ENCYCLOPEDIA OF NATURAL HAZARDS

Volume Editor
Peter Bobrowsky is an Adjunct Professor at the Center for Natural Hazards Research, Department of Earth Sciences, Simon Fraser University, Burnaby, BC, Canada (ptbobrow@sfu.ca). With over 30 years of professional experience as an environmental and engineering geologist he has worked in Africa, China, India, North America, Middle East and South America. He has published extensively on a variety of subjects and has served/serves on a number of bodies and organizations: Secretary General of IUGS, President of the Geological Association of Canada, President of the Canadian Quaternary Association, Vice President of the International Consortium on Landslides, editorial board for Landslides Quaternary International and several others. The project to compile and publish this volume was completed during his tenure as SG of IUGS.

Aims of the Series
The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to http://www.springerlink.com/reference-works/ to visit the "Earth Sciences Series" online.

About the Series Editor
Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 28 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Professor Emeritus at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor
Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Preface

Few subjects have caught the attention of the entire world as much as those dealing with natural hazards. The first decade of this new millennium provides a litany of tragic examples of various hazards that turned into disasters affecting millions of individuals around the globe. The human losses (some 225,000 people) associated with the 2004 Indian Ocean earthquake and tsunami, the economic costs (approximately 200 billion USD) of the 2011 Tohoku Japan earthquake, tsunami, and reactor event, and the collective social impacts of human tragedies experienced during Hurricane Katrina in 2005 all provide repetitive reminders that we humans are temporary guests occupying a very active, angry, and ancient planet. Any examples here to stress the point that natural events on Earth may, and often do, lead to disasters and catastrophes when humans place themselves into situations of high risk.

Few subjects share the true interdisciplinary dependency that characterizes the field of natural hazards. From geology and geophysics to engineering and emergency response to social psychology and economics, the study of natural hazards draws input from an impressive suite of unique and previously independent specializations. Natural hazards provide a common platform to reduce disciplinary barriers or boundaries and facilitate a beneficial synergy in the provision of timely and useful information and action on the critical subject matter.

As social norms change regarding the concept of acceptable risk and human migration leads to an explosion in the number of megacities, costal overcrowding and unmanaged habitation in precarious environments such as mountainous slopes, the vulnerability of people and their susceptibility to natural hazards increase dramatically. Coupled with the concerns of changing climates, escalating recovery costs, and a growing divergence between more developed and less developed countries, the subject of natural hazards remains on the forefront of issues that affect all people, nations, and environments all the time.

At the start of a new decade, in the first few months of 2010 alone, a magnitude 7 earthquake near Port-au-Prince, Haiti, killed an estimated 230,000 people, exposed the inadequacies of their infrastructure and emergency response capacity, and virtually crippled an entire nation. In contrast, a month later, a significantly larger magnitude 8.8 earthquake off the coast of Chile provided a sober lesson that those areas with a long history of exposure to natural hazards are indeed much more capable to cope with the consequences of unexpected events. Shortly thereafter, the eruptive events from Eyjafjallajökull volcano in Iceland virtually paralyzed air traffic in the United Kingdom and Western Europe for days. Travelers from around the world were impacted and inconvenienced. The economic repercussions were significant and all nations quickly realized how unprepared they are to natural hazards occurring outside of their borders.

This treatise provides a compendium of critical, timely, and very detailed information and essential facts regarding the basic attributes of natural hazards and concomitant disasters. For instance, swelling soils cost some $2.3 billion in damage annually in the United States alone, some 3 billion people were affected and about 7 million people died from flooding in the twentieth century, there are over 45,000 dams around the world and 80% of the useful storage capacity for hydropower in Asia will be lost by 2035, wildfires release an estimated 3,431 million tons of CO_2 into the atmosphere annually, lightning strikes cost the insurance industry more than $5 billion annually, an individual's social perception of the environment has radically changed in recent decades with the advent of near-real-time media reporting (CNN effect), in 1800 only 3% of the global population was urbanized as compared to over 50% by 2008, and resilience is frequently the most common outcome among survivors exposed to natural disasters. This volume clarifies and defines many fundamental concepts and terms, for instance, P waves vs. S waves, comets vs. asteroids, debris flow vs. debris

avalanche, dispersive soil vs. expansive soil, or shield volcano vs. stratovolcano. Under a single cover, a diverse suite of topics ranging from solar flares, droughts, and blizzards to tiltmeters, seismographs, and GIS to cryological engineering and structural mitigation to post-traumatic stress disorder, coping capacity and religion, and hazards are addressed.

The *Encyclopedia of Natural Hazards* effectively captures and integrates contributions from an international portfolio of almost 300 specialists whose range of expertise addresses over 330 topics pertinent to the field of natural hazards. Disciplinary barriers are overcome in this comprehensive treatment of the subject matter. Clear illustrations and numerous color images enhance the primary aim to communicate and educate. The inclusion of a series of "classic case study" events interspersed throughout this volume provides tangible examples linking concepts, issues, outcomes, and solutions. These case studies illustrate different but notable recent, historic, and prehistoric events that have shaped the world as we now know it. They provide excellent focal points linking the remaining terms to the primary field of study. This *Encyclopedia of Natural Hazards* will remain a standard reference of choice for many years.

January 2013 Peter Bobrowsky

Acknowledgments

The editorial team is extremely grateful to the ca. 300 contributing authors who often willingly, but sometimes reluctantly, agreed to participate in this important endeavor. The success, utility, and widespread adoption of this encyclopedia owes considerable gratitude to all of these authors for sharing their knowledge and expertise toward a common cause of educating a broader population on the topic of natural hazards. All of the contributions were first read by the editor in chief; similarly, all of the contributions were also read by at least one of the ten editorial board members. Each contribution was critically reviewed by at least one external specialist. We are also grateful to the following individuals who each reviewed multiple papers to ensure the scientific integrity of the submissions was of the highest caliber: Orhan Altan, Mohsen Ashtiany, Tom Baldock, Martin Batterson, Allison Bent, Bruce Broster, Robert Buchwaldt, Tom Casadevall, Hubert Chason, Paul Croft, Heather Crow, Johannes Dahl, Miranda Dandoulaki, Tim Davies, A. Deganutti, Fabio Dell'Acqua, Angus Duncan, Frank Fiedrich, Charles Finkl, Duane Froese, Sven Fuchs, J.C. Gaillard, Matthias Garschagen, David Gauthier, Marten Geertsema, Thomas Gerz, Yuri Gorokhovich, Raisa Gracheva, Rick Guthrie, Fausto Guzetti, Reginald Hermanns, Lynn Highland, David Huntley, Kovacs Janos, Rohit Jigyasu, Kate Jones, Margareth Keiler, Julia Kloss, Jasper Knight, Robert Korty, Migala Krzystof, Steve LaDochy, Maurice Lamontagne, Craig Landry, Julie Lantos, Jean Francois Lenat, Suzanne Leroy, Jean-Sebastian L'Heureux, Colin Mackay, Brian Marker, Bruce Masse, James McCalpin, Scira Menoni, John Miles, Joann Mossa, Ilian Noy, Douglas Paton, Toon Pronk, Rajmund Przybylak, Fabrice Renaud, Tiziana Rosetto, Jeff Rubin, Zita Sebesvari, Vladimir Sokolov, Mauro Soldati, Anders Solheim, Ian Spooner, Sasha Strom, Bert Struik, Andy Stumpf, Peter Suhadolc, Brian Tang, Jakob Tendel, Vincent Parisi, Gonghui Wang, Brent Ward, Dennis Wenger, Tom Wilson, and Karl Otto Zendel. Following revisions of the contributions, the entries were read by the editorial board. The editorial board very much appreciates the guidance, perseverance, and patience of the managing staff at Springer Publishing, in particular Petra van Steenbergen, Sylvia Blago, and Simone Giesler. They were instrumental in the delivery of this volume. Peter Bobrowsky expresses his personal and sincere thanks to his wife Theresa for her unselfish support, appreciation, and understanding as to why so many precious evenings and weekends were sacrificed trying to influence and get along with 300 personalities during the past few years. Additional thanks go to the smaller members of the family, Michiko and Toba, for providing regular and amusing distractions during the entire process. Collectively we all hope that the information in this book serves its intended purpose to better inform, educate, and prepare all of those people who are directly or indirectly affected by natural hazards. Our aim is to help reduce the risk and losses associated with "things that go bump in the night."

a‘a; ‘a‘a; a-aa

Definition

Aa (derived from the Hawaiian word a’a’ for rough lava) lavas is the term for cooling textures of a highly viscous lava flow and was introduced as a technical term by Clarance Dutton in the year 1883. Aa is characterized by a rough rubbly surface composed of broken lava blocks called clinkers. When the molten rock cools, the lava flow increases its viscosity due to degassing and crystallization of minerals. At some point, the lava flows so slowly that it allows a thick crust to form. As flow continues to move, the cooler and brittle skin surface breaks into rough jagged blocks, or clinkers. The clinkers are carried along at the surface. At the leading edge of an aa flow, however, these cooled fragments often tumble down the steep front and are subsequently buried by the advancing flow. This process produces a layer of lava fragments both at the bottom and top of an aa flow. Accretionary lava balls as large as 3 m are common on aa flows (Figure 1).

Aa flows are emitted from vents at high rates ranging up to 50 km/h, often with much lava fountaining. They are characteristic of viscous magmas. Aa flows are animated with sporadic bursts of energy. Such flows may overturn houses, walls, and forests.

AA-LAVA, Figure 1 An aa flow front on the coastal plain of Isabella, one of the islands of the Galapagos archipelago, Ecuador (Robert Buchwaldt).

Definition

An accelerometer is defined as a transducer whose output is proportional to acceleration.

An accelerometer measures the proper acceleration it experiences relative to freefall. This is equivalent to inertial acceleration minus the local gravitational acceleration, where inertial acceleration is understood in the Newtonian sense of acceleration with respect to a fixed reference frame, which the Earth is often considered to approximate.

An accelerometer can be used for detecting magnitude and direction of the acceleration as a vector quantity.

An accelerometer consists of a proof mass, a reference frame, a sensor (an induction coil or a potentiometer and so on), a spring, a damper, and a casing. Because of the constraint of the reference frame, the proof mass can only move along an axis-line. According to Newton's law, when the casing experiences an acceleration in the axis, the proof mass with a certain inertia resists a change in its state of motion. The motion of the proof mass relative to the casing takes place. Therefore, the string creates deformation, and the proof mass begins to experience acceleration motion under the effect of the string force. Until the inertia force created by the moving proof mass equals the string force, the motion of the proof mass relative to the casing stops. The deformation of the string at this time reflects the magnitude of the measured acceleration. The induction coil or the potentiometer then converts the acceleration signal into the output electric-signal. The damper is used to improve the dynamic quality of the accelerometer.

A geophone is a type of accelerometer, and its output is proportional to the acceleration of earth particles. It is used to measure the seismic signals created by an earthquake or a seismic energy source.

A gravimeter also is a type of accelerometer, which is used for measuring the local gravitational field.

ACID RAIN

Mary J. Thornbush
University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Acid deposition; Acid precipitation

Definition

The US Environmental Protection Agency (EPA) refers to acid rain as a broad term that encompasses acidic particles and vapors deposited through dry and wet deposition. Wet deposition occurs in wet precipitation (such as rain, sleet, hail, snow, fog, or mist), with a pH normally less than 5.6. Half of atmospheric acidity falls to the ground as dry deposition (such as fly ash, sulfates, nitrates, and gases), where acidity is incorporated into dust and smoke, and then falls dry onto natural and human-made surfaces, including buildings. When gases come into contact with water, they become acids (such as sulfuric and nitric acids).

Sources: Natural (as from volcanoes and decaying vegetation) and anthropogenic (as from emissions into the atmosphere from human activities, including combustion). Primary anthropogenic emissions are of sulfur dioxide (SO_2) and nitrogen oxides (NO_x) from the burning of fossil fuels. Energy production through the combustion of coal remains a problem even in the developed world, where many power plants still rely on coal-burning. Coal-fired power stations account for more than 50% of global SO_2 emissions (Mohanty et al., 2009). Asian countries are now experiencing severe environmental degradation due to acidic precipitation, for example, China (cf. Wang et al., 2008).

Effects: Acidic pollution affects lakes, rivers, forests, soils, fish and wildlife populations, and buildings. Areas that comprise acidic bedrock (such as granite), as on the Precambrian Shield in Eastern Canada (Scanlon, 2001), have a low natural buffering capacity and support "acid-sensitive" ponds and lakes with an alkalinity less than 8 mg $CaCO_3$ per liter (Hagar et al., 2000). For instance, Sudbury, Ontario in Canada was artificially acidified by nickel mining and processing in the 1950s, which thinned soils and led to nutrient depletion, killed trees from soil acidity and chlorosis, and blackened surfaces by acid corrosion. Lakes in that area and in windward areas also suffered acidification. However, a sample of 44 acidic Sudbury lakes monitored since 1981 have shown a reduction in the number of highly acidic lakes ($pH < 5.0$) from 28 to 6 by 2004, indicating gradual recovery (Keller et al., 2007).

Extent: Acid rain is a trans-boundary environmental issue because wind-blown atmospheric pollutants can be carried great distances across political boundaries. For example, half of the acid deposits in Eastern Canada come from the USA (in the Muskoka-Haliburton area north of Toronto, this rises to three-quarters); similarly, acid rain in Japan comes from

Korea and China; whereas, acid rain in Norway is derived from England and Scotland (Scanlon, 2001).

Control: Acid rain monitoring programs were initiated in the 1970s in North America (for example, the USA Federal Clean Air Act of 1970), and policy has since changed to control environmental degradation in urban areas as well as in forests, rivers, and lakes associated with acid precipitation. The 1985 Eastern Canada Acid Rain Control Program and 1990 USA Clean Air Act Amendments both called for reduced annual SO_2 emissions by 40% from 1980 levels by 1994 and 2010, respectively (Venkatesh et al., 2000).

ADAPTATION

Philipp Schmidt-Thomé[1], Sirkku Juhola[2]
[1]Geological Survey of Finland (GTK), Espoo, Finland
[2]Aalto University, Aalto, Finland

Synonyms

Adjustment; Modification

Definition

In a geo-scientific context, the term adaptation is the ability of a species to adjust to (varying) environmental conditions. In association with a changing climate, adaptation refers to the processes, practices, or structures to moderate or offset potential damages or to take advantage of opportunities (Smit and Pilifosova, 2001). Adaptation of a society is dependent on the adaptive capacity of that particular society, irrespective of whether adaptation is automatic or planned.

Not all life forms are able to survive in all climate zones on the planet earth; human beings have permanently settled on all but one continent and in basically all climate zones, thus representing one of the most adaptive mammal species. By manufacturing clothing, tools, and other devices that enabled life in all kinds of natural conditions, humans have increased their adaptive capacity.

In the context of natural hazards, adaptation refers to the potential of humans to understand and respect natural extreme events that may affect life and human assets. In a strict sense, adaptation means the ability to respect extreme events in the design and shape of the living environment, for example, the structure of houses or the location of fields and pastures. In this sense, adaptation does not incorporate protective structures, as it refers to the possibilities to cope with the living conditions without restricting the total extent and exposure of an extreme event.

In practice (e.g., see entry *Land-Use Planning*), adaptation also encompasses protection and retreat. In the example of flood-prone areas, adaptation to life in regularly flooded areas is often met with the construction of houses on pillars or elevated mounds. In this case, protection means the construction of sea walls or dams to protect an area from being flooded whereas retreat refers to permanent abandonment of flood-prone areas. Historical examples of adaptation to flood-prone areas can be found in many places around the world, for example, on the island of Chiloe (Chile) to respect local tidal changes and on Lake Tong Le Sap (Cambodia) to maintain settlements in the yearly reoccurring flooding. One of the most flood-protected countries in the world is the Netherlands, where the entire coastline and the hinterland are integrated into flood protection measures and plans. Retreat can be found in areas that experienced sea level rise, such as historic settlements in the Black Sea Basin or on the Mediterranean shorelines.

With the introduction of protective measurements, humans have further increased their adaptive capacity, such as living closer to areas threatened by natural hazards. On the other hand, technical solutions to protect from natural hazards have also increased the exposure of life and assets to hazards and have thus increased the overall vulnerability (see entry *Vulnerability*). For instance, the building of dams along riverbeds has enabled the use of agriculture for crop production in flood plains, which were formerly used only as pastureland. The construction of dams has also often increased the river flow velocity and thus modified flood-prone areas, also because simultaneously natural flood retention basins have been removed. The benefits of increasing agricultural productivity have been acquired at the cost of increasing the vulnerability to floods.

Several disasters that occurred in the early twenty-first century have been attributed to climate change (see entry *Climate Change*), meanwhile the real causes for the increasing extent of damage is, at least to a great extent, caused by poorly-adapted location of settlement and inappropriate land use. The continuous development and change of vulnerability patterns therefore imply that adaptation and adaptive capacity are not static, but continuously evolving concepts.

Within the context of climate change, adaptation is seen as a response strategy involving adjustments to reduce vulnerability of communities, regions, or activities. Adaptive capacity, then, is defined as the ability or potential of a system to respond successfully to climate variability and change, and it includes adjustments in both behavior and in resources and technologies (IPCC, 2007). It has been argued that adaptive capacity, first and foremost, is context specific and varies from country to country and region to region and within social groups and individuals. It also varies over time, responding to society's changing economic, institutional, political, and social conditions (Smit and Wandel, 2006). In spatial terms, adaptive capacity is a nested concept: Capacities of regions are tied to the capacity of countries in terms of enabling or constraining environments for adaptation. The adaptive capacities at a national level may not always correspond to those at local level.

Irrespective of the complex nature of the concept, identifying the determinants of adaptive capacity is of importance to both scientists and policy-makers. Table 1 summarizes the most often used categories.

The list is not exhaustive, and these determinants are not independent of each other, nor are they mutually exclusive; rather, it should be recognized that the combination of these determinants varies between regions and countries. Several studies exist that have focused on identifying determinants of adaptive capacity – at the national level (Haddad, 2005; Yohe and Tol, 2002; Adger et al., 2005; Moss et al., 2001); at the local level (Posey, 2009; Engle and Lemos, in press); and across all levels of governance (Westerhoff et al., submitted).

The adaptive capacity within communities is extremely heterogeneous by locality, and also scale-dependent. There are two main possibilities on defining adaptation strategies: anticipatory and reactive (IPCC, 2007), with the former focusing on measures that can be taken as a result of expected changes, whilst the latter is in response and in reaction to changes that have already taken place. In the historical past, when scientific knowledge forecasts and planning were limited, basically all adaptation was taken in reaction to perceived climatic conditions. As the knowledge and information of climate change is steadily increasing, societies have an opportunity to engage in anticipatory adaptation.

Anticipatory adaptation mainly takes place through planned adaptations, although some automatic adaptation can take place (IPCC, 2007). Planned adaptation can be directed toward reducing the potential impacts of climate change or to reduce the general vulnerability of a society or toward building adaptive capacity. Planned adaptations can, for example, demand changes in current land-use and planning practices, highlighting the local nature of decisions related to adaptation. These are difficult and challenging and decisions often need to be taken on case-by-case basis, involving cost-benefit calculations of the measures involved. Thus, planned adaptation measures demand not only scientific knowledge and a balanced analysis of uncertainties of potential future developments, but also societal acceptance in order to be implemented and sustainable. The issuance and implementation of adaptation guidelines can be steered at a national level. The assessment of both the adaptive capacity and adaptation potential is to be assessed and planned for at regional or local levels that is, the level of detailed land-use planning.

Adaptation, Table 1 Determinants of adaptive capacity (Adapted from Smit and Pilifosova, 2001)

Economic resources	Economic assets, capital resources, financial means, and wealth
Technology	Technological resources enable adaptation options
Information and skills	Skilled, informed, and trained personnel enhance adaptive capacity, and access to information is likely to lead to timely and appropriate adaptation
Infrastructure	Greater variety of infrastructure enhances adaptive capacity
Institutions	Existing and well-functioning institutions enable adaptation and help to reduce the impacts of climate-related risks
Equity	Equitable distribution of resources contributes to adaptive capacity

Summary

Adaptation has reentered spatial development concepts in the wake of the discussion on climate change since the end of the twentieth century. In historic times, people generally were more used to adapting to extreme events, such as avoiding settlements in flood-prone areas or using crop types adjusted to existing water resources. A general attitude to use technical solutions to shape the living environment for human benefit and the belief one can control natural extreme events has not only led to straightening of river beds but also to inappropriate agriculture processes and overuse of water resources. These phenomena are accompanied by population increase, mainly in developing countries and, as an overall phenomenon, in coastal and flood-prone areas. The rise in costs caused by damages of natural hazards since the end of the twentieth century can so far not be attributed to a change in weather extremes (e.g., Barredo, 2009, 2010), but it shows an increase in overall vulnerability and thus the importance to adapt to natural hazards, as well as potential impacts of the changing climate. Traditional adaptation measures were non-structured and often reactive. The current debate on climate change impacts leads to the need to incorporate adaptation into land-use planning and have a stronger focus on cost-benefit analysis of anticipatory adaptation measures.

AIRPHOTO AND SATELLITE IMAGERY

J. D. Mollard
J.D. Mollard and Associates Ltd., Regina, SK, Canada

Synonyms

3D airphoto; Multispectral satellite imagery; Remote sensing

Definition

Stereoscopic (3D) and multispectral analysis of aerial photography and satellite imagery is used by skilled terrain analysts and interpreters to identify (remote sense) Earth processes, environments, landforms, and materials, and to use the information to map and evaluate the physical and cultural terrain characteristics and conditions that adversely affect people and property. These remotely sensed data are used with supporting literature and networked information to investigate, assess, and manage (monitor, mitigate, avoid, eliminate, treat) natural hazards, such as earthquake and volcanic activities, excessive *Erosion* and landslides, and climate effects that precipitate drought and wildfires among other hazards.

Discussion

Aerial photographs and satellite imagery are useful tools for viewing, identifying, and assessing natural hazards. Used in conjunction with easily accessible aids such as maps (topography, geology, climate), pocket stereoscopes, and computer programs, aerial and space imagery allow terrain analysts and interpreters to acquire information regarding the Earth's landscapes and environments at a distance without direct contact, a science commonly termed "remote sensing."

Some remote sensing specialists see differences between airphoto terrain analysis and airphoto terrain interpretation. Airphoto terrain analysis involves identifying physical environments and their geomorphic features (landforms) *on* the Earth's surface and inferring earth materials (soils and rocks) in them, and their material properties (e.g., permeability, compressibility, strength) and conditions (e.g., wet or dry, frozen or unfrozen) *under* the earth's surface. Airphoto terrain interpretation involves assessing what is important about the physical environment – the earth materials, properties, and conditions in it – for a specific use or objective. Both techniques are used in identifying, mapping, and assessing natural hazards that adversely affect human lives (loss of life, safety, property) in addition to damage to infrastructure, resources, and the natural environment.

Remote sensing requires an understanding of Earth materials, processes, and environments as well as their identifying features and characteristics in airphoto and satellite images. Today, airphoto and satellite image remote sensing technologies are widely used in locating, mapping, planning, exploring, and developing social and industrial infrastructure, energy, and natural resources. In terms of natural hazard assessment, these studies tend to emphasize the more densely populated places on Earth, where natural hazards and people come together.

Airphotos and global natural hazards

Remote sensing technologies involve information acquired through electromagnetic radiation (EMR) reflected and emitted from the Earth's surface. Useful information can be obtained from computer analysis of the captured EMR

signals along with the analysis and interpretation of conventional panchromatic, true color and false color airphotos, thermal infrared imagery, and radar images. Several wavebands (visible, near and thermal infrared, radar) are used to sense natural hazards from the air and space. Airphoto terrain analysis and interpretation applied to natural hazard appraisal are used by geologists, geographers, engineers, meteorologists, and environmental scientists with training and experience in understanding and recognizing natural hazard phenomena.

Both airphoto and satellite images display a wide field of view of the Earth's surface, revealing natural and cultural landscape features and patterns that may be completely obscured to viewers on the ground. This reorientation of perspective permits terrain analysts and interpreters to make sense of the Earth's surface and its hazardous features and conditions. Airphotos can also be used to map and evaluate terrain hazard features and conditions in two, three, and four dimensions – the fourth being time from different ages of imagery spanning several decades. Stereoscopic airphotos (pairs of photos taken of the same area from two different positions) allow the airphoto terrain analyst to study landscape relief in three dimensions (3D) using a simple handheld stereoscope. Two or more images taken years or decades apart reveal changes in the natural physical environment (topography, drainage, geology and geomorphology, and climate effects) as well as changes in human cultural activities that can contribute significantly to natural hazards. The airphoto and satellite image study of hazard-indicator clues over time is part of the technique of "change detection."

Small-scale airphotos (e.g., 1:60,000) and satellite images show landscapes in a regional context, allowing remote sensing interpreters to view diagnostic identification features of natural hazards in plan view and 3D. Large-scale airphotos on the other hand show subtle soil and rock tones, minor relief variations, and small drainage features in greater detail. Even though smaller and less obvious, these special characteristics are among a group of significant geoindicator clues used to assess different kinds of past, present, and future natural hazards.

Because most natural hazards involve ground movements – thus change on and below the Earth's surface – aerial and space imagery remote sensing specialists take advantage of three useful attributes of airphoto and satellite imagery: *multitemporal*, *multispatial*, and *multispectral* capabilities. Separately and together, these attributes are used to infer natural hazard *exposure*, *sensitivity,* and *vulnerability.* Exposure is the degree to which a particular hazard or phenomena is likely to occur and is largely related to topography, geology, and climate in the natural environment. Sensitivity is the potential degree to which a community and infrastructure could be affected by a natural hazard. Vulnerability is the degree to which a person or a system is likely to be adversely affected by a natural hazard. Vulnerability depends on both exposure and sensitivity. Although the hazard exposure may be high, the hazard sensitivity may be low because people have learned how to cope, having "adapted" to the hazard exposure conditions. (Adaptation is the response to natural hazards, environmental conditions, or stresses, especially those associated with climate change and variation.) Conversely, if the sensitivity is high and exposure is low, the vulnerability will be low. If both exposure and sensitivity are high, then the vulnerability could be very high.

Many terrain analysts and interpreters prefer conventional stereoscopic (3D) panchromatic airphotos because they are available in most areas of the world, because their coverage dates back to the 1930s and sometimes earlier, and because their applications are familiar to most users. Using good quality 3D airphotos, experienced terrain analysts can detect many shades of gray tone that aid inferring subtle changes in topography, soil moisture, and vegetation in addition to compositional, structural, and strength properties of soils and rocks in which earthquake and volcanic activity create landslides and other natural hazards.

In addition to conventional airphotos, specialists use true color and false color airphotos in their terrain analysis studies. Using special filters during photography, it is possible to isolate a "slice" of specific wavelengths of light, which may allow interpreters to pick out potential hazard targets for more precise, in-depth target classification and assessment. By combining black-and-white film with a filter that cuts out visible wavelengths, it is possible to produce airphotos in the reflected near infrared (light beyond the range of the human eye), which expresses vegetation differences more clearly. Near-infrared airphotos also show water clearly because water absorbs the infrared wavelengths and appears black, or nearly so, making it easier to assess the critical roles that surface water and groundwater play in causing landslides, snow avalanches (see entry *Avalanches*), major storms, flooding, drought, and other climate-variation effects.

Thermal infrared images in the far infrared wavelength capture heat emitted from the Earth's surface features. These images can be taken in both the daytime and nighttime to display differences in the way terrain materials absorb, hold, and release heat. Highly absorbent surfaces (e.g., sandstone) are strong nighttime emitters. Among the more dramatic thermal images are those taken of volcanoes, particularly ones with active vents that eject hot lava flows (lahars) and airborne rock fragments, ash, and gases, which can show up conspicuously in thermal imagery. Infrared anomalies in thermal images may reveal microearthquakes in terrains that are hydrothermally active. Thermal infrared images can also be used to detect warm and cold groundwater circulating in bedrock fracture systems and detect massive ground ice at shallow depths in permafrost terrain as well as the effects of global warming on permafrost and Arctic Ocean ice melting.

While visible, reflected near-infrared, and emitted thermal images are passive systems, radar is an active system that supplies its own energy source (the acronym *radar* comes from "radio detecting and ranging"). Radar uses

radio and microwave pulses to "see" great distances despite fog, rain, snow, clouds, and darkness. It is also used to highlight natural hazard features like steep slopes on mountain and valley sides, and different types of landslide and ground subsidence collapse and heave, as well as geological structures like faults, solution-widened joint systems and differentially eroded strata in sedimentary rock folds. There are several radar systems in use today: SAR (synthetic-aperture radar), SLAR (side-looking airborne radar), and InSAR (interferometric synthetic aperture radar). Some terrain attributes, such as topography, display dramatic three-dimensional relief in radar images, emphasizing long lineament trenches and troughs, a few of which might be structural in origin and therefore the location of past and future earthquake activity.

LiDAR (from "light detecting and ranging") uses laser pulses instead of microwaves, and is a highly useful remote sensing tool in transportation and communication system route-selection studies because it penetrates tree cover and other heavy vegetation, and records minor topographic features in remarkable detail, especially those distinguishing characteristics of different landslide types (see entry *Landslide Types*) and their change and evolution over time, important in determining monitoring strategies. Large-area mosaics assembled from them are a useful resource in the study of global natural hazards and disasters (i.e., catastrophic natural hazards).

Satellite images and global natural hazards

Satellite imagery has the timing, location, and larger area advantage of providing immediate information about Earth, its surface features and conditions, for those investigating the vulnerability of natural hazards in particular physical, geologic, and geomorphic settings and environments. Viewed digitally, Landsat images are used to identify landforms and infer the kinds of earth materials in them in addition to important soil and rock physical hazard properties, like strength. These kinds of information are used to variously help predict, prevent, monitor, mitigate, avoid, eliminate, and treat natural hazards. The challenge is which one to select and why and how. A list of hazards could include several landslide types and their distinguishing features in airphotos, snow avalanche tracks, faults and other geologic structural lineaments, active volcanic craters and calderas, lava flows and ejected pyroclastic materials (tephra), actively eroding coastlines and lake shorelines, flash-flooding river valleys, and melting sea ice and permafrost. Infrared and radar satellite images are also used to chart wave and current patterns, study pack ice on large lakes and the oceans, and track oil spills and thermal pollution in lakes and the oceans.

Meteorological satellites using visible and infrared wavebands are used to forecast weather and track major offshore and onshore storms. They are also used to detect, map, and monitor climate change effects and map different sizes and ages of wildfire burn areas and vegetation disease, land cover and land use change, and population growth. Remote sensing satellite images are also used to assess global natural hazard damage affecting people and property caused by such atmospheric and hydrometeorological events as hurricanes, typhoons, cyclones and tornadoes, major snow, rain and hail storms, flash floods, and droughts that cause desertification.

Earthquake hazards

Existing regional and local geological maps and data on regional and local seismicity (e.g., seismicity and earthquake zone maps) are collected and reviewed to provide a database for airphoto and satellite imagery studies of earthquake hazards and their damage. Maps showing the clustering, recurrence, and magnitude of past earthquakes are used to focus the analysis and interpretation of their visible effects from remotely sensed images. Visible effects include fault (see entry *Fault*) and rift lineaments and scarps, offset physical features like ridges and stream channels, tsunami effects, various slides (snow, ice and rock avalanches, and soil liquefaction), open fissures, ground deformations, and blocked groundwater. Most of these are recognizable and their significance inferred from suitably scaled aerial photography and space images, including visible, thermal infrared and radar. The technology can be used to map and evaluate earthquake damage (see entry *Earthquake Damage*) to buildings and critical infrastructure: bridges and tunnels, pipelines and power plants, and dams and reservoirs.

One can apply remote sensing technology to a major fault system like the *San Andreas Fault* – a 430-km long strike-slip fault that passes through San Francisco, the site of an April 18, 1906, catastrophic earthquake. Estimated at 8.3 magnitude, the earthquake caused ground displacements up to 6 m, resulted in the death of 450 people, and caused enormous destruction. It should be noted that the San Andreas is not a single fault; rather, it is a series of interconnected shorter, subparallel and interwoven fault ruptures that make up the width zone of seismic activity, where the tears can be viewed and measured from airphotos and passive and active satellite imageries. Longer lengths of main faults and wider zones of seismic activity and branching fault ruptures – as viewed along the San Andreas Fault system – can be measured from remotely sensed satellite images and correlated broadly with higher earthquake magnitudes, longer duration of ground shaking, and greater amounts and degrees of caused damage. Other relationships include fault displacement versus earthquake magnitude, fault length versus earthquake magnitude, and distance from a fault versus acceleration due to gravity – all useful in the study of earthquake features in aerial photographs and satellite images.

Volcanic hazards

Large numbers of volcanoes (as well as earthquakes) are largely concentrated along the edge of tectonic plates in the Earth's crust. The plates subduct, collide, pull apart, and slide past one another creating earthquakes and

volcanic activity. The most famous occurrence of tectonic plate action is located along the margins of continents encircling the Pacific Ocean, called the "Ring of Fire." Along this "ring of fire," airphotos and satellite images can be used to map, monitor, and track the behavior of active and potentially active volcanic vents as they heat up, stir, swell, and vibrate before they erupt, ejecting hot lavas (lahars) and hurling rock fragments and clouds of ash, dust, and poisonous gases (CO_2, H_2S, SO_2, Cl) into the air. Remote sensing specialists have been able to track clouds of ash across an entire continent using satellite radar imagery (AVHRR bands 4 and 5) and InSAR measurements can be made to assess the bulging side of composite volcanoes, such as Mount St. Helens.

