermath, psychological reactions do not disappear even when physical danger ceases. The reason is that loss and change are prominent features of the post-disaster environment. The hardships of enduring physical destruction, scarcity of basic needs, displacement, community-wide disruption of services, loss of resources, and painful rehabilitation from physical injury collectively act to maintain or amplify the stress level. For large-scale disasters, the protracted period of reconstruction perpetuates chronic stress.

Type of Disaster. Natural disasters are notable for their global frequency and diversity, generating both physical and psychological effects for millions of world citizens

annually. Natural disasters are relatively common, familiar, and predictable. The degree of psychological distress and the extent of mental health consequences found in survivors of these "acts of nature" tend to be less compared with victims of human-generated disasters, particularly human-perpetrated intentional acts of violence (Norris et al., 2002).

Forces of harm: Hazard characteristics related to psychological impacts

In this *Encyclopedia*, dedicated to the panoply of natural hazards, it is instructive to examine how hazard characteristics commingle and synergize to influence the extent, severity, and duration of psychological reactions (Shultz et al., 2007a, b). Predictably, the degree of psychosocial impact is directly proportional to the degree of physical harm and destruction. Five hazard descriptors predict the extent of mental and behavioral health ramifications.

First, the *absolute magnitude* (or *intensity*) of the forces of harm largely determines the extent of damage, destruction, displacement, death, and injury, as well as the amplitude of stress and trauma experienced by the disaster-affected population. Second, the *duration* of exposure to threat or overt forces of harm predicts the span of time during which survival stress responses are activated. Third, the *frequency* of discrete disaster impacts relates to psychological trauma; a sequence of multiple strikes tends to be more devastating than a single event. For example, repeated strong aftershocks following a major earthquake can provoke widespread fear reactions. As an illustration of multiple sequential strikes, in 2004, a series of four hurricanes made landfall in the state of Florida within a period of 3 months, potentiating stress levels and inducing statewide "hurricane fatigue." Fourth, *proximity* to the geographical "epicenter" of destruction forecasts the severity of exposure and the attendant psychological effects. Investigations of natural disasters commonly reveal gradations of impact, closely corresponding to the extremity and extent of physical and psychological harm sustained. Fifth, the *geographic scope and scale* defines both the expanse of territory impacted and the numbers of persons comprising the disaster-affected population; psychological consequences are experienced both individually and collectively.

Hazards as disaster stressors

Exposure to natural hazards during disaster impact, followed by the confrontation with loss and change in the wake of disaster, presents survivors with an array of disaster stressors. These "forces of harm" – exposure, loss, and change – trigger stress reactions, alter behavior patterns, and may lead to severe psychiatric outcomes for a subset of disaster-affected persons. Table 1 provides examples of disaster stressors in each of these three categories (Shultz et al., 2007a, b).

Hazard conditions that generate severe psychological impacts

According to Norris and colleagues (2002), the majority of declared disasters do not produce significant psychological repercussions because numbers of injuries and deaths are limited, the degree of destruction is not overwhelming, and community social structures remain intact. These investigators assert that pronounced disaster mental and behavioral health impacts are generally restricted to the subset of high-profile disasters that possess two or more of the following four characteristics: (1) large numbers of injuries and/or deaths, (2) widespread destruction and property damage, (3) disruption of social support and ongoing economic problems, and (4) intentional human causation. For the current focus on natural disasters, intentional causation is not applicable, so some combination of mass mortality, extreme damage, and social dislocation must occur to catapult psychological consequences to the forefront.

Psychological Impacts of Natural Disasters, Table 1 Disaster stressors associated with exposure to hazard, loss, and change

Exposure to hazards	Loss	Change
Perceived threat of harm	Bereavement	Disruption of services
Disaster warning (or) Lack of warning	Separation from loved ones	Physical displacement
Shopping/stockpiling	Physical harm, debility, pain	Separation from essential health services/medications
Evacuation	Loss of function	Lack of utilities
Sheltering	Loss of home	Lack of transportation
Perception of threat to life	Loss of worksite	Lack of communications
Exposure to physical forces of disaster impact	Property damage	Unemployment, job change
Personal physical harm	Lack of basic necessities	School closure
Witnessing	Loss of valued possessions	Disruption of community
Widespread destruction	Loss of social support	Community-wide grief
Mass casualties	Resource loss	Shortages, rationing
Death/injury to others	Financial loss	Refugee conditions
Exposure to	Loss of employment	Social violence
Grotesque scenes	Loss of independence	Poverty
Noxious agents	Loss of personal control	Disease outbreaks

Threat, harm, loss, change: Psychological impacts throughout the disaster life cycle

Disaster stress permeates all phases of the disaster life cycle. Threat alone is capable of stimulating the stress response even if physical harm does not materialize. Consider hundreds of county fair-goers frantically fleeing as a tornado funnel descends from a cloud bank overhead. Before reaching the ground, the funnel hovers, then retracts and dissipates. No touchdown, no damage, no physical injury ensues, yet the threat alone was able to set off palpable psychological stress reactions and provoke potentially injurious crowd behavior.

When disaster actually strikes a human population, physical harm and destruction is guaranteed to be accompanied by psychological distress. In the post-disaster environment, ongoing exposure to hazards, compounded by the profound realization of loss and change, combine to produce powerful psychological effects. Postimpact adversities are experienced by some survivors as more difficult than the disaster event itself. Mental health sequelae typically persist long after the physical threats abate in the postimpact phase. Table 2 contrasts physical harm and psychological impact in relation to the phases of the disaster life cycle.

In harm's way: Populations affected psychologically in disasters

During a natural disaster, the degree of psychological impact generally relates to the extent of exposure to the physical forces of harm, but a further distinction comes into play. "Direct victims" experience intense exposure to the forces of harm (Galea and Resnick, 2005; Norris and Wind, 2009). Some direct victims are physically injured. During impact, many direct victims perceive an imminent threat to life ("I thought I was going to die."). Survivors bear witness to scenes of massive physical destruction, death, and egregious harm to others. Posttrauma memories may be studded with images that are grotesque and deeply troubling. Survivors may experience traumatic bereavement due to the death, on-scene, of one or more loved ones.

Yet psychological distress also extends to "indirect victims" (Galea and Resnick, 2005), persons who are typically outside the geographical perimeter of the disaster footprint but are socially connected to the direct victims. While the mental and behavioral health impact tends to be less severe, the number of indirect victims far exceeds numbers of direct victims. During the 2010 Haiti earthquake, direct victims were concentrated around the focus of destruction, the capital city of Port au Prince. Indirect victims extended throughout the entire island nation and beyond, encompassing large Haitian immigrant communities in Miami and New York City, and Caribbean nations.

Spirals of psychological impact enfold direct impact victims and many rings of indirect victims. Indirect victims include family members, friends, and neighbors of the direct victims; colleagues and coworkers; and those who witnessed harm, death, and disturbing scenes. Moreover, both professional and volunteer disaster responders will experience psychological repercussions. The "Population Exposure Model" (USDHHS, 2004) aptly captures the concentric nature of the psychological impact of disasters. In general, the closer the person is to "ground zero" in a natural disaster, both physically and socially, the greater will be the psychological distress.

Populations at higher risk for psychiatric disorders by disaster phase

When dealing with disaster-affected populations, one important consideration is defining who is most likely to suffer serious psychological consequences (Shultz et al., 2007a; Watson and Shalev, 2005). Individuals and populations at elevated risk can be identified at each phase in the disaster life cycle.

Some risk factors that predict increased likelihood of unfavorable psychological outcomes following disaster are clearly definable in the pre-event period. Among these risk factors are demographic descriptors such as gender (higher risks for women), race/ethnicity (higher rates for ethnic and marginalized minorities), and socioeconomic status (increasing risk with decreasing SES). Pre-disaster functioning and psychiatric history are among the most forceful predictors of post-disaster symptoms (Norris et al., 2007). History of pre-disaster psychiatric diagnosis relates directly to risk for post-disaster PTSD. Past history of trauma or substance use elevates the postimpact risk for psychological consequences. Likewise, chronic physical health conditions and disability status add to risks for psychological distress.

However, many disaster survivors with no pre-event risk factors will experience significant psychological consequences. The traumatizing experiences of living through

Psychological Impacts of Natural Disasters, Table 2 Forces of harm: physical and psychological effects by disaster phase

Disaster phase	"Forces of harm"	Physical harm/Destruction	Psychological impact
Inter-disaster	Exposure to nonspecific threat (even without impact)	NO	YES
Preimpact/Warning	Exposure to specific threat	NO	YES
Impact	Exposure to hazard, harm, loss	YES	YES
Early postimpact	Exposure to hazard, loss, change	YES	YES
Late postimpact	Exposure to loss and change	NO	YES

Psychological Impacts of Natural Disasters, Table 3 High-risk groups for psychological consequences by disaster phase

Pre-disaster phase

Population Demographics
Female gender
Children
Older adults
Low socioeconomic status
  Minimal education
  Economic disadvantage
  Unemployment

Culture, race, ethnicity, language
Minority status
  Minority culture, race ethnicity
  Marginalized culture
Recent immigrant
Limited proficiency in dominant language

Family context characteristics
Adult with children
Single head of household
Child with dysfunctional parent
Family instability
Domestic violence

Social support/Adaptive skills
Limited coping skills
Limited social support network

Psychiatric/Psychological Health
Serious and persistent mental illness
History of trauma
Psychiatric diagnosis
Substance abuse diagnosis

Physical health
Pregnancy
Pre-existing chronic disease
Disease requiring life-sustaining treatment
Disease requiring essential medications
Immunosuppression

Disability status
Physical limitation and disability
Learning/language disability
Limitation of intellectual skills

Disaster impact phase

Direct victims
Experiencing the physical forces
Physical injury
Perception of threat to life
Extreme fear, horror, trauma
Witnessing destruction
Witnessing injury or death of others
Witnessing grotesque scenes

Indirect victims
Connection to disaster-affected community
Inability to help
Survivor guilt
Secondary trauma

Bereaved victims
Death of loved one
Death of close friends, neighbors

Post-disaster phase

Injured
Pain, rehabilitation, physical disability

Disaster-impacted community at large
Massive destruction
Desperate search for missing persons
Lack of basic needs
Loss of community function
Disruption of services
Diminished social support
Marital stress

Unemployed
Economic hardship
Lack of career identity
Inability to provide for dependents

Bereaved (loss of loved one in disaster)
Complicated grief

Disaster-displaced persons
Loss of home
Lack of shelter and safety
Relocation stress
Temporary housing
Crowding

Psychiatric "Peritraumatic" symptoms
Dissociation
Panic, extreme distress
Depression

the onslaught of disaster and encountering the extreme adversities in the aftermath tend to "reshuffle the deck." Planning for mental and behavioral health support for disaster-affected populations must consider the reality that some survivors with no salient preimpact risk indicators will urgently require focused help and psychological care following the disaster. These individuals emerge as members of a disaster-created special needs population (Table 3).

Psychological reactions to natural disasters

As first described under the topic of "spectrum of severity," from a public health, population-focused vantage point, no one goes through a traumatic event unchanged (Butler et al., 2003). Almost all persons exposed to a disaster are affected psychologically. Survivors will exhibit an array of distress reactions across all domains of human function (Table 4).

The intensity and variety of reactions vary based on individual differences as well as the nature of the exposure to disaster. Psychological reactions are time-phased and transient. For example, a person whose primary emotional response is extreme fear at the moment of forceful earthquake tremor may exhibit rage and anger later that same day, and possibly helplessness and despair several days into the postimpact phase.

For most persons, disaster stress responses will be relatively brief and transient, followed by return to pre-disaster levels of functioning (Butler et al., 2003). However, some persons will be distressed to the point of making behavioral changes such as avoidance of sleeping indoors after an earthquake, flocking to local healthcare centers for vague complaints, or increasing use of alcohol.

Finally, for a minority of exposed persons, symptoms will progress and persist to the point where a psychiatric diagnosis is warranted. For these individuals, the emotional sequelae of disasters may be enduring. A range of post-disaster mental health problems has been documented including posttraumatic stress disorder, major depressive disorder and complicated grief disorder, substance abuse, and physical illness.

Posttraumatic stress disorder (PTSD). PTSD is a common, frequently debilitating, psychiatric disorder among trauma-exposed populations. PTSD is classified as an anxiety disorder with three defining symptom domains: reexperiencing, avoidance, and hyperarousal (APA, 2004).

Reexperiencing entails terrifying flashbacks, disturbing thoughts, and intrusive memories of the disaster event. Avoidance involves both emotional "numbing" and behavioral choices to refrain from visiting locations or coming upon reminders of the trauma. Avoiding trauma reminders requires constant focus and can detour the survivor's lifestyle by limiting mobility, shrinking the social network, and diminishing the enjoyment of usual activities. Hyperarousal symptoms include a racing, fight-or-flight physiology; inability to calm or rest; extreme alertness; and an exaggerated startle reflex.

Psychological Impacts of Natural Disasters, Table 4 Disaster-induced stress and distress reactions across six dimensions of human function

Physical	*Emotional*	*Cognitive*
Adrenalin "rush"	Fear and terror	Disorientation
Increased heart rate	Horror and dread	Confusion
Increased respirations	Anxiety, emotional distress	Decreased concentration
Sweating	Excessive worry	Distractibility
"Butterflies" in stomach	Anger or rage	Memory problems
Muscle tension	Irritability	Reduced attention span
Headaches	Sadness, crying	Impaired problem solving
Dizziness	Depression	Difficulty making decisions
Heart palpitations	Helplessness	Difficulty setting priorities
Gastrointestinal problems	Hopelessness	Calculation impairment
Exaggerated startle reflex	Grief	Loss of objectivity
Tremors, muscle twitching	Guilt	Disbelief
Shortness of breath	Overwhelm	Distorted thinking
Visual disturbances	Apathy, denial	Inaccurate perceptions
Chronic fatigue	Numbing, shutting down	Alternatively:
	Alternatively:	Increased attention
Behavioral	Feeling heroic, euphoric	Heightened focus on tasks
Changes in sleep habits	Feeling "invulnerable"	
Inability to rest and relax		*Spiritual*
Changes in diet	*Social*	Crisis of faith
Weight loss or weight gain	Withdrawal	Questioning values
Hypervigilance	Isolation	Directing anger toward God
Impaired job performance	Interpersonal conflict	Cynicism
Academic problems	Hostility	Loss of meaning
Absenteeism	Aggression	Interpreting disaster as punishment
Inappropriate humor	Blaming	Alternatively:
Increased alcohol use	Dependency	Religious conversion
Increase medication use	Greater need for comfort	Increased reliance on faith
Decreased interest in pleasurable activities	Difficulty giving support	Increased religiosity
Avoidance of activities or places that trigger memories of disaster	Difficulty receiving support	Increased use of prayer
		Increased use of ritual
		Bargaining with God

To receive a definitive PTSD diagnosis, all three symptom clusters must be present for a period of 30 days following the traumatic event and cause impaired functioning. Up to 3 months posttrauma, the diagnosis is termed "acute PTSD" and thereafter, beyond 3 months, "chronic PTSD." For some disaster survivors, posttraumatic stress symptoms are evident across multiple domains within the first 30 days; some of these individuals meet criteria for a diagnosis of acute stress disorder (ASD), a strong predictor of future progression to PTSD beyond the 30 day threshold.

PTSD is the most investigated, and the most central, psychopathology in the aftermath of disasters (Norris et al., 2002; Breslau et al., 2004; Galea et al., 2005; Neria et al., 2008). Strong predictors of developing PTSD include serious physical injury, imminent threat to life, severe property damage, and high death toll.

The burden of PTSD among persons who were exposed to disasters is significant. Overall, studies of natural disasters report PTSD prevalence rates ranging from 3.7% to 60% in the first 2 years after the disaster, with most studies reporting prevalence estimates in the lower half of this range (Neria et al., 2008). Fortunately, PTSD symptoms and disease burden generally decrease over time (Galea et al., 2003).

The risk of PTSD has been repeatedly shown to be associated with the severity of exposure to the disaster. The prevalence of PTSD among direct victims of disasters ranges from 30% to 40%. PTSD prevalence among rescue workers is lower (10–20%), while the range of PTSD rates in the general population is the lowest (5–10%). These differentials in prevalence rates correspond to the intensity of exposure, evidence of a dose-response relationship. To validate this dose-response relationship, researchers have compared groups with quantifiably different levels of exposure. Studies that compared survivors based on proximity to the "ground zero" point of maximum impact consistently found highest PTSD rates in persons closest to the epicenter (Schlenger et al., 2002; Neria et al., 2006).

Prevalence rates of PTSD are higher for human-generated acts of mass violence compared with natural disasters. This partially reflects distinguishing features of mass violence that make such events especially troubling psychologically; these acts are intentional, perpetrated, and unpredictable (Shultz et al., 2007a). But the observed lower rates of PTSD in natural disasters may also reflect differences in study design. Compared to focalized human-made events, major natural disasters create destruction over a sweeping expanse of territory. Studies of natural disasters tend to enroll survivors with varying

gradients of exposure and a mix of direct and indirect victims, thus diluting the average "dose" of exposure and thus, potentially underestimating PTSD prevalence rates (Galea et al., 2005).

Mental health consequences, most notably PTSD, are not restricted to direct victims alone. Large numbers of indirectly exposed persons may also be affected. Though not exposed onsite, indirect victims may have sustained the loss of family members or close friends, experienced the destruction of personal property or homestead, or viewed intense coverage of the event through the media. While the dose of exposure is diminished, and symptoms tend to be less severe, indirect victims greatly outnumber direct victims. Therefore, a substantial burden of mental health impact be found within the large, broadly distributed population of those who were indirectly exposed (Galea et al., 2005).

Major Depressive Disorder (MDD). MDD is frequently diagnosed in individuals exhibiting persistent feelings of deep sadness, accompanied by additional symptoms such as loss of interest in activities they once enjoyed, decreased self-worth, guilt, sleep problems, and changes in appetite (APA, 2004), together leading to impaired function. While feelings of sadness and related symptoms of MDD are expectable following a disaster, for most individuals these reactions spontaneously remit as lost resources are replenished, daily activities are resumed, and future expectations brighten.

Several disaster-related stressors increase the risk for MDD in disaster survivors: death of a loved one, displacement, relocation, lack of social support, and being alone (Ahern and Galea, 2006; Kilic et al., 2006; van Griensven et al., 2006; Tak et al., 2007). Estimates of post-disaster MDD vary and frequently do not exceed expected rates of depression in the general population. MDD prevalence is higher for persons with more intense disaster exposure. For example, 14 months following an earthquake in Turkey, MDD prevalence was 16% for persons near the epicenter compared to 8% for persons away from the center (Başoğlu et al., 2007). Displacement away from home and community support also predicts MDD. Two months following the 2004 Southeast Asia tsunami, MDD prevalence for Thai survivors was 30% for displaced survivors and 21% for non-displaced individuals (van Griensven et al., 2006).