Volcanic explosions under snow and glacier-ice covers can create tremendous devastation. Many of their frozen features that are visible on the ground are also identifiable in aerial and space imageries. They include rock avalanches and lahars (consisting of mixtures of water, rock fragments, and mud), terrain effects from acid rain, flooding, fires, surface water and groundwater contamination, and forest destruction that denudes volcanic slopes and the surrounding outlying area. Precursor signs that aerial and space analysts look for and track when hot magma begins to rise in volcanoes are swelling, cracks and fractures, and microearthquakes– warning signs that can be used with seismic meter and tilt meter data to assess the level of volcanic hazard activity.

Slope failure (landslide) hazards

There are many recognizable landslide types. Virtually all are identifiable from their associated distinguishing characteristics in 3D airphotos and satellite images. The slope failures include creep (see entry *Creep*) (a slow earthflow), soil and rock topples and falls, planar translational rockslides and rock avalanches; rotational slides and slumps in soils and rocks; debris avalanches (see entry *Debris Avalanche*), slides, flows and torrents; lahars (volcanic mudflows); rapid earthflows (also called spreads, flowslides, and mudflows), shallow active-layer detachment (skin) flows and bimodal flows involving retrogressive ice-rich headscarp melting and long gently sloping tongue-like flows in horseshoe-shaped cavities in permafrost terrain.

Airphotos and satellite imagery terrain analysts and interpreters familiar with different soil and rock landslides are aware that certain types tend to be concentrated in regionally defined physical environments. Three common landslide-prone natural environments are tectonic plate boundaries, steep slopes in high mountain terrains, and deep river valleys where the toe of valley sides is being actively stream-eroded. Natural hazard investigators of landslides are familiar with geological materials that are landslide-prone. Three examples are Cretaceous marine clay shales, commonly with bentonite seams on steep, high valley sides; stacked rows of columnar basalt flows with weak weathered clayey surfaces between some of the basalt rows on canyon cliffs; and weathered volcaniclastic and serpentine rocks in steep, high slopes – mainly in tropical terrains. Steeply dipping interbedded sedimentary rock strata having weak clay shale layers that daylight on steeper slopes are also prone to translational slide failures. Eroded slopes on silty and clayey glaciolacustrine and sensitive glaciomarine sediments are also landslide-prone. Several geological rock structures– faults, joints and other rock fractures, bedding plane surfaces, and foliation– are rarely visible yet locally inferable from airphotos and satellite images, and they all can be significant factors in creating natural hazards.

As well as precursor topographic and geologic geoindicators of landslides in airphotos and satellite images, there can be adverse human indicators too. They include deep human-made excavations on lower slopes and loading placed on upper slopes, irrigation, mining activity, tree clearing, and broken water and sewer pipelines, among others. Any one of these can affect or trigger landslide instability. Landslides are usually triggered by specific natural events, such as earthquake shaking, volcanic explosions, and weather and climatic effects like intense prolonged rainfall and ice melting that causes soil and rock saturation and elevated porewater pressures on failure slip surfaces.

By evaluating the roles that topography, geology (especially geomorphology), human activities, and triggering factors play in creating landslides, aerial and space imagery interpreters may (depending on the situation on the ground) recommend avoiding, eliminating, monitoring, mitigating, or treating (e.g., stabilizing) the hazard conditions.

Ground subsidence, collapse, and heave hazards

Hazardous vertical ground subsidence is caused by seismic activity and oil, gas, and groundwater extraction, resulting in faulting and ground cracking, flooding, and destruction of human structures –visible, mappable, and assessable effects detectable from multidate, multiscale, and multispectral aerial and space images. Ground collapse can be caused by subsurface coal and metal mining, underground carbonate and evaporite dissolution forming collapse sinkholes in karstic topography, where near-surface cavities and caverns grow large enough for the roof above to collapse. Near-vertical piping erosion of cavities can develop in thick, loose loessial and glaciolacustrine silty and fine sandy soils. The resulting, commonly roundish hole-like depressions are usually recognizable from their multiple dot pattern in 3D airphotos. And shield volcanoes may develop collapse caldera (see entry *Calderas*), where surface rocks drop into the magma chamber. All these collapse features are identifiable on 3D aerial photographs. Ground swelling (heave) and shrinkage are significant economic hazards affecting buildings in large population centers constructed on high plasticity volcanic and lacustrine soils, where significant changes in moisture content occur in the upper

6 m or so. Three well-known North American cities where these natural hazard effects are major concerns are Mexico City, Long Beach, California, and Houston, Texas.

While other natural hazard examples could be given (e.g., river flooding, tsunamis, and climate variation causing permafrost melting, wildfires, drought, and desertification, etc.), the primary focus here are a few illustrative applications of airphoto and satellite remote sensing tools and technologies in natural hazard studies, rather than a comprehensive list of natural hazards and their identifying characteristics on the ground, in 3D airphotos and satellite images.

Summary

Geologists, geographers, engineers, and environmental scientists with training and experience in interpreting terrain conditions use 3D airphotos and satellite images to identify, map, and assess hazardous landforms and earth materials in natural and cultural landscapes. Such studies involve assessing potentially unstable and active hazard features and conditions, many of which are associated with adverse topography and geology along with severe weather and climate variation. In some cases, harmful human activities may also play a part. Aided by topographic, geologic, and other maps, remotely sensed information from airphoto and satellite images can be used to predict and evaluate hazards as well as make recommendations that may involve avoiding, eliminating, monitoring, mitigating, or treating (e.g., stabilizing) hazards – for example, in locating, planning, and developing new urban developments, social and industrial infrastructure, and energy and natural resources.

ALBEDO

Alan W. Harris
German Aerospace Center (DLR), Berlin, Germany

Definition

The albedo of a surface is a measure of its reflectivity. The albedos of planetary surfaces depend on their compositions and physical properties. Two types of albedo are often used in connection with planetary surfaces. One is the *geometric albedo* in a particular photometric band (normally denoted by p, with a subscript for the photometric band, e.g., p_V for visual geometric albedo), which is the ratio of the body's brightness at zero solar phase angle (i.e., as seen from the direction of the Sun) to the brightness of a perfectly diffusing (Lambertian) disk with the same apparent size and at the same position as the body. The visual geometric albedo is useful for most observational work because it is relevant to the visual brightness of the object. Values of p_V for

Albedo, Table 1 Values of visual geometric albedo for a selection of solar system bodies

Body	Visual geometric albedo, p_V
Moon	0.12
Venus	0.46
1 Ceres (dwarf planet in main asteroid belt)	0.09
4 Vesta (main-belt asteroid)	0.3
433 Eros (near-Earth asteroid)	0.23
C-type asteroid	0.06 (typical value)
S-type asteroid	0.20 (typical value)
E-type asteroid	0.50 (typical value)
Comet nucleus	0.04 (typical value)

a selection of bodies are given in Table 1. The second is the *bolometric Bond albedo*, which is the ratio of the total reflected radiation, summed over all wavelengths and directions, to the incident solar radiation. The bolometric Bond albedo, A, is relevant to the energy balance of a planetary body. For example, if the effects of thermal inertia and surface roughness are negligible, the thermal emission from any point on an atmosphereless body's surface can be considered to be in instantaneous equilibrium with the solar radiation absorbed at that point, thus:

$$\text{Total emitted thermal radiation} = (1 - A).S.a_p, \quad (1)$$

where S is the total incident solar radiation per unit area and a_p is the instantaneous sunward projected area of the body.

Overview

Albedo and size are two of the most fundamental physical properties of asteroids, especially for considerations of the impact hazard (e.g., Stuart and Binzel, 2004). Since the visual brightness of an asteroid depends on the *product* of p_V and projected area, an asteroid's size cannot be determined from optical observations alone without knowledge of the geometric albedo, p_V. Whereas (1) is an oversimplification because effects such as rotation and thermal inertia are ignored, a combination of infrared observations of an asteroid's thermal emission and observations of its visual brightness, together with an appropriate thermal model, can be used to derive both size and p_V (e.g., Delbo' et al., 2003). In the absence of infrared data, or other means of size determination, the sizes of asteroids are often estimated on the basis of measurements of the visual brightness and an assumed geometric albedo by means of the simple relationship:

$$D(\text{km}) = 1329.{p_V}^{-0.5}.10^{-H/5}, \quad (2)$$

where H is the absolute magnitude, defined as the brightness in the V band referred to zero solar phase angle and unit heliocentric and geocentric distances (in astronomical units, AU). However, in the case of near-Earth asteroids, which display a large range of visual geometric albedo, for example, 0.03–0.6, use of this relationship with an assumed value of p_V can result in significant errors. For example, if a "typical" albedo, for example $p_V = 0.16$, is assumed, the resulting diameter could be in error by a factor of 2 and the mass estimate by a factor of 8. Due to the present lack of albedo measurements, the size distribution of the near-Earth asteroid population is still largely based on estimates made with the help of (2) and an assumed value of p_V. As a consequence, only crude estimates of the destructive impact potential within the population of near-Earth asteroids can be made at present.

Summary

The reflectivities of planetary surfaces are governed by their compositions and physical characteristics. A measure of reflectivity is the albedo, which is often used in the sense of backscattered sunlight in a given spectral region, normally the visual (visual geometric albedo), or the total amount of reflected solar radiation in all directions and spectral bands (bolometric Bond albedo). In the case of asteroids, albedos are an important indicator of mineralogy and are often derived by means of observations in the thermal-infrared and visual spectral regions. The distribution of albedos in the population of near-Earth asteroids is of crucial importance for the determination of the size distribution of potential impactors on the Earth.

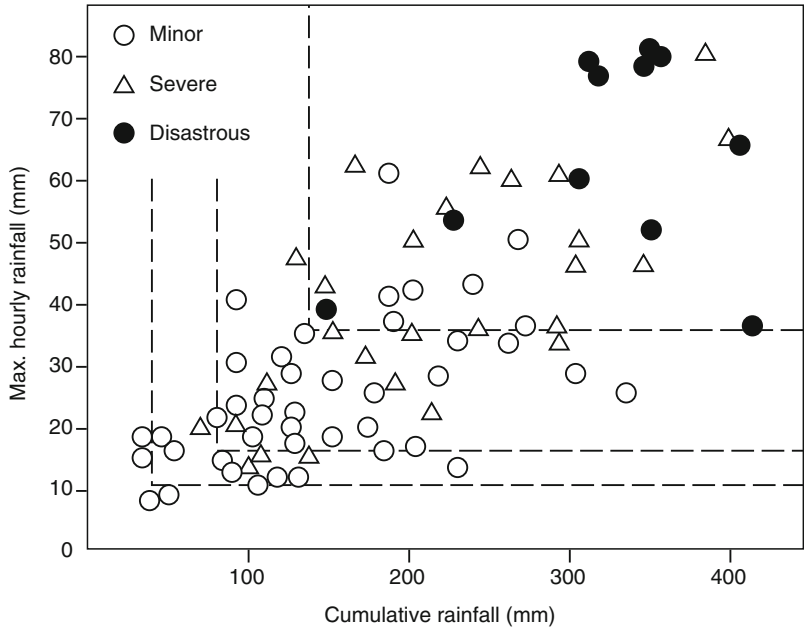
Antecedent Conditions, Figure 1 Conceptual climatic-hydrological model for shallow rainfall-triggered landslides.

Definition

Antecedent conditions represent a temporary state within dynamic natural and social systems that precedes and influences the onset and magnitude of a hazard and its consequences. They are distinct from, but influenced by, what are commonly referred to as preconditions (preexisting conditions). Preconditions are generally static or slow changing and influence the inherent (as opposed to temporary) susceptibility of an area. For example, in natural systems, rock type, soil structure, and topographic geometry are common preconditions that affect susceptibility to landslide occurrence, whereas groundwater level, soil moisture content, and under certain circumstances, vegetation cover are dynamic factors representing influential antecedent conditions for landsliding. In social systems, coping capacities such as the presence of emergency response organizations or availability of insurance schemes are preconditions whereas time of occurrence (e.g., day/night; workday/weekend; holiday, etc.) is a dynamic factor strongly influencing the consequences of a triggering event.



Examples of antecedent conditions for specific hazards include tidal phase (tsunami and storm surge), vegetation moisture levels (forest fire), humidity (heat waves), groundwater level (liquefaction and flooding), wind direction and strength (volcanic eruption), temperature and freeze/thaw history of snow packs (snow avalanching), and amount of debris accumulated in source areas (debris flow). Antecedent conditions can also be represented by hazard history. For instance, forest fires can induce hydrophobic conditions in soils that favor the development of debris flows during heavy rainfall, and foreshocks may weaken natural and man-made structures causing amplified damage in subsequent earthquakes.

An example of rainfall-triggered landslides illustrates the rationale and methods for assessing antecedent conditions. Antecedent conditions are represented in this case by the *antecedent soil water* (water accumulated in the slope over a period preceding landslide occurrence) which, along with *event water* (water accumulated on the day of landslide occurrence), forms the *critical water content* (CWC) within a slope, that is, the amount of water required to initiate landslide movement (Figure 1). Rainfall thresholds for landslide initiation established by historical observation essentially represent an approximation of the CWC (Crozier, 1989; Glade et al., 2000; Guzzetti et al., 2008). In a location where CWC for landsliding is known, real-time monitoring of the antecedent soil water, allows a continuous estimate of the amount of event water required to reach critical conditions. This in turn has been used to derive a probability of landslide occurrence based on frequency–magnitude distributions of rainfall conditions derived from the historical climate record (Crozier, 1999).

Water within the slope reduces stability by either decreasing cohesion or increasing buoyancy through the development of positive porewater pressures, to the point where strength of slope material is lowered below the prevailing shear stress and consequently failure occurs.

In practical terms, the *event water* component of the CWC can be represented by some parameter of rainfall at the time of landslide occurrence whereas *antecedent soil water* is represented by the *antecedent soil water status*. The value of the *antecedent soil water status* can be determined at any one point in time given knowledge of past precipitation and evapotranspiration rates, the regolith storage capacity (porosity and depth), and the drainage rate of *excess precipitation* (i.e., rainfall in excess of storage and evapotranspiration requirements).

In short, the *antecedent soil water status* is an index of the water content of the soil based on the climatic water balance, and provides a scale with negative values

Antecedent Conditions, Figure 2 Landslide event thresholds defined by intensity and 2-day antecedent rainfall, Korea (Source Kim et al., 1992).

representing soil storage below field capacity, held in the form of capillary or hygroscopic water, and positive values representing gravitational water that accumulates as groundwater in certain slope locations (Crozier, 1999).

Landsliding is usually (but not always) associated with positive values of the *antecedent soil water status index* calculated from *excess rainfall,* that is, rainfall exceeding potential evapotranspiration and soil storage requirements.

In the calculation of the *antecedent soil water status index* (Crozier, 1999)*, excess rainfall* is decayed on a daily basis and accumulated over a given period (often about 10 days) to represent antecedent excess rainfall values. These constitute the positive values of the *antecedent soil water status index.*

$$\mathrm{EPa}_0 = k\mathrm{EP}_1 + k^2\mathrm{EP}_2 + \cdots + k^n\mathrm{EP}^n$$

where EPa_0 = antecedent excess rainfall on day 0 (mm), EP^n = excess rainfall on the nth day before day 0 (mm), and k = constant decay factor.

The decay factor represents the rate of drainage from the soil and in some cases can be determined from the exponential decline of the recessional limb of flood hydrographs for streams within the locality under study (Glade et al., 2000). The use of stream hydrographs to indicate antecedent water status assumes that flow regimes have not been artificially modified by structures such as reservoirs or other drainage works.

Kim et al. (1992) (Figure 2), Glade (2000), and Garland and Olivier (1993) have demonstrated that, in certain regions, antecedent conditions have a major influence on the initiation of landslides, whereas in other regions, storm event characteristics appear to dominate (Caine, 1980; Wilson and Wieczorek, 1995). Similar findings for debris flows have been summarized by Wieczorek and Glade (2005).

Although critical preconditions and triggering factors can be established for a number of different hazards, the temporal variability of antecedent conditions provides a significant level of uncertainty to hazard assessments. The investigation of antecedent conditions is a critical component for both the prediction and explanation of hazard occurrence.

ARSENIC IN GROUNDWATER

Arindam Basu
University of Canterbury, Christchurch, New Zealand

Synonyms

Arsenate; Arsenite; As

Definition

Inorganic arsenic (abbreviation: As) is a trace element found in the earth's crust. Arsenic is present in groundwater as inorganic arsenate (As(V)) and arsenite (As(III)).

Origins of arsenic in groundwater

Arsenic enters groundwater from the surrounding substrate (soil and bedrock). It is generally believed that weathering reactions, microbial and human activities result in mobilization of inorganic arsenic from the substrate to groundwater (Appelo and Heederik, 2006).

In the substrate, As is commonly concentrated in sulfide bearing minerals, has strong affinity for pyrites, and is concentrated in hydrous iron oxides. Sulfide minerals usually contain high concentrations of As; consequently, oxidation of sulfide minerals releases inorganic As in groundwater. For instance, in the aquifers of alluvial river basins of the Ganges delta (parts of West Bengal, an Indian state, and Bangladesh), presence of organic matter in soil leads to complex redox reactions and loss of dissolved oxygen from groundwater; this, in turn, leads to dissolution of iron oxides and release of As in groundwater (Bhattacharyya et al., 2003; Nickson, 2000). Geothermal activities contain high concentration of sulfides, and are other sources of As in groundwater in those regions that are characterized by hot springs.

Anthropogenic sources of As in groundwater include mining, use of arsenic-based pesticides, and groundwater abstraction. Mineralized zones often contain arsenopyrites. Heavy and long-term mining is often associated with dissolution of these minerals, and release of As in the groundwater. Mine wastes and tailing ponds may have high concentrations of As in the water. It is believed that in the Ganges delta region of West Bengal and Bangladesh, overpumping of groundwater for irrigation has led to dewatering of sediments, anoxic soil conditions, and mobilization of high As into the groundwater. Alternatively, high As concentration in groundwater in this region may be due to the activity of naturally occurring organic carbons in a naturally occurring process.

Acceptable levels of as concentration in groundwater

In 1993, the World Health Organization (WHO) reduced the provisional guideline limit from 50 to 10 μg/L (WHO, 2010). This was based on the observation that at concentrations of 10 μg/L, there is a risk of 1 extra case of cancer per 100, 000 individuals. Whereas the developed countries follow this standard, the developing countries still limit the groundwater As concentration at 50 μg/L.

Geographical regions that have high concentrations of As in groundwater include young, unconsolidated sediments usually of Quarternary (Holocene) age, inland closed basins in arid or semiarid settings (Argentina, Mexico, Nevada, California), or alluvial or deltaic plains (Ganges delta in West Bengal and Bangladesh, Yellow River basin, Mekong Valley, Red River delta, Irrawaddy delta). The Ganges delta region has about 36 million individuals that are potentially exposed to arsenic over 50 μg/L. The Chaco-Pampean plain of Argentina is the largest high-As groundwater province in South America (1 million square kilometers).

Consequences of high concentrations of inorganic as in groundwater

Arsenic primarily enters the human body through consumption of groundwater since it is tasteless and odorfree. Small mass transfer of As to water is required for As toxicity to be manifested in humans.

Exposure to inorganic As in groundwater results in noncancerous health effects and cancers. The International Agency for Research on Cancer (IARC) classifies As as a class I carcinogen. The cancers associated with As in groundwater include those of skin, lungs, urinary bladder, kidney, and liver. Arsenic is also related to noncancer effects, including skin lesions, chronic cough, and possibly diabetes.

Minor planet; Planetoid; Small solar system body

Definition

An asteroid is an irregularly shaped, rocky body orbiting the Sun. In contrast to planets and dwarf planets, asteroids do not have sufficient mass for their self-gravity to form a spheroid. In contrast to comets, asteroids display neither a coma nor a tail.

Overview

Asteroids and comets are considered to be remnant bodies from the epoch of planet formation. Planet embryos formed in the protoplanetary disk about 4.5 billion years ago via the accretion of dust grains and collisions with smaller bodies (planetesimals). A number of planet embryos succeeded in developing into the planets we observe today; the growth of other planet embryos and planetesimals was terminated by catastrophic collisions or a lack of material in their orbital zones to accrete. Most asteroids are thought to be the fragments of bodies that formed in the inner Solar System and were subsequently broken up in collisions. Comets and related icy bodies are thought to have accreted in the cold, outer regions of the protoplanetary disk where volatile material, such as water and carbon dioxide, were abundant as ices.

The main asteroid belt between the orbits of Mars and Jupiter contains most of the known asteroids. An asteroid is assigned a permanent designation, that is, a sequential number, once its orbit has become accurately established through a sufficient number of astrometric observations. There are over 300,000 numbered asteroids in the main belt, consisting largely of silicates and metals and having sizes up to about 1,000 km in diameter.

Asteroids are classified dynamically according to their orbital elements (semimajor axis, period, inclination, eccentricity, etc.). Within the main belt, between about 2.0 and 3.5 astronomical units (AU, the mean Sun-Earth distance) from the Sun, there exist a number of "families" of asteroids, the members of which have very similar dynamical characteristics and may be fragments from relatively recent (relative to the history of the Solar System) collisions.

As a result of subtle thermal effects and the very strong gravitational field of Jupiter, small main-belt asteroids can drift into certain orbital zones from which they may be ejected under the influence of Jupiter into the inner Solar System. As a result there exists a population of near-Earth asteroids (NEAs), with orbits that can cross that of the Earth. NEAs are further categorized dynamically as Amors, Apollos, Atens, or Inner-Earth objects (IEOs) according to the semimajor axes, aphelion and perihelion distances of their orbits (Table 1). Interest in the population of NEAs is focused mainly on the associated impact hazard (see below), but close approaches of NEAs to the Earth facilitate detailed telescope observations, including radar investigations, which provide insight into the characteristics of asteroids in general.

The taxonomic classification and mineralogy of asteroids

Sunlight incident on the surface of an asteroid is absorbed in particular wavelength bands depending on the minerals present; reflected light, therefore, carries a spectral signature of the mineralogical composition of the asteroid's surface. Attempts have been made to classify asteroids according to details of the absorption features in their optical reflection spectra observed with astronomical telescopes. A number of classification schemes have been devised based on letters of the alphabet. Table 2 lists some of the main taxonomic types in use today and the likely mineralogical compositions associated with them.

Asteroid physical properties

The shapes of asteroids and their observed size distribution are consistent with a scenario in which collisions over billions of years have led to a grinding down of objects in the main belt and an ever increasing number of small collision fragments. Some insight into the internal structure of asteroids can be gained by considering their bulk densities. Reliable estimates of density are difficult to obtain, since techniques for obtaining accurate masses and sizes of asteroids are complex and subject to large uncertainties. There are various methods of determining asteroid masses (see Britt et al., 2002, for a review), which all require measurement of the asteroid's gravity field by means of a spacecraft, observations of the perturbations of the orbits of other asteroids or Mars (applicable to large asteroids only), or observations of a satellite or companion asteroid by means of precision optical or radar observations. Asteroid sizes can be determined from spacecraft, thermal-infrared measurements, radar observations, polarimetry, and occultation observations.

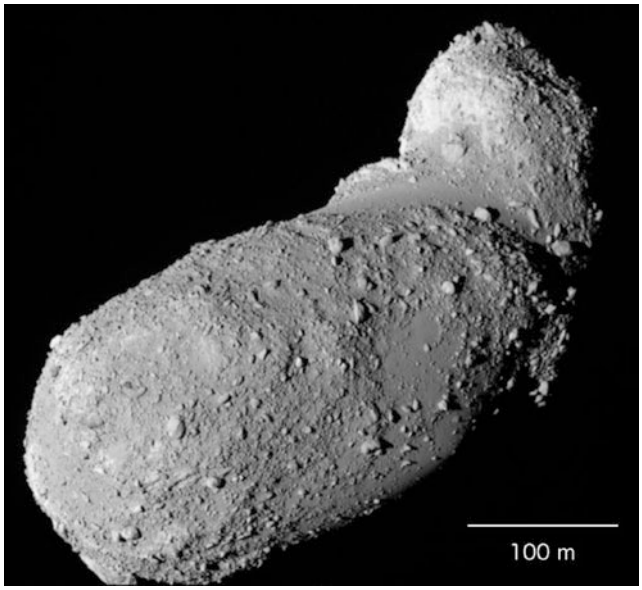
Density estimates for some 40 asteroids are available to date. An important finding is that asteroid bulk densities

Asteroid, Table 1 Dynamical groupings and numbers of near-Earth asteroids

Dynamical category	Semimajor axis [AU]	Perihelion/aphelion	Approximate number known
Amors	>1	1.017 < perihelion ≤ 1.3 AU	2,800
Apollos	≥1	Perihelion ≤ 1.017 AU	3,300
Atens	<1	Aphelion ≥ 0.983 AU	540
Inner Earth objects	<1	Aphelion < 0.983 AU	10

The orbital characteristics of the different classes of NEAs are defined with respect to the Earth's perihelion (0.983 AU) and aphelion (1.017 AU) distances. The listed approximate numbers of known objects are valid as of December 2009; these numbers increase rapidly with time as new objects are discovered. For more details and updates see the Minor Planet Center web site: http://www.cfa.harvard.edu/iau/mpc.html

Asteroid, Table 2 Important asteroid taxonomic (spectral) classes



Class	Probable mineralogy	Associated geometric albedo[a] (p_V) range	Approximate % of all classified asteroids[b]
D, P	Carbon, organic-rich silicates	0.03–0.06	2
C, B	Carbon, organics, hydrated silicates	0.03–0.1	30
M	Fe, Ni, enstatite	0.1–0.2	2
S	Olivine, pyroxene, metals	0.1–0.3	40
Q	Olivine, pyroxene, metals	0.2–0.5	1
V	Pyroxene, feldspar	0.2–0.5	3
E	Enstatite, other Fe-poor silicates	0.3–0.6	1
X	Unknown (signifies otherwise unclassifiable featureless spectrum)	0.03–0.6	15

[a]The geometric albedo p_v is the ratio of a body's (V-band) brightness at zero phase angle to the brightness of a perfectly diffusing (Lambertian) disk with the same apparent size and at the same position as the body
[b]Estimated from the data of Bus and Binzel (2002), and Tholen and Barucci (1989). Note that discovery and observation bias against objects with dark surfaces implies that the distribution of taxonomic classes in the known population may not be representative of the entire asteroid population

tend to be significantly lower in general than expected from measurements of meteorites and terrestrial analogues of asteroid material (2–8 g cm^{-3}). In fact the bulk densities of some asteroids appear to be similar to that of water (1 g cm^{-3}), implying that these bodies must be highly porous. Such results have increased speculation that some asteroids, for example 25143 Itokawa, may be aggregates of components of various sizes weakly bound by gravity, or "rubble piles." An asteroid that has been shattered by collisions with other objects may survive under the collective weak gravitational attraction of the resulting fragments as a cohesionless, consolidated rubble pile; this idea is supported by the images of Itokawa returned by the Hayabusa spacecraft (Figure 1), revealing a highly irregular object apparently consisting of separate component blocks of various shapes and sizes.

The known NEA population contains a confusing variety of objects. Some NEAs are thought to be largely metallic, indicative of material of high density and strength, whereas others are carbonaceous and probably of lower density and less robust. A number of NEAs may be evolved cometary nuclei that are presumably porous and of low density but otherwise with essentially unknown physical characteristics. In terms of large-scale structure NEAs range from monolithic slabs to rubble piles and binary systems. Some 40 NEAs in the currently known population are thought to be binary systems and many more are probably awaiting discovery.

Even fundamental parameters such as size and mass are very difficult to determine accurately, especially in the case of small asteroids, such as NEAs, which generally have irregular shapes and widely differing surface properties. Since the brightness of an asteroid is proportional to its surface albedo and cross-sectional area, a very rough size estimate can be obtained from the observed brightness and knowledge of the asteroid's orbit. Telescope observations in the thermal infrared combined with knowledge of an asteroid's optical brightness offer a means of obtaining more accurate information on size and albedo (e.g., Delbo' et al., 2003; Harris, 2006). Darker, low-albedo asteroids are less reflective in the visible spectral region and absorb more solar radiation; they

Asteroid, Figure 1 Near-Earth asteroid 25143 Itokawa was the target of the Japanese Hayabusa spacecraft in 2005–2006. Itokawa is 535 m in length and of type S. Itokawa may be an aggregate of components weakly bound by gravity, or "rubble pile" (Courtesy of JAXA).

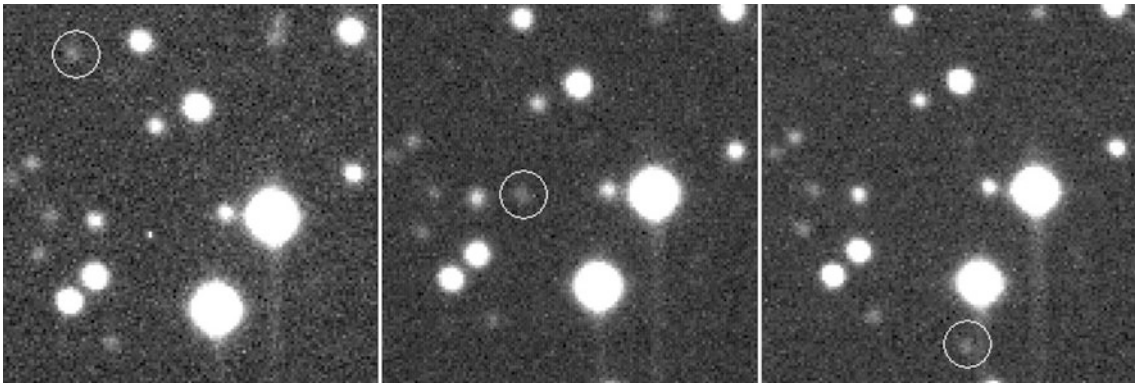
are, therefore, warmer and brighter in the thermal-infrared spectral range. The opposite is true for high-albedo asteroids. The two different physical relationships governing visible and thermal-infrared brightness enable simultaneous solutions for size and albedo to be obtained. While the number of asteroids observed in the thermal infrared is still only a very small fraction of the total known, this technique has provided the vast majority of size and albedo determinations to date (e.g., Tedesco et al., 2002), and on-going and future infrared surveys promise further results, especially for NEAs, using this technique.

An important result from thermal-infrared observations is the apparent size-dependence of the albedos of some types of NEA in the 0.1–10 km size range, such that the mean albedo appears to increase with decreasing size (Delbo' et al., 2003; Harris, 2006). As explained above, the mean albedo of NEAs is important for current estimates of their size distribution. If the mean albedo is higher, the diameter derived from a particular observed brightness is smaller and the overall impact hazard from NEAs is reduced (Stuart and Binzel, 2004).

The rate of discovery of NEAs has increased dramatically in recent years and is now seriously outstripping the rate at which the population can be physically characterized. The NEA population is still largely unexplored.

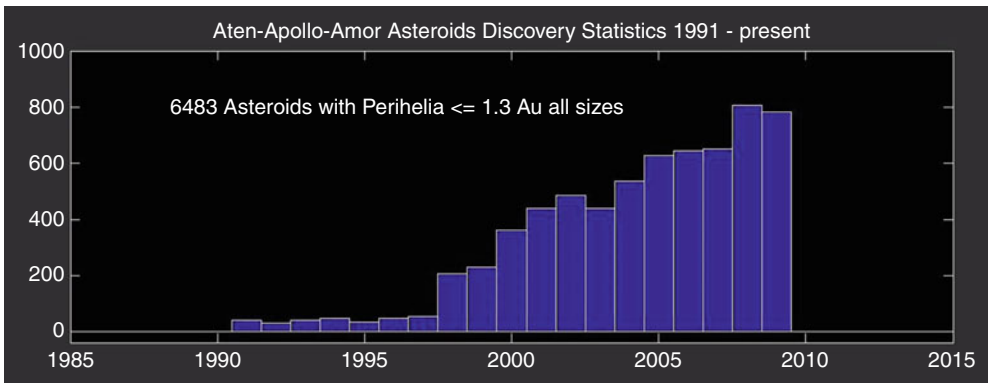
Near-earth asteroids and the impact hazard

The phenomenon of collisions in the history of our Solar System is very fundamental, having played the major role in forming the planets we observe today. Asteroids may have contributed to the delivery of water and organic materials to the early Earth necessary for the development of life, but later impacts of asteroids probably played a role in mass extinctions and they currently pose a small but significant threat to the future of our civilization. Collisions of asteroids with the Earth have taken place frequently over geological history and it is an irrefutable scientific fact that major collisions of asteroids and comets with the Earth will continue to occur at irregular, unpredictable intervals in the future. The risk of a comet impact is thought to be much lower than that of an NEA impact, although, given the potentially high relative velocities, the effects in the case of a comet impact could be much more devastating.



Near-earth object search programs

A number of observatories are operated specifically to discover near-Earth objects and establish their orbits. The main currently active asteroid search programs, such as the Catalina Sky Surveys, Lincoln Near-Earth Asteroid Research (LINEAR), and Spacewatch (e.g., see Yeomans and Baalke, 2009) are funded primarily by NASA and the US Air Force. The telescopes employed for asteroid searching have modest mirror diameters of around 1 m, large fields of view, and state-of-the art CCD detectors. Asteroids appear as star-like point sources in the focal planes of such telescopes and are discovered by virtue of their motion against the fixed stellar background (Figure 2). Sophisticated software enables the detection of asteroids to be carried out automatically. Observations of an asteroid over periods of months or years are required to enable its orbit to be calculated accurately. Many observers, including amateur astronomers, around the world contribute to the tracking of asteroids and submit their astrometric data to the Minor Planet Center in Cambridge, Massachusetts, which acts as a clearing house for asteroid position data and maintains databases of orbits.



As of December 2009 the number of known NEAs was about 6,500 (Figure 3), of which some 800 have diameters of 1 km or more; this number is close to the predicted final tally of NEAs with diameters of 1 km or more, including as yet undiscovered objects. A special term, "potentially hazardous asteroids" (PHAs), is reserved for those with diameters above 120 m and orbits that bring them within 0.05 AU of the Earth's orbit. PHAs are large enough to survive passage through the Earth's atmosphere and cause extensive damage on impact. As of December 2009 the number of known PHAs stands at about 1,100.

Summary

Planet embryos formed some 4.5 billion years ago from dust accretion and the collisional coalescence of primordial building blocks called planetesimals. Most asteroids are thought to be remnant collisional fragments of

Asteroid, Figure 2 Asteroids are discovered by virtue of their apparent motion on the sky relative to distant stars. A candidate asteroid (*encircled*) is seen to move between successive exposures of this field of stars taken some minutes apart.

Asteroid, Figure 3 Recent annual discovery rates of near-Earth asteroids (Courtesy of G. Hahn (DLR) and the European Asteroid Research Node, EARN: http://earn.dlr.de/).

planetesimals and planet embryos from the inner Solar System that were not incorporated into planets; comets, on the other hand, are remnants from the cold, outer regions of the Solar System. Subsequent impacts of asteroids and comets have played a major role in the development of planets, especially the Earth. Asteroids and comets probably contributed significantly to the early Earth's inventory of water and organic materials, facilitating the development of life. In contrast, impacts of asteroids and comets present a small but scientifically well-founded threat to the future of our civilization: There is no scientific reason why asteroids and comets should not continue to hit the Earth at irregular and unpredictable intervals in the future. As a result of modern observing techniques and directed efforts thousands of near-Earth asteroids have been discovered over the past 20 years and the reality of the impact hazard has been laid bare. Future observation programs and space missions will be crucial for a better understanding of the processes and conditions governing the development of planets and life, the composition and physical nature of asteroids, and the techniques that would be most effective in preventing a collision of an asteroid with the Earth.

Definition and introduction

Craters are a fundamental and common topographic form on the surfaces of planets, satellites, and asteroids. On large planetary bodies, of the size of the Moon and larger, craters can form in a variety of processes, including volcanism, impact, subsidence, secondary impact, and collapse. On smaller bodies (e.g., of the size of minor planets), impact may be the only process that can form craters. In the explanation of terrestrial crater-like structures, the interpretation as volcanic features and related structures (such as calderas, maars, cinder cones) has traditionally dominated over impact-related interpretations. The importance of impact cratering on terrestrial planets (Mercury, Venus, Mars), our Moon, and the satellites of the outer planets is obvious from the abundance of craters on their surfaces. On most bodies of the Solar System that have a solid surface, impact cratering is the most important surface-modifying process even today. On Earth, active geological processes rapidly obliterate the cratering record. To date only about 180 impact structures have been recognized on the Earth's surface. They come in various forms, shapes, and sizes, from 300 km to less than 100 m in diameter, and from recent to 2 billion years in age.

On the Moon and other planetary bodies that lack an appreciable atmosphere, it is usually easy to recognize impact craters on the basis of morphological characteristics. On the Earth, complications arise as a consequence of the obliteration, deformation, or burial of impact craters. Thus, it is ironic that despite the fact that impact craters on Earth can be studied directly in the field, they may be much more difficult to recognize than on other planets. Thus, the following diagnostic criteria for the identification and confirmation of impact structures on Earth were developed: (a) crater morphology, (b) geophysical anomalies, (c) evidence for shock metamorphism, and (d) the presence of meteorites or geochemical evidence for traces of the meteoritic projectile – of which only (c) and (d) can provide confirming evidence. Remote sensing, including morphological observations, as well as geophysical studies, cannot provide confirming evidence – which requires the study of actual rock samples.

Impacts influenced the geological and biological evolution of our own planet; the best known example is the link between the 200-km-diameter Chicxulub impact structure in Mexico and the Cretaceous-Tertiary boundary. Understanding impact structures, their formation processes, and their consequences should be of interest not only to Earth and planetary scientists, but also to society in general.

History of impact cratering studies

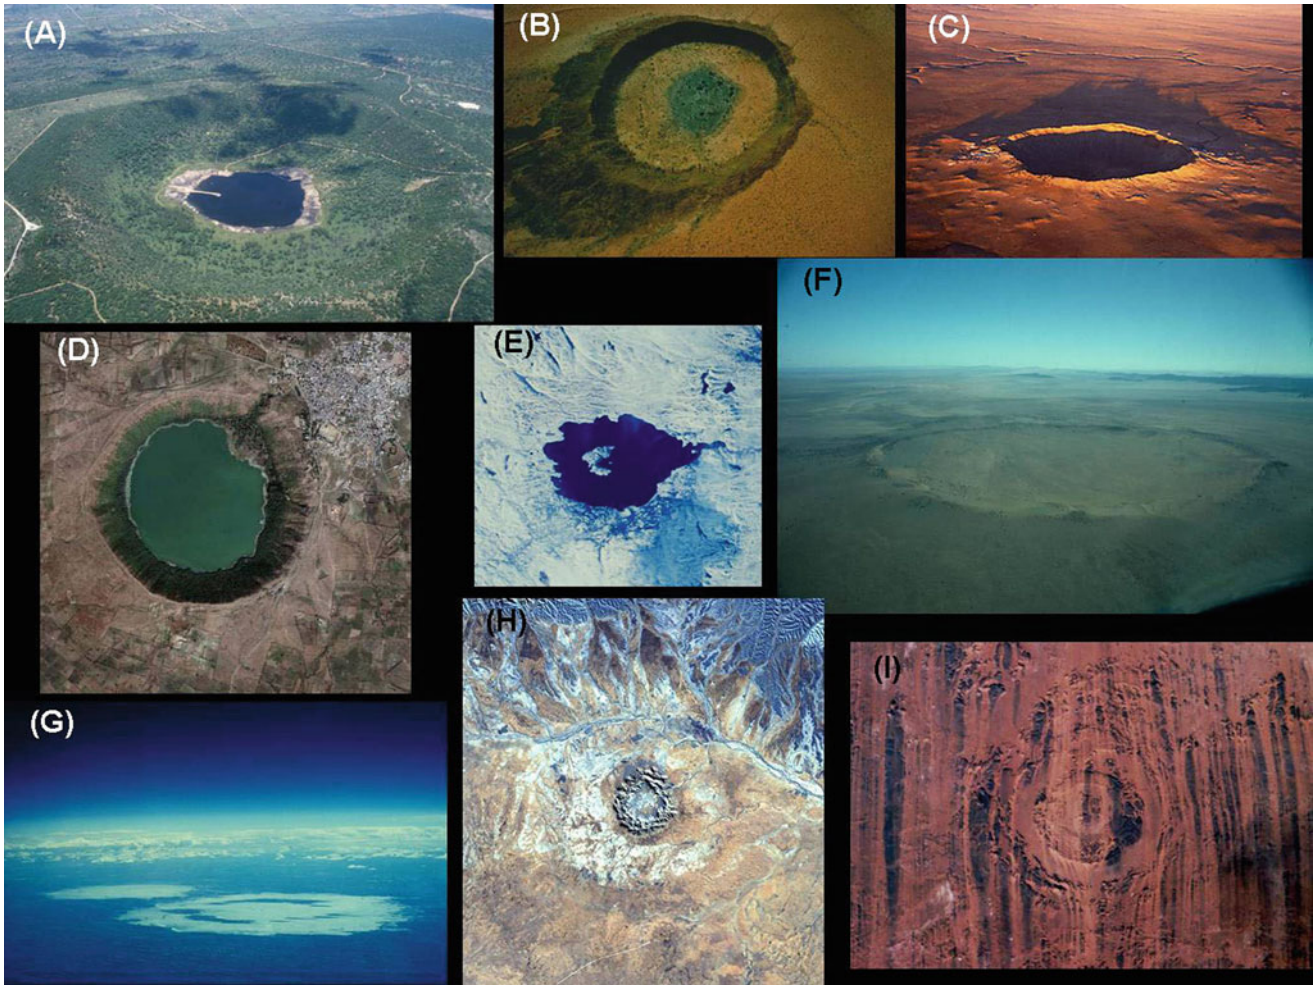
In the geological sciences, it has only recently been recognized how important the process of impact cratering is on a planetary scale. During the last few decades, planetary scientists and astronomers have demonstrated that our Moon, Mercury, Venus, Mars, the asteroids, and the moons of the outer gas planets are all covered (some surfaces to saturation) with meteorite impact craters (Figure 1). However, it is fairly recent that this observation has become accepted among astronomers and geologists, because up to the first third of the twentieth century, it was commonly accepted that all lunar craters are of volcanic origin (and at that time the presence of craters on planetary bodies other than the moon had not yet been established).

The origin of craters on the Moon was discussed since 1610, when Galileo Galilei first discovered them. Geologists paid no interest to the Moon for the following centuries, so that the discussion of lunar craters was left to the astronomers. One of the earliest researchers to speculate about the origin of lunar craters was Robert Hooke in 1665, who proposed two alternative hypotheses. First, he dropped solid objects into a mixture of clay and water and found that these experiments resulted in crater-like features. However, he rejected the possibility that the lunar craters could have formed by such "impact" processes, because it was not clear from "whence those bodies should come," as the interplanetary space was, at that time, considered to be empty. After all, Hooke made his experiments 135 years before the first asteroid, Ceres, was discovered by Piazzi in Palermo. Thus, he preferred a second hypothesis, in which, from experiments with "boiled alabaster," he concluded that the lunar craters formed by some kind of gas – rejecting a perfectly correct explanation because the "boundary conditions" were missing.

The eighteenth and nineteenth centuries were dominated by the volcanic theory, and only a few researchers at the end of the nineteenth century expressed the idea that

Asteroid Impact, Figure 1 The full moon, showing the large circular impact basins that are the remnants of large impacts during the late heavy bombardment (about 4 billion years ago); photo by the Galileo spacecraft (NASA).

impacts might form craters (on the moon and elsewhere). For example, at the end of the nineteenth century, in 1892, Grove Karl Gilbert, chief geologist of the US Geological Survey, concluded – partly based on experiments made in his hotel room during a lecture tour – that the formation of lunar craters can be best explained by the impact theory. In contrast, he rejected the hypothesis that Meteor Crater in Arizona was formed by impact. This was odd because fragments of iron meteorites were actually found around this crater.



Real progress was only made in the first decades of the twentieth century, when the mining engineer Daniel Moreau Barringer (1860–1929) studied the "Coon Butte" or "Crater Mountain" structure (as the "Meteor Crater" was then called) in Central Arizona. Despite the opinion of several leading geologists (including Gilbert) that this structure was of volcanic origin, and that the presence of the meteorite fragments was only a coincidence, Barringer was convinced that this was an impact crater, and his work laid the foundations for a wider acceptance of the existence of impact craters on Earth.

A well-known case in point is the Cretaceous-Tertiary (K-T) boundary, where the discovery of an extraterrestrial signature (Alvarez et al., 1980), together with the presence of shocked minerals (Bohor et al., 1984), led not only to the identification of an impact event as the cause of the end-Cretaceous mass extinction (Smit, 1999), but also to the discovery of a large buried impact structure about 200 km in diameter, the Chicxulub structure. Earlier, the idea that an extraterrestrial object would have influenced the geological and biological evolution on the Earth was not even seriously considered. This might explain the mixture of disbelief, rejection, and ridicule with which the suggestion was greeted that an asteroid or comet impact wiped out the dinosaurs and other species at the end of the Cretaceous. It was the debate that followed this suggestion, which, over the past 20–30 years, finally led to a more general realization that impact cratering is an important process on the Earth as well (Figure 2), and not only on the other planetary bodies of the Solar System.

Formation of impact craters

Impact cratering is a high-energy event that occurs at more or less irregular intervals (although over long periods of time, an average cratering rate can be established). Part of the problem regarding recognition of the remnants of impact events is the fact that terrestrial processes (weathering, plate tectonics, etc.) either cover or erase the surface expression of impact structures on Earth. Many impact structures are covered by younger (i.e., post-impact) sediments and are not visible on the surface. Others were mostly destroyed by erosion. In some cases, the ejecta have been found far from any possible impact structure. The study of these ejecta led, in turn, to the discovery of some impact craters.

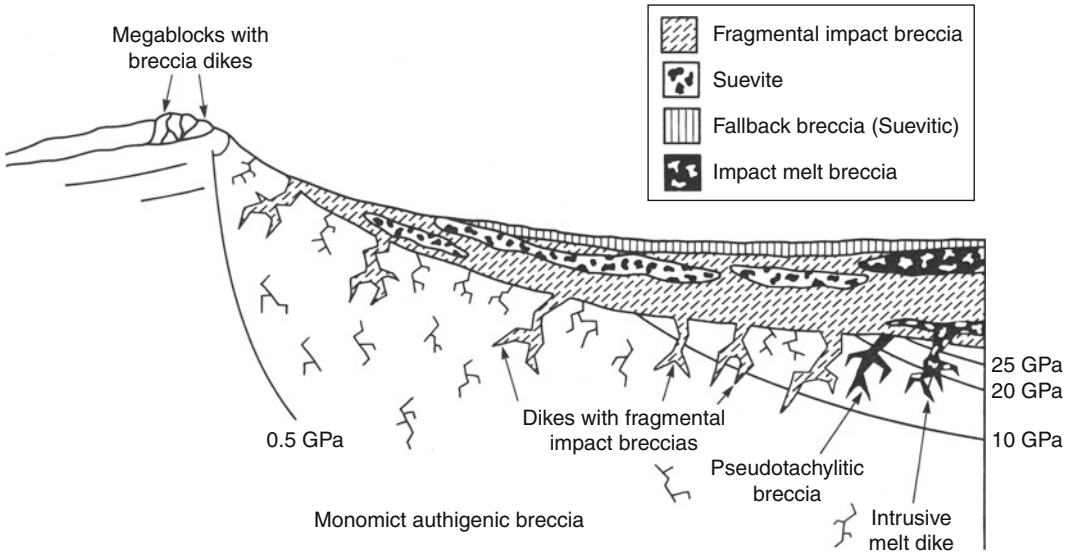
Before discussing the detailed mineralogical, petrographic, and geochemical characteristics of impact craters, it is important to give a short overview of their formation, criteria of recognition, and their general geology. From the morphological point of view, it is necessary to distinguish between an impact *crater*, that is, the feature that results from the impact, and an impact *structure*, which is what is observed today, that is, long after formation and modification of the crater. On Earth, two distinctly different morphological forms are known: *simple* craters (small bowl-shaped craters) with diameters of up to $\leq$2–4 km, and *complex* craters, which are larger and have diameters of $\geq$2–4 km (the exact changeover diameter between simple and complex crater depends on the composition of the target). Complex craters are characterized by a peak or peak ring that consists of rocks that are uplifted from greater depth and would not normally be exposed on the surface. The stratigraphic uplift amounts to about 0.1 of the crater diameter (e.g., Melosh, 1989). Craters of both types have an outer rim and are filled by a mixture of fallback ejecta and material slumped in from the walls and crater rim during the early phases of formation. Such crater infill may include brecciated and/or fractured rocks, and impact melt rocks. Fresh simple craters have an apparent depth (measured from the crater rim to present-day crater floor) that is about one third of the crater diameter, whereas that value for complex craters is closer to one sixth. On Earth basically all small craters are relatively young, because erosional processes obliterate small (0.5–10 km diameter) craters after a few million years, causing a severe deficit of such small craters.

Asteroid Impact, Figure 2 Examples of simple and complex impact craters on Earth. Craters in the upper row, and the one in the center row on the right, are simple craters, and the others are complex craters. Upper row: (**a**) Tswaing (Saltpan)-crater in South Africa (1.2 km diameter, 250,000 years old); (**b**) Wolfe Creek crater in Australia (1 km diameter, 1 Ma old); (**c**) Meteor Crater in Arizona, USA (1.2 km diameter, 50,000 years old); Center row: (**d**) Lonar crater, India (1.8 km diameter, age ca. 50,000 years); (**e**) Mistastin crater in Canada (28 km diameter, age ca. 38 Ma); (**f**) Roter Kamm crater in Namibia (2.5 km diameter, age ca. 4 Ma); bottom row: (**g**) Clearwater-double crater in Canada (24 and 32 km diameter, age ca. 250 Ma); (**h**) Gosses Bluff crater in Australia (24 km diameter, age 143 Ma); and (**i**) Aorounga crater in Chad (18 km diameter, age unknown but younger than ca. 300 Ma).

The formation of a crater by hypervelocity impact is – not only in geological terms – a very rapid process that is customarily divided into three stages: (1) contact/compression stage, (2) excavation stage, and (3) post-impact crater modification stage. For more detailed discussions of the physical principles of impact crater formation, the interested reader is referred to the literature (e.g., Melosh, 1989, and references therein). The most important aspect of impact cratering concerns the release of large amounts of kinetic energy (equal to $\frac{1}{2}mv^2$, m = mass, v = velocity) when an extraterrestrial body hits the surface of the Earth with cosmic velocities (ranging from about 11–72 km/s). The physical processes that govern the formation of an impact crater are the result of the extremely high amounts of energy that are liberated almost instantaneously when the projectile hits the ground. For example, a meteorite with a diameter of 250 m has a kinetic energy that is roughly equivalent to about 1,000 mt of TNT, which would lead to the formation of a crater about 5 km in diameter. There is a difference between the behavior of a stony impactor and an iron one. Due to the difference in mechanical strength, smaller iron meteorites can reach the ground intact, in contrast to stony meteorites, which may undergo catastrophic disintegration in the atmosphere. The impact energy can be compared to that of "normal" terrestrial processes, such as volcanic eruptions or earthquakes. During a small impact event, which may lead to craters of 5–10 km in diameter, about 10^{24-25} ergs (10^{17-18} J) are released, comparable to the about 6.10^{23} ergs (6.10^{16} J) that were released over several months during

the 1980 eruption of Mount St. Helens (see, e.g., French, 1998). In the case of an impact, the kinetic energy is concentrated more or less at a point on the Earth's surface, leading to an enormous local energy increase.

Schematically, the formation of an impact crater can be summarized as follows: First, a relatively small extraterrestrial body, traveling at a velocity of several tens of kilometers per second, hits the surface; this marks the beginning of the contact and compression stage. Almost immediately, a small amount of material is ejected from the impact site during a process called jetting with velocities that can approach about one half of the impact velocity. The jetted material is strongly contaminated with projectile material. When the projectile hits the surface, a shock wave is propagated hemispherically into the ground. Because the pressures in the shock waves are so high, the release of the pressure (decompression) results in almost instantaneous melting and vaporization of the projectile – and of large amounts of target rocks. Results of the interaction of the shock wave with matter can be observed in various forms of shocked minerals and rocks, all of which originate during the contact (or compression) stage, which only lasts up to a few seconds even for large impacts. After the passage of the shock wave, the high pressure is released by a so-called rarefaction wave (also called release wave), which follows the shock front. The rarefaction wave is a pressure wave, not a shock wave, and travels at the speed of sound in the shocked material. The rarefaction wave leads to the creation of a mass flow that opens up the crater, marking the beginning of the excavation phase. Important changes in the rocks and minerals occur upon decompression, when the material follows a release adiabat in a pressure versus specific volume diagram. Excess heat appears in the decompressed material, which may result in phase changes (e.g., melting or vaporization).



The actual crater is excavated during this stage. Complex interactions between the shock wave(s) and the target, as well as the release wave(s), lead to an excavation flow. In the upper layers of the target, material moves mainly upward and out, whereas in lower levels material moves mainly down and outward, which results in a bowl-shaped depression, the *transient cavity*. This cavity grows in size as long as the shock and release waves are energetic enough to excavate material from the impact location. At this point a note of caution is necessary. For a crater about 200 km in diameter, the depth of the transient cavity can easily reach 60 km. However, only about one third of this is excavation, the rest is simply material that is pushed down. Thus, even the largest craters known on Earth have not resulted in excavation of mantle material, and impact-induced volcanism is implausible and has never been found. Afterward, gravity and rock-mechanical effects lead to a collapse of the steep and unstable rims of the transient cavity, and widening and filling of the crater. Compared to the contact stage, the excavation stage takes longer, but still only up to a minute or 2 even in large craters of more than 200 km diameter. Details on the physics and mechanics of the formation of impact craters can be found in the publication by Melosh (1989).

Recognition criteria for an impact crater

The affected rocks are important witnesses for the characteristics of the impact process. As mentioned above, crater structures are filled with melted, shocked, and brecciated rocks (Figure 3). Some of these are in situ, and others have been transported, in some cases to considerable distances from the source crater. The latter are called ejecta. Some of that material can fall back directly into the crater, and most of the ejecta end up close to the crater (<5 crater radii; these are called *proximal* ejecta), but a small fraction may travel much greater distances and are then called *distal* ejecta. The book by Montanari and Koeberl (2000) contains more detailed information on impact ejecta (see also entry *Impact Ejecta*).

How to recognize an impact crater is an important topic. On the Moon and other planetary bodies that lack an appreciable atmosphere, impact craters can commonly be recognized from morphological characteristics, but on Earth complications arise as a consequence of the obliteration, deformation, or burial of impact craters. This problem made it necessary to develop diagnostic criteria for the identification and confirmation of impact structures on Earth (see French, 1998; French and Koeberl, 2010). The most important of these characteristics are as follows: (a) crater morphology, (b) geophysical anomalies, (c) evidence for shock metamorphism, and (d) the presence of meteorites or geochemical evidence for traces of the meteoritic projectile. Morphological and geophysical observations are important in providing supplementary (or initial) information. Geological structures with a circular outline that are located in places with no other obvious mechanism for producing near-circular features may be of impact origin and at least deserve further attention. Geophysical methods are also useful in identifying promising structures for further studies, especially in the case of subsurface features. In complex craters, the central uplift usually consists of dense basement rocks and usually contains severely shocked material. This uplift is often more resistant to erosion than the rest of the crater, and thus, in old eroded structures the central uplift may be the only remnant of the crater that can be identified. Geophysical characteristics of impact craters include gravity, magnetic properties, reflection and refraction seismics, electrical resistivity, and others (see Grieve and Pilkington, 1996, for a review).

Of the criteria mentioned above, only the presence of diagnostic shock metamorphic effects and, in some cases, the discovery of meteorites, or traces thereof, are generally accepted to provide unambiguous evidence for an impact origin. Shock deformation can be expressed in macroscopic form (shatter cones) or in microscopic form. The same two criteria apply to distal impact ejecta layers and allow to confirm that material found in such layers

Asteroid Impact, Figure 3 Cross-section through a hypothetical simple impact crater, showing the distribution of possible impact-derived materials and rock formations (After Koeberl, 2002).

originated in an impact event at a possibly still unknown location. As of 2010 about 180 impact structures have been identified on Earth based on these criteria.

Shock metamorphism

In nature, shock metamorphic effects are uniquely characteristic of shock levels associated with hypervelocity impact. The response of materials to shock has been the subject of study over much of the second half of the twentieth century, in part stimulated by military research. Using various techniques, controlled shock wave experiments, which allow the collection of shocked samples for further studies, have led to a good understanding of the conditions for the formation of shock metamorphic products and a pressure-temperature calibration of the effects of shock pressures up to about 100 GPa (see, e.g., French and Short, 1968; Stöffler and Langenhorst, 1994; Grieve et al., 1996; French and Koeberl, 2010; and references therein).

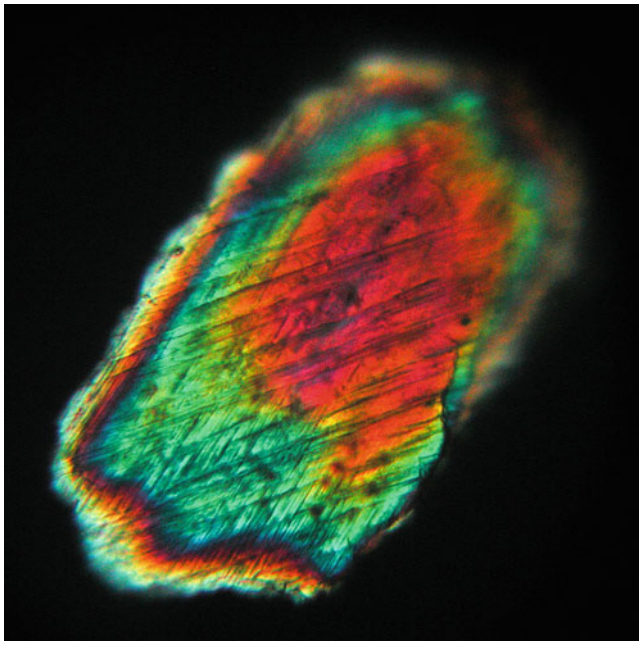
For the identification of meteorite impact structures, suevites and impact melt breccias (or impact melt rocks) are the most commonly studied units. It is easy to distinguish between the two impact formations, as suevites are polymict breccias that contain inclusions of melt rock (or impact glass) in a clastic groundmass, and impact melt breccias have a melt matrix with a variable amount of (often shocked) rock fragments as clasts (they are also referred to in the literature as "melt-matrix breccias"). Whether or not these various breccia types are present and/or preserved in a crater depends on factors including the size of the crater, the target composition (e.g., crystalline or sedimentary rocks), the degree of porosity of the target, and the level of erosion for an impact structure. In cases of very deeply eroded structures, only remnants of injected impact breccias in the form of veins or dikes may remain. Besides injections of suevite and impact melt rock, and local (in situ) formations of monomict or polymict clastic impact breccia, this may involve veins and pods of so-called "pseudotachylitic breccia" that are recorded from a number of impact structures. This material may closely resemble what is known as "pseudotachylite," the term for "friction melt." However, it has become clear in recent years that not all of the formations of such appearance actually represent friction melt, but may also include impact melt rock and even tectonically produced fault breccias (friction melt, mylonite, or cataclasite).

The rocks in the crater rim zone are usually only subjected to relatively low shock pressures (commonly <2 GPa), leading mostly to fracturing and brecciation, and often do not show shock-characteristic deformation. Even at craters of several kilometers in diameter, crater rim rocks that are in situ rarely show evidence for shock deformation. However, there may be injections of impact breccias that may contain shock metamorphosed mineral and rock fragments. In well-preserved impact structures, the area directly outside the crater rim is covered by a (vertical) sequence of different impactite deposits, which often allow the identification of these structures as being of impact origin.

The presence of shock metamorphic effects constitutes confirming evidence for impact processes. In nature, shock metamorphic effects are uniquely characteristic of shock levels associated with hypervelocity impact. Shock metamorphic effects are best studied in the various breccia types that are found within and around a crater structure, as well as in the formations exhumed in the central uplift area. During the impact, shock pressures of about

≥100 GPa and temperatures ≥3,000°C are produced in large volumes of target rock. These conditions are significantly different from conditions for endogenic metamorphism of crustal rocks, with maximum pressures of usually <2 GPa and temperatures <1,200°C. Shock compression is not a thermodynamically reversible process, and most of the structural and phase changes in minerals and rocks are uniquely characteristic of the high pressures (diagnostic shock effects are known for the range from 8 to >50 GPa) and extreme strain rates (10^6–10^8 s^{-1}) associated with impact. The products of static compression, as well as those of volcanic or tectonic processes, differ from those of shock metamorphism, because of lower peak pressures and strain rates that are different by many orders of magnitude.

A wide variety of microscopic shock metamorphic effects have been identified (see Table 1). The most common ones include planar microdeformation features; optical mosaicism; changes in refractive index, birefringence, and optical axis angle; isotropization (e.g., formation of diaplectic glasses); and phase changes (high-pressure phases; melting). Kink bands (mainly in micas) have also been described as a result of shock metamorphism, but can also be the result of normal tectonic deformation (for reviews and images of examples, refer to Stöffler and Langenhorst, 1994; Grieve et al., 1996; French, 1998; French and Koeberl, 2010).



Planar microstructures are the most characteristic expressions of shock metamorphism and occur as planar fractures (PFs) and planar deformation features (PDFs). The presence of PDFs in rock-forming minerals (e.g., quartz, feldspar, or olivine) provides diagnostic evidence for shock deformation, and thus, for the impact origin of a geological structure or ejecta layer (see, e.g., Stöffler and Langenhorst, 1994; Montanari and Koeberl, 2000; French and Koeberl, 2010, and references therein). Good examples are shown in Figure 4. PFs, in contrast to irregular, non-planar fractures, are thin fissures, spaced about 20 μm or more apart. While they are not considered shock diagnostic per se, should they be observed in significant abundance and particularly in densely spaced sets of multiple orientations, they can provide a strong indication of shock pressures around 5–10 GPa. To an inexperienced observer, it is not always easy to distinguish "true" PDFs from other lamellar features (fractures, fluid inclusion trails, tectonic deformation bands).

The most important characteristics of PDFs are that they are extremely narrow, closely and regularly spaced, completely straight, parallel, extend often (though not always) through a whole crystal, and, at shock pressures above about 15 GPa, occur in more than one set of specific crystallographic orientation per grain. This way, they can be distinguished from features that are produced at lower strain rates, such as the tectonically formed Böhm lamellae, which are not completely straight, occur only in one set, usually consist of bands that are >10 μm wide, and are spaced at distances of >10 μm. Transmission electron microscopy (TEM) studies demonstrate that PDFs consist of amorphous silica, that is, they are planes of amorphous quartz that extend through the quartz crystal. This allows them to be preferentially etched by, for example, hydrofluoric acid, thus accentuating the planar deformation features. PDFs occur in planes that correspond to specific rational crystallographic orientations (for details, see, e.g., Stöffler and Langenhorst, 1994). With increasing shock pressure, the distances

Asteroid Impact, Table 1 Characteristics of shock deformation features in rocks and minerals

Pressure (GPa)	Features	Target characteristics	Feature characteristics
2–45	Shatter cones	Best developed in homogeneous fine-grained, massive rocks.	Conical fracture surfaces with subordinate striations radiating from a focal point.
5–45	Planar fractures and Planar deformation features (PDFs)	Highest abundance in crystalline rocks; found in many rock-forming minerals (e.g., quartz, feldspar, olivine, and zircon).	PDFs: Sets of extremely straight, sharply defined parallel lamellae; may occur in multiple sets with specific crystallographic orientations.
30–40	Diaplectic glass	Most important in quartz and feldspar (e.g., maskelynite from plagioclase)	Isotropization through solid-state transformation under preservation of crystal habit as well as primary defects and sometimes planar features. Index of refraction lower than in corresponding crystal but higher than in fusion glass.
15–50	High-pressure polymorphs	Quartz polymorphs most common: coesite, stishovite; but also ringwoodite from olivine, and others	Recognizable by crystal parameters, confirmed usually with XRD or NMR; abundance influenced by post-shock temperature and shock duration; stishovite is temperature-labile.
>15	Impact diamonds	From carbon (graphite) present in target rocks; rare	Cubic (hexagonal?) form; usually very small but occasionally up to mm-size; inherits graphite crystal shape.
45– > 70	Mineral melts	Rock-forming minerals (e.g., lechatelierite from quartz)	Impact melts are either glassy (fusion glasses) or crystalline; of macroscopically homogeneous, but microscopically often heterogeneous composition.

XRD X-ray diffraction, *NMR* nuclear magnetic resonance, *PDF* planar deformation features
Table after Montanari and Koeberl (2000)

Asteroid Impact, Figure 4 Shock-characteristic planar deformation features (PDFs) in a quartz grain (in distal ejecta from the Manson impact crater, found in South Dakota). Width of the grain ca. 100 μm. Multiple intersecting sets of PDFs are clearly visible.

between the planes decrease, and the PDFs become more closely spaced and more homogeneously distributed through the grain, until at about 30–35 GPa the grains show complete isotropization. Depending on the peak pressure, PDFs are observed in about 2–10 orientations per grain. To confirm the presence of PDFs, it is necessary to measure their crystallographic orientations by using either a universal stage or a spindle stage with an optical microscope, or to characterize them by TEM. Because PDFs are well developed in quartz (Stöffler and Langenhorst, 1994), a very widely observed rock-forming mineral, and because their crystallographic orientations are easy to measure in this mineral, most studies report only shock features in quartz. However, other rock-forming minerals, as well as accessory minerals, also develop PDFs.

Higher shock pressures than those recorded in PDFs in quartz and other rock-forming minerals lead to shock-induced amorphization (without melting) of the minerals (producing "diaplectic" minerals, such as diaplectic quartz or feldspar), thermal decomposition or melting of selected minerals (e.g., the monomineralic melt of quartz is lechatelierite), and whole-rock melting. Impact glasses can form directly at a crater, or be ejected to great distances (e.g., tektites). These melt rocks and glasses are often the objects of geochemical investigations. For example, the detection of small amounts of meteoritic matter in breccias and melt rocks can also provide confirming evidence of impact (Koeberl, 2007).

Tektites and microtektites

Tektites are chemically homogeneous, often spherically symmetric natural glasses, with most being a few centimeters in size (Figure 5). Mainly due to chemical studies, it is now commonly accepted that tektites are the product of melting and quenching of terrestrial rocks during hypervelocity impact on the Earth. The chemistry of tektites is in many respects identical to the composition of upper crustal material. Tektites are currently known to occur in four strewn fields of Cenozoic age on the surface of the Earth. Strewn fields can be defined as geographically extended areas over which tektite material is found. The four strewn fields are the North American, Central European (moldavite), Ivory Coast, and Australasian strewn fields. Tektites found within each strewn field have the same age and similar petrological, physical, and chemical properties. Relatively reliable links between craters and tektite strewn fields have been established between the Bosumtwi (Ghana), the Ries (Germany), and the Chesapeake Bay (USA) craters and the Ivory Coast, Central European, and North American fields, respectively. The source crater of the Australasian strewn field has not yet been identified. Tektites have been the subject of much study, but their discussion is beyond the scope of the present review. For details on tektites see the reviews by Koeberl (1994) and Montanari and Koeberl (2000).