Complicated grief. Loss of a loved one in a natural disaster is one of the most psychologically devastating experiences. Traumatic bereavement, leading to complicated grief, is associated with a host of psychiatric disorders including PTSD and depression (Neria et al., 2007). Complicated (or prolonged) grief disorder (PGD) is a relatively new diagnosis, and different from normal grief in its extended duration and symptom profile (Horowitz et al., 1997). Correlates of PGD include severe functional impairment, decreased productivity, suicidality, and physical health problems (Lichtenthal et al., 2004; Neria et al., 2007). Yet to be explored is the interaction between disaster trauma and loss of a loved one (Neria and Litz, 2004); many survivors of the 2010 Haiti earthquake experienced both. More research is needed to fully understand the relations between PTSD and complicated grief, and whether they differ in their risk and protective factors.

Substance use. Trauma exposure is often associated with increased substance abuse, either directly or indirectly, through increased substance use associated with PTSD. Existing research does not indicate that exposure to disasters results in a substantial increase in substance use. Reported post-disaster increases in substance use (tobacco, alcohol, drugs) are typically restricted to persons who were using these substances before the disaster. Rates of substance use post-disaster generally decline over time. The field would greatly benefit from well designed, prospective examination of the relationships between substance use and disaster-related psychiatric disorders.

Triage, screening, and referral

Indicators for referral to mental health evaluation

Among the range of responses to disasters, mental health consultation and evaluation is warranted for survivors displaying any of the following symptoms (Shultz et al., 2007b; Reissman et al., 2010):

- Inability to perform necessary everyday functions
- Disorientation (confused, unable to give name/date/time/place)
- Suicidal or homicidal thoughts, plans, or actions
- Domestic violence
- Acute psychosis (hearing voices, seeing visions, delusional thinking)
- Significant disturbance of memory
- Severe anxiety, extreme fear of another disaster
- Problematic use of alcohol, prescription or illicit drugs
- Depression (hopelessness, despair, withdrawal)
- Hallucinations, paranoia
- Serious developmental regression

Triage and screening

Disaster survivors who are most likely to experience severe psychological reactions, impairment of function, and potential psychopathology are those who have experienced: (1) intense exposure, (2) loss of a loved one, (3) major disruption of basic needs and services, (4) prior trauma, and (5) major life stressors (Reissman et al., 2010). Even small increments in prevalence rates of psychiatric disorders will stimulate a daunting surge of demand for mental health services. Lacking mechanisms for triage, screening, and coordinated care systems, distress will create impairment and impairment will progress unnecessarily to psychiatric disorders and dysfunction across life roles (Reissman et al., 2010).

A psychological triage system has been developed that uses color-coded triage tags and data transmission devices, and importantly, connects persons in need of more intensive mental health evaluation to community-based "disaster systems of care." This system has been applied during the postimpact phase following the 2004

Southeast Asia tsunami and the Laguna Beach, California wildfires (Reissman et al., 2010). In practice, this mental health triage system operates separately from medical triage at a later stage in response.

Expert panels have convened to devise and standardize efficient triage systems for emergency and disaster victims. Consensus has emerged regarding the five critical features that exemplify the "ideal mass casualty triage system" for use during disaster impact and in the immediate aftermath.

The ideal triage system possesses these characteristics:

1. *Rapid* (less than 1 min per patient)
2. *Scalable* (saving time by triaging large groups collectively as numbers of incoming casualties mount)
3. *Recurring* (triage must be updated with every patient encounter)
4. *Integrates both medical and behavioral triage*
5. *Includes resource-based criteria for exclusion from care* (accounting for the possibility of insufficient medical/behavioral resources to treat all critical patients immediately)

Recently introduced as the "SALT" protocol (Sort, Assess, Lifesaving Intervention, Treatment/Transport), the Model Uniform Core Criteria for Mass Casualty Triage were developed as a consensus guideline for mass casualty triage to achieve standardization when responding to a catastrophic health event (Lerner et al., 2011). This well-publicized model matches 4-for-5 on the key triage attributes. What is lacking in the SALT structure is the ability to seamlessly integrate real-time medical and behavioral triage.

Disaster mental and behavioral health intervention

Prevention

From the vantage of public health, the greatest leverage for decreasing the burden of injured, traumatized, and bereaved disaster survivors resides in the domain of prevention. Citizen disaster preparedness carries great potential for diminishing disaster impact in all aspects. Preventive behaviors include development of family, school, worksite, and community disaster plans with regular updates and periodic drills (Schmitz et al., 2009). Stockpiling and rotation of disaster supplies and creation of Go-Kits for home, automobile, and worksite will provide a critical supply of basic needs. Citizen participation on volunteer community disaster teams will enhance the repertoire of preparedness and response skills and build social support and community cohesiveness. When disaster is approaching, heeding disaster warnings and engaging in appropriate response actions (including preparation of home site, notification of key contacts, timely evacuation, and safe sheltering) have life-saving implications (Shultz et al., 2009). Psycho-education on expectable psychological reactions and positive coping strategies for persons exposed to disasters, combined with acquisition of effective stress management skills, are important components of psychological preparedness.

Despite the wisdom and utility of disaster preparedness and the potential for significantly decreasing physical and psychological harm when disaster strikes, the vast majority of citizens do not engage in these preventive behaviors. A critical future direction for psychological research is to examine strategies to motivate citizens to participate actively in family and community disaster preparedness.

Post-disaster

Post-disaster mental and behavioral health interventions can be classified according to timing and intention. As Bryant and Litz (2009) point out, it is important to sensitively gauge receptivity to receiving services in persons exposed to the effects of trauma. Therefore, a critical factor to be considered when choosing interventions post-disaster is when to implement intervention efforts so as to avoid unnecessary taxing of already scarce resources. Further, when choosing interventions post-disaster a clear delineation according to the intervention's intention is important. One of the major aims of early post-disaster intervention is to reestablish a sense of safety and calm, whereas intermediate and long-term interventions focus on acquiring coping skills and ameliorating psychopathological presentations.

Early intervention

Early intervention for psychological impacts of disasters is presently in a quandary. The longtime standard bearer, psychological debriefing, has been scientifically discredited. The putative successor, psychological first aid, has not gained traction with disaster responders and its efficacy, to date, remains unevaluated in the field (Litz, 2008).

Psychological debriefing. Introduced in the 1980s under the name "critical incident stress debriefing" (CISD), psychological debriefing was promoted as an intervention to decrease acute stress and to eliminate or inhibit delayed stress reactions among emergency and disaster response personnel (Mitchell, 1983). Authors later championed CISD as effective for use with a broad spectrum of survivors of trauma (Everly and Mitchell, 1999). CISD was repackaged as a pivotal component among a suite of related interventions collectively titled critical incident stress management or CISM. Popularity escalated with broad adoption by first responders worldwide. Litz (2008) describes CISD as the modal intervention strategy in the immediate posttrauma phase prior to 2002.

CISD is intended for use within 48 h of the traumatic incident and features brief education about trauma reactions. This is followed by a stepwise process in which survivors are prompted to disclose cognitive and emotional aspects of the traumatic event. Participants are explicitly asked to describe "the worst part" of the experience and their accompanying psychological and physical reactions

(Bryant and Litz, 2009). Widely adopted by emergency responders and military organizations internationally, the intuitive appeal of CISD is based on its easy-to-learn, easy-to-apply, peer-provided, protocol-driven format that fits well within responder work cultures (Litz, 2008).

Despite favorable perceptions among both practitioners and persons receiving CISD, when subjected to scientific scrutiny, CISD has not been shown to prevent PTSD nor to confer any favorable benefits upon recipients when compared to those who do not receive this intervention (McNally et al., 2003; Roberts et al., 2009). The scientific critiques of CISD focus on the potential for re-traumatization of persons exposed to disaster by requiring them to recount their own vivid experiences and to listen to the oftentimes horrific stories of others (McNally et al., 2003; Roberts et al., 2009; Bryant and Litz, 2009). The process and timing involved in application of CISD may short-circuit the natural healing process, lead to ruminating thought processes, and provoke psychological hyperarousal in a manner that locks-in, or consolidates, the traumatic memories.

Under certain circumstances, such as mandatory, single-session CISD, there appears to be a low-level potential for harm and possibly elevated rates of PTSD. The absence of benefit, coupled with the potential for detrimental outcomes, violates the fundamental precept of "do no harm" (Bryant and Litz, 2009). Nevertheless, in apparent defiance of the scientific concerns, passionate advocates practice CISD undeterred, responder work-cultures continue to mandate debriefing, and teams using this approach are ever-present at disaster scenes.

Empirically informed early intervention. The demise of debriefing as the psychosocial standard created a void in the early psychological intervention armamentarium. International experts in disaster mental and behavioral health were convened by the National Institute of Mental Health in 2001 to develop consensus on early posttrauma intervention (NIMH, 2002). Their findings endorsed a movement away from debriefing and toward a more flexible, nonprescriptive, multifaceted approach. Rather than focusing narrowly on a single intervention technique, the committee recommended that a spectrum of actions be considered as components of early intervention: securing basic needs, applying the principles of psychological first aid, conducting needs assessments, monitoring the rescue and recovery environment, providing outreach and information, fostering resilience and recovery, conducting triage and referral, and providing psychiatric treatment for an identified subset of trauma survivors (NIMH, 2002).

This roster of recommendations emphasized strategies that can be applied at the community level through the concerted efforts of many responders, not just mental health professionals. In the earliest moments of response, actions directed toward reestablishing safety and security, coupled with provision of basic survival needs – mainstays of traditional disaster response – also provide a beneficial psychological effect. Trained mental health professionals are encouraged to activate an effective triage system as a safety net to identify those persons needing referral to expert psychological evaluation and possible treatment. Following initial screening, these professionals also deliver the appropriate level of intervention necessary to restore pre-disaster levels of functioning; options range from education, to psychotherapy, to prescription of therapeutic medications, to psychiatric hospitalization. Technical assistance and consultation to leadership was also included in the package of recommended early interventions. While some of these tactics are provided one-on-one, others are amenable to community-wide outreach and education.

Psychological first aid. The term "psychological first aid" was originally introduced in 1954 (Drayer et al., 1954) and models of psychological first aid had been in active use since the 1980s particularly by international relief agencies in Europe and Australia. Psychological first aid is rooted in the scientific evidence base supporting the assertion that a return to pre-disaster levels of functioning is the expected outcome for most disaster survivors. One of the major aims of psychological first aid is to draw upon survivors' strengths, and in the process help increase resiliency (Pynoos and Nader, 1988; Young, 2006). In contrast to CISD, psychological first aid allows flexible application of strategies tailored to each survivor's needs. Moreover, discussion of the trauma experience is not prompted, although such discussion is not precluded if the survivor chooses to talk about the event.

The release of the 2001 NIMH panel recommendations spurred a flurry of activity; new models of "PFA" proliferated within several years of the conference. In short order, psychological first aid was heralded by its proponents as the "acute intervention of choice" (NCTSN/NCPTSD, 2006). With multiple models in circulation and use, Bryant and Litz (2009) explored for common themes when they specified these three goals of psychological first aid: (1) reestablish safety, (2) reduce acute stress reactions, and (3) guide the survivor to access resources.

In 2004, world experts were convened to solidify the science behind early psychological support and intervention. Their primary output was a landmark publication describing the five essential elements of early intervention, defined as *safety, calming, connectedness, self-efficacy*, and *hope* (Hobfoll et al., 2007). These five principles are known to be psychologically beneficial based on scientific evidence and collectively they assist disaster survivors to cope with the stressors and challenges of disasters.

Actions taken to reestablish the physical *safety* of survivors also decrease perceptions of threat and vulnerability (Ozer et al., 2003). Efforts aimed at promoting *calming*, such as relaxation breathing, are beneficial psychologically by decreasing hyperarousal, a risk factor for PTSD. Endeavors to achieve *connectedness*, such as reuniting separated loved ones, draw upon the well-documented protective effects of social support (Norris et al, 2002). Actions that empower survivors to participate actively in recovery promote *self-efficacy* and help reestablish a degree of personal control for survivors in the

post-disaster environment. Rekindling *hope* can be beneficial psychologically based on studies that relate optimism and a hopeful appraisal style to favorable outcomes among survivors of trauma (e.g., Antonovsky, 1979).

Reissman and colleagues (2010) envision these five principles as pathways to guide survivors back from the traumatizing disaster experience to favorable adaptation. Effective early intervention, then, should move survivors (1) from risk to *safety*, (2) from fear to *calming*, (3) from loss to *connectedness*, (4) from helplessness to *self-efficacy*, and (5) from despair to *hope*. These five principles align with common sense disaster response actions throughout history. While many of the response strategies that embody these principles are not new, recently acquired scientific support indicates that they can be both helpful in a practical sense as well as beneficial psychologically.

Multiple models of psychological first aid coexist, each applying a variation of the empirically informed principles of early intervention. The most literal example comes from the Australian Psychological Society (2009) which explicitly organized its psychological first aid response to the Victorian bushfires around five "core components." Not surprisingly, these are: (1) *promote safety* by providing basic needs and emergency medical services, (2) *promote calming* by listening to the stories of survivors who wish to share their experiences and providing accurate information, (3) *promote connectedness* by keeping families together and helping separated family members make contact, (4) *promote self and community efficacy* by engaging people in meeting their own needs, and (5) *promote hope* by enhancing people's natural resilience.

During the 2000s, the use of psychological first aid received endorsement from a series of expert panels (NIMH, 2002; Hobfoll et al., 2007; National Biodefense Science Board, 2008). However, it has not been scientifically tested for efficacy in real disaster field applications (Litz, 2008; Raphael and Maguire, 2009). "Psychological first aid does not purport to prevent the future onset of psychiatric disorders, such as PTSD. Instead, its goals are more modest, decrease distress, and promote adaptive coping skills in post-disaster environment," (Bryant and Litz, 2009).

In summary, early intervention models continue to evolve. In the earliest moments after disaster strikes, what is needed is neither formal psychological treatment nor therapy. In fact, the greatest psychological good comes from actions that are not primarily "psychological," but draw on time-tested disaster response tactics. Moving survivors to safety, calming them by supplying basic needs, connecting survivors to missing loved ones, actively involving survivors in helping themselves, and maintaining a positive, optimistic presence – all mainstays of traditional disaster response – are now known to also be beneficial psychologically.

Intermediate-term intervention

In the intermediate aftermath of a disaster (i.e., weeks and months post-disaster), more specific psychological intervention may be appropriate for those persons exhibiting continued high levels of disaster distress (e.g., high levels of anxiety, high levels of physiological arousal, lack of coping skills) that markedly interfere with daily functioning.

Skills for Psychological Recovery. As an intermediate intervention, Skills for Psychological Recovery (Australian Psychological Society, 2009) focuses on providing survivors of disasters with appropriate coping skills aimed at alleviating persistent disaster distress. As such, SPR builds on psychological first aid, emphasizing the importance of gathering information and providing support. More specifically than psychological first aid, though, SPR delves into managing physiological arousal, modulating emotions and cognitions, increasing problem-solving skills, and scheduling positive activities.

Long-term intervention

In the long-term post-disaster aftermath, as disaster distress continues to persist, PTSD is the most commonly seen psychiatric disorder. The intervention of choice for PTSD is a cognitive-behaviorally based psychotherapy approach. The overall aims of such an approach are the restructuring of dysfunctional cognitions, redressing of problematic behaviors, and modulating affective responses.

Different variants of PTSD-specific cognitive behavioral therapy approaches have been developed, such as exposure therapy, stress inoculation therapy, systematic desensitization, cognitive processing therapy, cognitive therapy, assertiveness training, and biofeedback/relaxation training (Rothbaum et al., 2001). The exposure-based approach has been found to be most efficacious in treating PTSD (e.g., Foa and Meadows, 1997). An exposure-based approach addresses the pervasive avoidant behavioral patterns that often result from trauma exposure and lead to significant impairment in daily functioning. The approach seeks to reexpose survivors to the disaster experience in a therapeutic and safe manner.

Psychological trajectories following disaster

The severity and duration of psychological outcomes is highly variable for individuals even when the severity of disaster exposure is approximately equal. For persons who are psychologically impacted by exposure to a natural disaster, Layne et al. (2007) describe and contrast five possible trajectories from the moment of impact forward: resistance, resilience, protracted recovery, chronic severe distress, and posttraumatic growth.

Resistance. Some individuals, the rarest of the breed, maintain a near-steady course of highly adaptive functioning throughout the disaster episode. It seems as if they are psychologically impervious to the potentially traumatizing effects of disaster. Using a materials science analogy, it appears as if the disaster is psychologically deflected or merely "bounces off" without making a mark. This response is vanishingly rare.

Resilience. Resilience is the ability to rebound in the face of adversity and represents a more typical response pattern in which function and performance are negatively affected during disaster impact, but the individual rapidly reestablishes psychological equilibrium and regains function in short order. This is the psychological equivalent of what happens to an automobile bumper during a low-velocity collision; on impact the bumper deforms and contorts, but almost immediately springs back to its original contour. Psychological resilience is surprisingly common, and according to Shalev and Errera (2008), actually the "default" outcome for the majority of survivors.

Protracted recovery. A number of survivors will need a notable period of time to recover from the traumatic event. They will ultimately resume full function, but the path back will take time.

Chronic, severe, debilitating distress. These individuals remain at a decreased level of function over time and do not recover without intervention. Many meet criteria for psychopathology such as PTSD, MDD, or a combination.

Posttraumatic growth. Some individuals, despite bludgeoning disaster impact, followed by adversity and obstacles, overcome and strengthen through the experience, emerging healthier and more functional after the disaster than before. Posttraumatic growth describes those who resurface from disaster with an enhanced repertoire of coping skills and an enlivened appreciation for newfound capabilities forged by hardship.

Resilience

One of the trajectories described, resilience, is a topic that is garnering considerable attention in the disaster field. Remarkably, most disaster-exposed individuals are minimally affected by the adversities and are frequently able to adapt to the circumstances. This capacity has been termed resilience, defined as the human ability to maintain stable, healthy levels of psychological and physical functioning following a potentially highly-disruptive event (Bonanno, 2004). Resilient individuals post-disaster manifest only transient mild stress reactions which are not likely to significantly interfere with continued functioning and are typically of short duration.

According to the American Psychological Association (2005), "resilience is the process of adapting well in the face of adversity, trauma, tragedy, threats, or even significant sources of stress." In disasters, resilience is the rule rather than the exception (Shultz et al., 2007b). Resilience is frequently the most common outcome among survivors exposed to natural disasters and among responders who provide support to these survivors. Resilience can be learned and enhanced.

Some defining characteristics of resilience expand its description. Resilience appears to be a common phenomenon that results from positive adaptation to life challenges (Shalev and Errera, 2008). If human abilities to adapt remain intact, individuals are able to adjust healthfully to severe adversity. Many pathways to positive adaptation exist. When faced with traumatizing events, individuals may be resilient in some domains of life but not all; resilience is not a binary – all-or-none – phenomenon (Layne et al., 2007). "Ordinary magic" is a phrase that captures the surprising and optimistic finding that resilience is the expectable outcome for a large proportion of disaster survivors (Masten, 2001).

Summary

The psychological impacts of natural disasters are widespread, expand across a spectrum of severity, extend along a range of duration, and relate to the nature of the disaster event. The psychological consequences of disasters are spawned by, and directly proportional to, the degree of exposure to hazards, loss, and change, the "forces of harm" that characterize natural disasters. High-risk populations in harm's way, those that are particularly vulnerable to the ravages of disaster and the combination of physical and psychological consequences, can only be partially defined before disaster strikes. Disaster impact, compounded by adversities in the aftermath, "reshuffles the deck" by creating new special populations of persons needing medical and psychological support composed of those who have sustained extreme exposure to trauma and harm. While most persons exposed to disaster rebound quickly from transient distress reactions, others progress to psychopathology including PTSD, major depression, anxiety disorders, and substance abuse. Those who lose loved ones in a natural disaster are likely to grapple with complicated grief.

Prevention of psychological consequences of disaster holds great promise but is untried and untested. Early intervention is being redefined as psychological debriefing is supplanted by evidence-informed approaches; psychological first aid is the current contender. A stepped-care approach is advocated for moving survivors through a progression of early to intermediate psychological support and beyond this, for those whose distress is unabated, into psychological and psychiatric treatment.

While focus is understandably drawn to timely, empirically based support and treatment for those who are impacted psychologically, some of the most affirmative guidance to emerge is that resilience, positive adaptation in the face of disaster's adversity, is the most common and expectable outcome. Some survivors even emerge from the disaster experience stronger and more vital psychologically, a recently-recognized phenomenon known as posttraumatic growth. This sets the future agenda for the field; integrating disaster mental and behavioral health with the disciplines of public health, public safety, and emergency response to enhance preparedness for future catastrophic events.

PYROCLASTIC FLOW

Robert Buchwaldt
Massachusetts Institute of Technology, Cambridge, MA, USA

Synonyms

Ash flow; Nuées ardentes; Pyroclastic density current

Definition

Pyroclastic density currents are rapidly moving mixtures of hot volcanic particles and gas that flow across the ground under the influence of gravity. These processes are heavier-than-air emulsions that move much like a snow avalanche, except that they are fiercely hot, contain toxic gases, and move at phenomenal, hurricane-force speeds, often over 100 km/h.

Introduction

Pyroclastic flows are some of the most mysterious and dangerous volcanic features. They are also one of the most dramatic and picturesque ways to see the energy and destruction stored in our planet (Figure 1). Since the 1700s these currents have caused the death of several tens of thousands of people. During the eruption of Montagne Pelée in 1902, 28,000 people were killed when a cloud of hot gas and ash destroyed the peaceful village of Saint Pierre, of Martinique in the Lesser Antilles and the sole survivor was found days later in an underground prison (e.g., Anderson and Flett, 1903; Scarth, 2002). Pyroclastic flows generated during the August 25, 79 AD eruption of Mount Vesuvius, Italy, contributed to the devastation of the Roman cities of Pompeii and Herculaneum and the deaths of 10,000–25,000 people (e.g., Sigurdsson et al., 1982; Pliny, 79 AD). During the eruption of Mount St. Helens on May 18, 1980, which was the deadliest and most economically destructive volcanic event in the history of the USA, 57 people were killed; 250 homes, 47 bridges, 15 miles (24 km) of railways, and 185 miles (298 km) of highway were destroyed by a combination of a lateral blast and pyroclastic density currents (Lipman and Mullineaux, 1981). Therefore, a detailed understanding of these natural phenomena is essential for the mitigation of volcanic hazards.

Pyroclastic Flow, Figure 1 Pyroclastic flows descend the southeastern flank of Mayon Volcano, Philippines during the September 23, 1984 eruption (Photograph by C.G. Newhall/USGS).

Terminology

The name Pyroclastic is derived from the Greek "pyro" (πῦρ), meaning fire; and "clastic" (κλαστός), meaning broken and was apparently first used by Francesco Serao (1738) in a short account written on the eruption of Vesuvius between May 14 and June 4, 1736. After this relatively straightforward term the terminology of ground-hugging flows of hot, variably inflated, lava particles, and variable amounts of magmatic gas, steam, and ingested air has been very confusing over the years, predominantly due to the fact that until recently scientists tried to develop genetic terms for something they inferred to have happened. Nevertheless, today the scientific community has largely agreed to use the term pyroclastic flow or better pyroclastic density current for inflated mixtures of hot volcanic particles that flow in variable concentrations and varying velocities along the ground. Based on the textural characteristics of their deposits, there are two end member types distinguished, the products of a dilute suspension called pyroclastic surges, in which particles are carried in turbulent suspension in a thin layer close to the ground, and a generally "thicker," more massive pyroclastic flows, (Fisher and Schmincke, 1984). The ranges of structures which can be found in pyroclastic surge deposits immediately evoke the idea of high energy and a very dynamic depositional environment and therefore have a great destructive potential. The most common depositional characteristics in this group are well-defined bedding, which show erosional unconformities, good to moderate sorting of the particles, the pumice particles are well rounded, and last but not least local lateral grading into massive flow deposits. Spatially, pyroclastic surges are usually not confined to a channeling valley as their path downslope but they can overflow these and can mantle the surrounding landscape. The typical distribution is nevertheless restricted to proximal area around volcanoes (circa 8 km from the vent).

In contrast, the deposits from pyroclastic flows are generally poorly sorted, massive, and are more confined to the valleys used to move downslope. The deposits thicken markedly toward the center and since they fill the channels they tend to flatten the existing morphology. The deposits are created by sedimentation from particle rich flows. Pyroclastic flow deposits containing pumice as a major constituent are called ignimbrites, sometimes ash flow tuffs. Smaller deposits are referred to as block and ash deposits or if the clasts are vesiculated then they are called pumice and ash deposits. From these two end member cases of pyroclastic density currents we can infer that the controlling factor of the deposition style is the amount of particles relative to the dilution medium, the containing gas. The more particles that are present the less the flow is able to travel because the particles try to settle, bouncing against each other and disturb the continuous laminar flow, whereas the less particles that are present the flow is more undisturbed and can travel farther. Therefore, in the first case we preferentially would get pyroclastic flows and in the second we would get pyroclastic surges.

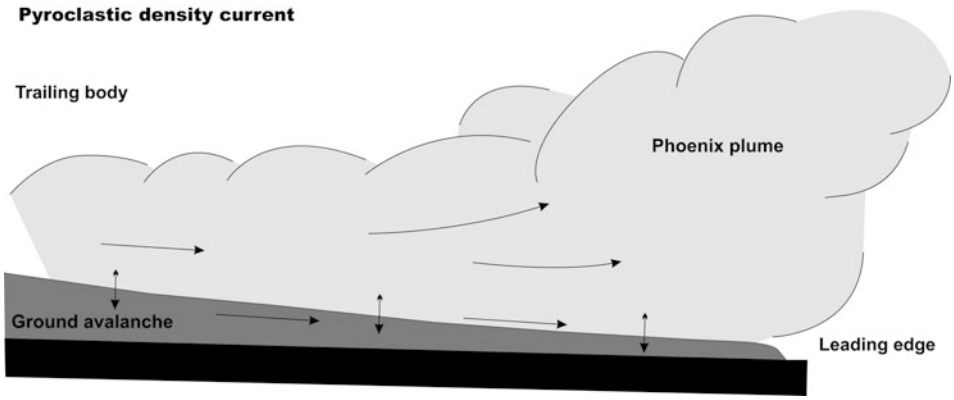
In practice, it is often impossible to conclude with any certainty which type has been deposited due to a process known as "aggradation." After an eruption of a pyroclastic density current, the behavior and character of the flow changes over time. The moving energy decreases, the incorporated particles have difficulty to stay in suspension, start to settle out and change the

morphology of the path, and therefore the flow encounters fewer barriers. The temperature of the flow cools along its path, which in turn changes the flow behavior. As a consequence, the deposits and its architecture can be very complex and probably reflects more processes at the base. Branney and Kokelaar (2003) suggested changing the terminology, to reflect this dynamic behavior, to just two end members. The first is a fully dilute pyroclastic flow in which collision between particles play a limited role. The second end member is a granular fluid-based pyroclastic flow in which the particle density is high enough that interaction is important and clasts can be supported by collision and by the flux of the surrounding dusty gas forced upward by the settling particles.

Origin

There are three common mechanisms for the generation of pyroclastic flows: (1) Simple gravitational collapse of a growing lava dome (Lava dome is a mound of volcanic rock extruded from a volcanic vent and the lava piles into a heap rather than flowing away and forms a round plug on top of the volcanic vent) or lava flow on a volcano, known as Merapi type, (2) The Peléean type is the explosion within a growing lava dome which trigger an eruption and collapse of the dome and (3) the Soufrière type is the collapse from eruption columns (The eruption column is a column of gases, ash, and larger rock fragments rising from a crater or other vent. If it is of sufficient volume and velocity, this gaseous column may reach many miles into the stratosphere), the most impressive and hazardous type.

Gravitational collapse of Lava Domes (Meriapi type) generates small pyroclastic flows rich in dense poorly vesicular components. The high temperature rockfalls formed by dome collapse transform rapidly into dusty, relatively small pyroclastic density currents due to the low mechanical strength of hot gas-poor lava (Mellors et al., 1988). Such flows commonly produce block and ash flows. In some cases, dome collapse is preceded by vigorous gas venting (Cole et al., 1998), which empties the shallow magma chamber (Magma chamber is a reservoir of molten rock material beneath the Earth's surface) and allows its roof to collapse (Peléean type). Block and ash flows are emplaced as highly concentrated avalanches overlain by a dilute ash cloud (Cole et al., 1998). The basal avalanche is gravity-driven and follows valleys. Large blocks bounce and roll in the avalanche. The accompanying ash cloud acts as a surge, so is less controlled topographically, allowing it to outrun the avalanche and spill over watersheds into adjacent valleys. The ability of ash cloud surges to decouple from the basal avalanche makes them particularly unpredictable and thus hazardous.



Pyroclastic density currents formed by column collapse (Soufrière type) are rich in gas components and are termed scoria flows if the juvenile material is moderately vesicular, or pumice flows or ash flows if the vesicularity is high. To understand the emplacement of these flows, we have to understand what changes the evolution of the erupting column or jet from a stable environment to an unstable environment. The stability of the erupting column is controlled by two main parameters. Either the erupting magma loses the gas phase and progresses into magma poorer in volatiles (the driving force for the thrust of explosive eruptions), or the size of the vent is increasing due to vent erosion. If either of these parameters change then the erupting column will become unstable and leads to a collapse of the column. When this occurs, part or the entire eruption column does not have sufficient thrust or energy to continue rising. The gas and pyroclastic particles lose buoyancy as they are now denser than the surrounding atmosphere and thus begin to fall under gravity forming pyroclastic flows. Column collapse generates a current in which the particles are suspended by turbulence.

Transport

Small pyroclastic density currents travel at speeds up to a few tens of meters per second (m/s). Particularly detailed measurements have been published by Hoblitt (1986) for the flow of August 7, 1986 Mount St. Helens, which reached a maximum speed of 30 m/s. Pumice flows from the August 1997 explosive eruptions at Monserrat had initial speeds of approximately 60 m/s and some pyroclastic density currents have been reported to be as fast as 100 m/s.

Taylor (1958) in his famous and groundbreaking analysis of the 1951 Mount Lamington eruption emphasized the importance of gravity as an energy source for pyroclastic flows, whether from vertical eruption columns or from collapsing domes growing in craters. He concluded that the thermal energy contained within hot magma may thrust an initial explosion and the ascent of the eruption column, but after the initial loss of energy it does not contribute much to the lateral movement of the pyroclastic flows. A gravity-driven pyroclastic flow may even accelerate and become more hazardous as it continues downslope. This simple and fundamental principle has withstood the test of time, and also it has been refined using more sophisticated computer models, has not changed in modern history and gravity is still considered to be the driving mechanism for pyroclastic density currents.

To understand the dynamics of the pyroclastic density current better, we have to understand first the morphology and architectures of these features (Figure 2). When we observe a single turbulent density current one can see that it consists of a leading edge, with various possible forms, and a long trailing body. The leading edge of the current typically has an overhanging nose and sometimes is thicker than the body. In more detail we can recognize that pyroclastic flows are composed of two parts. A basal "ground hugging avalanche" in which most particles are transported and deposited. This avalanche is usually hidden by an overriding billowing cloud of hot gases and fine ash particles, which can rise tens of kilometers into the atmosphere. This cloud is often termed as Phoenix column or Phoenix plume.

Pyroclastic Flow, Figure 2 Schematic cross-section through a pyroclastic density current. *Arrows* indicate particle movement direction (Adapted from Branney and Kokelaar, 2003).

In general, to see more details in situ and to understand the transport mechanism from pyroclastic density currents is very difficult because most of the dynamic processes within the currents are impossible to observe and are commonly inferred from the associated deposits or derived from numerical models. By examining the deposits of many pyroclastic density flows, we can often observe a thin fine grained basal layer 10–50 cm thick in which both pumice and rock fragments are inversely graded. This layer forms by the interaction of the flow with its substrate. The main division of the flow unit is massive or crudely stratified. In many cases, large pumices are reversely graded forming a concentration zone at the top.

To produce such a deposit we have to envision the following scenario. The gas particle mixture is following gravity and accelerates downhill along the volcanic slopes. If the avalanche would behave like a solid block the friction on the base of the flow should slow the system down, but rather than slowing the whole body the friction creates a small gas layer on which the rest of the flow rides relatively frictionless, similar to a Hovercraft. This mechanism allows for the incredible velocity and their ability to spread laterally. The nature and origin of the gas phase is still debatable. The principle source of the gas is thought to be from degassing of magmatic particles in transit, which is possibly not the major source, gases incorporated during the collapse of the eruption column, air ingested and heated at the front of the moving pyroclastic flows, or vaporized moisture from the ground (possibly only locally important). The top of the flow only slows through contact with the surrounding stagnant air. Thus, the flow travels fastest toward the middle and slower on the outside edges. The small gas layer beneath the flow allows the flow to travel much farther and faster resulting in greater devastation along the volcano's flanks.

Lateral blasts

Lateral Blasts like those at Mount St. Helens, Washington USA, in 1980 and Bezymianny, Kamchatka Russia, in 1955 are caused by the sudden decompression of magma by flank collapse. In these cases, the explosive event distributed the eruption energy horizontally instead of vertically as in a traditional eruption column. Nevertheless, the initial driving force of this glowing cloud is from the blast, at one point gravity takes over as the driving force and pyroclastic density currents form. Lateral blasts are less well understood than fountains, and computer simulations of these scenarios are in their infancy. The Mount St. Helens blast had an internal velocity as high as 235 m/s. This is consistent with simple theoretical models and is comparable to speed of currents formed by column collapse. The Mount St. Helens blast was originally supersonic relative to the internal sound speed of the erupting mixture. One difference between column collapse and lateral blast is that in the latter there is no initial vertical component. Thus, for a given exit velocity the largest block discharged might be smaller than the fountain. Pyroclastic currents formed by lateral blasts are short lived and highly unsteady. Peak discharge of the Mount St. Helens blast lasted no more than a few tens of seconds.

Volcanic hazard mitigation

Volcanic eruptions cannot be influenced by humans. They are governed by processes that start deep in the Earth and often reach the stratosphere. When a volcanic catastrophe occurs, the reasons are often rooted in society itself. There are, however, limited possibilities to reduce some of the impacts of volcanic eruptions. Whether a volcanic eruption leads to major loss in human lives or not depends on the population density in the proximity of a volcano and its state of preparedness and organization. It does not generally depend on the volume of magma erupted or the type of eruptive processes.

All types of mass flows pose a great hazard to communities because people tend to live in valleys that are convenient, support good soil, and have water resources nearby. High velocity, hot, particle-poor blasts are especially dangerous because their pathways are not confined

to valleys. The main loss of lives and the largest economic losses in the last few centuries from volcanism resulted from pyroclastic density currents hot blasts. Hot pyroclastic density currents, which consist of gas and particles, at temperatures sometimes exceeding 800°C, speed down the flanks of a volcano and may cover thousands of square kilometers. People caught within the flow path have little chance of surviving. Buildings, crops, and forests are destroyed and warning periods are extremely short. On the other hand the most likely pathways can be clearly delineated in hazard maps. Administrators responsible for land planning can effectively reduce the risk when restricting settlements in valleys that are likely pathways for volcanic mass flows. Each volcano behaves differently, requiring careful analysis of local factors. Effective prediction of pathways and evacuation is currently the main method for mitigating the risk of pyroclastic density currents. Most important in this endeavor is to define hazard zones, which are based on a very detailed analysis of the early history of a volcano, as well as an estimate of the possible scale and nature of eruptive processes at a particular volcano.

The path of some lava flows can be influenced slightly by building barriers. This costly mitigation technique has so far only worked on eruptions that are small and slow but are ineffective when the eruptive volume is very large. These dams are low concrete wall-type structures constructed perpendicular to the proposed flow direction. Such structures break the velocity and therefore the erosional energy of the pyroclastic density currents. In addition, they also act as temporary sediment traps. Dams parallel to valleys have been constructed on several volcanoes to direct the course of the flows.

Overall, the most successful mitigation of pyroclastic density currents is its integration into the volcanic hazard plan as a whole which includes monitoring, prediction, and prevention. A volcanic eruption is the result of a large number of factors and a reliable prediction can only be made in well-instrumented and well-monitored volcanic situations. The areas potentially affected during volcanic eruptions can usually be relatively well predetermined, depending on how well a volcano and its deposits have been analyzed, allowing early mitigation planning and significant minimizing of damage. Finally, communication between the public, scientists, and the administrative body is essential; to understand the risk a community has to know how to prepare for an eventual event. Two of the largest volcanic catastrophes in the last century could have been avoided if the political administrative bodies had taken seriously the fear and determination and of the people, or the warning of scientists.

Summary

In summary, we can define pyroclastic flows as high-density mixtures of hot, dry rock fragments and hot gases that move away from their source vents at high speeds. These flows are driven by gravity on a layer of hot air. During their travel, they damage or destroy structures and vegetation by impact of rock fragments moving at high speeds and may bury the ground surface with a layer of ash and coarser debris tens of centimeters or more thick. Because of their high temperatures, hot pyroclastic flows may start fires and kill or burn people and animals. Consequently, it is essential to comprehend the structure and dynamic of these devastating events. Also active mitigation is difficult for most of the pyroclastic density currents, but casualties and losses can be avoided by a careful integrated approach of the volcano as a whole, using historical data as well as modern computer models to create hazard maps, to understand the pathways of pyroclastic density currents and to create escape routes for the communities. Similarly, the prediction of pyroclastic density currents is complicated; well-monitored volcanoes have in recent years increased the success rate of warnings. Finally, it is an old story that the messenger is the culprit who brings the bad news; recently, the communication between the different parties has improved by bringing the message directly to the endangered populations, involving modern technologies, and thus ensuring that the scientific knowledge has a better chance to be integrated in the decision-making process for the good of society.