In addition to the "classical" tektites on land, microtektites (<1 mm in diameter) from three of the four strewn fields have been found in deep-sea cores. Microtektites have been very important for defining the extent of the strewn fields, as well as for constraining the stratigraphic age of tektites, and to provide evidence regarding the location of possible source craters. Microtektites have been found together with melt fragments, high-pressure phases, and shocked minerals and, therefore, provide confirming evidence for the association of tektites with an impact event. The variation of the microtektite concentrations in deep-sea sediments with location increases toward the assumed or known impact location.

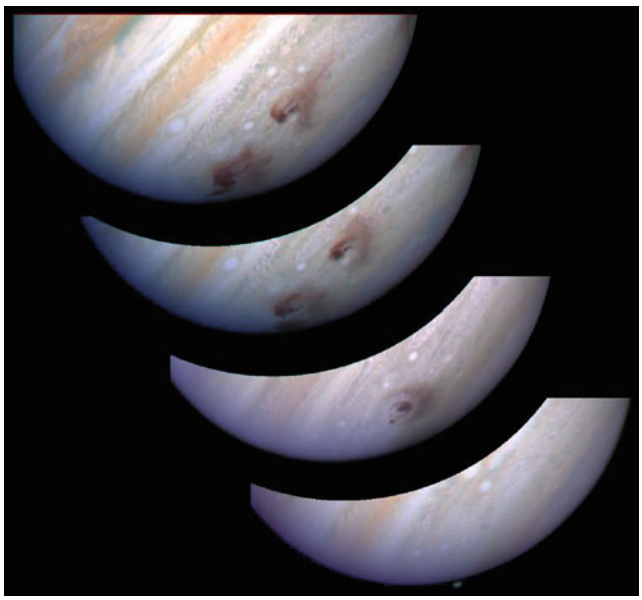
There has been some discussion about how to define a tektite, but the following characteristics should probably be included (see Koeberl, 1994; Montanari and Koeberl, 2000): (1) they are glassy (amorphous); (2) they are fairly homogeneous rock (not mineral) melts; (3) they contain abundant lechatelierite; (4) they occur in geographically extended strewn fields (not just at one or two closely related locations); (5) they are distal ejecta and do not occur directly in or around a source crater, or within typical impact lithologies (e.g., suevitic breccias, impact melt breccias); (6) they generally have low water contents and a very small extraterrestrial component; and (7) they seem to have formed from the uppermost layer of the target surface (see below).

An interesting group of tektites are the Muong Nong-type tektites, which, compared to "normal" (or splash-form) tektites are larger, more heterogeneous in

Asteroid Impact, Figure 5 Several Australasian tektites (from Thailand), showing the variety in shapes and forms. Tektites are distal impact ejecta, which formed by total melting of continental crustal target rocks.

composition, of irregular shape, have a layered structure, and show a much more restricted geographical distribution. They are also important because they contain relict mineral grains that indicate the nature of the parent material and contain shock-produced phases that indicate the conditions of formation. The occurrence of relict minerals in some tektites points to sedimentary source rocks. Muong Nong-type tektites contain unmelted relict inclusions, including zircon, chromite, quartz, rutile, and monazite, all showing evidence of various degrees of shock metamorphism. Coesite, stishovite, and shocked minerals were found in the North American and Australasian microtektite layers.

Despite knowing the source craters of three of the four tektite strewn fields, we still do not know exactly when and how during the impact process tektites form. Besides the characteristics mentioned above, tektites contain a relatively high amount of the cosmogenic isotope beryllium-10 (^{10}Be), which cannot have originated from direct irradiation with cosmic rays in space or on Earth, but can only have been introduced from sediments that have absorbed ^{10}Be that was produced in the terrestrial atmosphere. Tektites might be produced in the earliest stages of impact, which are poorly understood. It is clear, however, that tektites formed from the uppermost layers of terrestrial target material (otherwise they would not contain any ^{10}Be). However, the question of which process was responsible for tektite production and distribution remains the subject of further research.



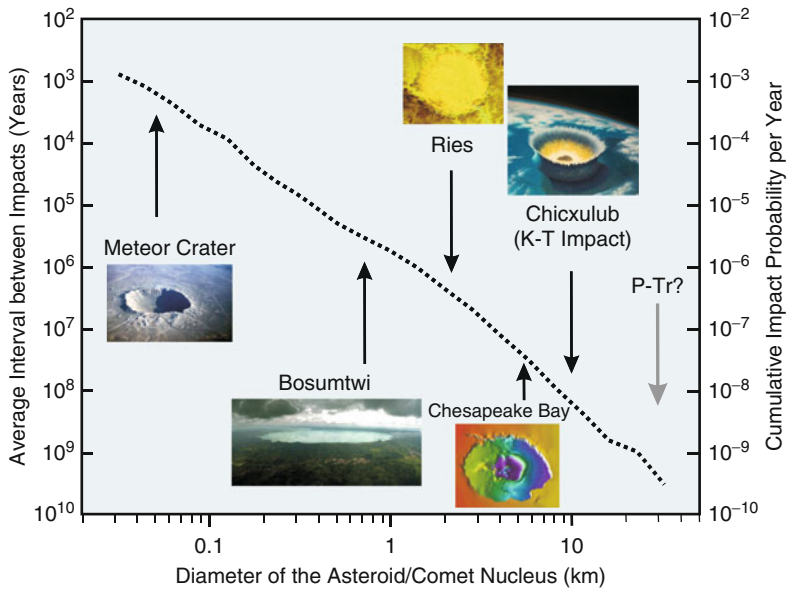
The hazards of asteroid impact

In July 1994, the fragments of comet Shoemaker-Levy 9 that crashed into the atmosphere of the planet Jupiter, producing impact plumes the size of our own planet (Figure 6), brought home to billions of people all over the world that impact catastrophes are not only a matter of the distant past but that they could happen any time, any place in the Solar System – also on Earth. And just about 100 years ago the Tunguska explosion of June 30, 1908, devastated some 2,000 km^2 of Siberian forests and caused environmental effects as far as London, and an air pressure signal around the world. Having been debated as the result of impact as much as of the explosion of a nuclear UFO, it is now widely accepted that this explosion was caused by the explosive disruption of a small (maybe 30–50 m wide) asteroid within the atmosphere, with an explosive energy of about 5–10 Mton TNT-equivalent.

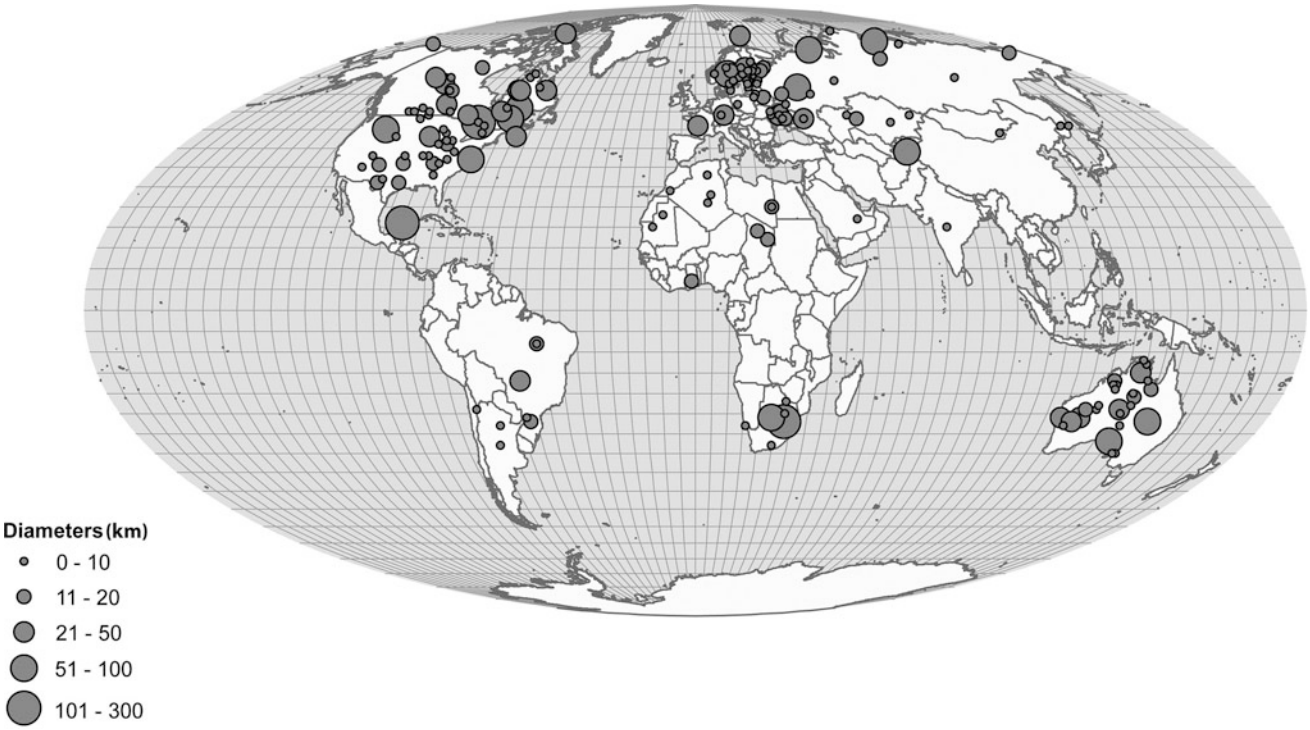
Even more recently, a small cosmic projectile impacted in Peru on September 15, 2007. The Carancas meteorite created a ca. 14-m-wide impact crater, in a rather remote area of that country, and besides several people sustaining a significant scare, no casualties are known. However, even though this impact event was of insignificant size on a planetary scale (the largest impact structure known in the Solar System, the South Pole-Aitken basin in the south polar region of the Moon, measures some 2,500 km in diameter), there would have been hundreds of victims if this event had occurred in densely populated areas of our Planet. Clearly the understanding of impact processes is an important issue for mankind – especially if one considers what happened to the dinosaurs and their contemporaries 65 Ma ago. The impact of a 5–15-km asteroid at Chicxulub on the Yucatán peninsula generated then a 180 km diameter impact structure with global catastrophic effects (e.g., papers in Ryder et al. 1996).

The 1994 impact of fragments of comet Shoemaker-Levy 9 into the atmosphere of Jupiter demonstrated to humankind that impact is not a threat of the past. Hardly a year goes by without a call of danger from a "rogue asteroid" to Earth – although so far, all of them seem to have remained without cause. However, the terrestrial cratering record predicts a Tunguska event – impact of a roughly 50-m-sized projectile – for every 1,500 years or so, and if this event had occurred in a highly populated region, this relatively minor event comparable to ca. 1,000 Hiroshima atom bombs could have caused a loss of life potentially going into the millions (Figure 7). A large event of Chicxulub magnitude might occur every 100 Ma, but this statistical approach does not predict when it might happen next. Depending on the actual velocity of the Chicxulub impactor, that projectile might have measured between 5 and 15 km in diameter, although scaling from the amount of extraterrestrial material around the world indicates a value of about 10 km. However, current predictions of impact consequences suggest that even a 1-km-sized bolide might be sufficient to cause potential harm to mankind through global environmental catastrophe.

Projectiles enough are out there – comets in the Kuiper-Edgeworth belt and in the Oort cloud, and near-Earth objects (those asteroids that approach the Sun closer than 1.3 AU) are not particularly rare in the asteroid belt, largely a result of the NASA-sponsored international Spaceguard surveying project. Data from these studies indicate that "the risk of any person's death by impact prior to Spaceguard was estimated at about the same as dying in an airplane crash" – something like 1 in 30,000, but since the successful work of Spaceguard, this estimate has changed to 1 in 600,000 as the danger from likely still undetected asteroids.



Asteroid Impact, Figure 6 Hubble space telescope image sequence of Comet Shoemaker-Levy 9 impacting Jupiter in 1994. Shown is a time-lapse sequence of the result of two fragments striking Jupiter. The fragments hit the atmosphere at about 60 km/s and left Earth-sized traces that could be observed for many weeks. Jupiter has a diameter that is about 12 times that of the Earth.



And still, much remains to be learned about the catastrophic impact effect. Space search programs for possible still unknown asteroids continue, and the danger from suddenly appearing comets remains anyway. The latter case provides a challenge for impact workers, as the behavior of large, low-density projectiles, and the effects of their impacts onto various planetary surfaces are far from being understood. The terrestrial impact record has to be improved to further constrain the past impact flux onto Earth, and the energy threshold for truly global devastation by impact still needs to be identified. Does it take an impact event of the magnitude of Chicxulub? Or was that impact particularly lethal because of the sulfate- and carbonate-rich target area at Yucatán? Can our highly evolved and, through its intricate civilization, highly vulnerable race survive a much smaller impact event, perhaps only creating a 40 km impact structure? And that will only take a 2–3-km-sized impactor. . ..

Conclusions

Mineralogical, petrographic, and geochemical methods have been used for many decades in the study of the effects of asteroid impact in the formation of terrestrial meteorite impact craters. Currently about 180 impact structures are known on Earth (Figure 8). A clear hiatus in the history of impact-related studies was the realization

Asteroid Impact, Figure 7 Relation between impact probability and crater (as well as impactor) diameter (Updated from Montanari and Koeberl, 2000).

Asteroid Impact, Figure 8 Map of Earth with the currently known impact craters.

that K-T boundary bears unambiguous evidence for a large-scale catastrophic impact event (related to the formation of the 200-km-diameter Chicxulub impact structure, Mexico). Analyses of the K-T ejecta layers led to improved detection sensitivities for impact markers, allowing identification of smaller events and the study of their effects. Distal impact ejecta layers can be used to study a possible relationship between biotic changes and impact events, because it is possible to study such a relationship in the same outcrops, whereas correlation with radiometric ages of a distant impact structure is always associated with larger errors. Investigations of impact markers yield important information regarding the physical and chemical conditions of their formation, such as temperature, pressure, oxygen fugacity, and composition of the atmosphere. These data are necessary to understand the mechanisms of interaction of impact events with the environment and should ultimately lead to a better appreciation of the importance of impact events in the geological and biological evolution of the Earth. New geochemical techniques, such as the use of the Cr and Os isotopic systems, or analyses of comet-dust-derived ^{3}He in sediments (e.g., Farley et al., 1998), have helped to confirm or better explain several important impact events. Recent improvements in analytical methods and techniques will certainly continue to influence our understanding of the interaction between cosmic bodies and the Earth.

Definition

The deflection of Near-Earth Asteroids and/or avoidance of the consequences of an impact.

Discussion

Near-Earth Asteroids (NEAs) present a potential hazard. Meteorites falling from the sky are a minimal threat. An NEA larger than ~20 m diameter could explode close enough to the Earth's surface to cause local damage whereas one larger than ~150 m could reach the ground or ocean with most of its cosmic velocity, causing an explosion far larger than any nuclear weapon tested. An NEA larger than ~2 km diameter could damage the global ecosphere sufficiently to threaten civilization.

Rescue and recovery would resemble that following most other natural disasters, should an impact not be forecast in advance. With warning, there are two basic approaches to NEA impact mitigation: (1) deflecting the NEA well before predicted impact by one of several technological approaches using spacecraft, and/or (2) evacuating regions around ground zero and preparing in advance for more widespread consequences, should there be inadequate warning to deflect the body or if deflection attempts fail.

Telescopic searches, and thus long-term warnings, are directed toward larger NEAs, that is, those larger than 100 m in diameter, and especially those larger than 1 km. If one is discovered with a decade or more advance notice, a space mission could probably be deployed in sufficient time to deflect it, and thus ensure that the impact does not happen. The best approach would be to launch one or more massive (e.g., 1 t or greater) spacecrafts, as early as possible before the expected impact, with an aim to collide with the NEA, triggering a small velocity change in the optimal direction such that it eventually arrives either early or late to the point in space where it would otherwise strike the Earth. Such "kinetic impactors" might be insufficient to deflect an NEA larger than ~1 km, in which case it might be necessary to detonate a nuclear device near the NEA in order to deflect it.

An NEA's response to a kinetic impactor or nuclear explosion cannot be perfectly predicted. Thus, it is possible that the NEA could be deflected into a so-called keyhole, resulting in it returning to impact Earth in a subsequent year. For this reason, it is highly desirable to have an observer spacecraft in the vicinity of the NEA to characterize its properties in advance of deflection and, afterward, to determine precisely how much deflection was achieved. If the observer spacecraft is equipped with thrusters so as to act as a "gravity tractor", the mutual gravity between the spacecraft and the NEA could be used to precisely change the NEA's velocity sufficiently so as to preclude any further danger.

NEAs smaller than ~100 m diameter are much more likely to impact Earth than larger NEAs, but telescopes are less likely to detect them years or decades prior to impact. There is a good chance (perhaps as high as 50%) that one would be found during the last days or weeks before impact. Such short notice precludes deflection by spacecraft (exploding an NEA on its way in is an especially bad idea), but there would likely be opportunity for warning, evacuation, and other approaches to mitigating the expected damage.

Asteroid; Minor planet

Definition

AU. Astronomical unit – approximately the mean distance between the earth and the sun, about 149 597 871 km.
Aphelion. Point in an orbit that is farthest from the sun.
Apophis. Asteroid (99942) = 2004 MN_4.
Minor planet center. The International Astronomical Union's central clearinghouse for positional observations and orbital data for asteroids, located at the Smithsonian Astrophysical Observatory, Cambridge, Mass.
MOID. Minimum orbit intersection distance – the closest separation of two orbits. A PHA (potentially hazardous asteroid) is an asteroid with a MOID relative to the earth of less than 0.05 AU.
Near-earth asteroid. An asteroid whose distance from the sun at perihelion is less than 1.30 AU.
Palermo scale. A more quantified version of the Torino scale, including consideration of the time remaining to potential impact.
Perihelion. Point in an orbit that is closest to the sun.
Purgatorio ratio. PR – the ratio of the time interval covered by the observations of an asteroid to the time remaining until its next impact possibility.
Resonant return. A situation where the actual configuration of the earth and an asteroid approximately repeats after an integral number of years.
Torino scale. An integer from 0 to 10 equating impact probability and energy, events with scale 0 having no consequence and events with scale 10 the certainty of worldwide destruction.
Väisälä orbit. Orbit in which the asteroid is assumed to be at perihelion or aphelion.

Introduction

There are two main aspects to the problem of asteroid impact prediction. The first involves the situation in which a newly discovered object might impact the earth within a matter of days or weeks. The second considers the possibility that an object that is already well known will hit the earth many years or decades in the future.

Newly discovered objects

In principle, any object that has just been discovered has some nonzero chance of striking the earth. Initially, there are measurements of its direction from the discovery site as it tracks essentially uniformly along a small arc of the sky over the course of an hour or so. There is no direct information about the distance from the observer, although if the object is not substantially brighter than and its angular motion is not greatly different from those of known main-belt asteroids in the same region of the sky, it is very likely to be just another member of this enormous population of harmless asteroids.

To quantify the situation, one can therefore examine the consequences of *assuming* various values of the object's distance from the observer at the two instants, t_0 and t_1. A more enlightened procedure (Marsden, 1999a), routinely used for unusual new discoveries reported to the Minor Planet Center, considers values of the distance ρ_0 at t_0 but rotates the coordinate system so that the xy plane passes through the two observations and the xz plane through the observation at t_1. This immediately provides values for the heliocentric vector $\mathbf{r}_0(x_0, y_0, z_0)$ at t_0, and, with the help of the first two terms of the well-known "f and g" expansions, the components $\dot{y}_0$ and $\dot{z}_0$ of the heliocentric velocity immediately follow.

For each selected value of ρ_0, it therefore remains only to assume a variety of values of $\dot{x}_0$. Use of the energy integral leads to $1/a$, the reciprocal of the orbital semimajor axis, and taking $\dot{x}_0 = 0$ will yield $1/a_M$, its largest possible value for the chosen ρ_0. If $1/a_M$ is positive (i.e., the $\dot{x}_0 = 0$ solution is elliptical), it follows that the choice of $\dot{x}_0 = \pm\sqrt{1/a_M}$ will produce a pair of parabolic solutions. Since $1/a_M$ shows a general decrease as ρ_0 increases from the value zero, all the orbits eventually become hyperbolic (and hence of no interest), although the decrease is not necessarily monotonic.

For a given ρ_0, there is readily found a particular value of $\dot{x}_0$ that ensures that the heliocentric radial velocity $\dot{r}_0 = 0$, i.e., the object is at either perihelion or aphelion, in what is often termed a "Väisälä" orbit (Väisälä, 1939). The transition between perihelic and aphelic solutions implies the existence of a ρ_0 value that yields an exactly circular orbit, and if this solution has a small-to-moderate direct inclination and is in the distance range corresponding to the main asteroid belt or the Jupiter Trojans, this can support the conclusion from the apparent motion and brightness that the object is not a threat.

On the other hand, the existence of a circular solution that is similar to the orbit of the earth is obviously cause for worry. Such was the situation with the initial observations of 2008 TC_3, an object discovered in October 2008 and routinely reported to the Minor Planet Center, which automatically solicited follow-up observations. The availability of several such observations over the course of a couple of hours was sufficient to show that the orbital eccentricity was as high as 0.3, but they confirmed that this object was at roughly the distance of the moon and approaching in such

a way that it would collide with the earth only 20 h after discovery. The observed faintness made it clear that 2008 TC_3 was at most a few meters across and thus of no danger, but this unique example provided a valuable exercise for studying the first of the situations posed in the first paragraph of this article.

More established objects

To study the second of those situations, a useful point to consider is that the minimum orbital intersection distance (MOID) (Bowell and Muinonen, 1994) between the orbits of an asteroid and the earth is less than 0.05 AU. Of course, the MOID will change over time due to the actual gravitational influence of the earth and other planets, so it is also helpful to be aware of the asteroid's MOIDs with respect to the other planets. Furthermore, if an asteroid does actually approach the earth within the MOID, a further approach around the same date some integral number of years later is to be expected, the uncertainty in our knowledge of the orbit being magnified during the initial encounter and thereby increasing the likelihood of a subsequent collision.

The significance of such "resonant returns" for impact prediction was first recognized for (35396) 1997 XF_{11} and (137108) 1999 AN_{10} (Marsden, 1999b; Milani et al., 1999; Milani et al., 2000), with impact probabilities in the range 1 in 100,000–1,000,000 computed for several dates a decade or two after the earth approaches in 2028 and 2027, respectively, a time when the observations spanned just a few months. With the recognition now of pre- and post-discovery observations covering decades, it can be unequivocally stated that we are safe from these objects for the foreseeable future. With a 6-month observed arc, the more extreme case of (99942) Apophis = 2004 MN_4 actually had a 1-in-37 chance of earth impact in 2029 (Chesley, 2006), and as the arc (including radar data) increased to some four years, the fact that this object approaches in 2029 to within some 35,000 km of the earth means that there are still impact probabilities in the 1 in 100,000–1,000,000 range in 2036 and during 2056–2076.

As of early 2010, there were 200–300 cases of near-earth asteroids with some nonzero (i.e., more than 1 in a billion) probability of earth impact during the next century. Computed independently by groups in Pasadena and Pisa, these are routinely tabulated at http://neo.jpl.nasa.gov/risk/ and http://newton.dm.unipi.it, respectively. In addition to specifying the impact probabilities for each object on the relevant dates (with hundreds of possibilities in some cases), these tabulations also estimate the impact energy and attempt to assess the relative danger of the potential impacts. For public consumption, this assessment is done in terms of the Torino Scale (Binzel, 2000), simply an integer from 0 to 10 that equates probability and energy, with no consideration of when the impact might occur. The time to impact is included in the logarithmic Palermo Scale (Chesley et al., 2002), largely with regard to the likely statistical background hazard due to impacts by unknown objects during the intervening time.

An alternative way of assessing impact threats is to consider the "Purgatorio Ratio" (PR), which is simply the ratio of the time interval covered by the observations to the time remaining until the date of the next impact possibility (Marsden, 2007). As of early 2010, the PR for Apophis was 15%. If the PR is less than 1%, it is reasonable to ignore the threat, in the general expectation that, as further observations are obtained, computations will show the threat to vanish. Obviously, this does not always happen, and as a potential impact date approaches, the PR will then not only rise well above 1%, but it will eventually become infinite. If, indeed, this continues to be the case with the acquisition of current observations, there is reason for concern, particularly if the impact probability is more than, say, 10%. But the PR eventually becomes infinite even if there are no further observations. Given that the vast majority of the entries on the Pasadena and Pisa lists are "lost," having had observed arcs of only a few days (even only 3 h!) several years ago, such threats can almost certainly be dismissed, although if this causes unease, one can endeavor to take the opportunity of checking beforehand to see if the objects are located at the points in the sky they would have to occupy if impacts really were to take place.

Summary

The procedures currently in place for the prediction of potential impacts of asteroids on the earth are described. Firstly, there is consideration of the possibility that an object may be near the earth and have a distinct chance of impacting it within a matter of days, as in the case of 2008 TC_3. Secondly, when an object has been under more extensive observation, like Apophis, there is some meaningful possibility of establishing whether there is even a remote chance of impact up to a century hence. Various ways of assessing the impact hazard are discussed.

AUTOMATED LOCAL EVALUATION IN REAL TIME (ALERT)

Lev I. Dorman
Tel Aviv University, TECHNION, Qazrin, Israel
Russian Academy of Science, Moscow, Russia

Definition

ALERT (Automated Local Evaluation in Real Time) is a system for the automated production of a special signal forecasting different types of natural phenomena: earthquakes, tsunami, magnetic storms, changes in weather, solar cosmic ray events, radiation hazard, and so on. The forecasting is based on real-time observation data and theoretical and/or correlation models.

Importance for practice

The production of ALERT is especially important if the phenomenon may be dangerous to people, infrastructure, and/or technology. In many cases, if developed and deployed in time, ALERT can help to completely avoid or sufficiently minimize the negative consequences which can result from different natural and dangerous phenomena.

The probabilities T and F that ALERT is true or may be false

Any ALERT system that is adopted is done so with the expectation that some probability T is to be true (adjust accurately, fit exactly) and another probability F that it can be false (not true; counterfeit; deceitful; wrong), so $T + F = 1$.

The probability M that ALERT will be missing

Some natural phenomena may occur without producing a corresponding ALERT. The missing of ALERT may be the result of poor quality data or an insufficient number of observations as well as by not applying a fully adequate model. The probability M, that ALERT will be missing, decreases considerably on increasing the quality and number of observations used in the real-time data. It is important that the value M decreases with an increasing amplitude of the natural hazard phenomenon.

The forecasting time Δt between ALERT and expected natural hazardous phenomenon

This forecasting time Δt is a very important characteristic of any ALERT system. It may concern millions or thousands of years of forecasting of certain natural phenomena such as crossings of our solar system through galactic arms and galactic dust-molecular clouds (which may lead to long-term changes of the Earth's climate – decreasing of planetary temperature on several degrees; these natural hazard phenomena have occurred in the past many times), or impacts of asteroids with the Earth (which can lead to significant disasters in the biosphere), or nearby supernova explosions (accompanied with an increase of ultraviolet and neutrino radiation as well as cosmic ray fluxes, see entry *Supernova*). The forecasting time Δt can be hundreds or tens of years for estimation of expected global climate change and expected changes in seismic activity in some local regions. The value Δt can be years or months for forecasting phenomena connected with variations of solar and geomagnetic activity, and other similar processes in interplanetary space.

It is especially important in practice that now and in the near future that the forecasting time Δt be reduced, as days and hours for many natural phenomena such as magnetic storms, radiation hazards from large fluxes of solar cosmic rays, local meteorological conditions, volcanic eruptions, tsunami, and hurricanes. The forecasting of especially large natural hazards is usually recurrent, and with a subsequent reduction in forecasting time Δt the quality of the forecasts may increase.

AVALANCHES

Chris Stethem
Chris Stethem & Associates Ltd., Canmore, AB, Canada

Definition

A snow avalanche ensues when a pent up snow mass loses its hold and is discharged from the mountainside (Seligman, 1936, 292).

Introduction

Human interaction with snow avalanches undoubtedly began before recorded history when travelers first encountered steep slopes and deep snow. Written accounts and studies on snow avalanches began in the European Alps in the mid-nineteenth century (Seligman, 1936). Whereas at one time the majority of loss of life and property damage was associated with natural avalanches affecting those living and working in the mountains, today the majority of victims are recreationists who trigger such avalanches themselves. Over the 5-year period from 2004–2005 to 2008–2009, between 120 and 195 avalanche fatalities per year were reported to the International Commission on Alpine Rescue (www.ikar-cisa.org).

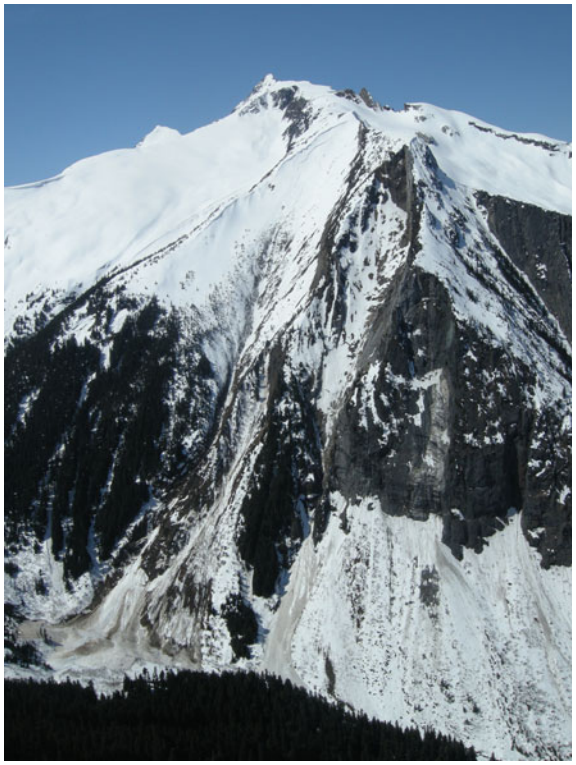
Avalanche phenomena

Avalanche types include *loose snow* avalanches which start from a point and spread downhill (Figure 1) and *slab* avalanches which have a distinctive fracture line or crown at their top (Figure 2). Dry slab avalanches initiate by a rapidly propagating shear fracture in a thin weak layer that underlies a more cohesive planar slab (McClung and Schaerer, 2006, 80). *Avalanche size* is dependent on *terrain* and *snow supply.* Slab avalanches are usually larger in size than loose snow avalanches and hence more dangerous.

Avalanches may initiate in either *dry* or *wet* snow. Dry snow avalanches have been observed to reach speeds exceeding 60 ms^{-1} (McClung, 1990) and consequently will tend to overrun terrain features in their path. Wet snow avalanches will move more slowly and are more easily diverted or channeled by terrain features such as gullies. A moving avalanche can exhibit a variety of flow characteristics depending on speed, terrain, and moisture content. A dry avalanche is often observed to have a *dense flow* at the base and a *powder* component above, termed a *mixed motion* avalanche (McClung and Schaerer, 2006). A fluidized saltation layer is also described to surround the dense core (European Commission, 2009). It is also possible that a powder avalanche will be observed without the dense flowing core, especially on very steep terrain, or that the powder component may separate from the dense flow in the course of its descent. Wet snow avalanches move with a flowing motion without the powder characteristic.

The *impact pressure* of avalanches is proportional to the avalanche speed squared, v^2, and the flowing density, ρ, of the moving material (McClung and Schaerer, 2006). Impact pressure measurements show that the highest impact pressures result from the initial impact of the dense flowing core of large, dry avalanches. Measured impact pressures range from <50 KPa to as much as 700 KPa (McClung and Schaerer, 1985; Sovilla et al., 2008). The impact pressures of wet avalanches are also significant given the higher density of flow and speeds which can exceed 30 ms^{-1}.

Avalanches, Figure 1 A loose snow avalanche starting from a point below the rocks at the top of the slope.



Avalanches, Figure 2 A dry slab avalanche fracture line at the convex feature near the top of a steep slope.

Avalanche terrain

An avalanche path (Figure 3) consists of a *starting zone*, a *track*, and a *runout zone*. Within the starting zone, the avalanche releases and begins to accelerate. The track connects the starting zone and runout and is the section of the avalanche path where maximum speeds are usually observed. Significant entrainment of additional snow or debris by the moving avalanche may also be observed in the track (Sovilla et al., 2004). The runout zone is the location where the avalanche decelerates and stops.

The primary terrain characteristic for avalanche formation is slope *incline*. The lower limit of incline in the starting zone for dry snow avalanches is >25° (McClung and Schaerer, 2006). Large slab avalanches are usually observed on slopes with inclines in the range of 30–45°,

Avalanches, Figure 3 A group of avalanche paths with adjacent starting zones (*top*), tracks (*middle*), and runout zones (*bottom*). Wet avalanche deposits are evident in the runout zones.

with a mean incline of 38° (Perla, 1977). More frequent and smaller avalanches are observed on steeper terrain. The lower limit of incline can be reduced in wet snow as liquid water content rises, the extreme case of which is a slush flow where average starting zone inclines have been reported in the range of 5–20° (Hestenes, 1985, 1998).

Slope *aspect* or orientation in regard to the wind and sun is generally regarded as the second most important terrain factor. Exposure to wind (Schaerer, 1977) will determine the extent to which wind transport increases or decreases snow load in potential starting zones. Certain terrain features such as bowls and gullies act as natural catchments for blowing snow. The orientation in regard to the sun and time of year will influence the radiation balance at the snow surface and resultant changes in snow temperatures and properties.