CASE STUDY

QUEENSLAND FLOODS (2010–2011) AND "TWEETING"

France Cheong, Christopher Cheong
RMIT University, Melbourne, VIC, Australia

Introduction

Australia experienced its worst flooding disaster in 2010 and 2011 with a series of floods occurring in several states between March 2010 and February 2011. Worst of all were the Queensland floods which caused three-quarters of the state to be declared a disaster zone (*Brisbane Times*, 2011).

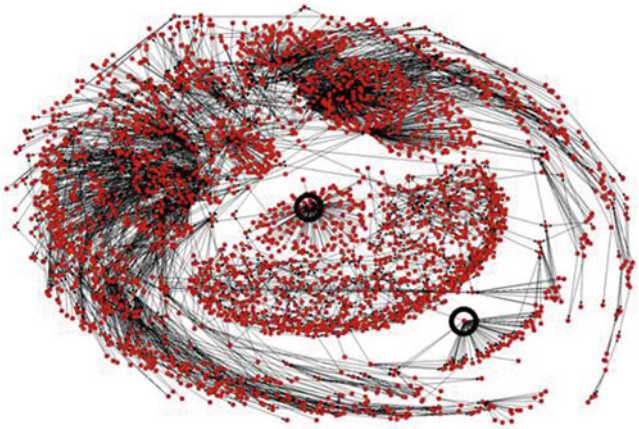
In times of mass emergencies, a phenomenon known as collective behavior becomes apparent (Dynes and Quarantelli, 1968). It consists of socio-behaviors that include intensified information search and information contagion (Starbird et al., 2010). In these situations, people want to know where exactly their families and friends are, as not being able to reach them or knowing they might not be able to contact you, can be very frightening moments during such situations. Information is critical during emergencies as the availability of immediate information can save lives. People share information about approaching threats, where to evacuate, where to go for help, etc. Not only do they want to know about the destruction that has occurred, but they are also eager to help those affected by giving a helping hand and raise funds from donations. Thus, there is a need to keep abreast of the latest developments; however, this is difficult since information produced under crisis situations is usually scattered and of varying quality.

Social media is media for social interaction enabled by communication technologies such as the web and smartphones. The distributed, decentralized, and real-time nature of these interactions provide the necessary breadth and immediacy of information required in times of emergencies (Palen and Vieweg, 2008). Since social media offer a uniquely rapid and powerful way to disseminate information, accurate and inaccurate, good and bad information spread equally alike as incorrect information can spread like wild fire. However, there is indication that social networks tend to favor valid information over rumors (Castillo et al., 2011).

Twitter is a microblogging service, a form of lightweight chat allowing users to post and exchange short 140-character-long messages known as *tweets*. Although most tweets are conversation and chatter, they are also used to share relevant information and report news (Castillo et al., 2011). Twitter is becoming a valuable tool in disaster and emergency situations as there is increasing evidence that it is not just a social network, it is also a news service (Yates and Paquette, 2011). In emergency situations, tweets provide either first-person observations or bring relevant knowledge from external sources (Vieweg, 2010). Information from official and reputable sources is regarded as valuable and hence is actively sought and propagated. Other users then elaborate and synthesize this pool of information to produce derived interpretations.

We studied the community of Twitter users disseminating information during the crisis caused by the Queensland floods in 2010–2011 in order to reveal interesting patterns and features within this online community. Our aim was to develop an understanding of the online community that was active during that period by answering the following questions: What was the online social behavior during that period? In particular, who were the active players communicating information and how effective were they? What type of information was of importance? How can the information discovered be useful for the management of such situations in the future?

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013



Techniques from Social Network Analysis (SNA) were used to analyze the online community. SNA is a sociological approach for analyzing patterns of relationships and interactions between social actors in order to discover underlying social structure such as: central nodes that act as hubs, leaders or gatekeepers; highly connected groups; and patterns of interactions between groups (Wasserman and Faust, 1994). SNA was used to gain an understanding of two types of networks. First, when a Twitter user (or *twitterer*) responds to a tweet, a network of twitterers is created with nodes (or vertices) representing twitterers and edges (or links) representing responses to particular tweets of particular twitterers. Since a response flows from a responder to a recipient, the links in this network are directed links. A second type of network that can be constructed from tweets is an "online resources" network as very often tweets contain links to web pages due to the 140-word limit of tweets preventing more detailed description of "what is happening." Such a network contains two types of nodes, namely, twitterers and resources and these networks are known as bimodal or bipartite networks in the SNA and graph theory literature (Borgatti, 2010; Borgatti and Everett, 1997).

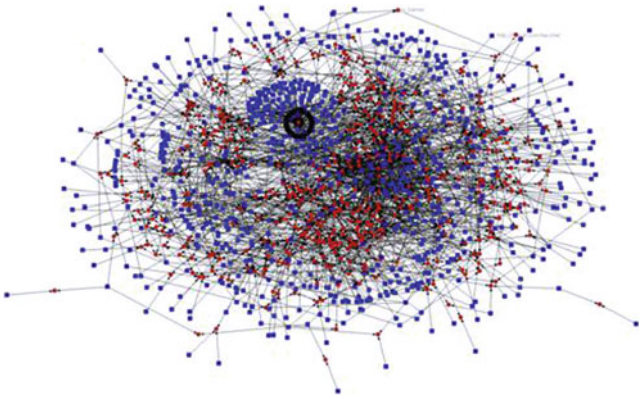
Data collection

Tweets were harvested from Twitter using the *#qldfloods* hashtag by means of an in-house script created for the purpose. For the period February 3–20, 2011, 6,014 tweets were collected. In order to obtain the nodes and links (edgelists) required to generate the "users" and "users-resources" networks, individual tweets were parsed to extract the identity of the owner of the current tweet, the identity of the owner of the tweet that triggered a response, and the URL of the link contained in the tweet. Tweets that were not a response to another tweet or did not contain a URL were ignored for the purpose of the analysis.

Visual network analysis

The "users" network generated is shown in Figure 1. Nodes represent users and are shown as circles whereas directed links represent responses from one user to another for a particular tweet. Although it can be seen from the graph that there are individuals with high number of links (a couple of them is shown circled with thick lines), the diagram is too dense to clearly identify these individuals. Thus, as a next step in the analysis, the main component (the largest subnetwork in which there is a path from a user to any other user) was extracted for further visual analysis. The main component is shown in Figure 2. This network still has too many nodes to be able to identify the major players (again a few popular players are shown by means of thick circles). Thus, the next step was to resort to ego analysis, that is, quantitative analysis of the individual actors or "egos" that make up the nodes of the network, for identification of influential and popular twitterers.

Queensland Floods (2010–2011) and "Tweeting", Figure 1 Users network.



Queensland Floods (2010–2011) and "Tweeting", Figure 2 Main component of users network.

The "users-resources" network is shown in Figure 3. Two types of nodes are involved in this network. User nodes are represented as circles and online resources as squares. Since tweets of users are referring to these resources, the direction of the link is from the user node to the resource node. It can be seen from the figure that some of the resources were quite popular as many users were referring to them and at the same time some users were quite prolific in terms of the number of resources they were suggesting to others. Similarly to the "users" network, ego analysis was required to objectively determine the important nodes as this could not be done visually in a network of this size.

Ego analysis

Twitter users (nodes) were analyzed in terms of their centrality in the online community in order to find popular users or users at the center of attention (Scott, 2007). The centrality of a node can be measured locally in terms

Queensland Floods (2010–2011) and "Tweeting", Figure 3 Users-resources network.

of the number of direct connections to the node or globally to include indirect connections. Global centrality measures include:

- Closeness (Freeman, 1979), which is based on distances among nodes.
- Betweenness (Freeman, 1979), which is based on the extent to which a particular node lies between other nodes. A node of relatively low degree may play an important intermediary role (e.g., broker, gatekeeper, etc.) and hence be a central node in the network.
- Eigenvector (Bonacich, 1972), which is based on local centrality scores of nodes to which the node is connected, with high-score nodes contributing more than low-score nodes.
- Structural hole (Burt, 1992), which is based on the positional advantage (or disadvantage) of the node in the network.

Table 1 shows the top 24 users in the main component of the online community ranked by order of importance on previously discussed centrality measures, namely: (1) centrality, (2) betweenness, (3) closeness, (4) eigenvector, and (5) structural holes. In order to have a better idea who these users are, we visited their Twitter page and extracted their real names and biographies whenever these details were publicly available.

Since we represented the "users-network" as a directed network, a centrality degree analysis yielded two scores: *out degree* (number of tweets sent out by a particular user when responding to tweets of other users) and *in degree* (number of tweets received by a particular user as response from other users). The first section of Table 1 shows the ranking of the top 24 individuals on their *out degree* score while the second section of the table ranks individuals by their *in degree* score. Top scorers in terms of *out degree* were users having high influence in the network and just to name a few of them, they were: Sean Robertson (Australian Extreme Weather Event & Disaster Updates), Alexandra Worlson (Not-for-profit organization), Isagold Button (virtual name), Wilson Voight (virtual name), Cathy Border (Ten News), George Hall (social media volunteer), etc. Although these users and others from news channels and humanitarian organizations were busy posting tweets, online shopping organizations were also doing the same. The time of tweet collection was during the aftermath of the flood and these organizations were busy promoting their products.

Users with high *in degree* scores are regarded as prestigious or popular individuals and some of them were: Wilson Voight (virtual name), Tony Abbott (Leader of the Opposition), Queensland Police Service (QPS) Media Unit, Andrew Bartlett (ex-Senator), Rove McManus (media personality), Anna Bligh (Queensland Premier), ABC News, Julia Gillard (Prime Minister), Michael Bubble (Canadian singer), etc. In regards to betweenness centrality, the top individuals were: QPS Media Unit, Tony Abbott, Anna Bligh, Andrew Bartlett, Wilson Voight, Rove MacManus, ABC News, Sean Robertson, Animal Welfare League, Julia Gillard, etc. These users can be viewed as leaders in the online network since being on the shortest paths between other users they were able to control the flow of information in the network.

In terms of closeness centrality, leaders were: QPS Media Unit, George Hall (social media volunteer), Liz Baillie (anonymous user), Alexandra Worlson, Wilson Voight, Sean Robertson, Tony Abbott, Operation Angel (Humanitarian Org), Anna Bligh (Queensland Premier), etc. Since closeness centrality measures the distance of a node to all others in the network, the closer a node is to others, the more favored that node is. Nodes with high closeness scores are likely to receive information quicker than others as there are fewer intermediaries between them. It is well known that the Queensland Police Service played a very active role in the network and is thus acknowledged as the leader in terms of closeness centrality. Tony Abbott was the leading user when the eigenvector centrality criterion was used. This means that he was connected to many other users who were well connected and thus was most likely to receive new ideas. This fits well with his role as the leader of the opposition.

Structural holes were measured in terms of Effective size of the network, i.e., the number of connections a user has, minus the average number of connections that each individual has to other users. Tony Abbott, QPS Media Unit, Andrew Bartlett, Rove MacManus, Anna Bligh, etc. led on this criterion suggesting that they had more opportunities to act as brokers or coordinators.

The users-resources network was analyzed as a 2-node network (Borgatti, 2010; Borgatti and Everett, 1997) using centrality measures for online resources as well as users. The top 25 resources as measured by the degree centrality measure are shown in Table 2. At the top of the list, were online resources discussing the proposed flood levy (as this was the post-flood period) followed by web pages related to the following: people with disability, animal rescue, donations, legal help, damaged

A degree centrality analysis was also performed on the users on this users-resources network and details are shown in Table 3. Some of the users actively disseminating information on these resources included: Wilson Voight, Sean Robertson, Alexandra Worlson, etc.

Discussion

Based on Powell and Rayner's widely used taxonomy (1952), several stages can be identified in a disaster, namely: (1) warning, (2) threat, (3) impact, (4) inventory, (5) rescue, (6) remedy, and (7) recovery. Most studies focus on the impact, inventory, and rescue stages since traditional communications are less effective during these stages (Mendoza et al., 2010). In this aspect, Twitter

proved itself to be a valuable platform for disseminating vital information.

Although the tweets were collected after the impact stage, we believe they are still valuable since social network analysis revealed a number of users who were known to be active in that online community (StreetCorner, 2011). Additionally, using several local and global centrality measures, SNA helped to identify the effectiveness of these users who were identified as: local authorities (mainly the Queensland Police Services), political personalities (Queensland Premier, Prime Minister, Opposition Leader, Member of Parliament), social media volunteers, traditional media reporters, and people from not-for-profit, humanitarian, and community associations.

It is well known that Queensland Police took a very active role on Twitter, providing the public with regular updates on the situation every few minutes as well as dealing with the spread of misinformation on Twitter (StreetCorner, 2011). Queensland Police was also very active on Facebook, providing more detailed updates than is possible with 140-character tweets.

Although the analysis of the users-resources network identified a wide range of important resources, they were mostly web pages and blogs providing information of a more general nature rather than vital information and updates on the disaster. Since it is more effective to disseminate critical information on Facebook (because of high penetration) and mining Facebook was not part of the study, we missed such information. If this was the case, it makes sense to conclude that the resources identified supplemented the resources posted on Facebook.

The Federal Emergency Management Agency (FEMA) of the US Department of Homeland Security recognizes the usefulness of Twitter (and other social media) during emergencies and uses Twitter during all stages of a disaster.

Given the positive results obtained by the involvement of the local authorities and government officials in Queensland, and the increasing adoption of Twitter in other parts of the world for emergency situations, it seems reasonable to push for greater adoption of Twitter by local and federal authorities during periods of mass emergencies. This will help to ensure that vital information of an official and reliable nature is quickly propagated throughout the network and false rumors dealt with as they emerge.

Summary

SNA was used to study interactions between Twitter users during the Queensland 2010–2011 floods, one of the worst Australian flooding disasters. Influential members of the online community that emerged during the floods as well as important resources being referred to were identified. The analysis confirmed the active part taken by local authorities, namely, Queensland Police, government officials, and volunteers. Concerning online resources suggested by users, no sensible conclusion can be drawn as important resources identified were more of a general rather than critical nature. This might be comprehensible as it was the post-flood period.

QUICK CLAY

Marten Geertsema
British Columbia Forest Service, Prince George, BC, Canada

Synonyms

Glaciomarine sediment; Leda clay; Sensitive clay

Definition

Quick clay is a special type of clay prone to sudden strength loss upon disturbance. From a relatively stiff material in the undisturbed condition, an imposed stress can turn such clay into a liquid gel.

Discussion

A quick clay is defined as a clay where the undisturbed shear strength of the soil is at least 30 times greater than the remolded (or disturbed) shear strength. The ratio of undisturbed to disturbed strength is termed *sensitivity*. Thus, a quick clay is defined as very sensitive.

Quick clays tend to occur along previously glaciated coastlines, especially in parts of Canada and Scandinavia, but they have also been found in Japan and in Alaska. Coastlines in these areas were once submerged by the weight of glaciers during glaciation. As glaciers retreated, the sea migrated inland in concert with the retreating icefronts. Glacially ground sediments composed of rock flour, silt, and clay minerals were deposited in the saltwater of these ice marginal seas by glacial meltwater. These sediments had a porous flocculated structure (Figure 1).

As the glaciers disappeared the land began to rebound isostatically, rising as much as 300 m above present day sea level in some parts of the world such as the Hudson Bay area of Canada. The uplifted glaciomarine sediments were then exposed to rainfall and groundwater. Salts in the clays were gradually leached out of the sediments by freshwater. Salt contents would decrease from initial concentrations as high as 30 g/l in the sea to less than 1 g/l. With a lower salt content, repulsive forces between particles increased, leaving the saturated, porous sediment prone to collapse. Given the ideal clay mineralogy, some sediments that underwent this process can become quick clays.

In freshwater, clay particles settle more slowly than the larger silt particles. In saltwater, clays and silts flocculate and settle with a random orientation. Negative, repulsive charges on the clay particles are neutralized by cations such as Na^{+} and Ca^{2+} in seawater. The resulting sediment has an open structure with high water content. The positive charges of the salts maintain the interparticle bonds.

An imposed load, vibration, or bank erosion can trigger collapse of the sedimentary structure in sensitive glaciomarine soil, often causing liquefaction. During liquefaction, the weight of the soil is transferred from the solids to the porewater.

Quick clays are hazardous because they can lead to sudden rapid landslides on extremely low gradients. An example of a quick clay landslide is shown in Figure 1. Here some 2.5 million m^3 of sediment travelled 1200 m on a 2 degree slope, near terrace, British Columbia in January 1994. Other significant quick clay landslides occurred in Norway and Eastern Canada. On April 29, 1978, a sudden landslide occurred near the town of Rissa, Norway. The largest landslide of the century in Norway, it covered 33 ha and involved 5–6 million m^3 of quick clay. The landslide was triggered by a small external load: earth fill from the excavation of a barn. Seven farms and five houses were destroyed.

Quick Clay, Figure 1 Liquefaction of quick clays may generate large, rapid landslides, such as this one at Mink Creek in British Columbia. This 1994 landslide covered 43 ha and involved 2.5 million cubic meters of soil. Photo Marten Geertsema.

On May 4, 1971, 7 million m^3 of quick clay at Saint Jean Vianney, Quebec, Canada, suddenly began to flow at a rate of more than 25 km/hour into the Rivière du Petit-Bras carrying with it some 40 homes. The crater left by the landslide was 32 ha in area and up to 30-m deep.

Quick Sand

QUICK SAND

János Kovács
University of Pécs, Pécs, Hungary

Synonyms

Running sand

Definition

A mass or bed of fine sand, as at the mouth of a river or along a seacoast, or in the desert, that consists of smooth rounded grains with little tendency to mutual adherence and that is usually thoroughly saturated with water flowing upward through the voids, forming a soft, shifting, semiliquid, highly mobile mass that yields easily to pressure and tends to suck down and readily swallow heavy objects resting on or touching its surface.

Discussion

According to Yamasaki (2003), quicksand is a mixture of sand and water, or sand and air that looks solid, but becomes unstable when disturbed by any additional stress. In normal sand, grains are packed tightly together to form a rigid mass, with about 25–30% of the space (voids) between the grains filled with air or water. Because many sand grains are elongate rather than spherical, loose packing of the grains can produce sand in which voids make up 30–70% of the mass (Yamasaki, 2003). This arrangement is similar to a house of cards in that the space between the cards is significantly greater than the space occupied by the cards. The sand collapses, or becomes "quick," when additional force from loading, vibration, or the upward

migration of water overcomes the friction holding the grains together (Yamasaki, 2003).

Most quicksand occurs in settings where there are natural springs, either at the base of alluvial fans (cone-shaped bodies of sand and gravel formed by rivers flowing from mountains), along riverbanks, or on beaches at low tide (Yamasaki, 2003). In such cases, the loose packing is maintained by the upward movement of water. Quicksand does occur in deserts, but only very rarely: where loosely packed sands occur, such as on the down-wind sides of dunes, the amount of sinking is limited to a few centimeters, because once the air in the voids is expelled, the grains are too densely packed to allow further compaction (Yamasaki, 2003).

The nature and danger of quicksand have been disputed for a long time (Freundlich and Juliusburger, 1935; Khaldoun et al., 2005; Matthes, 1953). Despite widespread belief that humans can be swallowed or even sucked in, engineers of soil mechanics have typically asserted that, since the density of sludge is larger than that of water, a person cannot fully submerge (Kadau et al., 2009). The fluidization of a soil due to an increase in ground water pressure, which in fact is often responsible for catastrophic failures at construction sites, is called by engineers the "quick condition" and can theoretically happen to any soil. Another way for fluidization can result from vibrations either from mechanical engines or an earthquake (Kadau et al., 2009).

R

RADIATION HAZARDS

Lev I. Dorman
Israel Cosmic Ray and Space Weather Center and Emilio Segre' Observatory, Tel Aviv University, TECHNION, and Israel Space Agency, Qazrin, Israel
IZMIRAN of Russian Academy of Sciences, Troitsk, Moscow region, Russia

Definition

Radiation hazards for people and technology are determined by electromagnetic radiation (from intense radio waves up to UV, X-rays, and γ-rays) and by fluxes of corpuscular radiation (energetic protons, neutrons, nucleous, electrons, pions, muons, and in case of nearby Supernova even by great fluxes of neutrino, see *Supernova*).

Main sources

Radiation hazards for people and technology on the ground and at different altitudes in atmosphere are determined by natural sources (mainly from galactic and solar cosmic rays and from radioactive elements in soil and in air) and by artificial (man-made) sources which generate different types of electromagnetic and corpuscular radiation (from home-used devices such as TV, microwave heaters, mobile phones to atomic and H-bomb explosions). With an increase of altitude, the natural radiation hazard from cosmic rays increases considerably and from radioactive elements – sufficiently decreases. For satellites and astronauts situated in the magnetospheres of the Earth and other planets (especially as Jupiter and Saturn), important natural sources of radiation hazard are cosmic rays and radiation belts; for spaceprobes and astronauts inside the Heliosphere – galactic, solar, planetary, and anomaly cosmic rays, and outside the Heliosphere – mainly galactic cosmic rays.

The basic unit of radiation dose

The basic unit for radiation dose is *rad*, defined in terms of the energy (in ergs or J) deposited by radiation per unit mass (gramm or kg) of exposed matter: 1 *rad* = 100 erg/g = 0.01 J/kg.

Relative biological effectiveness of different types of radiation

Different types of radiation have very different influence on human health. As a result the special factor relative biological effectiveness (RBE), averaged for full body, was introduced. For X-rays, γ-rays, and energetic electrons RBE = 1, for thermal neutrons RBE = 3, for energetic neutrons, protons, and α-particles RBE = 10, and for energetic nucleus heavier than α-particles RBE = 20. Therefore, the unit of radiation, effectively influenced on people is rem (Roentgen Equivalent to Man), defined as *rem* = RBE × *rad* = 0.01 *seivert*. The unit *seivert* was named after Rolf Sievert (1898–1966), a pioneering Swedish radiation physicist.

Effects of radiation on people

The large radiation dose which can kill outright is about ***5,000 rem*** (so-called Instant Death). The radiation dose near ***900 rem*** leads to death over the course of one day (so-called Overnight Death). The dose approximating ***500 rem*** causes severe radiation sickness (nausea, hair loss, skin lesions, etc.) as the body's short-lived cells fail to provide new generations to replace their normal mortality (cell reproductive death). It is not this trauma which usually kills, however, but the complications that arise from a lack of resistance to infection, in turn due to the lack of new generations of white blood cells. If one can survive the initial radiation sickness and avoid infection,

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

one will probably recover completely in the short term but will very likely develop cancer (especially leukemia) in some 10–20 years with a high probability for genetic mutations. From a whole-body dose of about ***100 rem*** delivered in less than about a week, it is unlikely one can notice any immediate severe symptoms. However, an individual is likely to develop leukemia in 10–30 years, and will have a significant chance of genetic mutations. The average exposure from natural sources of radiation on the ground is about ***0.3 rem*** per year. The part of exposure caused by local radioactivity decreases very much with increasing altitude and varies sufficiently from place to place. The part of exposure caused by cosmic rays of galactic and solar origin increases many times with increasing altitude and geomagnetic latitude, and varies considerably with time during the 22-year magnetic solar activity cycle and during great solar flare events.

Different resistance to radiation of different parts of body

It is important to note that different organs or body parts have dramatically different resistance to radiation. The hands, in particular, are able to withstand radiation doses that would kill if the whole body were subjected to this level. The lens of the eye and the gonads are considered to be the most vulnerable and should be protected the most.

Effects of radiation on high level technology systems

Large fluxes of energetic particles (from cosmic rays and radiation belts) very much influence electronics and computers on satellites with different orbits (especially characterized at altitudes $\geq$1,000 km and inclinations to the equatorial plane $\geq$45°) and airplanes on different airlines (especially characterized by altitudes $\geq$10 km and those crossing high latitudes). Energetic particles produced in electronic device ionic tracks and along these tracks can discharge with the destruction of some part of electronics. With increasing energetic particle fluxes the probability of electronic systems destruction sufficiently increases and leads to satellite malfunctions and even satellite loss. The destruction of airplane electronic systems may lead to problems in operations and even in the continuation of flight.

Protection from radiation

For protection from dangerous radiation generated by artificial sources there are two main methods: (1) increasing the distance from the source of radiation (e.g., increasing the distance by 10 times leads to a decrease of the level of radiation by 100 times); and (2) shielding people and electronic devices by thin plates of lead (from X-rays and γ-rays) and/or by thick concrete (from neutrons and high-energy charged particles). For protection of people and electronic devices from natural dangerous radiation the first method cannot be used and is only effective with the second method. In this case it is very important to produce ALERT (by using real time 1-min data of continued registration of cosmic rays through a ground network of neutron monitors and on satellites) and other parameters of space environment, (see *Automated Local Evaluation in Real Time (ALERT)*) with information on the expected time and level of natural radiation hazard. According to collected data astronauts should go for several hours inside special structures comprising shielding and to save electronic devices they should switch off some parts from electric power. To save passengers and crew on airplanes dispatchers should decide what to do (e.g., for airplanes at high latitudes to decrease the altitude for some short time) after receiving an ALERT. In case of ALERT for radiation from a nearby Supernova explosion (see *Supernova*) and with an estimation of the expected radiation hazard, Governments would need to decide how to save humanity and the biosphere (e.g., to prepare in several tens of years special buildings to protect them from significant radiation dose and/or to live under few meters below ground for several hundreds of years).

RADON HAZARDS*

James D. Appleton
British Geological Survey, Nottingham, UK

Definition

Radon (^{222}Rn) is a natural radioactive gas produced by the radioactive decay of radium (^{226}Ra), which in turn is derived from the radioactive decay of uranium. Uranium is found in small quantities in all soils and rocks, although the amount varies from place to place. Radon occurs in the ^{238}U decay series, has a half-life of 3.82 days, and emanates from rocks and soil. Radon provides about 50% of the total ionizing radiation dose to the general world population although the dose received by an individual depends upon where one lives and ones' life style (see *Dose Rate*). Most exposure to radon results from living indoors. Radon decays to form very small, solid, short-lived radioactive decay products (^{218}Po and ^{214}Po) that become attached to natural aerosol and dust particles.

*©British Geological Survey

When inhaled, these can irradiate the bronchial epithelial cells of the lung with alpha particles and cause DNA damage. Epidemiological studies confirm that exposure to radon in homes increases the risk of lung cancer in people. It is estimated that between 3% and 14% of all lung cancers are linked to radon. Radon is the second most important cause of lung cancer after smoking and is much more likely to cause lung cancer in people who smoke, or who have smoked, than in lifelong nonsmokers for whom radon is the primary cause of lung cancer. There is no evidence for a threshold radon concentration below which radon exposure is safe. The majority of radon-induced lung cancers are calculated to be caused by low and moderate radon concentrations rather than by high radon concentrations. This is because less people are, in general, exposed to high indoor radon concentrations (WHO, 2009). It is estimated that radon in drinking water causes about 170 cancer deaths per year in the USA, about 90% from lung cancer caused by breathing radon released from water, and about 10% from stomach cancer caused by drinking radon-containing water.

The concentration of radioactivity in the air due to radon is measured in becquerels per cubic meter (Bq m^{-3}) of air. Radon concentrations in outdoor air are generally low (4–8 Bq m^{-3}) whereas radon in indoor air ranges from less than 20 Bq m^{-3} to about 110,000 Bq m^{-3} with a population-weighted world average of 40 Bq m^{-3}. Country arithmetic means range from 20 Bq m^{-3} in the UK, 22 Bq m^{-3} in New Zealand, 44 Bq m^{-3} in China, and 46 Bq m^{-3} in the USA, to 120 Bq m^{-3} in Finland (UNSCEAR, 2009). Radon in the air that occupies the pores in soil commonly varies from 5 to 50 Bq L^{-1} but may be <1 or more than 2,500 Bq L^{-1}. The amount of radon dissolved in ground water ranges from about 3 to nearly 80,000 Bq L^{-1} (Appleton, 2007).

Geological associations

Geology exerts a strong control on indoor radon and radon hazard (Appleton and Miles, 2010). Relatively high concentrations of radon are associated with particular types of bedrock and unconsolidated deposits, for example, some granites, uranium-enriched phosphatic rocks and black shales, limestones, sedimentary ironstones, permeable sandstones, and uraniferous metamorphic rocks. Fault shear zones, glacial deposits derived from uranium-bearing rock, and even clay-rich sediments from which high radon emanation reflects large surface area and high permeability caused by cracking may be radon prone along with uranium and radium-enriched soils derived from limestone (especially karstic terrain), uranium mining residues, and mine tailings. In SW England and Scotland (Scheib et al., 2009), there is a correlation between areas where it is estimated that more than 30% of the house radon levels are above 200 Bq m^{-3} and the major granite areas. In England and Wales, 10% to more than 30% of houses built on Carboniferous limestones have radon concentrations greater than 200 Bq m^{-3}. Similar associations between high radon and Lower Carboniferous limestone, Namurian uraniferous and phosphatic black shales, some granites, and highly permeable fluvioglacial deposits have also been recorded in Ireland (Cliff and Miles, 1997).

In the Czech Republic, the highest indoor and soil gas radon concentrations are associated with the Variscan granites, granodiorites, syenites (12–20 mg kg^{-1} U in bedrock), and phonolites (10–35 mg kg^{-1} U in bedrock) of the Bohemian massif as well as Palaeozoic metamorphic and volcanic rocks and also with uranium mineralization (Barnet et al., 2008). The highest radon in Germany occurs over the granites and Palaeozoic basement rocks (Kemski et al., 2009). High radon potential in Belgium is associated with strongly folded and fractured Cambrian to Lower Devonian bedrocks in which uranium preferentially concentrated in ferric oxyhydroxides in fractures and joints is considered to be the main source of radon (Zhu et al., 2001). In France, some of the highest radon levels occur over peraluminous leucogranites or metagranitoids (8 mg kg^{-1} U in bedrock) in a stable Hercynian basement area located in South Brittany (Ielsch et al., 2001). Granite and alum shale have high radon potential in Sweden, Norway and Belgium.

Permeability and uranium composition of unconsolidated deposits are the main factors influencing their radon potential. Fragments and mineral grains of uranium-rich granites, pegmatites, and black alum shales are dispersed in till and glaciofluvial deposits leading to high radon in soils and dwellings in Sweden, especially when the glaciofluvial deposits are highly permeable sands and gravels (Clavensjö and Åkerblom, 1994). In Norway, high radon levels are associated with highly permeable fluvioglacial and fluvial deposits derived from all rock types and also with moderately permeable unconsolidated sediments (mainly basal till) containing radium-rich rock fragments (Smethurst et al., 2008).

Release and migration of radon gas

The rate of release of radon from rocks and soils is largely controlled by their uranium and radium concentrations, grain size, and by the types of minerals in which the uranium and radium occur (Ball et al., 1991). Most of the radon formed from the decay of radium remains in the mineral grains. Normally 20–40% of the newly generated radon emanates to pore spaces where it is mixed in the soil air or water that fill the pore spaces and from which it can be transported by diffusion or by flow in carrier fluids (soil air or water). After uranium and radium concentration, the porosity, permeability, and moisture content of rocks and soils are probably the next most significant factors influencing the concentration of radon in soil gas and buildings. Soil air containing radon is transported along natural pathways, which include planar discontinuities and openings such as bedding planes, joints, shear zones, and faults as well as potholes and swallow holes in limestone. Artificial migration pathways underground include

mine workings, disused tunnels, and shafts as well as near-surface installations for electricity, gas, water, sewage, and telecommunications services.

Radon from soils and rocks is transported into buildings through cracks in solid floors and walls below construction level; through gaps in suspended concrete and timber floors and around service pipes; through crawl spaces, cavities in walls, construction joints and small cracks or pores in hollow-block walls. Warm air rising within a building, called the stack effect, and the suction effects on the roof caused by wind action draws radon in from the ground. Whereas soil air is the dominant source of indoor radon and most houses draw less than 1% of their indoor air from the soil, some houses with low indoor air pressures, poorly sealed foundations, permeable ground underneath, and several entry points for soil air may draw as much as 20% of their indoor air from the soil. Consequently, radon levels inside the house may be very high even in situations where the soil air has only moderate amounts of radon. The design, construction, and ventilation of the home affect indoor radon levels as do both the season and the weather.

Homes that use surface water do not have a radon problem from their water because radon decays in a few days; so water reservoirs usually contain very little radon. In addition, water processing in large municipal systems aerates the water, which allows radon to escape, and also delays the use of water until most of the remaining radon has decayed. However, in some parts of the USA and Sweden with high levels of uranium in the underlying rocks and where ground water is the main water supply for homes and communities, radon from the domestic water released during showering and other household activities could add radon to the indoor air.

Building materials generally contribute only a very small percentage of the indoor air radon concentrations, although in a few areas, concrete, blocks, or wallboard made using radioactive shale or waste products from uranium mining will make a larger contribution to the indoor radon.

Radon hazard mapping

Accurate mapping of radon-prone areas can help to ensure that the health of occupants of new and existing dwellings and workplaces is adequately protected. Radon potential maps can be used to assess whether radon preventive measures may be required in new buildings, for the cost-effective targeting of radon monitoring in existing dwellings and workplaces, and to provide a radon assessment for homebuyers and sellers. National authorities are recommended to set a reference level for radon that represents the maximum accepted radon concentration in a residential dwelling. Remedial actions may be recommended or required for homes in which radon exceeds the reference level. Various factors such as the distribution of radon concentrations, the number of existing homes with high radon concentrations, the arithmetic mean indoor radon level, and the prevalence of smoking are usually considered when setting a national radon reference level. WHO (2009) proposed a reference level of 100 Bq m^{-3} to minimize health hazards due to indoor radon exposure although if this concentration cannot be reached, the reference level should not exceed 300 Bq m^{-3}. This represents approximately 10 mSv per year according to recent calculations and recommendations by the International Commission on Radiation Protection (ICRP, 2007, 2009) which also recommends 1,000 Bq m^{-3} as the entry point for applying occupational radiological protection requirements.

Two main procedures have been used for mapping radon-prone areas. The first uses radon measurements in existing dwellings to map the variation of radon potential between administrative or postal districts, or grid squares, or within geological polygons. Since the main purpose of maps of radon-prone areas is to indicate radon levels in buildings, maps based on actual measurements of radon in buildings are generally preferable to those based on other data. Requirements for mapping radon-prone areas using indoor radon data are similar whether the maps are made on the basis of grid squares or geological units. These requirements include accurate radon measurements made using a reliable and consistent protocol; centralized data holdings; sufficient data evenly spread; and automatic conversion of addresses to geographical coordinates. Great Britain is currently the only country that meets all of these requirements for large areas (Miles and Appleton, 2005). Where lesser quality or quantity of indoor radon data are available, there is greater reliance on proxy data for radon potential mapping (e.g., Czech Republic, Germany, Sweden, and USA). The factors that influence radon concentrations in buildings are largely independent and multiplicative, the distribution of radon concentrations is usually lognormal. Therefore, lognormal modeling was used to produce accurate estimates of the proportion of homes above a reference level in the UK (Miles et al., 2007). Radon maps based on indoor radon data grouped by geological unit have the capacity to accurately estimate the percentage of dwellings affected together with the spatial detail and precision conferred by the geological map data. Combining the grid square and geological mapping methods gives more accurate maps than either method can provide separately (Miles and Appleton, 2005). Radon potential mapping using indoor radon measurements has been carried out in other European countries, including Austria, France, Ireland, and Luxembourg (Dubois, 2005). In Austria, indoor radon data, normalized to a defined "standard room" to reduce variations related to house type, are combined with geological information to produce a national radon potential map (Friedmann and Gröller, 2010).

In other countries, geological radon potential maps predict the average indoor radon concentration (USA; Gundersen et al., 1992) or give a more qualitative indication of radon risk (Germany and the Czech Republic). Radon hazard mapping of the Czech Republic is based upon airborne radiometry, geology, pedology, hydrogeology, ground radiometry, and soil gas radon data (Barnet et al., 2008). Soil gas radon measurements combined with an assessment of ground permeability have been used to map geological

radon potential in the absence of sufficient indoor radon measurements. Ten to fifteen soil gas radon measurements are generally required to characterize a site or geological unit. Ground classifications based on geology, permeability, and soil gas radon measurement have been developed in Sweden (Clavensjö and Åkerblom, 1994), Finland, Germany (Kemski et al., 2009), Estonia, and the Czech Republic (Barnet et al., 2008). In some cases, soil gas radon data may be difficult to interpret due to the effects of large diurnal and seasonal variations in soil gas radon close to the ground surface as well as variations in soil gas radon on a scale of a few meters.

Uranium and radium concentrations in surface rocks and soils are a useful indicator of the potential for radon emissions from the ground. Uranium can be estimated by gamma spectrometry either in the laboratory or by ground, vehicle, or airborne surveys. The relatively close correlation between airborne and ground radiometric measurements and indoor radon concentrations has been demonstrated in Virginia and New Jersey in the USA, Nova Scotia in Canada, and also in parts of the UK (Appleton et al., 2008) and Norway (Smethurst et al., 2008). Areas with high permeability tend to have significantly higher indoor radon levels than would be otherwise expected from the equivalent ^{226}Ra concentrations, reflecting an enhanced radon flux from permeable ground.