Other important terrain characteristics include slope *size and configuration*, *ground surface roughness*, *vegetation*, *and elevation*. Starting zone area and avalanche path length are important determinants of potential avalanche size. Certain terrain configurations such as gullies will tend to channel moving avalanches. Where the ground is rough, more snow is required to reach the threshold depth for avalanche formation. Slab avalanches are rare where the forest cover density reaches 500–1,000 stems per hectare (McClung and Schaerer, 2006), depending on slope incline and forest type (Schneebeli and Myer-Grass, 1992). Different snow, weather, ground conditions and vegetation can be expected at different elevations.

Avalanche *runout distance* is the farthest point reached by an avalanche in the runout zone. Determination of maximum runout distance is an important task in engineering and planning which combines physical evidence gathering with modeling of the runout distance of design avalanches. Physical evidence includes the historic record of avalanche occurrence, anecdotal history, topographic mapping, vegetation evident in aerial photography, and field observation. These are analyzed to identify key terrain features and indications of past damage or avalanche deposition. A variety of statistical and dynamic methods can then be applied to model the runout of maximum events with runout intervals of 100 years or more. The various dynamic models and their development are described by Salm (2004). Statistical models are described by Lied and Bakkehøi (1980) and McClung and Mears (1991). Different preferences in method are apparent in different parts of the world, and a combined approach may yield the best results (Jamieson et al., 2008). Experience in application of the methods is required for selection of appropriate data sets for statistical models or input parameters for dynamic models and expression of uncertainty.

Predicting avalanches

The data elements for interpreting *snow instability* can be grouped into direct evidence of instability (Class I), snowpack factors (Class II), and meteorological factors (Class III) (LaChapelle, 1980; McClung and Schaerer, 2006).

The most direct information on snow instability (Class 1) is gained through observation of avalanche occurrences, cracking or sudden collapse during slope tests, and quality of shear failure gained in instability tests.

The potential for slab avalanche formation and especially the identification of deep-seated instability is dependent on snowpack structure (Class II) or the layering of the snow cover. Where a weak layer or poor bond between layers exists, there is a greater potential for shear failure and slab avalanche release. Rule-based approaches to interpretation of snowpack data can be applied (Schweizer et al., 2004).

The most important snow and weather factors (Class III) in avalanche formation include amount and rate of loading by precipitation and wind, temperature (air and snow), and temperature trend (Perla, 1970; McClung, 2002; Exner and Jamieson, 2009). Other snow and weather variables which are monitored include precipitation type, new snow density, total snow depth, radiation, humidity, resistance to penetration, and surface condition.

The interaction of these factors with mountain terrain is a complex and uncertain process, and targeted education and experience are required to accurately identify existing snow instability or forecast future trends in instability and avalanche hazard.

AVIATION (HAZARDS TO)

Thomas Gerz, Ulrich Schumann
Institut für Physik der Atmosphäre, Oberpfaffenhofen, Germany

Definition

Aviation. Worldwide commercial and noncommercial flying aircraft.
Hazard. Weather condition that impacts the safe flight of an aircraft. Such conditions include phenomena as strong wind, turbulence, clear-air turbulence, wind shear, downbursts, strong convection, storms, heavy precipitation, hail, lightning, icing, snow, fog, sandstorm, volcanic ash, and aircraft wake vortices.

Introduction

Aircraft by definition move through airspace. Therefore, the natural hazards to aviation described in this section are atmospheric events, collectively called weather. The safety (and efficiency) of flight in general is most influenced by weather events. "No other industry is more sensitive to weather than the aeronautical industry" (Sprinkle and Macleod, 1991). Although weather can be observed and forecast with considerable accuracy, adverse weather still has a large impact to operational safety and efficiency. The bulk of the fatal accidents in aviation are associated with visual flight-rules general-aviation pilots in single engine fixed gear aircraft attempting to operate under instrument meteorological conditions (IMC). As the capability of the pilot (e.g., IMC qualified) and plane (e.g., multiengine with retractable wheels) increases, thunderstorms become a much more important factor in accidents (Evans, 2006). Accident and incident analyses show that there is always more than one cause. Weather very often contributes to an accident or incident even if it is not the primary cause. Nevertheless, 13% of all hull losses between 1995 and 2004 were primarily caused by weather (Boeing, 2005), and in 33% of all aviation accidents, weather was a primary or secondary factor (NTSB, 2007). Weather impacts aviation in terms of safety, efficiency, and capacity. Risks (safety) and efficiency (delays) are under certain conditions positively correlated in aviation when their common source is insufficient weather hazard awareness by the flight crew.

Phenomena such as volcanic ash and aircraft wake vortices, themselves not atmospheric hazards, are also considered here since their hazardous attributes are controlled by weather conditions, in particular wind.

When flying an aircraft from one place to another, certain atmospheric and weather conditions have to be favorable. The atmospheric state parameters have to stay within certain ranges to allow for safe aircraft attitudes, and the weather conditions have to be suitable to allow the crew to maneuver the aircraft.

Most of the weather-related accidents occur during takeoff or landing, because several weather hazards such as turbulence, down-draughts, heavy rain, and shear winds are found predominantly in the lower atmospheric levels. Moreover, due to the necessity of having to land at a certain location and on a runway in a given direction, weather hazards in that last flight phase are not able to be circumvented. Visibility and a minimum cloud ceiling are still required for a safe landing and/or takeoff. During these flight phases, the margin to stall the aircraft is at its lowest since the aircraft is flying relatively slow and at a relatively high angle of attack.

Atmospheric state parameters, flight envelope, and hazardous weather

Atmospheric state parameters include wind, temperature, pressure, and density, as well as the chemical composition of the atmosphere, dust and aerosol concentration and liquid water content. The safe operation of a specific aircraft requires that the actual state parameters, together with flight state parameters such as true airspeed, Mach number, pressure altitude, and angle of attack, lay within a certain range, usually referred to as the flight envelope of the given aircraft. For example, a certain range of air density values is required to provide the necessary lift for a given aircraft in order to fly. A typical hazard relating to this is the incorrect calculation of the cruising or maximum flight altitude of an aircraft when flying over high topography or at high temperatures. As another example, the liquid water content along the flight track may be too high, resulting in an engine flameout. Further, parts of the aircraft such as the engine blades or air inlets may be degraded, leading to substantial loss of performance of the engine up to its flameout when flying through air with a high density of sand particles (e.g., in sandstorms) or through clouds of volcanic ash or smoke from fires.

If we consider weather as the variable part of the atmospheric state parameters, suitable weather conditions mean a range of weather conditions in which aircraft are certified to fly and in which the pilot in command can safely maneuver the aircraft. One may then call "hazardous weather" situations or conditions during flight which put an aircraft outside its flight envelope or where the crew may lose control over the aircraft.

The critical "aviation-weather" events which generally reduce safety margins and facilitate the occurrence of incidents and possibly accidents can be listed as:

- Severe storms
- Fog, low clouds (causing low visibility)
- Thunderstorms and tornadoes
- Supercooled clouds (causing in-flight icing)
- Clear-air turbulence
- Sandstorms and volcanic ash
- Aircraft wake vortices

The physical features characterizing these phenomena and causing the hazard include:

- Turbulence (in clouds or in clear air)
- Wind shear, gusts, downbursts
- Lightning
- Heavy precipitation (rain, snow), hail
- Supercooled liquid water in air (with temperatures below 0°C)

Typically, wind shear and gusts, fog and heavy snow or rainfall affect the takeoff and landing phases, whereas clear-air turbulence is a characteristic en route hazard. Basic characteristics of an airport such as orientation of runways, precision landing equipment, topography, and local weather phenomena make it susceptible to certain weather events. An airport or an airspace also become more vulnerable to adverse weather when they operate at their capacity limits, in particular when the demand exceeds the capacity.

In the following sections, the text focuses on the weather hazards to aviation and identifies the related impacts. It closely follows a report by Theusner and Röhner (2006) who investigated aviation weather hazards, aviation weather impact areas, and evaluation methods in the framework of the European Integrated Project FLYSAFE (http://www.eu-flysafe.org/). The reader is also referred to the weather section of EUROCONTROL's "SKYbrary" (http://www.skybrary.aero/index.php/Weather).

Severe storms

Severe storms, such as hurricanes or typhoons in the tropics or severe storms in the mid-latitudes and polar regions, are large-scale, long-lasting, and highly energetic weather patterns. They are a general threat and, as such, can cause considerable damage also to airports, the air traffic control infrastructure, and aircraft. Today, the development and movement of large storms can be forecast with an accuracy that is high enough to allow for appropriate actions, like closing of airports, diversion of traffic to other airports, alternate flight routing, adaptation of traffic density, etc. These mitigation measures may not prevent the destruction of infrastructure but will likely save human lives.

Low visibility

Today, reduced or low visibility due to fog, clouds, rain, snow, a moonless night, a smoke plume, or a sandstorm is still the main hazardous weather condition for aviation. Controlled flight into terrain resulting from a loss of orientation due to poor visibility is one of the most frequent primary causes of accidents in aviation (Boeing, 2005). Fog, a cloud sitting on the surface, also has a significant impact

on flight operations particularly during takeoff, landing, and taxiing. The safety situation in poor visibility will improve in the future due to fully automated navigation and guidance as well as enhanced vision systems.

Thunderstorms and tornadoes

A thunderstorm (cumulonimbus with lightning) describes a cloud of strong and deep convection (vertical motion) of warm and moist air. Within thunderstorms, areas of downbursts, strong wind shear, turbulence, icing, heavy rain, hail, and lightning strikes exist simultaneously in the same volume of air or close by. All of these phenomena are a possible threat to aircraft as they can alter the aerodynamic state of flight, damage the hull or engines of the aircraft, or cause malfunctions of the onboard equipment.

A *tornado* is a violently spinning vortex of air extending down from the base of a cumulonimbus cloud and in contact with the surface, often visible as a funnel cloud. The central core of the funnel exhibits an extremely low pressure and winds surrounding the tornado typically reach 50 m/s (180 km/h). A tornado can cause considerable damage to airport and air traffic control infrastructure if it touches down on an aerodrome and, clearly, any aircraft caught on the ground in the path of a tornado will most likely be damaged beyond repair.

Lightning

Lightning is a transient, high-current electric discharge over a path length of several kilometers in the atmosphere (Betz et al., 2009). The majority of lightning in Earth's atmosphere is associated with convective thunderstorms. Lightning is the result of a breakdown of electrical charge separation in thunderstorms. Charge separation is strongest in powerful updrafts containing supercooled liquid water, ice crystals, and hail or graupel. The lightning discharge in its totality is called a flash. One distinguishes between cloud-to-ground lightning and various other lightning types, including intracloud, intercloud, and cloud-to-air lightning.

Most lightning strikes to aircraft (90% of events) are triggered by the intrusion of the aircraft into a region of the thunderstorm where the electrostatic field is sufficiently strong. The other case may be the interception by the aircraft of a branch of natural lightning. An aircraft passing close to an area of charge can initiate a discharge, and this may also occur some distance from a thunderstorm. Lightning also occurs within clouds of volcanic ash, again because of the vertical movement and collision between particles within the cloud which generates static charge.

Physical damage by a lightning strike to an aircraft is rare and not likely to threaten the safety of the aircraft. Damage is usually confined to parts of the avionics system, aerials and compasses, and the burning of small holes in the fuselage. There is, however, a potential for engine shutdown caused by the transient airflow interruption associated with lightning.

Lightning strikes from cloud to ground are dangerous for humans on the ground and in the area. Therefore, airport ground operations including baggage handling or refueling of the aircraft have to be suspended when a lightning strike has been observed within a radius of 5 km of an airport.

Downburst or microburst and wind shear

A downburst or microburst is created by an area of significantly rain-cooled, descending air (downdraught) that, after hitting ground level, spreads out in all directions producing strong and rapidly changing winds (wind shear). Surrounding dry air is mixed into the rain fall region which causes the rain to evaporate. The process of evaporation cools the air which then becomes heavier than the surrounding air, and thus, descends even faster. Microbursts normally cover an area of approximately 4 km in diameter, although the area of resulting high winds, created when the microburst hits the ground, can be much larger. Winds of up to 65 m/s (240 km/h) may result when a microburst is formed. Most microbursts last for a few minutes, and generally less than 10 min. Microbursts can occur also in rain showers or virga. (Virga is rain that evaporates before it reaches the ground and is associated with a "dry" microburst.)

Severe wind shear is a rapid change in wind direction and/or velocity and causes horizontal velocity changes of at least 15 m/s over distances of 1–4 km, or vertical speed changes greater than 2.5 m/s. Close to the ground, where the impact upon safety is largest, the phenomenon is called low-level wind shear. The terms "microburst" and "wind shear" are often used interchangeably because the vast majority of dangerous wind shears result from microbursts.

Downbursts can be an extreme hazard to aircraft during the landing and takeoff phases of flight, since an aircraft flying through a microburst may experience extremely hazardous fluctuations in airspeed and lift. Roughly 50% of all microbursts are truly hazardous to aircraft (Chambers, 2003). Although the downdraught region from a microburst can be dangerous to an aircraft by itself, the greatest threat comes from the change in wind direction – or wind shear – near the center of the microburst which may result in a corresponding loss of airspeed: An aircraft approaching a downburst will first encounter a strong headwind often combined with a turbulent upward motion which leads to an increase in indicated airspeed and lift. The temptation to reduce the power of the engines would be very dangerous because soon the aircraft enters the downdraught area, forcing the aircraft downward, and finally, as the aircraft has passed through it, the wind becomes a tailwind where the indicated airspeed decays and the lift drops even further. Once caught in a downburst, escape is only possible by flying straight ahead; whichever way the aircraft turns, it will encounter the tail winds and the associated performance impact.

Hail and heavy rain

Hail develops in thunderstorm clouds in several steps and cycles. When rising moist warm air becomes saturated and liquid water particles form, these particles continue to be carried upward by the updraught. When they rise beyond the freezing level, they start to turn to ice. These small ice

particles, due to their shape and weight, rise slower or even descend where they meet and melt with water droplets (coalescence). They may again be carried upward by strong updraughts in the cloud, freezing again to become an ice pellet or hail. The cycle repeats and the ice pellets grow each time until the cumulonimbus becomes mature. Then the updraughts weaken and are insufficient to carry the weight of the ice pellets which fall out of the cloud, start to melt, and reach the ground as large rain drops (heavy precipitation) or still in solid form as hail.

Hail pellets may grow to a size larger than a golf ball and can cause considerable damage to aircraft whether on ground or in the air. Other precipitation, such as snow, sleet, or rain, may contaminate airfield and runway surfaces creating a hazard to aircraft attempting to take off or land. Heavy rain can result in the flameout of an engine.

In-flight icing

In-flight icing is the accretion of ice on an aircraft structure, its engines or the air inlets as a result of flight in atmospheric icing conditions. Airframe icing can lead to reduced performance, loss of lift, altered controllability and ultimately stall and subsequent loss of control of the aircraft. Longitudinal stability may also be affected by a degradation of the tail control surfaces. The modified airflow pattern may significantly alter the pressure distribution around flight control surfaces such as ailerons and elevators which can severely affect flight. Blockage of the air inlet to any part of a pitot static system can produce errors in pressure instruments such as altimeters, airspeed indicators, and vertical speed indicators.

Water in the air continues to exist in liquid form well below 0°C and is typically observed in stratus clouds, convective clouds embedded in stratus clouds, or in cumulonimbus clouds. This considerable quantity of "supercooled" water steadily decreases with lower temperature until most has frozen at about −40°C. Ice accretion can be defined as (1) the freezing of supercooled liquid cloud droplets after impacting the cold surface of an aircraft, (2) liquid drops freezing on the supercooled aircraft, or (3) the accumulation of solid particles like snowflakes and ice crystals by melting and refreezing to warm or wet parts of the aircraft.

Icing is observed in the atmosphere in the temperature range between −40°C and +6°C. (Carburettor icing on piston engines can occur at positive air temperatures due to expansion and subsequent cooling of air.) The size of supercooled water droplets and the nature of the airflow around the aircraft surface determine how many of the droplets will impact the surface. The size of a droplet also determines what happens after impact, for example, larger droplets tend to splash and break up into smaller ones. Finally, the size is related to the mass of water in the droplet, which determines the time required for the physical state change. Larger droplets which do not break up into smaller ones will take longer to freeze and can form a surface layer of liquid water before freezing takes place.

Small cloud droplets with diameters of approximately 20 μm impact the aircraft and freeze immediately to an opaque coating of the impact area (rime ice). Larger drizzle drops (50–500 μm), also called supercooled large drops (SLD), take longer to freeze and form clear ice. The larger the droplets and the slower the freezing process, the more transparent is the ice. If the freezing process is sufficiently slow to allow the water to spread more evenly before freezing, the resultant transparent sheet of ice may be difficult to detect. Furthermore, SLD do not freeze completely when impacting the leading edge of the wing (like the 20 μm sized cloud drops do), but they remain liquid long enough to flow back across the wing chord for up to 1 m and freeze there, potentially outside the area covered by de-icing equipment (runback ice). Freezing rain drops (>500 μm) finally originate from rain drops which fall through a supercooled layer of air before impacting the aircraft. If such a layer of air reaches the ground, it results in freezing rain at the surface and all runways and airport buildings and structures are affected.

In-flight icing is observed more in winter than in summer because of the generally lower air temperatures in winter. Icing mainly affects turboprop and small aircraft, since they usually cannot climb high enough to fly above the clouds and, therefore, spend a large fraction of flight time inside the clouds. Also, small aircraft can remove ice only pneumatically by so-called rubber boots, since such systems consume less energy than thermal ones that are used by larger aircraft to melt away the ice using hot exhaust gases.

The special risk emanating from freezing drizzle is that aircraft are only tested for average drop sizes of up to 50 μm (FAA, 1999). Though aircraft comply with international certification regulations, they are not necessarily qualified for all types of icing conditions. SLD therefore pose a special risk also because the atmospheric conditions leading to their occurrence are not well known and even more difficult to forecast.

Turbulence

The irregular fluctuation of the wind is called turbulence. It originates from thermal or mechanical forces and may occur either within a cloud or in clear air (clear-air turbulence, CAT). Turbulence is patchy and intermittent. The absolute severity of turbulence depends directly upon the rate at which the wind vector is changing; however, the perception of the severity of the turbulence is also affected by the inertia and hence the mass of the encountering aircraft. Significant mechanical turbulence, most often as CAT, results from the airflow over irregular terrain (combined with mountain waves) or obstacles and also occurs in certain regions of the jet stream at cruising level. Thermally induced turbulence arises from air movements associated with convective activity, especially in or near deep convection like a thunderstorm where it may occur inside or outside the cloud. Also zones of downbursts and wind shear are always accompanied by turbulence.

Turbulence is graded on a relative scale, according to its perceived or potential effect on a "typical" aircraft, as "light," "moderate," "severe," and "extreme." Light

turbulence results in slight, erratic changes in attitude and/or altitude of the aircraft. Moderate turbulence has similar effects as light turbulence, but of greater intensity – variations in speed as well as altitude and attitude may occur, but the aircraft remains in control all the time. Severe turbulence is characterized by large, abrupt changes in attitude and altitude with large variations in airspeed. There may be brief periods where effective control of the aircraft is impossible. Loose objects may move around the cabin and damage to aircraft structures may occur. Extreme turbulence is capable of causing structural damage and a loss of control of the aircraft.

Even though turbulence is seldom damaging to modern aircraft, which are designed to withstand associated stresses, it is the leading cause of in-flight nonfatal accidents of passengers and flight attendants. Whereas turbulence in the context of clouds can be "seen" and respective measures can be taken, there is currently no effective warning system for clear-air turbulence. In June 1995, the FAA issued a public advisory to airlines urging the use of seat belts at all times when passengers are seated as a precaution against unexpected turbulence (FAA, 1997). Nevertheless, the number of turbulence accidents per million departures (USA carriers) has increased markedly between 1982 and 2003 (FAA, 2005) and cannot be explained by the increase in air traffic volume alone. Instead, load factors might be the controlling factor, too.

Convective turbulence

Convective turbulence is a phenomenon that can be found throughout the troposphere in the vicinity of convection of varying strength. It can be found in the planetary boundary layer (the lower few hundred meters of the Earth's atmosphere) where it is especially dangerous as the aircraft usually are in the stages directly prior to landing or directly after takeoff at that altitude and are flying at low speeds (risk of stalling). Any turbulence enforced change in altitude therefore bears the risk of collision with terrain.

In mid-level shower clouds and shallow convection, turbulence usually does not pose a serious risk to the aircraft itself. It does, however, reduce the flight comfort of the passengers and may even lead to serious injuries, if no seat belt is worn, which is usually the case for cabin attendants. The typical up- and downdraught speeds are of the order of up to ± 5 m/s.

The real threat to aircraft is convective turbulence found in thunderstorms. There, updraughts of up to +65 m/s and downdraughts of -25 m/s can exist in close proximity. The strong wind shear and turbulence induced by these draughts is a serious safety hazard for passengers and also the structural integrity of aircraft. Turbulence can not only be found within the convective systems, but convection can induce turbulence far away from the originating systems through the excitation of gravity waves.

Clear-air turbulence, CAT

Patches or regions of turbulence without the presence of clouds at high altitudes (usually above 4,500 m) are referred to as clear-air turbulence (CAT). Its sudden appearance in an otherwise calm and clear atmosphere is mostly a safety and convenience problem for passengers. Nevertheless, CAT can also become a safety problem for the structural integrity of the aircraft, for example, if inappropriate movements of the elevators or rudders are performed. Turbulence also leads to frequent load alternation and, consequently, to structural loads with resulting material fatigue.

CAT develops mostly in the vicinity of jet streams, above and below the wind maximum, where the wind shear is strongest. The three ingredients of jet stream curvature, upward vertical moist convection (from, e.g., thunderstorms), and cold air advection together dramatically increase the risk of severe, possibly accident-producing CAT (Kaplan et al., 2005). Another important source for CAT is by breaking gravity waves above mountain ranges and above convective weather systems.

Dust storms and volcanic ash

A dust storm is a cloud of blowing very fine sand or dust. The sediment is lifted by the wind when it exceeds the threshold speed necessary to lift and transport the surface particles. Dust storms can be created by an advancing gust front ahead of a cumulonimbus cloud (typical in the Sahara desert) or along a cold front where cool air, passing over hot ground, creates instability in the air above (typical in the midwest of the USA). The height of the dust "wall" can be roughly 2 km, but with the support of updraughts in an unstable atmosphere, the dust can reach heights of 6 km. The sediment significantly reduces visibility and its ingestion into engines, pitot static system, conditioning packs causes blockage and erosion.

Volcanic ash clouds are clouds of very small particles of rock ejected from a volcano during an eruption. Large quantities of material can be ejected into the atmosphere during an eruption; the smaller particles reach great heights where they are transported horizontally by the wind. Since moist deposition processes and sedimentation are slow, the small particles can remain for a long time at aircraft cruising levels and, thus, a threat to aviation. The ash does not show up on an aircraft's weather radar because of the small size of the particles. These particles conduct electricity, and the electrical charges within a cloud of volcanic ash can give rise to thunder and lightning. St. Elmo's fire, created when the charged particles hit the aircraft, may be the first indication to a crew that they are flying into volcanic ash clouds. Other indications are the smell of sulfur and dust in the cabin.

The rock particles cause significant damage to the surface of the aircraft skin and engine components. Rock particles entering a jet engine can, if the inlet temperature is hot enough, melt and/or burn leaving deposits which clog the engine and may result in engine surges and ultimately flameout.

Aircraft wake vortices

Wake vortices shed by an aircraft are a natural consequence of its lift. The vortices can be described as two coherent counterrotating swirling flows, like horizontal tornadoes, of about equal strength. Each vortex has a strong circulation, which is proportional to the weight and inversely proportional to the speed of the aircraft, and a significant size in the order of the wing span. The vortices are transported by the wind and sink downward due to mutual velocity induction. The vortices generally persist for between one and three minutes, sometimes much longer. They decay due to turbulent mixing processes in the atmosphere. The calmer the atmosphere the longer the life time of the vortices (Gerz et al., 2002). Decay is faster in the atmospheric boundary layer in turbulent conditions and slower in the free atmosphere at cruising level.

Mature aircraft wake vortices can produce a significant rotational or structural influence on an aircraft encountering them for several minutes after they have been generated. Especially, during an aircraft's critical landing phase, the vortices can endanger any aircraft following close behind. Today, wake vortices are a capacity issue rather than a safety problem because a following aircraft must maintain a safe distance from a landing aircraft up ahead of it to avoid wake-vortex encounters. But in the light of increasing air traffic, airspace becomes a limiting factor, en route but even more in the vicinity of airports. Hence, in the future, wake vortices may become a safety issue, too.

Conclusions

Hazards to aviation are weather hazards. An abrupt or vigorous change of the atmospheric state parameters (wind, temperature, pressure, density, liquid water content, dust, and aerosols) may lead to a hazard when it results in an unfavorable attitude of the aircraft, or in a lack of awareness of the crew maneuvering the aircraft, or both.

Safety, efficiency, and capacity of aviation are influenced by weather. Risks and delays have a common source: insufficient weather hazard awareness. Our skills to observe and forecast weather with high accuracy and our ability to communicate worldwide within seconds from ground to air, air to air, and air to ground will be combined to build new expert systems for aviation weather. The situational awareness of pilots and controllers regarding weather will be enhanced when all actors perceive the coming threat by consistent, tailored, dedicated, unambiguous, and timely weather information. Flights will become safer when all (re-)act according to that information and avoid the hazard.

AVULSION

Joann Mossa
University of Florida, Gainesville, FL, USA

Synonyms

Channel abandonment; Channel shifting; Diversion

Definition

Avulsion is recognized as an abrupt change in the course of a stream.

Background

An avulsion is when a river channel switches location, often abruptly, along part of its course. Avulsions are characteristic of fluvial and deltaic environments, including alluvial fans and rivers with multiple channels. Partial or complete abandonment of the active channel results in an inactive channel or a channel with substantially less flow. Avulsions usually occur during floods, either through levee breaching via lowlands or occupying a preexisting channel with which it is connected. Frequency, spatial scale, and causes vary widely depending on the type of river and environmental setting (Jones and Schumm, 1999; Slingerland and Smith, 2004; Stouthamer and Berendsen, 2007). Human activities may cause or promote avulsions where levees have been destroyed during floods, intentionally harming some areas with the aim to protect others, and during wartime, with the intent to create havoc. Excavated pits on mined floodplains create a landscape vulnerable to avulsions during overbank flooding (Mossa and Marks, 2011). Also, avulsion frequency may increase inadvertently from dam-building (Ethridge et al., 1999).

Avulsion hazards

The redistribution of discharge and sediment, and associated channel geometry change, can be hazardous in a number of ways. Where the channel is abandoned, hazards include loss of water supply, navigational benefits, increased coastal land loss, and loss of connections to irrigation canals. A potentially catastrophic avulsion of the Mississippi River into the Atchafalaya River in south Louisiana was averted in the mid-1900s. As the Atchafalaya received increased amounts of flow, it threatened New Orleans' water supply and major ports there and in Baton Rouge. Flow control structures were built near the juncture of these rivers to control diversion and prevent an avulsion from occurring; one of the first structures was partially undermined in the 1973 flood and subsequently two other diversions were built.

The new path that the channel now occupies experiences other hazards. Sudden flooding is a considerable danger as has happened repeatedly on the Yellow River in China (Slingerland and Smith, 2004) and in lowland Bangladesh. Economic costs of avulsions include property loss and subsequent homelessness, damage to bridges and infrastructure, ecosystem losses, and engineering mitigation such as artificial levee building to protect new floodplains.

BASE SURGE

Catherine J. Hickson
Magma Energy Corp., Vancouver, BC, Canada
Alterra Power Corp., Vancouver, BC, Canada

Synonyms

Blast; Ground-based surge; Ground surge; Pyroclastic density flow; Pyroclastic surge; Surtseyan eruption

Definition

A destructive, dilute, fast-moving (30 m/s) turbulent density current (flow) of particles and gas and/or liquid that is the result of an explosion.

Discussion

Base surges are highly destructive and dangerous (Nakada, 2000). The term has been used to describe high-velocity (up to 30 m/s) flows of material emanating from explosions. The term was first used to describe the ground-hugging clouds observed after underwater and underground nuclear explosions (e.g., Trinity Atomic Web Site). In photographs of nuclear explosions, there is a characteristic ring-shaped cloud that moves outward close to the ground – the base surge (Trinity Atomic Web Site Figure 2.97). It was first documented at the eruption of Capelinhos volcano, Azores October 10th, 1957 and then adopted by the volcanological community based on the work of James G. Moore (1966a, b) and his observations of the eruption of Taal volcano in the Philippines. Moore adopted the term "base surge" to describe phreatic to phreatomagmatic explosions and their fine grained (pulverized, broken clasts), bedded deposits. The term has become synonymous with "Surtseyan eruptions" which are phreatomagmatic (hydromagmatic). From these early observations, the term has been used in a number of ways making a precise definition in volcanological literature problematic. The term has also been used to describe the turbulent, dilute flow fronts visible in pyroclastic flows. Thus, the usage of the term now spans cold, wet, phreatic explosions, to moderate temperature wet phreatomagmatic (or hydromagmatic) explosions (usually now referred to as "pyroclastic surges") to the basal portions of hot, dry pyroclastic flows. Work by Sulpizio et al. (2008) and others using large-scale experiments show the continuum and the use of the term "pyroclastic density current" (PDC) has now become more common. In all cases (wet or dry), the explosive discharges can be extremely vigorous and will propel eruption plumes of particles and gases many kilometers into the air. The resultant surges can sculpt the landscape by being highly erosive near source, stripping and scouring underlying soils and vegetation and more distally, depositing material as pyroclastic surge (base surge) deposits.

BEACH NOURISHMENT (REPLENISHMENT)

Charles W. Finkl
Florida Atlantic University, Boca Raton, FL, USA

Synonyms

Renourishment; Replenishment; Restoration

Definition

Beach nourishment is the artificial placement of sand on an eroded shore to stabilize the shoreline position and provide protection from shoreline retreat and coastal flooding. This multipurpose procedure provides coastal protection, habitat, and recreation sites in an attempt to mitigate coastal erosion hazards. Replacement of sand lost to erosion can take place naturally (e.g., by alongshore littoral transport or onshore sand movement) or artificially (e.g., by deposition of sediment dredged from offshore or mined inland).

History and procedures

The term *beach nourishment* came into general use after the first renourishment project in the United States at Coney Island in 1922 (Dornhelm, 1995). In engineering parlance, the terms *beach (re)nourishment*, *beach replenishment*, and *beach restoration* are often used more or less interchangeably in reference to the artificial (mechanical) placement of sand along an eroded stretch of coast where only a small beach, or no beach, previously existed. There are, however, subtle connotations in the application of each term (Finkl and Walker, 2002, 2005), as described below.

Sediments that accumulate along the shore in the form of beaches are naturally derived from a variety of sources including fluvial transport in rivers to deposition of sediments in deltas, from preexisting sediments on the offshore seabed, from chemical precipitates (e.g., oolites on carbonate banks in tropical and subtropical environments), or from organisms living along the shore (e.g., shells and exoskeletons from marine organisms). When the natural sediment supply is interrupted, beaches become sediment-starved and the shoreline retreats landward due to volume loss. Efforts to artificially maintain beaches that are deprived of natural sediment supply thus attempt to proxy nature and (re)nourish the beach by mechanical placement of sand. The beach sediment is thus *replenished* by artificial means. *Beach restoration* implies an attempt to restore the beach to some desired previous condition. A nourished or *constructed beach* could be placed along a previously beach-less shore, whereas a restored beach is revitalized by the mechanical placement of sediment. Beach nourishment projects involve placement of sand on beaches to form a *designed structure* so that an appropriate level of protection from storms is achieved. The placement of sand is commonly by methods involving dredging sand from borrow areas on the seafloor (e.g., Finkl et al., 1997), bypassing sand around deepwater inlets or other obstructions (e.g., groins) along the coast that interrupt the littoral drift, or trucking sand from inland quarries to the coast. Pumping sand from offshore is the most widespread method of application due to the large volumes of sediment that are required to combat erosion hazards.

Along undeveloped shores, beaches provide natural habitat (e.g., nesting grounds for sea turtles and shorebirds) but on developed shores, beaches additionally protect coastal infrastructure from storms and are important recreational sites for a globally expanding tourist industry. When beaches are degraded by decreased width and lowering of berms, many communities choose to replace lost sediment by pumping beach quality sand from offshore to eroded sites onshore. Sand artificially placed on an eroded shore is sacrificial in the sense that it must be periodically replaced as erosion progresses in order to provide coastal defense. The beach is thus said to be renourished, replenished, or restored.

Beaufort Wind Scale, Table 1 Beaufort scale of wind

Beaufort Number	Descriptive term	Velocity equivalent at a standard height of 10 m above open flat ground				Specifications			Probable wave height* in metres	Probable wave height* in feet
		Mean velocity in knots	ms^{-1}	$km\ h^{-1}$	m.p.h.	Land	Sea	Coast		
0	Calm	< 1	0–0.2	< 1	< 1	Calm; smoke rises vertically	Sea like a mirror	Calm	—	—
1	Light air	1–3	0.3–1.5	1–5	1–3	Direction of wind shown by smoke drift but not by wind vanes	Ripples with the appearance of scales are formed, but without foam crests	Fishing smack just has steerage way	0.1 (0.1)	¼ (¼)
2	Light breeze	4–6	1.6–3.3	6–11	4–7	Wind felt on face; leaves rustle; ordinary vanes moved by wind	Small wavelets, still short but more pronounced; crests have a glassy appearance and do not break	Wind fills the sails of smacks which then travel at about 1–2 knots	0.2 (0.3)	½ (1)
3	Gentle breeze	7–10	3.4–5.4	12–19	8–12	Leaves and small twigs in constant motion; wind extends light flag	Large wavelets; crests begin to break; foam of glassy appearance; perhaps scattered white horses	Smacks begin to careen and travel about 3–4 knots	0.6 (1)	2 (3)
4	Moderate breeze	11–16	5.5–7.9	20–28	13–18	Raises dust and loose paper; small branches are moved	Small waves, becoming longer; fairly frequent white horses	Good working breeze, smacks carry all canvas with good list	1 (1.5)	3½ (5)
5	Fresh breeze	17–21	8.0–10.7	29–38	19–24	Small trees in leaf begin to sway; crested wavelets form on inland waters	Moderate waves, taking a more pronounced long form; many white horses are formed (chance of some spray)	Smacks shorten sail	2 (2.5)	6 (8½)
6	Strong breeze	22–27	10.8–13.8	39–49	25–31	Large branches in motion; whistling heard in telegraph wires; umbrellas used with difficulty	Large waves begin to form; the white foam crests are more extensive everywhere (probably some spray)	Smacks have double reef in mainsail; care required when fishing	3 (4)	9½ (13)
7	Near gale	28–33	13.9–17.1	50–61	32–38	Whole trees in motion; inconvenience felt when walking against wind	Sea heaps up and white foam from breaking waves begins to be blown in streaks along the direction of the wind	Smacks remain in harbour and those at sea lie to	4 (5.5)	13½ (19)
8	Gale	34–40	17.2–20.7	62–74	39–46	Breaks twigs off trees; generally impedes progress	Moderately high waves of greater length; edges of crests begin to break into the spindrift; the foam is blown in well-marked streaks along the direction of the wind	All smacks make for harbor, if near	5.5 (7.5)	18 (25)

Beaufort Wind Scale, Table 1 (Continued)

Beaufort Number	Descriptive term	Velocity equivalent at a standard height of 10 m above open flat ground				Specifications			Probable wave height* in metres	Probable wave height* in feet
		Mean velocity in knots	ms^{-1}	$km\ h^{-1}$	m.p.h.	Land	Sea	Coast		
9	Strong gale	41–47	20.8–24.4	75–88	47–54	Slight structural damage occurs (chimney pots and slates removed)	High waves; dense streaks of foam along the direction of the wind; crests of waves begin to topple, tumble and roll over; spray may affect visibility	—	7 (10)	23 (32)
10	Storm	48–55	24.5–28.4	89–102	55–63	Seldom experienced inland; trees uprooted; considerable structural damage occurs	Very high waves with long overhanging crests; the resulting foam, in great patches, is blown in dense white streaks along the direction of the wind; on the whole, the surface of the sea takes on a white appearance; the tumbling of the sea becomes heavy and shocklike; visibility affected	—	9 (12.5)	29 (41)
11	Violent storm	56–63	28.5–32.6	103–117	64–72	Very rarely experienced; accompanied by widespread damage	Exceptionally high waves (small and medium-sized ships might be for a time lost to view behind the waves); the sea is completely covered with long white patches of foam lying along the direction of the wind; everywhere the edges of the wave crests are blown into froth; visibility affected	—	11.5 (16)	37 (52)
12	Hurricane	64 and over	32.7 and over	118 and over	73 and over	—	The air is filled with foam and spray; sea completely white with driving spray; visibility very seriously affected	—	14 (—)	45 (—)

*This table is only intended as a guide to show roughly what may be expected in the open sea, remote from land. It should never be used in the reverse way; i.e., for logging or reporting the state of the sea. In enclosed waters, or when near land, with an off-shore wind, wave heights will be smaller and the waves steeper. Figures in brackets indicate the probable maximum height of waves.

Definition

An empirical measure (0–12) for describing the force (speed) of the wind.

Discussion

The Beaufort scale of wind speed, which is displayed in the accompanying table, provides an ordinal scale for wind speed that ranges from 0 to 12 and is based on visual estimates (Table 1). It is named after Admiral Sir Francis Beaufort who developed the measure as a young naval officer and later introduced it for use by the British navy. In 1853, it was adopted for international use. Kinsman (1969), List (1951: p. 119), and WMO (1970) document the history.

Experienced observers will regularly estimate the same Beaufort number for the same wind. There is less agreement on the actual wind speed to which this corresponds. The wind speed conversions presently in use (WMO, 1995) are based on measurements taken 10 m above the ground of the Scilly Isles by Dr. G.C. Simpson in 1906. His formula relates wind speed V (in m/s) and Beaufort number B by V = 0.836*B^1.5.

As noted from the formula, the Beaufort scale relates wind speed and the Beaufort number. The scale officially ceases at Beaufort number 12, which equates to hurricane force winds (above 33 m/s). The WMO manual of codes provides a guide to conditions that may be expected from a particular Beaufort number.

There have been attempts to extend the Beaufort scale beyond 12 up to Beaufort number 16, so as to describe tornadoes and hurricanes. It is, however, more usual to measure tornadoes using the Fujita scale, and hurricanes with the Saffir–Simpson scale.

Synonyms

Biblical disaster; Biblical hazard

Definition

Biblical disaster. As described in the Christian Bible, but also in other non-Christian, influential texts, a Biblical disaster is an extraordinary disruption resulting in massive human suffering. Usually represented by a natural occurrence such as a flood, earthquake or plague, the event symbolizes God's displeasure with humanity, demonstrates God's supremacy and timelessness, or reveals aspects of the End Time (Christian eschatology). Each of these aspects, perhaps simplified as *punishment*, *power*, and *prophecy*, varies in interpretation (allegorical versus literal) among Christian followers.

Introduction

The need to explain natural hazards and their impact upon humans extends across societies, time, and geographic location (Taylor, 1978; Hoffman and Oliver-Smith, 1999). Differing explanations have been identified and include the naturalistic, fatalistic (chance), and supernaturalistic (Dynes and Yutzey, 1965). The latter holds a supernatural power, typically a Deity, as responsible for the event. The persistent reference to disaster as an *act of God* or *bolt from the blue* confirms this link with religion (Mitchell, 2000; Steinburg, 2000; Harbaugh, 2001) and has been used in the legal arena to excuse human culpability. Although disaster events appear within the many important texts of other faith traditions (Schmuck, 2000), the Christian Bible makes use of "Biblical events" or "Biblical disasters" in a variety of ways, often as a show of God's power or his plan for Earth. Most references are far from subtle; in fact, describing an event today as one of "Biblical proportions" conjures a notion of something quite large, direct, and significant.

Regarding the topic of disaster, as well as many others, controversy and debate exist within the Christian church over the timing and order of certain events and whether a literal or figurative interpretation of Scripture is appropriate. An additional confound is the numerous translations of the Bible, with a dozen plus available in English alone. For ease, here, all scripture cited is from the *New International Version*. The Apocrypha (e.g., Gospel of Thomas), the Septuagint (e.g., Sirach), and other non-Christian texts were not considered for these examples, but also are worthy of inspection (see, e.g., Sirach 41:9).

Punishment

For some Christians the God of the Old Testament differs from his depiction in the New Testament. The former is vengeful, the latter is forgiving. Whereas Christians acknowledge that the God of all Biblical books is the same, the oft portrayal of God as cause of disaster in the Old Testament lends itself to this dualistic view. Several passages of the Bible call attention to God as punishing humanity for its disobedience or acts of evil. The fact that humans face natural hazards at all can be initially ascribed to the Fall (Genesis 3:17–19) where the disobedience of Adam and Eve brought about a difficult life for them and their descendants.

Perhaps the best known story is of the Flood, a global catastrophe brought about by wickedness and evil. As written in Genesis 6:13, 17, "so God said to Noah, "I am going to put an end to all people, for the earth is filled with violence because of them. I am surely going to destroy both them and the earth . . . I am going to bring floodwaters on the earth to destroy all life under the heavens, every creature that has the breath of life in it. Everything on earth will perish." The Bible is far from alone, here, as other ancient texts, such as *The Epic of Gilgamesh*, also recount large flood events. Proof of a great deluge as a historic event remains of interest to both religionists and scientists (Ryan and Pitman, 2000).

In another example from Genesis (19:1–29), the cities of Sodom and Gomorrah are destroyed when ". . .the Lord rained down burning sulfur on Sodom and Gomorrah – from the Lord out of the heavens" (v. 24). But this "angry" God also rescues his people by bringing catastrophe upon their enemies. Exodus 7–10 recounts the plagues of frogs, flies, and hail, among others that befall the Egyptian captors of the Israelites. The Red Sea is parted (a reverse flood?) to allow the chosen to escape and then set back in its regular course to drown the pursuers. God is shown as capable of enacting disaster *and* controlling the events set in motion.

Supernatural interpretations of disaster intersperse human history beyond these Biblical accounts. The Lisbon earthquake, tsunami, and fire of November 1 (All Saints Day), 1755, is an excellent example (Dynes and Yutzey, 1965; Shrady, 2008). John Wesley, founder of Methodism, published the tract *Serious Thoughts occasioned by the late Earthquake at Lisbon*. Within he faulted human misbehavior and the Portuguese inquisition (a telling stab at Catholicism) for the earthquake, even noting that "men of fortune" without faith could find no comfort (de Boer and Sanders, 2004). Although proclamations of this type have generally lessened over time, some religious commentators today continue to explain disaster in terms of human "decadence," for example, making connections between Hurricane Katrina (2005) and homosexual behavior and the Haitian earthquake (2010) and voodoo. The Biblical allegory is this: a lack of faith and/or right behavior leads to a poor foundation unable to withstand rains, winds, or flood (Matthew 7:24–27).

Power

Another representation is the natural event designed as a show of God's power. The ultimate example is at the very beginning with the Creation story where chaos surrenders to order. Light is separated from darkness, mountains are hewn, waters are gathered, and Earth is populated. The theme of God in control of all nature extends through his Old Testament prophets up to the work of his Son (Jesus) in the New Testament. A passage from Luke 8 (also Mark 4:35–41 and Matthew 8:23–27) is illustrative:

> One day Jesus said to his disciples, "Let's go over to the other side of the lake." So they got into a boat and set out. As they sailed, he fell asleep. A squall came down on the lake, so that the boat was being swamped, and they were in great danger. The disciples went and woke him, saying, "Master, Master, we're going to drown!" He got up and rebuked the wind and the raging waters; the storm subsided, and all was calm. "Where is your faith?" he asked his disciples. In fear and amazement they asked one another, "Who is this? He commands even the winds and the water, and they obey him." (v. 22–25)

As this text illustrates, Jesus' power is above that of the "natural," physical world. The storms of the natural world and the storms that rock the spiritual boats of humanity both have the same master.

Later, an earthquake is felt at the death of Jesus (Matthew 27:51: "At that moment the curtain of the temple was torn in two from top to bottom. The earth shook and the rocks split"). In neither this nor the previous example does the event rise to the level of disaster; no one is hurt and property remains intact. But the supremacy of God over all things, including a tumultuous natural world, is unquestionable. This, however, opens up an enduring debate among Christian followers: how to reconcile an all-knowing, powerful, and *loving* God with human suffering (Chester and Duncan, 2009).

Prophecy and prediction

Biblical disasters also emerge within both Old and New Testament discourses about the End Time (see the Books of Daniel or Revelation). Christian eschatology is the study of the beliefs that surround final events, including the Second Coming of Christ and Armageddon. Several historic examples exist where theologians, other thinkers, and even the laity have attempted to draw parallels between disaster events and Biblical prophecy, but Biblical passages also are used to explain the occurrence of contemporary disaster events. For example, in Revelation 8:11 the text reads ". . .the name of the star is Wormwood. A third of the waters turned bitter, and many people died from the waters that had become bitter." An arguably loose translation of *Wormwood* in Ukrainian is "*polyn* . . . a very close botanical cousin to *chornobyl*" (Mycio, 2005). Suddenly, the nuclear accident at Chernobyl (1986) took on prophetic meaning for some Christian believers. Prophetic visions are not the sole purview of Christians as in

this case the seer Nostradamus is also credited with a Chernobyl prediction.

Other present challenges on Earth have been interpreted Biblically. From Jeremiah 47:2: "See how the waters are rising in the north; they will become an overflowing torrent. They will overflow the land and everything in it, the towns and those who live in them. The people will cry out; all who dwell in the land will wail." For a few the rising waters from the north refer to glacial ice melt as a result of global climate change, specifically from human-induced warming. Irrespective of prophecy, this reading is also compatible with creation-care, a growing environmental stewardship movement within Christianity where believers focus on how "God so loved the *world*" (John 3:16; author emphasis), not just the human part of it.

Another common reference to the End Time specifically uses disaster as a sign. From Matthew 24:7 (and its Gospel parallels Luke 21:11 and Mark 13:8), we read that "nation will rise against nation, and kingdom against kingdom. There will be famines and earthquakes in various places." How to read contemporary events as signs within this prophecy is challenged by a later passage in the same entry: "No one knows about that day or hour, not even the angels in heaven, nor the Son, but only the Father." (Matthew 24:36).

Biblical disasters are part of an ongoing story in Christianity, reflected not only in Biblical text but also in the present and the future. Punishment, power, and prophecy are among the most recognizable themes. But for many Christians, especially aid societies, Biblical events also provide direction to help people mitigate, prepare, respond, and rebuild (i.e., the emergency management cycle). Davis and Wall (1992) provide several examples: Noah exhibited preparedness before the Flood (Genesis 6:13–22); relief for famine is detailed in Acts 11:27–30; Jerusalem is rehabilitated and reconstructed following disaster (Nehemiah 6:15); and starvation is mitigated in Egypt with the storage of food (Genesis 41:34–36). As the perception of disaster varies between Christian faith groups (Mitchell, 2000), among other religions, and among the unchurched, a delicate balance is needed. Within the scientific realm the notion of an *act of God* has been replaced by a demoralized nature, yet "religion is an essential element of culture and must be carefully considered in the [disaster] planning process, and not simply dismissed as a symptom of ignorance, superstition and backwardness" (Chester, 2005). In other words, hazard protection efforts will be more effective when respect is given to cultural beliefs. As such, the historic Biblical disaster event does bear on the present.

BODY WAVE

Zhengwen Zeng[1], Lin Fa[1,2]
[1]University of North Dakota, Grand Forks, ND, USA
[2]Xi'an Institute of Post and Telecommunications, Xi'an, Shaanxi, China

Synonyms

Seismic waves

Definition

Seismic waves that travel through the entire earth.

Discussion

Body waves are defined as waves that travel through the body of a medium, as opposed to surface waves that travel near the surface of the medium. They follow ray paths bent by the varying density and modulus (stiffness)

of the medium. The density and modulus, in turn, vary according to temperature, composition, and phase. This effect is similar to the refraction of light waves. Seismic waves are body waves, and they are the primary means of transferring information regarding the Earth's interior. Main kinds of body waves are the *P*-wave and the *S*-wave.

The mediums of Earth's interior are generally considered as isotropic or transversely isotropic. A transversely isotropic medium with a vertical axis of symmetry is called a VTI medium.

P-wave (primary wave) is a longitudinal or compressional wave. It can travel in both solids and fluids.

S-wave (secondary waves) is a transverse or shear wave. It can only propagate through a solid.

Generally, the ray or phase velocity of the *P*-wave is greater than the ray or phase velocity of the *S*-wave.

For an elastic isotropic medium, the particle motion of the *P*-wave is in its propagation direction whereas that of the *S*-wave is perpendicular to its propagation direction. For either the *P*-wave or *S*-wave, the direction and magnitude of its ray (travel) velocity are the same as those of its phase velocity.

For an elastic VTI medium, generally the *P*-wave is not polarized in either the phase velocity or energy (ray) velocity direction. There are two types of shear waves: (1) the *SV*-wave which is polarized in a plane constructed by the measurement line (a source and a line array receiver) and its ray path, and generally its particle motion is not perpendicular to either the slowness or ray directions and (2) the *SH*-wave which is polarized perpendicularly to a plane constructed by the measurement line and its ray path. The magnitude and direction of phase velocity are different from those of the ray velocity for each of the *P*-, *SV*-, and *SH*-waves, respectively. The magnitude of the phase (or ray) velocity for either the *P*-wave or *SV*-wave is not related to the modulus of medium, but also to its propagation direction. The magnitude of the phase (or ray) velocity for the *SH*-wave only depends on the modulus of the medium.

BREAKWATERS

Giovanni Cuomo
Hydraulics Applied Research & Engineering Consulting (HAREC) s.r.l, Rome, Italy

Synonyms

Barrier; Caisson; Dam; Rubble mound; Screen

Definition

Breakwaters are maritime structures constructed to provide shelter from waves.

Discussion

There are two basic types of breakwaters: rubble mound and vertical breakwaters. Rubble mound breakwaters are generally used in shallow water, whereas vertical breakwaters become more convenient in deeper water. A typical rubble mound breakwater consists of an armor layer of heavy rocks or concrete units usually protecting a less permeable filter beneath and a core comprising smaller sized rocks; the mound can be submerged or extend above the sea level. When above sea level, the crest of the breakwater can be completed by a concrete crownwall, usually cast in situ. A vertical breakwater consists of a vertical structure of various designs resting on a rubble foundation. Composite breakwaters consist of a combination (either vertical or horizontal) of a rubble mound and a vertical superstructure.

Due to the enormous power of waves, the construction of breakwaters can be very difficult and the history of constructed breakwaters includes a long list of damages and failures. The oldest known existing rubble-mound breakwater is located in Civitavecchia (Italy) and was constructed by the Roman Emperor Trajanus (AD 53–117). The age of modern breakwaters nevertheless began only in the eighteenth century with the introduction of concrete armor units and composite breakwaters. Armor units were made possible by the invention of the Portland cement in 1824, allowing the production of large, geometrically complex, un-reinforced concrete armor units with improved interlocking capability (e.g., Cubes, Tetrapods, Antifers, Dolos, Accropodes, X-blocks). The possibility of casting very large units allowed the construction of breakwaters in very exposed locations such as the Atlantic coast of Spain and Portugal. The use of slender armor units was nevertheless suddenly interrupted when their structural fragility became evident during the disastrous failure of the Sines breakwater in 1978.

Composite breakwaters originally consisted of high mounds and block work superstructures; over large tidal excursions, the mound could nevertheless induce wave breaking onto the structure causing severe damage and destruction of many breakwaters. The stability of vertically composite breakwaters was later substantially

improved with the reduction of the mound and the introduction of taller and heavier superstructures, which was made possible by the use of superimposed Cyclopean blocks, again later replaced by concrete caissons. The introduction of float over caissons made possible the construction of Cyclopean structures such as the Tsunami breakwater at Kamaishi (Japan) in a water depth of 60 m.

Recent development of vertical caisson breakwaters include sloping top, perforated and recurve-wall caissons, respectively, to increase their stability, reduce wave reflection, and transmission. Caissons have also been equipped with OWC wave energy devices.

Berm (or reshaping) breakwaters have a large berm along their seaward face. These are dynamically stable structures made of medium-sized, high-quality rocks and their front reshapes to adapt to wave action during severe storm. Other "special type breakwaters" include piled structures (including wave screens), horizontal plate breakwater, floating breakwater (supported on piles or chained to the seabed), and pneumatic breakwaters, which reduce wave agitation by forcing an airflow.

BUILDING CODE

Rohit Jigyasu
Ritsumeikan University, Komatsubara, Kita-ku, Kyoto, Japan

Synonyms

Building control; Building law

Definition

A building code is a set of rules or standards that specify the minimum acceptable level of safety for buildings to secure life and property from all hazards such as earthquakes, hurricanes, flood, fires, etc. to which the building maybe exposed.

Introduction

Natural hazards have potential to cause immense loss of life and property if buildings are not designed according to the standards specified in the code. This is demonstrated by recent disasters such as the 2010 Haiti Earthquake and 2001 Gujarat Earthquake in India. Moreover building codes ensure safe evacuation in the event of any emergency such as fire. The standards may apply not only to individual buildings but also to the planning of neighborhoods, towns, and cities.

Criteria for designing codes

Since various types of buildings have different vulnerabilities and capacities with respect to different hazards, such codes are designed according to the types of buildings. Building codes may therefore be different for professionally engineered urban structures in contrast to non-engineered buildings that are commonly found in rural areas. Also the codes vary according to the nature of materials; for example, random rubble stone masonry structures, brick, and reinforced cement concrete constructions would all require different codes. These may also differ according to the performance requirement based on usage; for example, schools and office buildings will have different requirements compared to housing. Significantly, codes for repair and retrofitting of historic buildings would need to take into account not only the special nature of the building but also its heritage values.

The codes are formulated by deciding the thresholds of acceptable risks depending on the nature of hazard, building, and the local context. However building codes go beyond hazard mitigation and also provide standards to regulate the structural integrity, adequate ventilation, natural light, sanitation, means of egress, density, topography as well as minimum heights and areas.

Types of building codes

The codes can be either prescriptive rules and descriptions of exactly how something is to be done, or these can be based on performance requirements, leaving it to the designer to decide how this is to be achieved. The former may be effective at higher levels by enforcement through controls; however, compliance is more effective at the local level through indirect control tools such as housing loans and insurance (UNCRD, 2008).

The users

Such codes are generally developed by the government agencies and then reinforced across the country. However, in countries where the power of regulating construction and disaster preparedness is vested in local authorities, a system of model building codes is often used. These

codes are a set of guidelines that have no legal status unless adopted or adapted by an authority having such jurisdiction.

The code contains regulations, which can be immediately adopted or enacted for use by various departments, municipal administrations, and public bodies. However, architects and engineers are the primary preconstruction users of the building codes. The initial designs and drawings must satisfy all the requirements embedded in these codes.

Implementing building codes

Many disaster-prone countries now have building codes that address the specific nature of disaster risks. However, their implementation is poor in many cases and many unsafe buildings are still being raised. One of the reasons is that a minimum acceptable house structure according to a building code is often beyond the means of the poor and sometimes even middle-income families. For example, this was the case in Kenya prior to the updating of the building codes in 1990, when the Intermediate Technology Development Group (ITDG) initiated participatory effort to modify the codes to reflect the local building practices while still encouraging safe building practices (Jha et al., 2010).

Although updating a building code is the first step toward improving building safety and increasing disaster resilience, other challenges such as simplifying approval processes and establishing incentives to fully apply the building codes also need to be tackled.

Professionals often understand the code's intent but do not know how to perform the necessary calculations to build hazard resistant constructions. Therefore, engineers must be given training to design structures that are resistant to specific hazards. Also it is important to bridge the gap between professional engineers, who design the structures, and the craftsmen, who put them into practice at the construction site. This is particularly a challenge in developing countries

Moreover, despite the existence of building codes and serious intention for its effective implementation, realization of safe buildings in the field requires quality material, good workmanship, and awareness in masons, builders, and house owners (UNCRD, 2008).

Also there is a constant need for the engagement of skilled and responsible experts for developing or updating the codes by adopting holistic approaches that take into account the local hazards, as well as climate, resources, cultural needs that new buildings must meet.

Summary

Building codes are a necessary instrument for reducing vulnerability to natural hazards. They should be followed by architects and engineers while designing new buildings or retrofitting existing buildings in hazard-prone areas. They must take into account the nature of building and local social, economic, and geographical context. Effective implementation of building codes requires good institutional structure and training of engineers as well as contractors and masons, who are responsible for construction.

University College London, London, UK

Synonyms

Building collapse; Structure failure

Definition

Building failure occurs when the building loses its ability to perform its intended (design) function. Hence, building failures can be categorized into the two broad groups of physical (structural) failures (which result in the loss of certain characteristics, e.g., strength) and performance failures (which means a reduction in function below an

established acceptable limit) (Douglas and Ransom, 2007).

Structural failure corresponds to the exceedance of ultimate limit state in many of the load-carrying elements, which compromise the structural stability of the building. In practice, this corresponds to extensive damage, partial or total collapse of the building, resulting in repair costs that are high relative to the replacement value of the building.

Performance failure can be induced by the failure of structural elements (as per above), nonstructural component (non-load-bearing elements or equipment) failures or combinations thereof. For example, the use of a hospital might be affected by damage to infill walls and cladding (nonstructural components) that may compromise hygiene or damage essential equipment. In the context of natural hazards, however, the established acceptable limit to function, defining the threshold of performance failure may vary according to the type of natural hazard and its frequency of occurrence. For instance, in the case of frequent events, it may not be acceptable to lose any functionality but for rare events some degree of performance failure may be deemed acceptable, (e.g., the concept of performance-based assessment in earthquake engineering, see Calvi, 1998 amongst others).

BUILDINGS, STRUCTURES, AND PUBLIC SAFETY

John M. Logan
University of Oregon, Bandon, OR, USA

Definitions

Fault. A surface or zone of rock fracture along which there has been displacement from a few centimeters to kilometers.

Tsunami. A gravitational sea wave produced by any large-scale, short-duration disturbance of the ocean floor.

Marble. A metamorphic rock consisting primarily of recrystallized calcite.

Granite. An igneous rock composed primarily of quartz and feldspar with possibly lesser amounts of mica.

Introduction

The questions and issues of public safety around buildings and structures have occupied scientific and engineering research for many years and are still of major concern. Relevant questions include: (a) to what extent can buildings withstand the ground shaking associated with earthquakes or associated tsunamis, and (b) how long will building stones such as granite and marble or concrete withstand environmental weathering processes? Large buildings and structures such as major office buildings, extensive museums, libraries, and entertainment centers located in heavily populated areas are often the focus of attention because of the potential loss of life if failure occurs.

Earthquakes and tsunamis

Earthquakes occurring on land

Public safety associated with earthquakes and tsunamis in many cases is dependent upon warnings of such events (Figure 1). The anticipated ground motions depend upon not just earthquake magnitudes, but as importantly distance from the source, travel path, and near surface materials, which may produce various amplification effects. Both are caused by sudden ruptures of the Earth's crust, generally along preexisting failure surfaces called faults. The slip on the fault may be primarily horizontal (strike slip), vertical (dip slip), or a combination of both (oblique slip).

The severity of an earthquake is described by both magnitude and intensity. Magnitude, usually expressed as an "Arabic Numeral" and is not dependent upon distance from the epicenter. It is calculated by measuring the amplitude of the released seismic waves. One scale that is used to measure this magnitude is called the Richter scale. It is logarithmic assigning values from 1 to 10. As it is logarithmic, an earthquake of value 5.0 is ten times greater than one measuring 4.0 (Richter, 1958). The more recent moment magnitude scale is also used today, which gives another estimate of earthquake size (Kanamori, 1977).

The intensity of an earthquake is a measure of the ground shaking occurring at any given point on the Earth's surface. Unlike magnitude scales, they do not have a mathematical basis; instead they are a ranking based on observed effects and is contingent upon local conditions. A number of intensity scales are used throughout the world, but the Modified Mercalli Scale is commonly used in the USA (Table 1). It includes the behavior of people, responses of houses, and larger buildings, and natural phenomena. It is dependent upon distance from the earthquake epicenter, underlying rock and soil structure, and other geologic features. Earthquakes range from intensity

Buildings, Structures, and Public Safety, Figure 1 Building damage from Loma Prieta Earthquake in California, USA, of October 17, 1989. The earthquake caused 62 deaths, 3,757 injuries, 12,053 persons displaced, 18,306 homes damaged, 2,575 businesses damaged, and repairs to damaged structures over US$6 billion.

levels of I to XII on the Modified Mercalli Scale, with events not felt by most people until about level III.

It is the amplitude and duration of ground motion that pose threats to buildings, structures, and public safety. The correlation between earthquake magnitude and intensity clearly depends on local factors. The US Geological Survey shows a typical correlation in Table 2 for the USA. A local issue such as fault slip may be critical. For instance, for an event of magnitude 7t, slip along a fault segment may occur for a few tens of miles, for an event of magnitude 8, the slip may be for a few hundred miles (Bolt, 1988).

Efforts to predict earthquakes today are primarily based upon documentation of events in a specific area and the possible historic cyclic nature of such events. Research looks at not just seismic records, but rapid changes in surface elevations, inundations of coastal tidal sediments, and other geologic evidence of cyclic changes. One primary observation is that earthquakes historically have occurred along the same fault or fault array such as the San Andreas in California and the Cascadia in the Oregon-Washington region in the USA, so considerations of public safety are critical in such areas. The exact periodicity of events even in a specific region is not known except that there are cycles of seismic motion followed by periods of quiet (Witter et al., 2003). Reviewing historical records of prior earthquakes and damage, particularly with respect to specific locations, can help to mitigate public safety associated with earthquakes.

The ground motion may directly damage buildings. Damage may as well be produced by liquefaction of the wet sand at the surface to produce quicksand. Seismically induced quicksand forms when wet sand fill is sheared by the seismic waves and becomes more tightly packed. The reduced pore volume squeezes out part of the water in the pores, which migrates upward, exerting pressure on the overlying sand grains and keeping them from making contact, thus reducing the strength to near zero. In addition to potentially altering the strength of underlying material, earthquakes may also induce landslides which may pose additional threats.

Earthquakes often occur in sequences with "foreshocks" or small magnitude events preceding a large or "main shock" and frequently followed by events of lower magnitudes, called "after shocks." Presently, there are no dependable criteria to separate foreshocks from a main shock. There may only be a number of small events, or a major shock, which may not be preceded by recognized smaller events. The awareness of new small events should alert the public to the possibility of a larger one. Weakness associated with homes include foundations not anchored, unreinforced walls of any material, buildings on tall walls or posts. These issues have caused review of building codes in large cities and in smaller rural areas. It is also clear that structures such as bridges, water, and electric lines may be disrupted and poses threats to emergency routes, communications systems, and essential utilities. This may impact not just private homes but critical

Buildings, Structures, and Public Safety, Table 1 Abbreviated modified Mercalli intensity scale

I.	Not felt except by a very few under especially favorable conditions
II.	Felt only by a few persons at rest, especially on upper floors of buildings
III.	Felt quite noticeably by persons indoors, especially on upper floors of building. Many people do not recognize it as an earthquake. Standing motor cars may rock slightly. Vibrations similar to the passing of a truck
IV.	Felt indoors by many, outdoors by few during the day. At night, some are awakened. Dishes, windows, doors disturbed; walls make cracking sound. Sensation like heavy truck striking building. Standing motor cars rock noticeably
V.	Felt by nearly everyone, many awakened. Some dishes, windows broken. Unstable objects overturned
VI.	Felt by all, many frightened. Some heavy furniture moved; a few instances of fallen plaster. Damage slight
VII.	Damage negligible in building of good design and construction, slight to moderate in well-built ordinary structures; considerable damage in poorly built or badly designed structures; some chimneys broken
VIII.	Damage slight in specially designed structures; considerable damage in ordinary substantial buildings with partial collapse. Damage great in poorly built structures. Fall of chimneys, factory stacks, columns, monuments, and walls. Heavy furniture overturned
IX.	Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb. Damage great in substantial buildings, with partial collapse. Buildings shifted off foundations
X.	Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations. Rails bent
XI.	Few, if any (masonry) structures remain standing. Bridges destroyed. Rails bent greatly
XII.	Damage total. Lines of sight and level are distorted. Objects thrown into the air

facilities such as hospitals, ambulance services, fire-fighting equipment, and others.

Tsunamis and fault rupture at sea

If faults rupture underwater so that the fault slip is primarily vertical and the sea floor is rapidly displaced, it produces a wave. Tsunami waves may also be produced by landslides associated with fault motion. Volcanic activity may also produce tsunami waves. Most tsunamis occur in the Pacific Ocean as very active features such as deep ocean trenches, which are fault bounded, and explosive volcanic islands, surround it. Tsunami waves differ from ordinary ocean waves as they may often measure 1,600 km from crest to crest and move at more than 100 km per hour. As the waves near shore they decrease in velocity but they increase in height dramatically. An initial apparent withdrawal after the first wave maybe followed by much larger one, minutes later (Dudley and Lee, 1988).

Buildings, Structures, and Public Safety, Table 2 Earthquake magnitude and intensity comparison. Magnitude and intensity relate different characteristics of earthquakes. Magnitude quantifies the energy released at the source of the earthquake. This is determined from measurements on seismographs. Intensity measures the strength of shaking produced by the earthquake at a particular location. Intensity is determined from effects on people, human structures, and the natural environment. The following gives intensities that are typically observed at locations near the epicenter of earthquakes of different magnitudes

Earthquake magnitude	Typical maximum modified Mercalli intensity
1.0–3.0	I
3.0–3.9	II–III
4.0–4.9	IV–V
5.0–5.9	VI–VII
6.0–6.9	VII–IX
7.0 and higher	VIII or higher

Reference: US Geological Survey, Earthquake Hazards Program, (2012)

Clearly, tsunamis cause building and structure damage, which may pose significant threats to the public. Major devastating events resulting in deaths have been recorded since about 1600 BC, with recent catastrophic ones occurring in 2004 in the Indian Ocean and the Tohoku earthquake and ensuing tsunami in 2011. Often warnings are issued for those waves traveling across long distances, but in may cases are disregarded by the public who rush to the sea shores to see the waves and are often caught by the water or are trapped by bridge and highway failures as in the 2011 Japanese earthquake and subsequent tsunami.

Buildings and structures with exteriors subject to environmental fatigue

The question of buildings and public safety raises complex issues. The most frequent issues for public safety come not from the foundation failures but from exposed portions of the structures. These areas are subject to possible deterioration from environmental factors such as heavy winds, atmospheric chemistry, and seasonal changes in temperatures. The problem of public safety arises as many buildings that potentially pose problems are often close to the center of urban areas. The price of land often leads to multi-storey, high-rise buildings. The buildings generally have steel frameworks that are covered with veneers of glass, metal, natural stones such as marble, granite or sandstone, or recently of composite materials. It is the veneers that pose the greatest issue for public safety as they often deteriorate over time with the potential for failure and pieces falling from high places on the building and endangering the public below (Toronto Star, May 17, 2007, front page, p. A1). The basic issue is the ability of the materials to withstand the wind loads generated by storms, hurricanes, and tornados.