Summary

Radon is a natural radioactive gas produced by the radioactive decay of radium, which in turn is derived from the radioactive decay of uranium found in all rocks and soils. Radon is the second most important cause of lung cancer after smoking. Radon emanated from rocks and soil tends to concentrate in enclosed spaces such as houses and underground spaces including mines and tunnels. Infiltration of radon in soil gas is the most important source of radon in buildings. Radon levels often vary widely between adjacent buildings due to differences in the radon potential of the underlying ground as well as differences in construction style and use. Although a radon potential map can indicate the relative radon risk for a building in a particular locality, it cannot predict the radon risk for an individual building. Radon from building materials and from water extracted from wells is generally less important.

RECOVERY AND RECONSTRUCTION AFTER DISASTER

Michael K. Lindell
Texas A&M University, College Station, TX, USA

Definition

Disaster recovery. Disaster recovery has three distinct but interrelated meanings. First, it is a *goal* that involves the restoration of normal community activities that were disrupted by disaster impacts – in most people's minds, exactly as they were before the disaster struck. Second, it is a *phase* in the emergency management cycle that begins with stabilization of the disaster conditions (the end of the emergency response phase) and ends when the community has returned to its normal routines. Third, it is a *process* by which the community achieves the goal of returning to normal routines. The recovery process involves both activities that were planned before disaster impact and those that were improvised after disaster impact.

Disaster impacts. These are the physical and social disturbances that a hazard agent inflicts when it strikes a community. Physical impacts comprise casualties (deaths, injuries, and illnesses) and damage to agriculture, structures, infrastructure, and the natural environment. Social impacts comprise psychological impacts, demographic impacts, economic impacts, and political impacts.

Incident stabilization. This is the point in time at which the immediate threats to human safety and property resulting from the physical impacts of the hazard agents have been resolved and the community as a whole can focus on disaster recovery.

Disaster impacts

As noted earlier, disaster impacts comprise both physical and social impacts. The physical impacts are casualties (deaths and injuries) and property damage, and both vary substantially across hazard agents. The physical impacts of a disaster are usually the most obvious, easily measured, and first reported by the news media. Social impacts include psychosocial, demographic, economic, and political impacts. A very important aspect of disaster impacts is their *impact ratio* – the amount of damage divided by the amount of community resources. Long-term social impacts tend to be minimal in the USA because most hazard agents have a relatively small scope of impact and tend to strike undeveloped areas more frequently than intensely developed areas simply because there are more of the former than the latter. Thus, the numerator of the impact ratio tends to be low and local resources are sufficient to prevent long-term effects from occurring. Even when a disaster has a large scope of impact and strikes a large developed area (causing a large impact ratio in the short term), state and federal agencies and NGOs (nongovernmental organizations such as the American Red Cross) direct recovery resources to the affected area, thus preventing long-term impacts from occurring. For example, 1992 Hurricane Andrew inflicted $26.5 billion in losses to the Miami Florida USA area, but this was only 0.4% of the US GDP (Charvériat, 2000). However, the fact that communities *as a whole* recover does not mean that specific neighborhoods or households within those neighborhoods recover at the same rate or even at all. Similarly, it does not mean specific economic sectors or individual businesses within those sectors will be able to maintain or even resume operations. Thus, it is important to anticipate which population segments and economic sectors will have the most difficulty in recovering. This will enable community authorities to intervene with technical and financial assistance when it is needed, monitor their recovery, and encourage them to adopt hazard mitigation measures to reduce their hazard vulnerability.

Disaster impacts vary among households and businesses because of preexisting variation in the vulnerability of social units within each of these categories. Specifically, social vulnerability is people's "capacity to anticipate, cope with, resist and recover from the impacts of a natural hazard" (Wisner et al., 2004, p. 11). Whereas people's physical vulnerability refers to their susceptibility to biological changes (i.e., impacts on anatomical structures and physiological functioning), their social vulnerability refers to limitations in their physical assets (buildings, furnishings, vehicles) and psychological (knowledge, skills, and abilities), social (community integration), economic (financial savings), and political (public policy influence) resources. The central point of the social vulnerability perspective is that, just as people's occupancy of hazard prone areas and the physical vulnerability of the structures in which they live and work are not randomly distributed, neither is social vulnerability randomly distributed – either geographically or demographically. Thus, just as variations in structural vulnerability can increase or decrease the effect of hazard exposure on physical impacts (property damage and casualties), so too can variations in social vulnerability (Bolin, 2006; Enarson et al., 2006). In particular, households that are elderly, female-headed, lower income, and ethnic minority are likely to have high vulnerability to disasters.

Physical impacts

Casualties. According to the EM-DAT database (www.emdat.be/database), there were 25 geophysical, hydrological, or meteorological disasters that produced more than 50,000 deaths between 1900 and 2011. Of these, 12 were earthquakes (maximum = 242,000), seven were tropical cyclones (maximum = 300,000), and six were floods (maximum = 3,700,000). There is significant variation by region, with Asia experiencing 54% of the earthquakes but 71% of the casualties from these events, 41% of the floods but 98% of the casualties, and 41% of the storms but 92% of the casualties. By contrast, the Americans experienced 22% of the earthquakes but 17% of the casualties from these events, 24% of the floods but less than

2% of the casualties, and 33% of the storms and 8% of the casualties. Berke (1995) found that developing countries in Asia, Africa, and South America accounted for approximately 3,000 deaths per disaster, whereas the corresponding figure for high-income countries was approximately 500 deaths per disaster. Moreover, these disparities appear to be increasing because the average annual death toll in developed countries declined by at least 75% between 1960 and 1990, but the same time period saw increases of over 400% in developing countries.

Damage. Losses of structures, animals, and crops also are important measures of physical impacts, and the EM-DAT database shows that these have been rising exponentially throughout the world since 1970. Moreover, Berke (1995) reported that the rate of increase is even greater in developing countries such as India and Kenya. Such losses usually result from physical damage or destruction of property, but they also can be caused by losses of land use to chemical or radiological contamination or loss of the land itself to subsidence or erosion. Damage to the built environment can be classified broadly as affecting residential, commercial, industrial, infrastructure (water, waste disposal, electric power, fuel, telecommunications, and transportation), or community services (public safety, health, education) sectors. Moreover, damage within each of these sectors can be divided into damage to structures and damage to contents. It usually is the case that damage to contents results from collapsing structures (e.g., hurricane winds failing the building envelope and allowing rain to destroy the furniture inside the building). Because collapsing buildings are a major cause of casualties as well, this suggests that strengthening the structure will protect the contents and occupants. However, some hazard agents can damage building contents without affecting the structure itself (e.g., earthquakes striking seismically resistant buildings whose contents are not securely fastened). Thus, risk area residents may need to adopt additional hazard adjustments to protect contents and occupants even if they already have structural protection.

Other important physical impacts include damage or contamination to cropland, rangeland, and woodlands. Such impacts may be well understood for some hazard agents but not others. For example, ashfall from the 1980 Mt. St. Helens (USA) eruption was initially expected to devastate crops and livestock in downwind areas, but no significant losses materialized (Warrick et al., 1981). There also is concern about damage or contamination to the natural environment (wild lands) because these areas serve valuable functions such as damping the extremes of river discharge and providing habitat for wildlife. In part, concern arises from the potential for indirect consequences such as increased runoff and silting of downstream river beds, but many people also are concerned about the natural environment simply because they value it for its own sake.

Social impacts

Psychosocial impacts. Research reviews conducted over a period of 25 years have concluded that disasters can cause a wide range of negative psychological responses (Gerrity and Flynn, 1997; Norris et al., 2002a, b). In most cases, the observed effects are mild and transitory – the result of "normal people, responding normally, to a very abnormal situation" (Gerrity and Flynn, 1997, p. 108). The vast majority of disaster victims experience only mild psychological distress. For example, Bolin and Bolton (1986) found negative impacts such as upsets with storms (61%), time pressures (48%), lack of patience (38%), and strained family relationships (31%) after the 1982 Paris Texas USA tornado. However, victims also experienced positive impacts including strengthened family relationships (91%), decreased importance of material possessions (62%), and increased family happiness (23%). The data showed only minor differences between Blacks and Whites in the prevalence of psychosocial impacts.

Researchers have also examined public records in their search for psychological impacts of disasters. For example, Morrow's (1997) examination of vital statistics (births, marriages, deaths, and divorce applications) had no significant long-term trends due to Hurricane Andrew. However, domestic violence rates remained constant for about 6 months after the hurricane but increased about 50% for nearly 2 years after that. Nonetheless, there are especially vulnerable groups that might need extra attention if they show signs of long-standing problems due to the disaster. This includes youth, people with preexisting mental conditions, and victims who have witnessed the death or severe injury of loved ones. Single minority female heads of household who have limited psychosocial resources for coping with severe exposures and secondary stressors have the most adverse outcomes, especially in developing countries (Morrow, 1997; Norris et al., 2002a).

The negative psychological impacts described above, which Lazarus and Folkman (1984) call *emotion focused coping*, generally disrupt the social functioning of only a very small portion of the victim population. Instead, the majority of disaster victims engage in adaptive *problem focused coping* activities to save their own lives and those of their closest associates. Further, there is an increased incidence in prosocial behaviors such as donating material aid and a decreased incidence of antisocial behaviors such as crime (Drabek, 1986; Siegel et al., 1999). In some cases, people even engage in altruistic behaviors that risk their own lives to save the lives of others (Tierney et al., 2001).

There also are psychological impacts with long-term adaptive consequences, such as changes in risk perception (beliefs in the likelihood of the occurrence a disaster and its personal consequences for the individual) and increased hazard intrusiveness (frequency of thought and discussion about a hazard). In turn, these beliefs can affect risk area residents' adoption of household hazard adjustments that reduce their vulnerability to future disasters.

However, these cognitive impacts of disaster experience do not appear to be large in aggregate, resulting in modest effects on household hazard adjustment (see Lindell and Perry, 2000, and Spittal et al., 2008, for literature on seismic hazard adjustment).

Demographic impacts. The demographic impact of a disaster can be assessed by adapting the *demographic balancing equation*, $P_a - P_b = B - D + IM - OM$, where P_a is the population size after the disaster, P_b is the population size before the disaster, B is the number of births, D is the number of deaths, IM is the number of immigrants, and OM is the number of emigrants (Smith et al., 2001). The magnitude of the disaster impact, $P_a - P_b$, is computed at two specific points in time for the population of a specific geographical area. The identification of the "impact area" is especially important in assessing demographic impacts because early US research (Friesma et al., 1979; Wright et al., 1979) suggested disasters have negligible demographic impacts. However, the highly aggregated level of analysis in these studies did not preclude the possibility of significant impacts at lower levels of aggregation (census tracts, block groups, or blocks). For example, casualties and emigration decreased the population of Lampuuk in the Aceh province of Indonesia to approximately 6% of its preimpact population immediately after the 2004 Indian Ocean tsunami (Fanany, 2010). Although there can be a major loss of life in some disasters, the most likely demographic impacts are the emigration of population segments that have lost housing and the (temporary) immigration of construction workers. In many cases, housing-related emigration is also temporary, but census data showed that the city of New Orleans dropped to 44% of its preimpact population in the year after Hurricane Katrina and only returned to 78% of its preimpact population 6 years later. Moreover, there are documented cases in which housing reconstruction has been delayed indefinitely – leading to "ghost towns" (Comerio, 1998). Other potential causes of emigration are psychological impacts (belief that the likelihood of disaster recurrence is unacceptably high), economic impacts (loss of jobs or community services), or political impacts (increased neighborhood or community conflict).

Economic impacts. The property damage caused by disaster impact creates losses in asset values that can be measured by the cost of repair or replacement (CACND, 1999). In most cases, disaster losses are initially borne by the affected households, businesses, and local government agencies whose property is damaged or destroyed. However, some of these losses are redistributed during the disaster recovery process through insurance and disaster relief. In addition to direct economic losses, there are indirect losses that arise from the interdependence of community subunits. Research on the economic impacts of disasters (Alesch et al., 1993; Rose and Limb, 2002; Tierney, 2006) suggests the relationships among the social units within a community can be described as a state of dynamic equilibrium involving a steady flow of resources, especially money. Specifically, a household's linkages with the community are defined by the money it must pay for products, services, and infrastructure support. This money is obtained from the wages that employers pay for the household's labor. Similarly, the linkages that a business has with the community are defined by the money it provides to its employees, suppliers, and infrastructure in exchange for inputs such as labor, materials and services, electric power, fuel, water/wastewater, telecommunications, and transportation. Conversely, it provides products or services to customers in exchange for the money it uses to pay for its inputs.

It also is important to recognize the financial impacts of recovery (in addition to the financial impacts of emergency response) on local government. Costs must be incurred for tasks such as damage assessment, emergency demolition, debris removal, infrastructure restoration, and replanning stricken areas. In addition to these costs, there are decreased revenues due to loss or deferral of sales taxes, business taxes, property taxes, personal income taxes, and user fees.

Political impacts. There is substantial evidence that disaster impacts can cause social activism resulting in political disruption, especially during the seemingly interminable period of disaster recovery. The disaster recovery period is a source of many victim grievances and this creates many opportunities for community conflict (Bates and Peacock, 1993; Bolin, 1982, 1993). Victims usually attempt to recreate preimpact housing patterns, which can thwart government attempts at relocation to less hazardous areas (Dove, 2008). Such attempts also can be problematic for their neighbors if victims attempt to site temporary housing, such as mobile homes, on their own lots while awaiting the reconstruction of permanent housing. Conflicts arise when such housing is considered to be a blight on the neighborhood and neighbors are afraid the "temporary" housing will become permanent. Neighbors also are pitted against each other when developers attempt to buy damaged or destroyed properties and build multifamily units on lots previously zoned for single family dwellings. Such rezoning attempts are a major threat to the market value of owner-occupied homes but tend to have less impact on renters because they have less incentive to remain in the neighborhood. There are exceptions to this generalization because some ethnic groups have very close ties to their neighborhoods, even if they rent rather than own.

Attempts to change prevailing patterns of civil governance can arise when individuals sharing a grievance about the handling of the recovery process seek to redress that grievance through collective action. This is most likely when government agencies or NGOs relate to local communities through manipulation or consultation rather than partnership or ownership (Kenny, 2010). Consistent with Dynes's (1970) typology of organizations, existing community groups with an explicit political agenda can *expand* their membership to increase their strength, whereas community groups without an explicit political agenda can *extend* their domains to include

disaster-related grievances. Alternatively, new groups can *emerge* to influence local, state, or federal government agencies and legislators to take actions that they support and to terminate actions that they disapprove. Indeed, such was the case for Latinos in Watsonville, California following the 1989 Loma Prieta earthquake (Tierney et al., 2001). Usually, community action groups pressure government to provide additional resources for recovering from disaster impact, but may oppose candidates' reelections or even seek to recall some politicians from office (Olson and Drury, 1997; Prater and Lindell, 2000; Shefner, 1999). The point here is not that disasters produce political behavior that is different from that encountered in normal life. Rather, disaster impacts might only produce a different set of victims and grievances and, therefore, a minor variation on the prevailing political agenda (Morrow and Peacock, 1997).

Disaster recovery goals

Most people's goal in disaster recovery is to restore household, business, and government activity to the "normal" patterns that existed before the disaster struck. To do this, they typically assume they must restore the buildings and infrastructure as they were before the disaster. However, it is increasingly understood that restoring the community to its previous condition will also reproduce its previous hazard vulnerability. When cities allow too much development in floodplains or allow substandard housing to be built that collapses in an earthquake, "normal" is an unsustainable condition. Consequently, a disaster resilient community learns from experience which areas of the community have excessive levels of hazard exposure. It also identifies the buildings and infrastructure that have inadequate designs, construction methods, and construction materials. In short, communities need to incorporate hazard mitigation into their disaster recovery. That is, they need to adopt hazard source control, community protection works, land-use practices, building construction practices, and building contents protection practices (Federal Emergency Management Agency, 1986; Lindell et al., 2006, Chapter 7). *Hazard source control* involves intervention at the point of hazard generation to reduce the probability or magnitude of an event. By contrast, *community protection works* attenuate disaster impact by altering the hazard transmission process, especially by confining or diverting materials flows to reduce the hazard exposure of target locations and populations. *Land-use practices* limit hazard exposure by minimizing development in areas where the likelihood of hazard impact is high. By contrast, *building construction practices* limit physical vulnerability by building structures whose resistance to hazard impact is high. Finally, *building contents protection* prevents furniture, equipment (e.g., furnaces, air conditioners, washers, dryers), and other building contents from being damaged or destroyed. In many cases, but not all, appropriate building construction practices protect building contents at the same time as they protect the structure itself. For example, preventing wind damage to a structure will also prevent damage to its contents. However, seismic shaking can overturn water heaters and refrigerators without causing any damage to the building structure itself.

Disaster recovery stages and functions

The identification of disaster recovery as an emergency management phase has led some authors to divide it into stages, but there has been little agreement on the number and definitions of recovery stages (Alexander, 1993; Kates and Pijawka, 1977; Sullivan, 2003; UNDRO, 1984; Schwab et al., 1998). It is now generally accepted that disaster recovery encompasses multiple activities, some implemented sequentially and others implemented simultaneously. At any one time, some households and businesses might be engaged in one set of recovery activities whereas others are engaged in other recovery activities. Indeed, some households and businesses might be fully recovered months or years after others and there might be others that never recover at all. Thus, it is more useful to think of disaster recovery in terms of four functions: disaster assessment, short-term recovery, long-term reconstruction, and recovery management (see Table 1). The recovery phase's *disaster assessment* function should be integrated with the emergency response phase's emergency assessment function in identifying the physical impacts of the disaster. *Short-term recovery* focuses on the immediate tasks of securing the impact area, housing victims, and establishing conditions under which households and businesses can begin the process of recovery.

Recovery and Reconstruction After Disaster, Table 1 Disaster recovery functions

Disaster assessment	
• Rapid assessment	• Victims' needs assessments
• Preliminary damage assessment	• "Lessons learned"
• Site assessment	
Short-term recovery	
• Impact area security	• Emergency demolition
• Temporary shelter/housing	• Repair permitting
• Infrastructure restoration	• Donations management
• Debris management	• Disaster assistance
Long-term reconstruction	
• Hazard source control and area protection	• Economic development
	• Infrastructure resilience
• Land-use practices	• Historic preservation
• Building construction practices	• Environmental recovery
• Public health/mental health recovery	• Disaster memorialization
Recovery management	
• Agency notification and mobilization	• Recovery legal authority and financing
• Mobilization of recovery facilities and equipment	• Administrative and logistical support
• Internal direction and control	• Documentation
• External coordination	
• Public information	

Long-term reconstruction actually implements the reconstruction of the disaster impact area and manages the disaster's psychological, demographic, economic, and political impacts. Finally, *recovery management* monitors the performance of the disaster assessment, short-term recovery, and long-term reconstruction functions. It also ensures they are coordinated and provides the resources needed to accomplish them.

Disaster recovery processes

There are three relatively distinct types of social units that should be considered in disaster recovery: households, businesses, and government agencies. Households and businesses focus primarily on their own recovery but government agencies must address the recovery needs of the entire community.