Although there is often warning of approaching hurricanes and tornados, the high winds sometimes associated with seasonal storms are not often given as much public notice. The intrinsic strength of the material is augmented by increasing thickness, reducing the panel size, and supplementing the anchoring system.

Glass windows and panels have fractured endangering vehicles and pedestrians when they fall. In some cases, the winds will carry pieces for kilometers. Stone veneers have received the most attention and particularly those formed by marble panels. Marble panels on architectural icons such as the Amoco tower in Chicago, USA, the Finlandia Concert Hall in Helsinki, Finland, and the Grande Arche de la Defense in Paris, France all began bowing to the extent that they posed risks of fracturing and falling off the building. The potential for public injuries or deaths and the resulting wide publicity has lead to extensive research regarding the physical properties and the loss of strength of marble (Raleigh, 1934). Chemical interaction during weathering leading to mineral dissolution and fracture corrosion and subsequent loss of strength has been postulated, especially in environments of acid rain (Winkler, 1967). Cycles of freeze-thawing which could result in fractures on the microscopic or even macroscopic scale, thus reducing the marble strength, and possibly leading to panel failure have also been proposed (Bortz et al., 1993). Thermal expansion due to diurnal cycles in temperature has been extensively researched especially with respect to buildings where the vertical panels do not retain significant rain or snow fall (Logan, 2006; Koch and Siegesmund, 2004). The principal factor here is that the mineral calcite, which is the primary component of marble, is thermally anisotropic. It expands parallel to the c-crystallographic axis but contracts perpendicular to it when subjected to temperatures above the average ambient state, which makes it unique. This differential expansion during elevated temperatures followed by relaxation as the temperatures return to ambient, produces fatigue within the grain-to-grain contacts eventually weakening the marble.

With thermal cycling leading to a loss of strength, a second effect may become significant, specifically the release of residual elastic strain stored in the rock as a result of incomplete annealing upon recrystallization of the limestone to form marble (Logan, 2004; Siegsmund et al., 2000). This strain release produces increases in dimensions of the marble panel. If the panel is constrained laterally, it will bow from its original flat geometry, with the weight of the panel producing a horizontal bow. To accommodate this change in shape, microfractures will occur which further weakens the panel. The bow amplitude may become sufficient to induce bending stresses in the panel, exacerbating the condition, potentially leading to macroscopic fracture and failure of the panel at about the middle of the panel height. Additionally, as the panels are anchored to retain them on the building, the bowing may load the anchors and produce failure there. To remove the possibility of moisture accumulating behind a panel and possibly producing corrosion of the metal framework and anchors, calk is installed around the edges of the panel. Even if a horizontal fracture forms leading to complete loss of panel strength, the calk may have sufficient strength to keep the pieces from falling for a limited time.

Granite has not exhibited the extreme deterioration from environmental conditions that marble has, although laboratory studies have looked at the bowing potential (Siegsmund et al., 2007). As it is multimineralic, the major components quartz, feldspar, and micas all have different responses to the atmosphere, mitigating the effects seen in calcite marble. It does often have, however, a pronounced strength anisotropy due to the crystallization process where the crystals often have a preferred orientation parallel to each other. Although this is not an evident layering, it often results in a "rift" with the rock weaker parallel to this feature, and stronger perpendicular to it. Specifications for granite exterior panels stipulate that the rift be parallel to panel face to minimize failure due to wind loads. It is frequently presumed that the rift is consistent within a quarry so that granite may be removed with respect to the assumed rift orientation, but geological mapping of quarries has shown that the rift orientation may change considerably (Logan et al., 1993).

This variation of physical and resulting mechanical properties is common in rocks. Although buildings with marble exterior cladding showing extreme signs of weathering have received considerable attention, there are other buildings with little evidence of deterioration. Marble from Carrara, Italy, is widely used in buildings because of its white color and the fame that it achieved from sculptures, such as those produced by Michaelangelo. But there are over 50 varieties of marble all commonly known as Carrara Marble and all with different physical and mechanical properties (ERTAG, 1980). The marble types conducive to sculpture have porosities of 6% or greater which makes them very susceptible to weathering. Marble from all over the world has differing properties of composition, grain size and orientation, porosity, residual strain, and others. Variations in properties are also found in other materials such as glass due to potential differences in their processing. To ensure public safety, extensive testing of all material installed is highly desirable.

The issues of public safety become paramount when evidence of deterioration of the exterior materials becomes evident. In some cases, surveys of the exterior may determine that the problems exist locally and can be remedied by replacement in those areas. Such a step was taken on the Amoco Building when it was decided that the problems were only extreme at the corners of the building. This building was the third tallest building in the world in 1989 and the tallest marble-clad one. It was decided to install straps across each marble panel so that if failure did occur the pieces would be retained until they could be removed. In this case, unfortunately, the installation of the straps severely damaged the panels. Even thought no panels fell from the building, the result was a decision to remove all of the 43,000 marble panels from

the building to avoid any panels or partial ones falling from the building and endangering the public (Williams, 2009). The building was about 15-years old at that time with cost estimated at that time to range from $60 to $100 million, to ensure public safety (Chicago Sun-Times, March 7, 1989, p. 1). It was decided to replace the marble with granite, which due to extensive quality control during replacement has remained without problems.

In contrast, 45,000 marble panels at First Canadian Place, Toronto, Canada's tallest skyscraper, were also removed as a result of two incidents in which whole or portions of panels fell from the building. The first event did not result in damage. During the second event, one panel weighing 115 kg fell from the 51st storey, and landed on a third floor roof; fortunately no one was injured. As a result of the second accident, and because the building was in the center of the downtown financial district, surrounding streets were closed to vehicle traffic for a number of days leaving some 48,000 streetcar riders and thousands of car drivers dealing with major delays (Toronto Star, May 17, 2007, front page, p. A1). The marble suffered from the same deterioration processes that affected the Amoco Building. It has been decided to remove all the marble cladding and replace it with other material.

Summary

Public safety is in most cases contingent upon proximity to buildings or structures and an awareness of conditions that may infringe on the safety. In cases of high-rise buildings and structures, the integrity of the exteriors is critical as many materials used are subject to environmental deterioration over extended periods of time. This degeneration of strength may lead to failure, especially under high wind loads with pieces falling from the buildings. In contrast, building integrity in earthquake and tsunami prone regions is dependent upon the ability to withstand sustained ground shaking or high waves. Potentially damaging earthquakes may occur without any warning, but tsunami warning systems may help to mitigate damage and public safety.

CALDERAS

James W. Cole
University of Canterbury, Christchurch, New Zealand

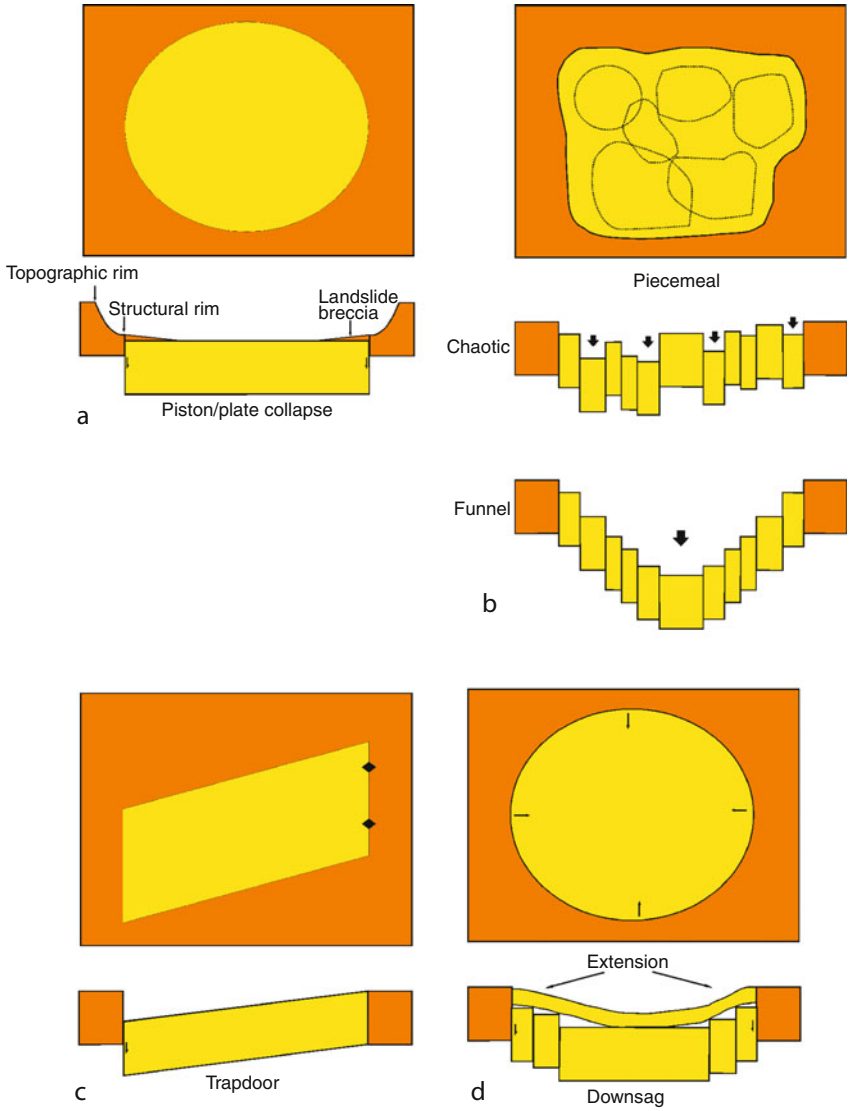
Synonyms

Cauldrons

Definition

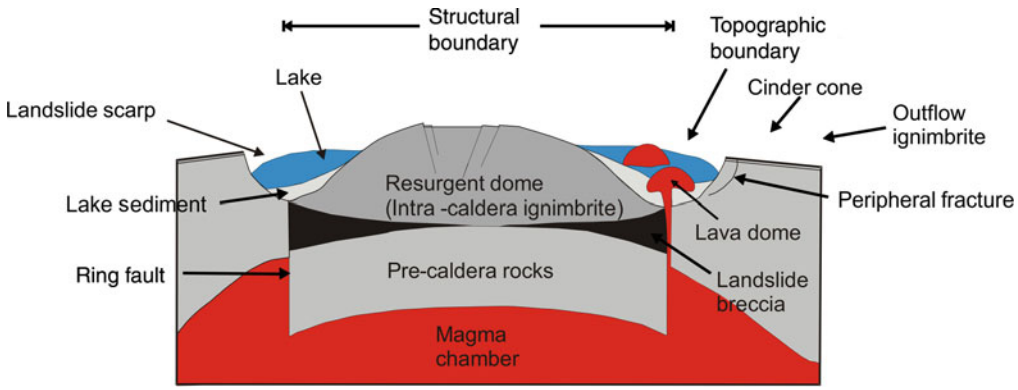
Calderas are volcanic depressions, roughly circular in surface plan, with a diameter greater than depth, and representing roof collapse into shallow underlying magma reservoirs.

Discussion



The term "caldera" comes from the Latin word "caldaria" meaning "boiling pot," and was originally used in the Canary Islands for any large "bowl-shaped" depression. Only in the last 50 years has their origin and potential hazards been fully appreciated. Calderas may occur in volcanoes of all compositions, in all tectonic environments, and show a wide range of forms. Consequently, it is difficult to classify calderas, although common collapse processes, provide "end-member" possibilities (Figure 1). The simplest form is "piston" or "plate" collapse within a cylindrical (ring) fault. This occurs within many smaller (typically basaltic) calderas, but is rare in larger (typically rhyolitic) structures. The latter are more likely to show either "piecemeal" collapse, around a number of centers in the caldera, or "downsag," where parts of the structure dip towards the center of the caldera. Regional faults can be an important boundary influence, and collapse may preferentially occur along one of these faults, with the opposite side showing "downsag," to produce a "trapdoor" caldera.

Many larger calderas have experienced multiple collapse events, often separated by tens of thousands of years. Such calderas should more correctly be called "caldera complexes". Each collapse is likely to be accompanied by explosive eruptions, usually producing pyroclastic flows, which deposit widespread ignimbrites (ash flow tuffs). Some of the ignimbrite will pond in the caldera (intra-caldera ignimbrite), whereas the remainder will be distributed radially around the caldera (outflow sheets).



While collapse is the key to caldera formation and is rapid (hours to days), it is only one phase in a process that may take tens to hundreds of thousand years. Pre-collapse volcanism is common, sometimes accompanied by uplift ("tumescence"), and most rhyolitic calderas are followed by post-collapse volcanism (usually forming lava domes and airfall tephra), often accompanied by uplift ("resurgence"). A cross section of a generalized "piston" caldera is shown in Figure 2. Hydrothermal activity and mineralization is likely to occur throughout the life of a caldera volcano, but is particularly important in the post-collapse stages. Once volcanism ceases, erosion will progressively remove much of the surface volcanism (over millions of years). This structure is called a "cauldron," when caldera-floor rocks become exposed. Once a substantial amount of the underlying magma reservoir is exposed, the term "ring-structure" is commonly used.

Calderas are a major natural hazard. The accompanying pyroclastic flows can cause total devastation for hundreds to thousands of square kilometers around the volcano. The largest of these, the "Supervolcano" eruptions, can produce $>1{,}000$ km^3 of ignimbrite and can influence climate with fine ash remaining in the atmosphere to cause a "global winter" for many years! During pre-collapse tumescence and post-collapse resurgence, ground movement is likely, which will affect structures built in the area. While there are likely to be precursor events to caldera formation (e.g., earthquake swarms, gas discharge, etc.), such

events do not always culminate in an eruption. Such "false alarms" are a major problem for effective prediction.

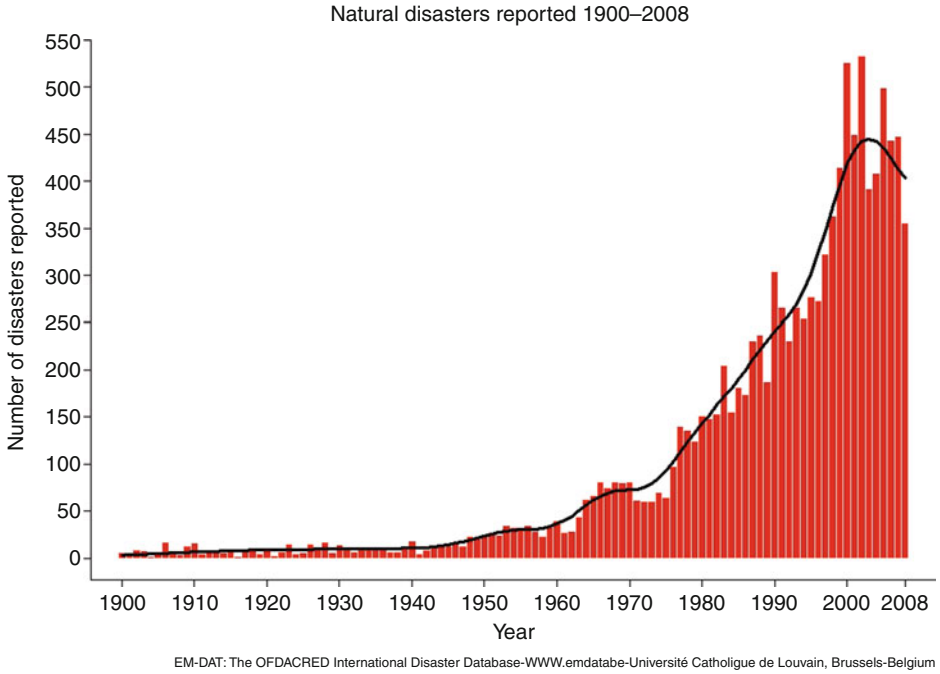
CASUALTIES FOLLOWING NATURAL HAZARDS

Kerrianne Watt[1], Philip Weinstein[2]
[1]Tropical Medicine & Rehabilitation Sciences; James Cook University, Townsville, QLD, Australia
[2]University of South Australia, Adelaide, SA, Australia

Synonyms

Casualties; Fatal and nonfatal injuries; Mass casualty events; Natural disasters, forces of nature

Definition



A casualty of a natural disaster can be defined as any person suffering a physical or psychological injury therefrom. Injury, in turn, is "unintentional or intentional damage to the anatomical structures or physiological processes of the body incurred from acute exposure to an exchange of energy (thermal, mechanical, electrical, or chemical), or the absence of such essentials as heat or oxygen" (p. 4, National Committee for Injury Prevention and Control, 1989; Driscoll et al., 2004). For the purposes of this contribution, a natural disaster is considered an event with one of the following: 10 or more human fatalities; 100 or more people affected; a state of emergency declared; and international assistance sought (Scheuren et al., 2008).

Introduction/background

Since the beginning of recorded history, natural disasters have been measured by the severity of their impact on human populations – beginning with the "Biblical flood" that apparently drowned all people on Earth, with the exception of one family group. More recently, it has been estimated that 6,367 natural disasters have occurred between 1974 and 2003, which involved approximately 3,135 fatalities per 100,000 population (Guha-Sapir et al., 2004). The number of people affected by natural disasters is much greater than the fatalities that occur due to such events. From 1989 to 2003, it was estimated that worldwide, approximately 13,706 persons were affected by any type of natural disaster, for every person killed (Guha-Sapir et al., 2004). Not all of the people affected by a natural disaster are physically injured – however this contribution focuses on those who experience injury as a consequence of natural disasters.

The incidence of reported natural disasters has increased substantially over the last 100 years (Figure 1). Advances in technology and communication account for some of this increase through better ascertainment, but there is also an element of increasing impact because of the rapid growth of the human population. Over the last three decades, there has been a decrease in the number of deaths caused by natural disasters, but an increase in the number of people affected by these events (Scheuren et al., 2008). These changes can be attributed to more people in bigger cities with more structures, but also to improvements in disaster preparedness, public awareness, infrastructure (e.g., anti-seismic housing and medical facilities), and our ability to manage and respond to disasters (Noji, 1992). Disaster epidemiologists, who measure and describe the health effects of disasters, and identify the factors that contribute to such adverse effects, have largely been credited with advocating for the introduction of such improvements (Noji, 1992). Whereas more people survive natural disasters, many of the survivors experience injuries and/or illness as a consequence, some of which require long-term rehabilitation and may impact on quality of life. The resultant medical burden in turn has implications for economies. The current approach to measuring the impact of disasters (the number of people affected) may therefore significantly underestimate the true public health impact of such events. An alternative approach, such as estimating Disability Adjusted Life Years (DALYS), may provide a more accurate description of the impact of natural disasters.

The severity of the impact of a natural disaster is determined by four factors: (1) population at risk (size, location, susceptibility, age distribution); (2) exposure to the effects of the disaster; (3) short-term and long-term adverse health effects resulting from such exposures; and (4) effect modifiers (building infrastructure; living conditions, communication systems including media and internet) (Dominic et al., 2005). For these reasons, the impact of a natural disaster is usually much greater in less developed regions, with higher population densities. Less infrastructure (including access to healthcare, water, electricity; financial assets and access to loans/insurance), greater communication difficulties, and less emergency response capacity exacerbate this situation (Guha-Sapir et al., 2004). Often, such regions/countries are more vulnerable to natural disasters given their geographical location (located on a flood plain or region of high seismic activity) or other environmental characteristics (e.g., soil degradation/erosion, pollution, deforestation) (Guha-Sapir et al., 2004).

Casualties Following Natural Hazards, Figure 1 Natural disasters reported in the period 1900–2008.

The proportion of casualties (number of fatalities and severity of injuries) that occur as a consequence of natural disasters is associated with delays in reaching victims, which is in itself dependent on factors such as communication systems and the density and integrity of buildings (Chang et al., 2003). Physical location during the event has been identified as a factor that increases risk of injury and death as the result of a natural disaster. Being in a multiple unit residential or commercial structure is associated with increased risk of injury/death following an earthquake (Peek-Asa et al., 2003). Therefore, areas where there is high proportion of multilevel buildings are likely to experience higher numbers of casualties from these types of events. The very young, the elderly, and people of low socioeconomic status are also more likely to experience worse outcomes after a natural disaster (Peek-Asa et al., 2003; Milsten, 2000).

Disaster types

Natural disasters can be categorized into a range of subgroups. The classification system recently developed by EMDAT (the International Disaster database) is used for the purposes of this contribution: Climatological (droughts, extreme temperatures, wildfires); Geophysical (earthquakes, volcanoes, dry mass movements); hydrological (floods, wet mass movements); and meteorological (storms such as hurricanes, cyclones, tornadoes, etc.). This focuses on the latter three hazard types.

Geophysical

From 1974 to 2003, an estimated 767 geological disasters occurred worldwide (Guha-Sapir et al., 2004). The main subtypes of geophysical natural disasters include earthquakes and volcanoes.

Earthquakes

There were approximately 660 earthquake disasters from 1974 to 2003, which resulted in 559,608 fatalities, and affected more than 82 million people (Guha-Sapir et al., 2004). It has been estimated that over 500,000 earthquakes occur every year, and 7–11 of these cause substantial fatalities (Ramirez and Peek-Asa, 2005). Over the past 200 years, approximately 1.9 million deaths have been reported due to earthquakes (Shulz et al., 2005). Of all natural disasters, the highest rate of mortality is associated with earthquakes – 36% of deaths that have occurred due to natural disasters from 1970 to 2009 were due to earthquakes (Centre for Research on the Epidemiology of Disaster (CRED), 2010).

In addition to the generic factors that impact on injuries from natural disasters described thus far, earthquake injuries depend on several factors: number of occupants in an affected dwelling, floor surface, and time of day (Milsten, 2000). The highest rate of post-disaster suicides is associated with earthquakes (Milsten, 2000; Friedman, 1994).

Injuries associated with earthquakes commonly occur due to being trapped inside buildings, falling, or being hit by falling objects. Injuries include: asphyxiation, hemorrhage, crush syndrome, internal injuries (abdominal

and pelvic), severe chest trauma, upper and lower extremity injuries, fractures, soft tissue injuries, and multiple traumatic injuries (Chang et al., 2003; Milsten, 2000). Major head injuries are usually fatal and peripheral limb injuries are also characteristic of major earthquakes, as evident in the 2003 Bam (Schnitzer and Briggs, 2004) and 2005 Kashmir (Dhar et al., 2007; Redmond, 2005) events. A significant proportion of earthquake-related injuries are sustained in the post-disaster period (i.e., "clean up") – where 22–47% of earthquake injuries have been cited as aftermath injuries (Milsten, 2000).

For instance, two catastrophic earthquakes had struck Haiti on January 12, 2010, devastating much of the country's capital city, Port-au-Prince, and surrounding regions. Most of the fatalities were due to building collapses, which were in turn influenced by structures built on unstable land (International Strategy for Disaster Reduction, 2010). Estimates by the UN in late January suggest that in excess of 80,000 were killed as a consequence of this earthquake and 200,000 injured (United Nations, 2010).

Earthquakes can also trigger other types of natural hazards, which have different patterns of injury (e.g., tsunamis, landslides, floods) (Jones, 2006). For example, the Indian Ocean Tsunami that hit several countries across southeast Asia on December 26, 2004, was triggered by an earthquake (9.3 on the Richter scale). This event is considered to be the worst natural disaster in the last decade. It resulted in 226,408 deaths in 12 countries, with injuries estimated to be in hundreds of thousands, affecting more than two million people (ISDR, 2010; Guhar-Sapir et al., 2006).

Tsunami-related injuries most frequently occur due to exposure to the extreme water forces and pressures of a tsunami, as well as oxygen deprivation, chemical reactions due to contaminants, impact from debris, and flood-related fire consequences (Guhar-Sapir et al., 2006). Suction of debris back out to sea through receding waters can also cause injury (Guhar-Sapir et al., 2006). Drowning is the most common type of injury sustained during a tsunami, but many fatalities are also caused by respiratory complications from episodes of near drowning. Traumatic injuries, contusions, open wounds, fractures, head injuries, and compression barotraumas of the tympanic membrane are common (Guhar-Sapir and van Panhuis, 2005; Fan, 2006). In Thailand, the pattern of injuries that was described following the Indian Ocean Tsunami was of small-medium multiple injuries along the head, face, and extremities, as well as the back of head, back, buttocks, and legs (Guhar-Sapir and van Panhuis, 2005).

Volcanoes

Between 1974 and 2003, 123 volcanic disasters were reported, resulting in deaths of 25,703 people, and affecting in excess of three million people (Guha-Sapir et al., 2004). The worst volcano in modern history occurred in Colombia in 1985 with the eruption of Volcano del Ruiz, which killed some 21,800 people (Guha-Sapir et al., 2004). Injuries resulting from volcanoes are influenced by four factors: (1) eruptive variables (explosive: large quantities of gas, hot ash, and dust; effusive: large lava flows; combination), which influence the duration and chemical composition of emissions, and dispersal range; (2) toxin-specific properties; (3) patterns of toxic dispersal and persistence; and (4) biological variables (Weinstein and Cook, 2005). Injuries that occur close to the site of volcanic eruption can occur due to the explosion: burns (internal and external), trauma, lacerations, asphyxiation; or due to the emission of toxic gases (asphyxiation, airway constriction, burns; ocular injuries, upper airway, and skin irritations) (Weinstein and Cook, 2005; Weinstein and Patel, 1997).

Toxic elements (e.g., Sulfur, fluoride, chlorine, carbon, silica, mercury) and compounds can be ejected to significant distances, and consequently volcanic injuries often occur well after the initial explosion (Weinstein and Cook, 2005). Injuries can occur due to resulting electrical storms, reduced visibility, water supplies contaminated with toxic substances, and air/road crashes (Jones, 2006). Other common injuries in this category are: eye/skin/airway irritations, ocular injuries (foreign bodies in eyes, corneal abrasions), and sometimes suffocation (Jones, 2006; Weinstein and Cook, 2005).

Meteorological

From 1974 to 2003, 1955 windstorm disasters (cyclones, hurricanes, tornadoes) were recorded, resulting in 293,758 fatalities and affecting an additional 557 million people (Guha-Sapir et al., 2004). Cyclone Nargis, which struck Myanmar in Burma on May 2, 2008, has been identified as the second worst natural disaster in the last decade (ISDR, 2010). The cyclone resulted in the deaths of 138,366 people, but affected many more – 19,359 were injured, and approximately 2.4 million people were severely affected (Kim et al., 2010; World Health Organization, 2008).

Injuries from windstorm events are often classified according to the disaster phase during which they occurred (Shulz et al., 2005): pre-event; event; post-event. Falls, blunt trauma, lacerations, and muscle strains are common during the pre-event phase, as people prepare their properties and communities for the destructive winds (Shulz et al., 2005). Injuries associated with evacuation also incurred during this phase, including road traffic crashes (Shulz et al., 2005; Jones, 2006).

During windstorm events, individuals are at risk of injury from the direct exposure of the forces of the event (building collapse, flying debris, falling trees, power lines, etc.) (Shulz et al., 2005; Cook et al., 2008). The three most common injuries arising from such events are lacerations, blunt trauma, and puncture wounds, the majority of which are sustained to the lower extremities (Noji, 1993). For example, over half of the disaster-related injuries that occurred after Hurricane Iniki in 1997 were open wounds

(Hendrickson and Vogt, 1996; Hendrickson et al., 1997). Other common injuries experienced during windstorm events include: asphyxiation, abdominal injuries, spinal injuries, abrasions, contusions, sprains, fractures, ocular injuries, crush syndrome, carbon monoxide poisoning, ear/nose/throat injury, burns, and electrocution (Milsten, 2000; Shulz et al., 2005; Jones, 2006; Noji, 1993).

Injuries also occur due to storm surges, which can raise coastal waters many meters above normal tide level, and heavy rainfall, which can result in flooding (Cook et al., 2008). The principal injuries reported after such events include lacerations, blunt trauma, puncture wounds (often in the feet and lower extremities), and drowning (Cook et al., 2008).

Typically, the pattern of injury presentations changes in the aftermath (and associated cleanup) of wind storm events, and these injuries are often greater in number than injuries sustained during the event (Milsten, 2000). Electrocutions due to powerlines present a problem during this phase, but injuries such as lacerations, puncture wounds, abrasions, contusions, fractures, strains/sprains, insect stings, dog bites, and dermatitis are commonly reported as a consequence of cleaning up activities involving chainsaws, falls from heights, disturbing nests, etc. (Milsten, 2000; Shulz et al., 2005; Jones, 2006). Also common are burns (from using alternative light/heat sources such as candles, open fires, portable stoves, etc.) (Shulz et al., 2005). Injuries related to suicide attempts also occur during this phase (Jones, 2006).

Floods

An estimated 206,303 fatalities occurred as a consequence of 2,553 flood disasters between 1974 and 2003, affecting more than 2.6 billion people (Guha-Sapir et al., 2004). Whereas earthquakes have been responsible for the most natural disaster mortality, floods have affected the most number of people (ISDR, 2010). Of the estimated two billion people affected by natural disasters of any kind in the last decade, 44% were affected by floods (ISDR, 2010). Floods account for approximately 40% of all natural disasters, and importantly, can occur as a consequence of several other natural disasters (volcanoes, earthquakes, wind events, and tsunamis) (Jones, 2006). Much of the projected impact of future natural disasters is likely to occur in coastal areas, due to rising sea levels that will place these regions at increased risk of storm surges and flooding (Ahern et al. 2005; Dasgupta et al., 2007; 2009; Rodriguez et al., 2009).

The most common flood injuries are drowning, near drowning, and being hit by objects in fast flowing water (Jones, 2006; Ahern et al. 2005). A significant proportion of drowning/near drowning episodes are caused by vehicles being swept away (Milsten, 2000; Ahern et al. 2005). Hypothermia as a consequence of near drowning episodes is common (Jones, 2006). In a review of flood-related injuries, the three most common injury types were identified as: sprains/strains (34%), lacerations (24%), other injuries (11%), and abrasions/contusions (11%) (Ahern et al. 2005). Other types of injuries include multiple traumas, contusions, and minor cuts (Jones, 2006).

Suicides

This entry focuses on acute injuries experienced as a consequence of natural hazards. However, it is acknowledged that depression and suicides are commonly experienced after natural disasters – most typically after hurricanes, floods, and earthquakes (Ahern et al. 2005; Krug et al., 1998), with increased rates of both for up to 4 years post-disaster (Krug et al., 1999; Galea et al., 2005; Procter, 2005).

Long-term sequelae for casualties

Although most injuries that arise from natural disasters are specific and non-disabling, recovery for many individuals is challenging. Brain injury, amputation, or paralysis may require prolonged rehabilitation and institutional care (Pan American Health Organization and Pan American Sanitary Bureau, 2000). Orthopedic services are often limited in less developed countries, as are options for postsurgical management, such as fitting of prostheses, physical and occupational therapies, and other pathways for remobilization and return to daily activities (Dhar et al., 2007; Calder and Mannion, 2005). One year after the Gujarat earthquake of 2001, which killed 13,805 people and left 166,000 injured, many thousands still required assistance for paraplegia, poorly healed fractures, amputations, and other mobility problems (Chatterjee, 2002). Organ damage may also require long-term management, such as dialysis after renal crush injuries. Following the Armenian earthquake in 1988, the medical needs of 600 cases of acute renal failure – of which at least 225 victims required dialysis – created a second catastrophe described as the "renal disaster" (Sever et al., 2006).

Management to minimize casualties

Accurately estimating the impact of natural hazards in terms of fatalities, injuries sustained, and the long-term physical, psychological, social, and economic impacts can be difficult. There is no one agency that is responsible for collecting reliable, valid disaster data (current data sources include newspapers, insurance reports, government agencies, and humanitarian agencies) (Guha-Sapir et al., 2004). There is no standardized method for assessing damage (definitions, data collection methods), verifying information, and storing data (Guha-Sapir and Below, 2002). This is compounded by difficulties associated with obtaining data on populations affected by disasters (e.g., population size; geographical boundaries). Accurate data are essential to estimate the impact of the event, and for effective disaster management, and disaster preparedness.

Despite such limitations in disaster data, a sound public health approach can still be adopted to minimize casualties

from natural disasters. Such a public health approach to injury control is based on a four-stage process that includes: defining the nature and extent of the problem; identifying associated risk and protective factors; developing effective interventions; and implementing these interventions in effective programs (Sleet et al., 1998). In the traditional injury epidemiology framework, the risk factors for injury relate to host, agent, and environment (Kraus and Roberston, 1992). Natural disaster–related injuries can be examined within this context (Ramirez and Peek-Asa, 2005). Host characteristics include demographics (age, gender, etc.), individual behaviors (running out of building, heeding evacuation warnings), and resiliency. In the natural disaster model, the agent is the energy (e.g., force of wind, magnitude of earthquake). The environment in this context is the physical location, including buildings, roads, and infrastructure where the natural disaster occurs. From the public health perspective, points of intervention most likely to reduce harm arising from natural disasters should focus on host and environment characteristics. Consequences of natural disasters can be direct or indirect (Combs et al., 1998). Direct casualties are those that occur due to the physical forces associated with the event, and indirect casualties are those that occur due to unsafe or unhealthy conditions that exist in the post-disaster phase. In public health terms, indirect consequences should be the target for intervention, as it is these factors that can be altered in the preparedness phase, and through effective disaster management.