Household recovery

There are three basic components to household recovery. These are housing recovery, economic recovery, and psychological recovery (Bolin and Trainer, 1978). All three of these components require resources to recover, but households must invest time to obtain these resources. This includes time to find and purchase alternate shelter, clothing, food, furniture, and appliances to support daily living (Yelvington, 1997). Time is also needed to file insurance claims, apply for loans and grants, and search for jobs. The time required for these tasks is increased by multiple trips to obtain required documentation and understaffing of providers (Morrow, 1997). Finally, victims need skill and self confidence to cope with the disaster assistance bureaucracy (Morrow, 1997).

Housing recovery. Households typically use four types of housing recovery following a disaster (Quarantelli, 1982). The first type, *emergency shelter*, consists of unplanned and spontaneously sought locations that are intended only to provide protection from the elements, typically open yards and cars after earthquakes (Bolin and Stanford, 1991, 1998). The second type is *temporary shelter*, which includes food preparation and sleeping facilities that usually are sought from friends and relatives or are found in commercial lodging, although mass care facilities in school gymnasiums or church auditoriums are acceptable as a last resort. The third type is *temporary housing*, which allows victims to reestablish household routines in nonpreferred locations or structures. The last type is *permanent housing*, which reestablishes household routines in preferred locations and structures. There is no single pattern of progression through the stages of housing because households vary in number and sequence of movements and the duration of their stays in each type of housing (Cole, 2003). Indeed, the transition from one stage to another can be delayed unpredictably, as when it took 9 days for shelter occupancy to peak after the 1987 Whittier Narrows California earthquake (Bolin, 1993). Yelvington (1997) reported that temporary shelters experienced increased demand as buildings were condemned by authorities or landlords begin reconstruction on damaged structures.

There are significant variations among households in their housing recovery and these are correlated with households' demographic characteristics (Peacock et al., 2006). Severity of damage and the availability of relatives nearby predict who stays with relatives, whereas income, homeownership, and availability of relatives nearby predict who accepts relatives (Morrow, 1997). Moreover, kin networks are likely to seek temporary shelter together, especially if all relatives became victims because they lived so close together (Yelvington, 1997). Households with higher incomes who lack nearby friends and relatives with undamaged homes seek commercial facilities, whereas lower-income households in such conditions are forced to accept mass care facilities.

Sites for temporary housing include homes of friends and relatives, commercial facilities such as rental houses and apartments, and mass facilities such as trailer parks. Some of these sites are in or near the stricken community, but others are hundreds or even thousands of kilometers away. Lack of alternative housing within an acceptable distance of jobs or peers led some households to leave the Miami area after Hurricane Andrew. The population loss was 18% in South Dade County, 33% in Florida City, and 31% in Homestead (Dash et al., 1997). Other households remained in severely damaged units – or even condemned units – without electric power or telephone service for months (Yelvington, 1997) or doubled up with relatives (Morrow, 1997).

Households encounter many problems during reconstruction, including high prices for repairs, poor quality work, and contract breaches (Bolin, 1993). The rebuilt structures do benefit from improved quality and hazard resistance (Bolin, 1993, indicates 50% of respondents reported this) and this is especially true for public housing (Morrow, 1997). However, few victims think the improvements are worth the inconvenience they experienced. Lower-income households tend to have higher hazard exposure because they often live in more hazard prone locations. They also have higher physical vulnerability because they live in structures that were built according to older, less stringent building codes, used lower quality construction materials and methods, and have been less well maintained (Bolin and Bolton, 1986). Because lower-income households have fewer resources on which to draw for recovery, they also take longer to return to permanent housing, sometimes remaining for extended periods of time in severely damaged homes (Girard and Peacock, 1997). Indeed, they sometimes are forced to accept as permanent what originally was intended as temporary housing (Peacock et al., 1987). Consequently, there might still be low-income households in temporary sheltering and temporary housing even after high-income households all have relocated to permanent housing (Berke et al., 1993; Rubin et al., 1985).

Economic recovery. Some households' economic recovery takes place quickly, but others' takes much

longer. For example, the percentage of households reporting complete economic recovery after the Whittier earthquake was 50% at the end of the first year but 21% reported little of no recovery even at the end of 4 years (Bolin, 1993). Economic recovery was positively related to household income and negatively related to structural damage, household size, and the total number of moves (Bolin, 1993). In some cases, this is due to the loss of permanent jobs that are replaced only by temporary jobs in temporary shelter management, debris cleanup, and construction – or are not replaced at all (Yelvington, 1997).

There are systematic differences in the rate of economic recovery among ethnic groups. For example, Bolin and Bolton (1986) found that Black households (30%) lagged behind Whites (51%) in their return to preimpact economic conditions 8 months after the Paris, Texas, tornado. However, the variables affecting economic recovery were relatively similar for Black and White families. In both ethnic groups, economic recovery was negatively related to family size (larger families had lower levels of recovery), but positively related to socioeconomic status (SES – education, profession, and income), use of disaster assistance, insurance adequacy, and aid adequacy. In addition, Black household recovery was negatively related to primary group aid and the number of household moves. The direct effect of family size and SES on economic recovery was compounded by the indirect effects of these variables via their impacts on the use of disaster assistance, insurance adequacy, aid adequacy, and household moves. The variables that had positive direct effects on economic recovery (use of disaster assistance, insurance adequacy, aid adequacy) were negatively related to family size and positively related to SES. That is, larger households were less likely – and higher SES households were more likely – to use disaster assistance, have adequate insurance, or receive adequate aid. Moreover, these variables were positively related to family size and negatively related to SES. That is, larger households made more moves and higher SES households made fewer moves. The overall effect of this complex pattern of relationships is for large poor households to be doubly handicapped in their economic recovery.

Psychological recovery. Few disaster victims require psychiatric diagnosis and most benefit more from a *crisis counseling* orientation than from a *mental health treatment* orientation, especially if their normal social support networks of friends, relatives, neighbors, and coworkers remain largely intact. However, there are population segments requiring special attention and active outreach. These include children, frail elderly, people with preexisting mental illness, racial and ethnic minorities, and families of those who have died in the disaster. Emergency workers also need attention because they often work long hours without rest, have witnessed horrific sights, and are members of organizations in which discussion of emotional issues may be regarded as a sign of weakness (Rubin, 1991). Thus, professionals involved in particularly difficult search operations and medical personnel who handle extraordinary workloads during disaster periods might also benefit from post-disaster counseling. However, there is little evidence of emergency workers needing directive therapies. In particular, there appears to be little scientific evidence that some widely used programs such as *Critical Incident Stress Debriefing* are effective (McNally et al., 2003).

In summary, the majority of victims and responders recover relatively quickly from the stress of disasters without psychological interventions. Those who suffer the greatest losses to their material resources (e.g., the destruction of their homes) and their social networks (e.g., spouses and other family members) are likely to experience the most psychological distress, but not necessarily an amount that is personally unmanageable. Thus, the appropriate strategy for psychological recovery by victims and first responders seems to be one of minimal intervention to provide information about sources of material support (for victims) and to facilitate optional involvement in social and emotional support groups (for victims and first responders).

Business recovery

Several studies of the economic impacts of environmental disasters have examined the ways in which individual businesses prepare for, are disrupted by, and recover from these events (see Tierney, 2006 and Zhang et al., 2009 for reviews). These studies found older, larger (measured by the number of employees), and more financially stable businesses are more likely to adopt hazard adjustments, as are businesses in the manufacturing, professional services, finance, insurance, and real estate sectors. Small businesses are more physically vulnerable because they are more likely than large businesses to be located in nonengineered buildings and are less likely to have the capacity to design and implement hazard management programs to reduce this physical vulnerability. At the same time as they face increased costs to repair structures and replace contents, these businesses also face reduced patronage if they must move far from their previous locations. Ultimately, many small businesses have failed by the time the space is available for reoccupancy at their original locations.

There also is variation among business sectors in their patterns of recovery. Whereas wholesale and retail businesses generally report experiencing significant sales losses, manufacturing and construction companies often show gains following a disaster (Webb et al., 2000). Moreover, businesses that serve a large (e.g., regional or international) market tend to recover more rapidly than those that only serve local markets (Webb et al., 2002). Small businesses, in particular, have been found to experience more obstacles than large firms and chains in their attempts to regain their predisaster levels of operations. Compared to their large counterparts, small firms are more likely to depend primarily on neighborhood customers, lack the financial resources needed for recovery, and lack

access to governmental recovery programs (Alesch et al., 2001; Tierney, 2006). Thus, business sector and business size can be seen as indicators of operational vulnerability that are equivalent to the demographic indicators of social vulnerability in households.

Sources of recovery assistance

There are three fundamental patterns of household recovery that are defined by the three corresponding sources of assistance (Bolin and Trainer, 1978). These are autonomous (own resources), kinship (extended family resources), or institutional (governmental) – although few households actually rely on only one source.

Autonomous recovery depends on the household's available human, material, and financial resources. Human resources are available to the extent household members can continue to derive generate income from employment, rental of physical assets, or interest/dividends from financial assets. Moreover, household recovery depends on the degree to which material resources are available. This includes the extent to which its possessions – land, buildings, equipment, furniture, clothes, vehicles, crops, and animals – are undamaged or can be restored at reasonable expense. A household's recovery also depends on the degree to which its financial resources are available. This includes an ability to withdraw savings quickly from banks, to quickly liquidate stocks and bonds at a fair price, and to receive adequate compensation from its insurer. In some cases, household recovery also depends on the degree to which creditors will accept delayed payments on financial liabilities such as loans, mortgages, and credit card debt. Finally, household recovery depends on the degree to which members can reduce consumption such as purchases of shelter, food, clothing, medical care, entertainment, and other goods and services. Kinship recovery depends on the physical proximity of other nuclear families in the kin network, the closeness of the psychological ties within the network, the assets of the other families and, of course, the extent to which those families also suffered losses. Institutional recovery depends on whether victims meet the qualification standards, usually documented residence in the impact area and proof of loss.

Some aspects of household recovery are relatively similar across ethnic groups, but others reveal distinct differences. After Hurricane Andrew, Anglos, Blacks, and Hispanics experienced similar levels of frustration in coping with the challenges of living in damaged homes, job relocation, dealing with agencies, behavioral problems with children, and loss of household members (Morrow, 1997). However, there were significant differences in the experience of other problems. For example, Blacks reported the greatest frequency of frustration about living in temporary quarters, whereas Hispanics experienced the greatest frustrations in dealing with building inspectors.

Hazard insurance

Hazard insurance is important because it decreases government workload and expense after disasters by shifting part of the administrative burden for evaluating damage to insurance companies in the private sector. Moreover, hazard insurance defines the terms of coverage in advance, thus reducing opportunities for politicians to increase benefits after disaster. Unfortunately, the potential contribution of hazard insurance remains to be fully realized. There are many difficulties in developing and maintaining an actuarially sound hazard insurance program, so hazard insurance varies significantly in its availability and cost – flood, hurricane, and earthquake insurance being particularly problematic (Kunreuther and Roth, 1998). In particular, the National Flood Insurance Program has made significant strides over the past 30 years, but it continues to require operational subsidies.

One of the basic problems is that those who are most likely to purchase flood insurance are, in fact, those who are most likely to file claims (Kunreuther, 1998). This problem of *adverse selection* makes it impossible to sustain a market in private flood insurance. In some cases, the homeowners are underinsured or lack any insurance because they cannot afford quality insurance or were denied access to it (Peacock and Girard, 1997). In addition, there are cognitive obstacles to developing a comprehensive hazard insurance program. Building on earlier hazards research (see Burton et al., 1993, for a summary) and psychological research on judgment and decision making (see Slovic et al., 1974, for an early statement and Baron, 2000, for a more recent summary), researchers have identified numerous logical deficiencies in the ways people process information in laboratory studies of risk. One important issue concerns what economists call *moral hazard* and psychologists refer to as a *lack of perceived personal responsibility for protection*. The concept of moral hazard has important policy implications because the Interagency Floodplain Review Committee (1994) report concluded federal disaster relief policy creates this condition by relieving households of the responsibility for providing their own disaster recovery resources.

Hazard insurance can make a significant contribution to household recovery but coverage varies by hazard agent, with Bolin and Bolton (1986) reporting 86% coverage for a tornado and Bolin (1993) reporting 25% for an earthquake. Risk area residents are particularly likely to forego earthquake insurance because they consider premiums to be too high and deductibles too large (Palm et al., 1990). Income, education, and occupational status all correlate with earthquake insurance purchase (Bolin, 1993). Strategies for coping with uninsured losses include obtaining government or commercial loans, obtaining government or nongovernmental organization (NGO) grants, withdrawing savings, and deciding not to replace damaged items (Bolin, 1993). Loans can be problematic because they involve long-term debt that takes many years to repay (Bolin, 1993). Government grants require households to

meet specific standards, including proof that they are indeed residents of the disaster impact area. However, there can be problems in registering people who evacuated or were rescued without identification (Yelvington, 1997). Relaxed standards seem humane but can allow the chronically homeless and out of area construction workers to obtain access to services intended only for disaster victims. In turn, resentment toward "freeloaders" can curtail services to victims.

Higher levels of government

Countries across the world vary in the relative roles of local, state (provincial), and federal (national) levels of government. In some cases, the entire burden of government assistance falls on the federal/national government whereas, in others, responsibility is distributed across multiple levels of government. Because of this diversity, this section focuses on the system in the United States because it illustrates types of complexities that arise in a federal system of distributed responsibility.

In the USA, state and federal agencies can play significant roles in disaster recovery, but the burden most frequently falls on local governments because only about 19% of all disasters receive state disaster declarations and 1% qualifies for Presidential Disaster Declarations (PDDs). Thus, local governments should prepare to undertake a variety of functions during a disaster recovery process, understanding that they might not receive any aid from higher levels of government for minor disasters. The main factor affecting the level of involvement of state and federal government is the scope of the event. After a major disaster, a PDD opens a broad range of programs for relief and reconstruction. In such cases, the state plays a coordinating role, working with both federal and local governments.

The lead agency at the federal level is FEMA, but other federal agencies might be called upon when a PDD is granted, including the Small Business Administration, the US Army Corps of Engineers, the Department of Housing and Urban Development, the National Oceanographic and Atmospheric Administration, and the Economic Development Administration, among others. Each of these agencies funds specific disaster recovery programs. According to the National Response Framework, these agencies can be housed in Disaster Field Offices (DFOs) in the vicinity of the disaster. Emergency Response Teams (ERTs) are located in the DFOs. These include an Operations Section that coordinates federal, state, and voluntary efforts, and an Infrastructure Support Branch to facilitate restoration of public utilities and other infrastructure services.

The main types of programs providing recovery assistance are Individual Assistance, Infrastructure Support (formerly Public Assistance), and Hazard Mitigation Grant Program. Individual Assistance is available to households through the Temporary Housing Assistance program, Individual and Family Grants, Disaster Unemployment assistance, legal services, special tax considerations, and crisis counseling programs. Individuals and businesses can receive aid through the Small Business Administration Disaster Loans program, which can provide loans for repairs to housing and businesses, and also for operating expenses. In the past, many loan programs have been inaccessible to low-income households, which tend to rent rather than own their housing. Thus, they failed to qualify for loans because of their low incomes and lack of collateral. The Individual and Family Grant Program was intended to fill the need for a program targeting those whose needs were not being met by the SBA loan program, private insurance, or NGO assistance. However, the amounts awarded tend to be small.

Assistance provided under the Hazard Mitigation Grant Program has increased in importance since the passage of the Disaster Mitigation Act of 2000. This legislation requires local governments to identify potential mitigation measures that could be incorporated into the repair of damaged facilities in order to be eligible for pre- and post-disaster funding. These activities include hazard mapping, mitigation planning, development of building codes, development of training and public education programs, establishing Reconstruction Information Centers, and assisting communities to promote sustainable development. In addition, there may be state programs that also provide assistance to households and local governments for recovery from disasters that do not receive a PDD.

Nongovernmental organizations and community-based organizations

The role of NGOs such as the American Red Cross, Salvation Army, and Mennonite Disaster Service is widely publicized and the role of community-based organizations (CBOs) such as local churches and service organizations is increasingly recognized. Such organizations provide housing, food, clothing, medicine, and financial assistance to disaster victims. In most cases, the *existing* government social service agencies are supplemented by NGOs that *expand* their membership to perform the tasks they are expected to perform during disaster recovery (Dynes, 1970). By contrast, existing CBOs typically *extend* themselves beyond their normal tasks to perform novel activities. In addition, there are situations in which existing, expanding, and extending organizations cannot successfully meet the recovery needs of disaster victims. In such cases, government agencies, NGOs, and CBOs form an *Unmet Needs Committee*, which is an *emergent* organization that is designed to serve those whose needs are not being addressed by existing programs. In some cases, the need for such emergent organizations arises from political organization and activism by population segments that believe they are being neglected (Morrow and Peacock, 1997; Phillips, 1993).

Local government recovery functions

Rubin (1991) accounted for community recovery in terms of six variables – *federal influences and conditions*, *state*

influences and conditions, *community-based needs and demands for action*, *personal leadership*, *ability to act*, and *knowing what to do*. One important commonality among the 14 cases Rubin et al. (1985) studied is that the speed, efficiency, and equity of community recovery depended significantly upon local government's ability to improvise effective recovery strategies. That is, communities recovered more quickly and effectively if they could identify and respond to the specific problems that arose from its unique circumstances. More recently, practitioners and researchers have begun to agree that community disaster recovery is even faster and more effective if it is based on a recovery plan that has been developed prior to disaster impact (Olson et al., 1998; Schwab et al., 1998; Wilson, 1991; Wu and Lindell, 2004). The recovery plan needs to establish clear goals and an implementation strategy (Smith and Wenger, 2006), preferably one that does not reproduce the community's preimpact hazard vulnerability.

After a disaster, local government needs to perform many tasks very quickly, and many of these must be performed simultaneously. It is therefore critical to plan for disaster recovery, as well as for disaster response (Schwab et al., 1998). The line between emergency response and disaster recovery is not clear because some sectors of the community might be in response mode whereas others are moving into recovery, and some organizations will be carrying on both types of activity at the same time. This means that there will be little time to plan for disaster recovery once the emergency response has begun. By planning for recovery before disaster strikes, resources can be allocated more effectively and efficiently, increasing the probability of a rapid and full recovery.

Local government agencies will frequently find during disaster recovery that some households and businesses fail to perform the tasks that are required to recover from the disaster. Whether households and businesses lack the knowledge of how to recover or the resources needed to recover, government can provide assistance. Local government must also perform specific tasks during disaster recovery, some of which involve restoring services it performed before the disaster (e.g., providing functioning roads, street lights and signs, and traffic control devices). In addition, local government must rebuild any critical facilities (e.g., police and fire stations) that were damaged or destroyed. Finally, local government has a heightened need to perform its regulatory functions regarding land-use and building construction. These two functions require rapid action under conditions of a greatly multiplied workload, so special provisions are required to expedite the procedures for reviewing and approving the (re)development of private property.

In approaching the task of preimpact recovery planning, a community must overcome three major misconceptions about disaster recovery. The first misconception is that the entire recovery effort can be improvised after the emergency response is complete. In fact, a timely and effective disaster recovery requires a significant amount of data collection and planning that will delay the recovery if they are postponed until after the emergency response is over. It is important to recognize that the disaster response phase's uncertainty and urgency about human safety has been replaced by households' and businesses' urgency to return to normal patterns of functioning and government agencies' uncertainty about how to organize the community to accomplish this.

The second misconception is that there will be ample time to collect data and plan the recovery during the emergency response. It is true that some recovery relevant data must be collected during the emergency response. However, an assessment of "lessons learned" from the disaster impact should be used to make final adjustments to a recovery process that has been designed before the disaster strikes. Finally, the third misconception is that the objective of disaster recovery should be to restore the community to the conditions that existed before the disaster. As noted earlier, this will simply reproduce the community's existing disaster vulnerability.

In many ways, the process of preparedness for disaster recovery is quite similar to the process of preparedness for emergency response. Thus, the community should establish a Recovery/Mitigation Committee before disaster strikes that will establish a vision of community disaster recovery and articulate the basic strategies that will be implemented before and after disaster impact. In addition, the committee should assign each recovery function to a specific organization, develop a Recovery Operations Plan, and acquire any necessary resources to implement it. Finally, the committee should conduct the training and tabletop exercises needed to ensure the ROP can be implemented effectively.

The recovery/mitigation committee

The Recovery/Mitigation Committee can be an important part of an effective, rapid disaster recovery process. This committee should be established before a disaster during the preimpact recovery planning process. The Recovery/Mitigation Committee should examine the findings from the community hazard/vulnerability analysis to identify the locations having the highest levels of hazard exposure, physical vulnerability, and social vulnerability. The committee should begin to work with the rest of the community, and especially with those at greatest risk, to formulate a vision of the disaster recovery it intends to implement.

The Recovery/Mitigation Committee needs to work with the community before and after a disaster to articulate a vision of community disaster recovery. The recovery process needs to strike a balance between corporate centered and community-based economic development (Blair and Bingham, 2000). According to a *corporate centered economic development*, usually advocated by the local business community, government provides resources such as land and money to the private sector to invest without any restrictions. This market-based strategy

tends to produce results that are good in aggregate but produces an inequitable recovery. By contrast, *community-based economic development* involves active participation by government to ensure that the benefits of recovery will also be shared by economically disadvantaged segments of the community.

The short-term recovery following a major disaster can generate an economic boom as state and federal money flows into the community to reconstruct damaged buildings and infrastructure. These funds are used to pay for construction materials and the construction workforce and, to the extent that the materials and labor are acquired locally, they generate local revenues. In addition, the building suppliers hire additional workers and these, along with the construction workers, spend their wages on places to live, food to eat, and entertainment. Unless there are undamaged communities within commuting distance that can compete for this money, it will all be spent within the community.

Communities must also consider the long-term economic consequences of disaster recovery. What will happen after the reconstruction boom is over? They can attract new businesses if they have a skilled labor pool and good schools – especially colleges whose faculty and students can support knowledge-based industries. Other assets include low crime rates, low cost of living, good housing, and environmental amenities such as mountains, rivers, or lakes (Blakely, 2000). A community can also enhance its economic base if it can attract businesses that are compatible with the ones that are already there. Such firms can be identified by asking existing firms to identify their suppliers and distributors. These new firms might be attracted by the newer buildings and enhanced infrastructure that has been produced during disaster reconstruction.

If a disaster stricken community does not already have such assets, they can invest in four fundamental components of economic development – locality development, business development, human resources development, and community development. *Locality development* enhances a community's existing physical assets by improving roads or establishing parks on river and lakefronts. *Business development* involves efforts to retain existing businesses or attract new ones. Although it is not easy, this can be accomplished working with businesses to identify their critical needs. In some cases, this might involve establishing a business incubator that allows startup companies to obtain low cost space and share meetings rooms. *Human resources development* expands the skilled workforce, possibly through customized worker training. Finally, *community development* utilizes NGOs, CBOs, and local firms that will hire current residents of the community whose household incomes are below the poverty level. For example, a comprehensive program for developing small businesses, affordable housing, community health clinics, and inexpensive child care can help to eliminate some of what new businesses might consider to be one of the risks of relocating to the community.

Developing a recovery operations plan

There are six important features of a preimpact recovery operations plan. First, it should define a disaster recovery organization. Second, it should identify the location of temporary housing because resolving this issue can cause conflicts that delay consideration of longer-term issues of permanent housing and distract policymakers altogether from hazard mitigation (Bolin and Trainer, 1978; Bolin, 1982). Third, the plan should indicate how to accomplish essential tasks such as damage assessment, condemnation, debris removal and disposal, rezoning, infrastructure restoration, temporary repair permits, development moratoria, and permit processing because all of these tasks must be addressed before the reconstruction of permanent housing can begin (Schwab et al., 1998).

Fourth, preimpact recovery plans also should address the licensing and monitoring of contractors and retail price controls to ensure victims are not exploited and also should address the jurisdiction's administrative powers and resources, especially the level of staffing that is available. It is almost inevitable that local government will have insufficient staff to perform critical recovery tasks such as damage assessment and building permit processing, so arrangements should be made to borrow staff from other jurisdictions (via preexisting Memoranda of Agreement) and to use trained volunteers such as local engineers, architects, and planners. Fifth, these plans also need to address the ways in which recovery tasks will be implemented at historical sites (Spennemann and Look, 1998). Finally, preimpact recovery plans should recognize the recovery period as a unique time to enact policies for hazard mitigation and make provision for incorporating this objective into the recovery planning process.

Communities that develop recovery plans addressing these functions will be better positioned to move promptly from emergency response into disaster recovery and, in turn, from disaster recovery to normal social and economic functioning. Not only will housing recovery be accelerated, but there is a greater likelihood that hazard mitigation will be integrated into the recovery process. The inclusion of hazard mitigation means that homes, businesses, and critical facilities such as schools and hospitals can be moved out of hazard prone areas. Moreover, any residential, commercial, or industrial structures that remain in hazard prone areas can be retrofitted to higher standards of hazard resistance. Thus, a preimpact plan can not only accelerate recovery but also decrease the community's vulnerability to future disasters.

Summary

Disaster recovery is a *phase* in the emergency management cycle that frequently overlaps with the emergency response. Its *goal* is to restore normal community activities that were disrupted by disaster impacts through a *process* involving both activities that were planned before disaster impact and those that were improvised after disaster impact. Disaster recovery is most rapidly

and effectively achieved when communities engage in a preimpact planning process that addresses the major recovery functions and incorporates hazard mitigation and hazard insurance into a recovery operations plan.

RECURRENCE INTERVAL

Glenn Biasi
University of Nevada Reno, Reno, NV, USA

Synonyms

Earthquake period; Recurrence period

Definition

Recurrence interval is the expected length of time between occurrences of a geologic event.

Discussion

Usage of the term recurrence interval varies somewhat among geoscience disciplines. In paleoseismology, recurrence interval refers to the time between ground-rupturing events at a point on a fault. Strong ground shaking is presumed, but in most cases, the magnitude of the earthquake is poorly known. For instrumentally measured earthquakes, the recurrence interval may be more precisely applied, such as with the specification of both the earthquake size and location. When applied to hydrological events, the recurrence interval refers to the average period between floods of a given size or greater. The distinction leads to some difference in statistical definition. Because usage of the term varies, the definition of the recurring event should be provided with the estimate itself.

Estimation: The most common estimator of the recurrence interval is the mean recurrence time based on a record over which detection of the events is considered certain. A useful estimate of the uncertainty of the recurrence interval is given by the standard error of the mean (the standard deviation divided by the square root of the number of intervals). If the number of intervals is small, an adjustment may be made for the distinction between sample and population statistics. The estimate may also be adjusted if it is known that no events occurred for a significant period before the first or after the last event in the sequence.

Application to hazard estimation: The recurrence interval estimate by itself implies nothing about the probability of an event in any particular period of time. Conditional probabilities of occurrence of the event depend on the probability distribution of the intervals themselves. Only when the events are random in time and thus modeled as a Poisson distribution can the reciprocal of the recurrence interval in years be interpreted as the annual probability of an event. If it is known that the process is clustered or quasi-periodic, the distribution model for intervals will affect the conditional probability of a future event. The term "return period" is sometimes used interchangeably with recurrence interval, but this should be done with care. In seismic engineering, return period can refer to the return of some level of ground motion, but when more than one fault contributes to the hazard, the return period may not match the recurrence interval on any contributing faults.

RED CROSS AND RED CRESCENT

Donald J. Shropshire
Municipality of Chatham-Kent, Chatham, ON, Canada

Synonyms

International Federation of Red Cross and Red Crescent Societies; IFRC; League of Red Cross Societies

Definition

The International Federation of Red Cross and Red Crescent Societies is the world's largest humanitarian organization.

Discussion

The Federation's work focuses on four core areas: promoting humanitarian values, disaster response, disaster preparedness, and health and community care. The Red Cross was formed in 1864, at the Geneva Convention, to provide humanitarian assistance in times of war. In response to the many conflicts in Europe, the International Committee of the Red Cross (ICRC) grew dramatically. Following the cessation of World War 1, members of the Red Cross recognized the potential to apply the Red Cross's unparalleled capacity to provide humanitarian assistance in response to other tragedies such as disasters. The League of Red Cross Societies was formed in 1919 to carry out this work (Moorehead 1999, p. 261).

Renamed in 1991, the International Federation of Red Cross and Red Crescent Societies, the Federation now comprises 186 Red Cross and Red Crescent national societies that engage almost 100 million volunteers and staff, a Secretariat in Geneva and more than 60 delegations strategically located to support activities around the world. There are more societies in formation. The unique network of National Societies is the Federation's principal strength. The Federation, together with National Red Cross or Red Crescent Societies and the ICRC, makes up the International Red Cross and Red Crescent Movement (IFRC 2009, p. 7). The Movement works in cooperation with UN agencies, governments, donors, and other aid organizations to assist vulnerable people around the world.

National Societies support the public authorities in their own countries as independent auxiliaries to the government in the humanitarian field. Their local knowledge and expertise, access to communities, and infrastructure enable the Movement to rapidly mobilize to get the right kind of help where it is most needed. Its local presence and community-based approach, coupled with the Movement's global outreach, resources, and know-how, give the Red Cross and Red Crescent a distinct advantage when it comes to dealing with today's complex humanitarian challenges. (www.ifrc.org)

Strategy 2020

Strategy 2020 was adopted by the Federation's General Assembly in November 2009 to guide the actions of the Federation during the next ten years in order to achieve its common vision:

"To inspire, encourage, facilitate, and promote at all times all forms of humanitarian activities by National Societies, with a view to preventing and alleviating human suffering, and thereby contributing to the maintenance and promotion of human dignity and peace in the world."

The *strategic aims* of *Strategy 2020* are:

1. Save lives, protect livelihoods, and strengthen recovery from disasters and crises.
2. Enable healthy and safe living.
3. Promote social inclusion and a culture of non-violence and peace.

The *enabling actions* to deliver our Strategic Aims are:

1. Build strong National Red Cross and Red Crescent Societies.
2. Pursue humanitarian diplomacy to prevent and reduce vulnerability in a globalized world.
3. Function effectively as the International Federation.

Guided by the statutes and strategy of the Movement, *Strategy 2010* consolidates previous policies and strategies and provides the basis for doing more, doing better, and reaching further. (IFRC 2009, p. 9)

RED TIDES

Philip Weinstein
University of South Australia, Adelaide, SA, Australia

Synonyms

Harmful algal bloom

Definition

A "red tide" or "harmful algal bloom (HAB)" is a local overgrowth of particular species of plankton. Plankton are single-celled microscopic organisms that include algae and dinoflagellates, many of which are capable of photosynthesis while floating in the water column. Their colors vary from green to reddish-brown depending on which photosynthetic pigments they contain. Unfortunately, they can also contain toxins, and when large coastal blooms occur, they pose a hazard to recreational water users, local seafood supplies, and sometimes downwind coastal residents.

Causes

The mechanisms that drive red tides are complex, and include both natural and anthropogenic phenomena. Essentially plankton are, like all organisms, nutrient dependent, and blooms occur in response to increased nutrient availability. Coastal upwelling (deep, nutrient-rich waters rising) thus provides a natural driver of blooms, but so does fertilizer-rich runoff from agricultural lands. Different species also depend on specific wind and sea surface temperature conditions for optimal growth. The interactions of these factors are not yet well enough understood to allow public health officials to predict blooms and issue proactive warnings. The hazard can, therefore, only be managed reactively, generally by public warnings not to engage in recreational activities in or on the water, and sometimes by the imposition of a withholding period for affected seafood (filter-feeding shellfish can accumulate the toxin, rendering them unfit for human consumption). Many reasons have been postulated for toxin production by plankton, ranging from incidental by-products of metabolism to creation of a competitive advantage by poisoning other organisms utilizing the same resources. The recently discovered *Pfiesteria* is a controversial organism that may have evolved the ability to capitalize on the sudden increase in food availability from the fish killed by its own toxins – an intriguing story that has been popularized elsewhere (Barker, 1998).

Effects

The toxins produced include extremely potent neurotoxins (e.g., brevetoxin and saxitoxin, commonly from species of *Gymnodinium* and *Alexandrium,* respectively) and various gastrointestinal irritants (e.g., dinophysistoxin and domoic acid, commonly from species of *Dinophysis* and *Pseudo-nitzschia,* respectively) (Heymann, 2004). The effect on humans depends on the dose and route of exposure, commonly involving the consumption of toxic shellfish because the dose is large and intestinal absorption high. "Neurotoxic shellfish poisoning (NSP)" is one classic outcome associated with brevetoxin exposure, giving rise to tingling around the mouth and extremities as well as dizziness. It tends to be a much milder disease than "Paralytic shellfish poisoning (PSP)," which can kill by paralyzing the respiratory muscles, sometimes within 12 hours of saxitoxin ingestion (Heymann, 2004). In windy conditions, toxins can also be aerosolized as sea spray, with eye and respiratory irritation occurring in beachgoers or coastal residents. Because of the complexities of bloom ecology as well as human behavior, both disease and disease intervention can be highly regionally variable. To plan hazard mitigation strategies, it is therefore important to regionalize recommendations based on the relevant scientific literature (e.g., Florida; Kirkpatrick et al., 2004).

Outlook

The hazard posed by red tides and other HABs is likely to increase substantially in the future as a result of: increasing nutrient runoff from expanding agriculture; increasing sea surface temperatures with global *Climate Change*; and increasing human contact with coastal waters as populations expand, and seek more food and recreational opportunities.

REFLECTIONS ON MODELING DISASTER

David A. Etkin
York University, Toronto, ON, Canada

Synonyms

Catastrophe models; Emergency models

Definition of disaster by United Nations

A serious disruption of the functioning of a community or a society causing widespread human, material, economic, or environmental losses which exceed the ability of the affected community or society to cope using its own resources.

Introduction

People and institutions, especially those that employ scientists and analysts, use models to help them understand, predict, and manage aspects of their environment. Within the context of models used to represent disasters, this process has traditionally been rooted in notions of cause and effect, determinism, free will, and power. When combined these notions result in the belief that people can understand, predict, and control the systems in order to create more desirable outcomes. Evidence of this in modern technological society is abundant. However, there is also contrary evidence – of massive failures with catastrophic consequences – and the traditional paradigm has, at least in part, been challenged by the advent of theories that incorporate notions of chaos, complexity, and adaptive systems. As a result, disaster models have become broader and more sophisticated over time. It should also be noted that fatalistic attitudes are not uncommon, reflected at times in the belief that disasters are, for example, sent by God to punish people because of moral transgressions (Taylor, 1999), or that people have no power to control futures predetermined by Fate.

How people, communities, and institutions conceptualize disaster has important consequences for the selection of coping strategies. Different strategies vary, for example, according to culture and professional discipline (Quarantelli, 1989). Engineering and physical sciences tend to emphasize hazard management, whereas social sciences emphasize reducing vulnerability and enhancing resilience. Some strategies emphasize formal plans, whereas others focus on the development of informal networks. Sometimes strategies are formalized as, or result from, explicit conceptual models (particularly by academics and disaster professionals), and at other times they are better described as nebulous attitudes (particularly with respect to the general public). Each strategy is useful to some degree and depends upon the larger social, political, economic, environmental, and geographical context. One could argue that many of the models used in the field of disaster management suffer from the generic problem of narrowly defining the context within which disasters should be understood, with the result of leading users into perilous overconfidence (Hewitt, 2010, personal communication). An example is the use of levees to reduce flood risk; the well-known levee effect, described by Gilbert White, occurs when the presence of flood protection spurs new development within the flood plain. This explains much of the development in New Orleans. Disaster management is best accomplished by utilizing and applying a spectrum of models that are situationally effective.

What is a disaster?

Disasters occur over a wide range of space and time scales and can be of many different types. Historically, they have been categorized as natural, technological, or human-caused (according to the trigger that initiates the event; even so, many disasters have significant components of two or all three of these categories), though the phrase "unnatural disaster" is sometimes used to emphasize the notion that the causes are more rooted in social processes than natural ones (Steinberg, 2000). Even within this structure there is great complexity, and a disaster may or may not cause deaths or economic loss.

Defining disaster is far from simple. For some organizations the answer is direct and quantitative. The Centre for Research on the Epidemiology of Disasters (CRED, 2007), for example, whose data are frequently quoted along with that of reinsurance companies, defines disaster using a threshold approach, as an event that satisfies at least one of the following criteria:

- Ten or more people killed
- One hundred or more people affected
- Declaration of a state of emergency
- Call for international assistance

This and other similar definitions have the advantage of being straight-forward, measurable, and useful from an operational perspective, though attributions of cause of death and the definition of "affected" can be challenging.

Other definitions of disaster are less specific, particularly those in the academic realm. Disciplinary perspectives often frame the meaning of disaster. For example, physical scientists have historically defined disaster in terms of physical processes, whereas sociologists have defined it in terms of the meaning that the communities give to it and how it affects normal community functioning (Quarantelli, 1998). Much of the literature on this topic assumes that a disaster is an externally triggered event that comes and goes, after which people and institutions recover. For some, a disaster is not constrained to a specific damaging event. Hewitt (1983, 1997) emphasizes the "normal" everyday sets of decisions and actions that create vulnerable communities, and views disaster less as a particular damaging event and more in terms of day-to-day community functions. Along these lines Mulvihill and Ali (2007) discuss the importance of "disaster incubation" (the process by which communities create vulnerable conditions) as a precursor to the actual

event. Papers and books on this topic (e.g., Quarantelli, 1998; Perry and Quarantelli, 2005) demonstrate a lack of common agreement on a definition. Although there are recurring themes, many definitions emphasize disasters as cultural events that are "*rationalized and interpreted according to the canons and preoccupations of the contemporary period*" (Alexander, 2005).