Summary/conclusion

Over five billion natural disaster events have occurred in the last three decades, yielding more than two million deaths, and affecting more than 5.1 billion people. The incidence of natural disasters has increased significantly over the last 100 years. The World Climate Change Conference recognized that during the last five decades, nine out of ten natural disasters were the result of extreme weather and climate events (World Meteorological Organization (WMO), 2009). Further, climate change models demonstrate that there will be an increase in the frequency and intensity of extreme natural hazards such as heat waves, storms, floods, wildfires, and droughts (World Meteorological Organization (WMO), 2009; IPCC, 2001; Haines and Patz, 2005). Death and injury are direct consequences of natural disasters. Although there has been a reduction in fatalities from these events, many of the survivors experience injuries and/or illness as a consequence, some of which require long-term rehabilitation, and impact on quality of life. This has important implications for public health. Many factors influence the severity of the impact of a natural disaster, including the density, geographical location, and infrastructure and disaster response capacity. The impact of a natural disaster is usually greatest in less developed regions. The disaster type itself affects the severity of the impact, and different natural hazards yield different patterns of injury. We anticipate that the increased incidence and intensity of extreme natural hazards will be reflected in changing epidemiology of disaster-related injuries (e.g., more floods will result in more drowning/near drowning). Information about any natural disaster and the devastation it brings is limited by the quality of the data relating to the event. A unified system of definitions, data collection methods, verification, and storage will significantly improve disaster preparedness, management, and recovery.

CHALLENGES TO AGRICULTURE

Julie A. March
United States Agency for International Development (USAID), Washington, DC, USA

Definitions

Food Security: When all people at all times have both physical and economic access to sufficient food to meet their dietary needs for a productive and healthy life (USAID, 1992).

Introduction

Worldwide, farmers rely on a complex combination of seed, water, sunlight, and soil nutrients to assure a season of good production. Natural hazards can disrupt the unique balance necessary for a successful harvest. In cases where farmers are able to control for some of these factors (for example, irrigation to compensate for lack of rain or fertilizer to enhance poor soil fertility), negative effects leading to a poor harvest can be mitigated. Subsistence farmers are often more susceptible to the risks associated with natural hazards as they have limited access to costly inputs to mitigate natural disasters. In some cases though, mitigation measures are not an option for any farmers, especially if the hazard is not predicted. Hazards include events such as storm surges, volcanic eruptions, droughts, and floods. The impact of natural hazards on agricultural production can be evident immediately following a disaster and recovery can take many years. Both subsistence agriculture and commercial agriculture can be damaged by extreme events. While some small-scale farmers may lose their seed stocks and their food stores for the coming season, commercial farmers may face disruption or destruction of local market and market chains for their crops and for access to agricultural inputs. Widespread damage to a region or a particular crop can affect the price of agricultural products in international markets. The extent of the damage caused to agricultural systems will depend on a variety of factors, including topography, weather, crop selection, and stage of crop growth when the hazard strikes. The speed of recovery for affected farmers will be influenced by all of those factors as well as the general resilience of the farming population.

Rainfall irregularity and drought

Many parts of the world have experienced great climatic variability over the past few decades. In parts of Africa, which depend primarily on rain-fed agriculture, these changes have had a negative impact on food security of subsistence farmers. Droughts can both decrease food security in the near term, whereas in the longer term, successive droughts can erode the ability of farmers and pastoralists to recover as recurrent shocks lead to loss of assets and erosion of coping capacity for vulnerable populations. Throughout Africa, drought has contributed greatly to large magnitude food security crises. Some examples include the famine in Ethiopia (1984), and the food insecurity in Niger (2005). These countries and many others affected by drought are still struggling with food insecurity, highlighting the need to address emergency needs related to current hazards while at the same time examining the agricultural system, farming methods, and underdevelopment related to the agriculture sector as a whole with sustainability of the system as a major objective (Trench et al., 2007).

Subsistence farmers who depend on rain-fed agriculture are often challenged by the inability to determine when rains will begin. For example, in Southern Sudan in 2010, rains began later than anticipated (WFP CFSAM, 2010). Farmers quickly planted once rains began, yet subsequently they lost the seed when the rain stopped soon after, leading to crop failure. With a shortened planting season, a short cycle crop variety may have produced a decent harvest, yet it is difficult to anticipate this prior to planting. Deciding what varieties to plant is difficult for farmers who lack reliable information on what the rainy season may bring, when it is likely to arrive, and how long it will last. Even with knowledge of weather predictions, access to or availability of preferred seed varieties to respond to the altered weather patterns can be limited.

Choosing alternative crops, irrigation, soil management, and improved information and early warning are common approaches to mitigating drought effects, yet these strategies are not simple to implement. Crop and varietal preferences develop over many years and are reflective of cultural preferences – complicating efforts to simply trade out crops for drought-resistant alternatives. For example, although orange fleshed sweet potato is vitamin rich and can withstand periods of drought, The International Potato Center (CIP) is working diligently to breed varieties that meet consumer preferences and that can compete in local markets with less resilient but preferred varieties (http://cipotato.org/research/sweetpotato-in-africa). Irrigation can be costly for automatic pump models, and labor intensive for human powered models. Additionally, if there is a drought, there may already be competing needs for water resources. Soil and watershed management for improved moisture retention can enhance water availability but they are longer-term programs that are not suited for the short time frame of many emergency programs. Early warning systems such as the Famine Early Warning System Network (FEWS NET) (www.fews.net) can be used to understand food security and weather trends by sharing information on rains, planting, market data, and general climate trends such as the presence of an El Niño or La Niña phenomenon. Ideally, by using early warning information of low rainfall or soil moisture, farmers can be proactive in selecting and implementing their mitigation strategies.

The views expressed in this chapter are those of the author and do not necessarily reflect the views of the United States Agency for International Development or the US Government.

While there are many easily predicted effects of irregular rainfall, such as crop failure and food insecurity, there can also be social effects of reduced water availability in the form of conflict over scarce resources. Climate variability can increase friction between different livelihood groups. For example, in parts of West Africa where farmers and pastoralists have established a system of resource sharing over time which is mutually beneficial, scarcity of water can stress this relationship. When the relationship is optimally beneficial, the pastoralists arrive with their animals in their seasonal migration just after the farmers harvest their crops. In exchange for the benefit the animal manure contributes to their fields, the farmers allow animals to graze on the stover from the harvested crops. In years where water and fodder are scarce, pastoralists begin moving early, and may even arrive prior to harvest. This can lead to land and resource conflict between the farmers and the pastoralists. Competition for scarce water resources and the potential for the livestock to consume the not-yet harvested crops heightens tensions, as do larger issues related to land tenure and resources (Shettima and Tar, 2008).

Water events: storm surges, floods, tsunamis

Agricultural areas bordered by rivers or oceans are at risk when weather and hazards bring too much water too quickly to be utilized by crop production or inundate areas with water that is not suitable for crop production, such as saline water.

Farmers in southern Africa are regularly challenged with growing conditions that include long periods of limited rainfall or drought, followed by inundation with rain leading to *floods*, an overflow that comes from a river or other body of water and causes damage, or any relatively high stream flow overtopping the natural or artificial banks in any reach of a stream (http://ks.water.usgs.gov/waterwatch/flood/definition.html). Floods within the Zambezi River basin have become so common as to be almost an annual event. These floods regularly claim lives and submerge crops and assets, reducing food security and resiliency to future droughts. In response, humanitarian agencies are promoting a combination of early warning and early action. Early warning against floods has proven very effective and potentially reduces the loss of human lives (http://www.usaid.gov/our_work/humanitarian_assistance/disaster_assistance/publications/prep_mit/files/fy2012/mozambique_pounds_of_prevention.pdf). Early action involves developing response and mitigation plans with local communities.

Not all floods adversely affect food security. In many riverine areas, seasonal flooding can bring much needed soil moisture, nutrients, and organic material to the banks. As the water subsides, farmers then plant on the banks of the river, taking advantage of the extra soil moisture. This recessional planting can provide an additional short season for crop production.

Storm surges involve a rise in sea level due to a hurricane or similarly intense storm. The increase in water level over the normal tide then combines with wind and waves and finally, water is forced ashore, and may proceed to infiltrate agricultural areas. December 2008 brought one such storm surge to the Federated States of Micronesia (FSM) and resulted in sea water washing over taro fields on several of the islands. Taro is a starchy tuber and a major food security staple for FSM islanders. Salt water can inflict varying degrees of damage on the taro patches depending on the length of time the water stands on the patch and the timing and duration of rainfall afterward to flush out the salt. Damage can result in total loss where the taro rots in the ground (Figure 1). Storm surges can sometimes be anticipated but island nations often have limited area to use for agricultural production. Some mitigation strategies include moving agricultural production to higher ground where possible, planting reserve plots of taro seedlings to ensure healthy planting material, planting in concrete beds or forming other barriers to prevent salt water intrusion, and diversifying crop production. Many months can pass on the island without rains which in turn does not allow recharging of the groundwater supplies, making the thin freshwater lens vulnerable to contamination by salt water. Storm surges can also hamper agricultural production by displacement of the population, destruction of crops or agricultural land through erosion or salinization, or destruction of infrastructure (docking areas, bridges, boats).

Tsunamis can wreak havoc on agricultural systems. Unlike storm surges, tsunamis are generally not caused by surface weather but rather, by earthquakes, submarine landslides, volcanic eruptions, explosions, or meteorites. The Indian Ocean Tsunami which sent a wall of water to Aceh Indonesia is estimated by FAO to have caused damage to more than 61,000 ha of agricultural land. The most common damages to agricultural land reported for this event were: "(a) Crop destruction by waves, salt poisoning, and uprooting; (b) de-surfacing of landscape as a result of erosion and sedimentation; (c) deposition of salt sediment; (d) trash and debris accumulation; (e) salt infiltration; and (f) fertility depletion." (FAO, 2005a). Ample rainfall washed away much of the surface salt in the weeks and months following. What remains is a high concentration of salts in layers of clay and silt that were deposited during the event. These layers are fairly impermeable to water, making the removal of salt through leaching when rainwater passes through, very slow.

Volcanic eruptions

In many countries agricultural production takes place in the shadow of quiescent and active volcanoes. Volcanic eruptions can lead to the displacement of populations due to the threat of various volcanic hazards, including ash fall. Displacement can last until the immediate threat of an eruption has passed, or it can persist until infrastructure and services that were damaged by the eruption are

Challenges to Agriculture, Figure 1 Rotten taro root following a storm water surge.

repaired. Damage to roads and infrastructure can affect future market access for agricultural products and inputs.

Early warning and monitoring of potential volcanic activity can help farmers take some mitigative actions, such as moving animals or choosing alternative locations for planting. Once ash falls, irrigation to settle the ash, as well as mixing the ash into the soil is a key rehabilitation strategy to aid in topsoil development. Other methods such as selecting appropriate varieties and adding lime to modify soil acidity can help reduce the negative impacts on production (http://www.maf.govt.nz/environment-natural-resources/funding-programmes/natural-disaster-recovery/volcanic-eruptions).

In addition to lava flows, volcanic activity can yield lahars, a moving fluid mass composed of volcanic debris and water, (e.g., 1993 Mt. Pinatubo eruption) and pyroclastic flows – a surface-hugging cloud of very hot gas and volcanic particles that moves rapidly across the ground surface, (http://www.geonet.org.nz/volcano/glossary.html), as well as volcanic ash falling for many months. All of these can cause extensive agricultural destruction. The effect of ash fall on agriculture and livestock can be significant and depends primarily on thickness of the ash cover, composition of the ash (the presence of soluble fluoride), weather following the eruption, and availability of feed and water for livestock.

The thickness of the ash fall can largely determine whether soil will be completely deprived of oxygen and "sterilized" or not. Ash fall thicker than 10–15 cm typically results in a complete burial of soils (Folsom, 1986). Chances of plant survival after ash fall can be improved if rain follows within 2–3 days of an eruption as the rain will wash ash from plants, compact the thickness of the ash fall, and facilitate recovery. Complete burial for several days often results in the death of the plants. Because ash composition and ash pH varies between volcanoes, the effects of ash mixing into the soil cannot be predicted. In some cases, soils will have a pH post eruption that no longer supports the crops which were previously grown. In addition to causing crop loss, livestock loss can be high when available water and fodder resources are contaminated with ash. This is especially true if fluorine is present in the ash in high concentrations, causing fluorine poisoning and death. Interestingly, the majority of livestock deaths following a major eruption are due to starvation (Wilson et al., 2011). Provision of emergency fodder and feed from unaffected areas might be a strategy for maintaining herds after an eruption.

Ash can also affect agricultural production by changing the amount of sunlight hours, altering soil properties, or damaging leaves or other crop parts. Finally, when rain mixes with volcanic gas, there is the potential to produce acid rain, which is also detrimental to crop production.

Plant pests and diseases

Some hazards directly target the crops being produced. Two examples of this type of hazard include crop pests (e.g., insects) and plant diseases. Crop pests are responsible for tremendous amounts of crop loss both in the field and during storage (post-harvest.) Monitoring of the occurrence and movement of both plant pests and diseases is an important step in controlling damage to agricultural production. In most cases, damage due to these two categories of hazard is not restricted to one farmer's field as pests do not respect property boundaries when multiple fields are planted in their preferred food source. Plant pests and diseases can wreak havoc at the local

production level and potentially on an international scale unless effective control mechanisms are identified and utilized.

Some plant pests are confined at a household garden, farm or local level, restricted by available food sources, climate, and mobility. Then there are those such as the Desert Locusts, which have sufficient mobility to follow crop development and the weather pattern. Locusts travel in swarms which can vary in size from the small (hundreds of square meters) to enormous, covering 1,000 km^2. Desert locust swarms can damage 100% of the crop in a field where they land and they can fly hundreds to thousands of kilometers between their breeding sites (FAO EMPRES). The desert locust has made its way across Africa, Asia, the Middle East, and Europe and has been decimating crops and vegetation since biblical times. Control mechanisms include ground and aerial spraying with insecticides. This method must be done by trained personnel at a significant cost, and local population may not consume the locusts once sprayed. Other methods include digging trenches around fields to catch marching bands of nymphs or hoppers as they head in the direction of crops. Techniques have improved over the last decades. Emphasis on tracking the swarms increases efficiency of spraying programs, and supports a shift toward a combined approach of barrier spraying and use of less persistent and more environmentally friendly pesticides, including biological pesticides. The goal is to reach the gregarious locust populations before they reach their reproductive stage. Ideally, preventing gregarization would be the best control intervention, but this phenomenon often occurs in hard-to-reach areas. There is much support in the early warning sector for monitoring and identifying potential areas of outbreaks and subsequent invasions. Where possible, satellite imagery, field surveys, and monitoring are coordinated to predict and report the path of the swarms, providing advance notification to launch control interventions and where relief might be needed to meet food needs should the enormity of the pest invasion override control attempts.

Plant pathogens are organisms that cause a disease on a plant. As they spread and infect plants, they can significantly reduce yields. Major pathogenic outbreaks in the past include the fungus *Phytophthora infestans*, responsible for "potato blight" which culminated in the potato famine in Ireland (1845–1849). Potato blight was eventually controlled with a chemical mixture to kill the mold. More recent examples include cassava mosaic virus or cassava mosaic disease (CMD), affecting cassava crops in many African countries including Burundi, Uganda, and Democratic Republic of Congo. Cassava decimation is especially dangerous as it is a major food security staple for vulnerable populations; it is both drought resistant and able to remain in the ground for the duration of conflicts. CMD is currently managed by planting resistant varieties identified in the 1990s and, in many cases, distributed to vulnerable farmers through both emergency relief and development programs.

International agricultural research centers worldwide are challenged with new or modified pathogens. For instance, wheat stem rust can cause losses of 50% of a wheat harvest when conditions for its development are optimal. Losses of 100% are possible with susceptible cultivars. Although the Green revolution brought with it the identification of a gene with resistance to wheat stem rust, this gene was subsequently bred into most commonly grown wheat varieties over the past several decades, providing a single line of resistance against wheat rust. Then, in 1999, a strain of wheat rust arrived in Uganda (named Ug99). This strain was able to overcome the inbred resistance, attacking and decimating plants as it spread, windborne, through fields. This dispersal method facilitates spread to the many fields of wheat across the world, the vast majority of which carry no resistance to this new strain. The fungus has already made its way across Africa, Asia, and the Middle East and is particularly virulent, resulting in 100% crop loss. Scientists from more than 17 agricultural research centers and offices worldwide, including the Borlaug Global Rust Initiative, are currently committed to find new resistant varieties.

The ability of a pathogen to change and thereby render a single line of defense ineffective highlights the value of preservation of landrace and traditional crop varieties worldwide rather than conversion to one or two high performing varieties. Preservation of agro-biodiversity is a strategy for reducing the impact of pests and pathogens. When one variety is planted, a pathogen that is particularly virulent may be able to move quickly through the susceptible cultivar. When there is a wide diversity of cultivars, levels of resistance will differ, potentially slowing the spread and subsequent crop destruction. Additionally, planting multiple crops and varieties is a risk mitigating strategy for farmers against all of the hazards mentioned.

Looking forward and conclusions

Throughout history agricultural systems have faced challenges from natural hazards. Being able to anticipate hazards through monitoring or early warning systems may allow farmers to better prepare for and withstand disasters which affect agriculture. Farmers regularly employ a variety of mitigative strategies to avert disaster or enhance the speed with which they recover from disasters. These include diversification of their farms or plots and modification of planting methods to enhance sustainability and increase resiliency to hazards.

Diversification spreads risk in several ways. It provides more chances of crop survival against a particular threat. For example, if climate is not favorable for one type of crop, perhaps a different type of crop with different light, nutrient, and water requirements will survive, ensuring some measure of food security. On a global scale, crop diversity and a large genetic pool for any given crop can slow the spread of pathogens and pests. Being able to choose from a variety of characteristics provides the greatest chance to meet demands of climatic trends and

pest and pathogen threats. The same is true for attack by pests or pathogens. Within crops, maintaining genetic diversity is tremendously important to long-term agricultural sustainability. Maintaining many local varieties of a given crop such as maize provides a ready supply of genetic material to better respond to evolving hazards. When only one variety is planted, the resistance to pathogens/climate stress/insect damage is limited to what is contained in that one variety. If that particular variety is susceptible to the hazard presented, a complete loss is possible.

In addition as world population growth continues and pressure on land, water, and soil resources intensifies, farmers and agricultural scientists are increasingly interested in methods such as conservation agriculture which maintain soil and water resources, and a more holistic approach to farming which considers crops as one component of the larger agricultural system. This may mitigate against many of the challenges presented by increased climate variability. The goal of this approach (ideally) is a more integrated and efficient system with less cost and waste and, hopefully, more production.

CIVIL PROTECTION AND CRISIS MANAGEMENT

Scira Menoni[1], Antonio Pugliano[2]
[1]DIAP-Politecnico di Milano, Milan, Italy
[2]Lombardia Firemen Regional Headquarters, Milan, Italy

Definitions

Civil protection is a term used in several countries to indicate the institution that coordinates emergency and crisis management. This apparently simple definition hides in fact organizational complexities which in most cases stay beyond the comprehensive term "civil protection." The latter refers in several countries to a single agency which holds the responsibility of coordinating the many others which interact and intervene on the scene of a mass calamity, ranging from firemen to emergency medical doctors, to health-care departments, and several others. The coordination agency is generally lacking own resources and means while being in a strategic governmental position, close enough to the prime minister or to similar key political levels, so to have enough authority to take the lead of otherwise independent bodies and organizations.

At the European level, for example, the Community Mechanism for Civil Protection is in charge of activating aid and assistance whenever requested both inside and outside the Community's borders on a voluntary basis.

This means that member states activate their own resources to make part of a European international team or to assist another country in need of help, according to the subsidiarity principle. The latter refers to the fact that external communitarian assistance has to be asked in case national forces are overwhelmed by the crisis and cannot cope satisfactorily with their own means.

In Australia, Emergency Management (EMA) is a division of the Government Attorney General's Department, which pursues an "all agencies, all hazards" approach, with the aim of encouraging disaster preparedness, supporting states in developing their own emergency management policies and providing help in case of crises that overwhelm individual states' coping capability. Nevertheless, no national law clearly defines what the legally binding mandates of EMA are.

In Canada, in 2003, responsibilities for emergency management were assigned to Public Safety Canada, a department which coordinates other departments, through the Government Operations Center, constituting a "hub of a network of operation centers run by a variety of federal departments and agencies, including Health Canada, Foreign Affairs," the police, and others (see the website of Public Safety Canada in the references). Despite this apparently operationally centered goal, the Center holds also responsibilities regarding planning, mitigation, response, and recovery (see *Mitigation*; *Recovery and Reconstruction After Disaster*).

In the USA, FEMA (the Federal Emergency Management Agency) is in charge of coordinating the various activities necessary to face a federal emergency as well as to set guidelines, plans, and preparedness programs. Since its inclusion into the Department of Homeland Security, FEMA lost its direct contact with the White House, that is, its crucial key position that had permitted in the past the fast deployment of forces and resources. Perrow (2007) describes rather clearly the severe shortcomings and difficulties of the newly created department, as mentioned also by several observers on the occasion of the Katrina disaster. An interesting comparison among different emergency management models around the world can be found in the Fema website (see references below).

The term "civil protection" is sometimes used also to indicate in a general, comprehensive way the entire set of organizations, agencies, and forces intervening in a disaster. Following this philosophy, the public itself is part of civil protection for a number of reasons. First because peoples' coping capacity (see *Coping Capacity*) is deemed to be important in enacting self-protection. The active role the public may play in a crisis is then fully recognized and encouraged instead of condemning it to the passive role of a spectator, defying the willing to react. Second because many times laypeople are the first respondents: it is well known, for example, that in the immediate aftermath of earthquakes, those who try to rescue relatives and friends under the debris are the same escaped victims. Last but not least, the public intervenes in the form of associations of volunteers that range from rather professionalized bodies (like volunteer firemen or members of the Red Cross and International Red Crescent Movement) and NGOs to individuals who participate in various forms to emergency response (including the more recent movement of volunteers of the technical community providing free web services as described in Harvard Humanitarian Initiative, 2011).

However the term is intended, what clearly emerges is the complexity and articulation of any institutional and organizational form of emergency crisis management. The latter being an activity that significantly challenges several of the mentioned agencies, particularly those that do not tackle emergencies on an everyday basis, as will be discussed in the following part of the text.

A last consideration regarding civil protection reflects upon the boundaries of its activity. Among the functions that are generally attributed to the civil protection, when the latter identifies a specific agency or organization, besides crisis management, prevention and mitigation are contemplated as well. Problems arise when the latter must be clearly defined. In fact, the civil protection does not have an ordinary budget specifically allocated for the structural and nonstructural measures necessary for achieving risk reduction in the short and long term. Therefore, the idea of mitigation is rather broadly used to encompass the need for risk assessment and mapping as well as training and risk communication. Still, the boundaries remain somehow vague, leaving room for controversies and institutional overlapping.

Crisis management is the set of activities aimed at facing a complex, unexpected situation originated by an accident, a war, a terrorist attack, or a natural calamity. The two words actually represent almost an oxymoron, as by definition crises are characterized by high levels of uncertainty, disruption of normal life, chaotic environment, that make them hard to "manage." Nevertheless, there are better strategies than others to cope with crises, to respond to the challenges they pose, eventually to exit them in ways that not only permit a return to normalcy but exhibit high levels of resilience (see *Resilience*). In this respect, the term management refers to a set of general rules, deriving from past experience and understanding of how complex organizations behave under severe stress, that deserve to be analyzed by those whose responsibility is to provide help, rescue, and aid during emergencies.

The word "crisis" derives from the Greek verb "krino" which means "to judge." In fact, the most crucial thing during a "crisis" is the ability to judge the situation, estimate available resources, and make decisions on how to act and respond to problems. Actually, this is the most difficult task to fulfill, making decisions under the pressure of the stress provoked by crises. Lagadec (1993), for example, suggests that whenever decisions are not taken, the chaotic situation originated by the event takes over

and simply annihilates the reaction potential of exposed systems and organizations. Weick (1988) observes that action itself helps in finding interpretations to the crisis condition while reshaping its feature in the meantime. Nevertheless "there is a delicate trade off between dangerous action which produces understanding and safe inaction which produces confusion."

There are many types of crises, which are classifiable also with respect to the initial event that triggers them. Actually some crises occur without any identifiable triggering event, or in circumstances where there are many events to which the crisis can be linked to, while no one stands out in a clear cut way. In this respect, some blackouts can be cited as an example, or some political breakdowns. In this contribution, only crises originated by natural hazards are discussed.

It should be noted that the term "crisis" may be considered close to others, for example, "disaster" (see *Disasters*). In fact, in the UNISDR Glossary, the term crisis is missing, whereas the term disaster has many connotations that are attributed here to "crisis." It may be held though that in the common use, the term "disaster" is broader in its covering the entire event, from impact to longer term consequences, whereas "crisis" refers more to the initial phases, and in this respect, it gets closer to "emergency" and "contingency." The term crisis expresses the type of disruption that one is faced with, the situation in which it is necessary to decide under significant stress and disruption of normal life. Following this reasoning, while the term "disaster" depicts the overall condition for the entire affected community, the term "crisis" is the disaster seen from the eyes of the interveners, of those who have responsibilities and are attributed the means and the resources to intervene and respond.

This brief discussion points out that even though terms like "crisis," "disaster," "calamity," and the like seem obvious, they cannot be accepted in an uncritical way. As an example, the book by Quarantelli (1998) titled *What Is a Disaster?* convincingly shows how difficult it may be to provide satisfactory and universally agreed upon definitions. Actually, different organizations, including EM-DAT or Munich-Re, or various national legislations set rather different thresholds to distinguish between what can be considered a disaster and what cannot. Not any landslide nor any ground shaking produces a level of damage and devastation so as to call for a disaster declaration. Furthermore, what makes a disaster in one region of the world may not in another, a death toll is considered high in one country and negligible in another.

Similarly, it is not that easy to attach the definition of a crisis due to some natural hazards to the level of disruption and losses that a specific event may provoke. In the following paragraphs, some crucial elements and factors generating a crisis and requiring specific actions for its control and management in the aftermath of a natural extreme will be discussed.

Here, it will suffice to list some specific conditions that can be considered as specifically characterizing crises linked to natural events. The verb "linked" and not due to or provoked by is used because the assumption here is that not only large magnitude events provoke crises, the latter can arise also as a consequence of somewhat medium or even minor environmental stress, depending on the weaknesses of exposed systems. In fact, a crisis may be originated either by a severe natural event, for example, a high magnitude earthquake, a fast landslide mobilizing large volumes, a strong volcanic eruption, or be the consequence of highly vulnerable exposed systems (see *Vulnerability*).

Therefore, in investigating the types of crises that may occur as consequence of some natural event be it very severe or not, both the characteristics of the threat and of exposed systems must be identified and described.

Types of crises

Following what has been stated above, types of crises will be classified according to hazard and vulnerability aspects.

With respect to the first, spatial and time factors should be considered. From a spatial point of view, hazards may generate local, regional, or multisite events. Local events, like landslides, avalanches, or tornadoes, are such that they hit a given place, provoking concentrated damages and losses. In this case, even though the event can be very severe and provoke significant local disruption, it is possible to delimitate an area, an event core, around which a corona and a periphery from which help may come and to which victims can be temporarily or permanently evacuated can be clearly drawn. In terms of crises management, a local unit to tackle the event from a close post is generally sent so as to check needs and demands arising from the field and then control the situation from a safe place at the shortest possible distance from the core area. Concentration of rescuers, teams, and support goods must be managed and organized so as to avoid congestion that may end up getting the opposite result to the intended.

Regional events, on the contrary, involve large areas, comprising different types of settlements and infrastructures, from rural/natural areas to highly urbanized to metropolitan. Large regional events may be transboundary, across several administrative borders, including regional and national. In this case, several teams will be sent to the area; a number of advanced units must be forecasted and positioned in strategic zones. Challenges are clearly larger than in the case of local events, because of the extent of territories and the expectedly larger numbers of affected people. Whenever regional events affect different jurisdictions or even nations, a complex issue of coordination among levels of government, different governments, and authorities arises, making the crisis easily escalate beyond the

Civil Protection and Crisis Management, Table 1 Issues arising in crises that are differently characterized in terms of spatial and temporal scales. Self-elaboration. Concepts in this table can be found in Chaps. 2 and 4 of Menoni and Margottini (2011)

Space Time	Local	Regional	Multisite
Slow onset	Crisis may not be recognized by early signs	Crisis may escalate and involve large areas and more than one country	Similarities among events in different localities may not be recognized
Fast onset	Potential indirect consequences at larger scales may not be adequately foreseen	Crisis requires significant coordination in the area without any/enough prealerting time to make first common decisions	Challenge of recognizing the crisis' actual spatial extent
Long duration	Attention by the media and even by governmental offices may fade away as time passes	Turnation of a large number of officers and workers is required Large amount of resources Temporary solutions (like shelters) for partial return to normalcy	Problems in assuring resources to all affected sites
Short duration	When the most critical phase is over, the local community may be left alone even in cases when it does not have the resources to fully recover	Difficulties may arise to guarantee coordination particularly in cross-border and interregional crises Long-term effects may not be adequately considered or treated differently across borders	Challenge to assess the needs in multiple locations Challenge in dispatching forces to a variety of places simultaneously

control and management capacity of any of the involved authorities or agencies.

The adjective multisite can be attributed to otherwise local events that occur simultaneously in different places, for example, forest fires in the dry period or a storm affecting several places in the same days. Even though events like a fire or a landslide or a storm hit individual places, their contemporary occurrence puts a much stronger pressure on intervention agencies and teams. In fact, while local events, even though very severe, permit to concentrate response forces, multisite events challenge response teams, in that resources and means must be dispatched at the same time to a variety of places. The fires which occurred in Southern Europe in the summer of 2007 are a clear example of such events that distressed significantly the Community Mechanism of the European Union and required the rapid displacement of fire fighters from France to Portugal to Italy to Greece.

As far as time factors are concerned, as shown in Table 1, two criteria must be borne in mind. The first refers to the time of onset of an extreme event and the consequent crisis. Some natural events can be sudden and rather unexpected, not so much in general as for the actual circumstance, the hour and the day in which they occur. In other words, as commented by Hewitt (1983) in his *interpretation of calamities*, there is the possibility to forecast most natural hazards, such as earthquakes, floods, and landslides which occur in areas that are prone to them and historical evidence exists of their occurrence in the past. Nevertheless, the exact moment when they will occur may not be predictable, as premonitory signals are either weak, or inexistent, or highly uncertain.

Events characterized by fast onset may generate sudden, unexpected crises, particularly when mitigation has not or has been poorly carried out. Early warning and prealert is either impossible or possible with only few seconds to minutes in advance, so that crises start when most damages and losses have already occurred. Events like earthquakes, debris, and mud flows are not only sudden but also rather rapid in their development; in a short or very short time, they deploy all their destructive potential, leaving to rescuers only the possibility to respond to losses and death toll.

Events characterized by slow or relatively slow onset, like plain floods or droughts, may be predicted in advance and actions can be taken to protect people and goods as well as to secure the most critical and strategic facilities and places (see *Early Warning Systems*).

Even though examples have been provided for slow and rapid onset events, it is noteworthy that they are only indicative and cannot be considered as fully exhaustive or satisfactory. In fact, there are large earthquakes that are announced by a series of minor tremors months ahead; there are ash crises that can or cannot be followed by a big explosion; some types of landslides do show clear signals of movement, others do not. What can be said therefore is that monitoring devices, complete warning systems, comprising besides the technical component also the social and logistic aspects, may significantly change the type of crisis, from largely unexpected to highly anticipated. The ability to generate event scenarios, previous training, exercises and simulations permit to be ready for a given event in large advance, so as to downscale the magnitude of the consequent crisis.

What is crucial in most if not all instances described above is the capacity to deal with uncertainties and make decisions despite scientific and other types of uncertainties (including legal, institutional, societal, see De Marchi 1995). In fact, the classification of crises, as mentioned above, cannot be strictly associated to the characteristics of the threats. The interface between the latter and the exposed systems, considered not only as physical but also organizational and social, is equally important to determine how a crisis will look. As suggested by Sarewitz et al. (2000), not only by reducing the scientific uncertainty associated with some natural hazards one may improve the coping capacity (see *Coping Capacity*), but also by lowering all other types of uncertainties, particularly legal, institutional, and societal. By making timing and good decisions, the catastrophic potential of some events may be lowered by reinforcing the response capacity of likely to be affected systems.

In this respect, clearly, the vulnerability of the latter plays a key role.

It would be too long and perhaps beyond the scope of the present contribution to list the variety of conditions that may shape crises, according to the characteristics of the physical built environment, land use patterns, and the mode of use of buildings in exposed areas. Clearly, all those factors influence some logistics of the crises, in terms for example of accessibility to damaged zones and to resources and facilities (Ceudech and Galderisi 2010); they also strictly influence the extent of physical damage, which in turn translates into number of affected people and extent of resources to be deployed (for partial or total evacuation, etc., see also *Evacuation*).

Another vulnerability facet determining the level of crisis can be labeled as systemic or functional. How well and how long strategic facilities like lifelines can provide service is crucial to sustain help, search, and rescue activities and therefore directly influence the level of control that can be sustained by crisis managers.

Among the variables identifying communities' vulnerability and resilience, the response capacity of established organizations, like the firemen, the army, and the medical doctors, is essential. The response system constitutes a sort of standardized and predetermined body, whose preparation and training is independent from the specific features of the crisis at stake. According to the practical experience gained in the field within an operational organization like the firemen, a fundamental lesson that can be suggested refers to the importance of being able to rely on established rules and standardized procedures at least for the most repetitive tasks, for those operations and to use those devices that are most common. Formalized crisis management models may significantly improve the performance of teams, as they permit to achieve a good level of response at least for the most repetitive and trivial operations while devoting due energy to what really stands out (Wybo et al. 2001). Without standardization and preparation, coupled with strategic management, it would be extremely difficult to even recognize exceptions and surprises.

Last but not least, as for time factors, duration of crises must be accounted for. Most plain floods, for example, may affect very large portions of a given territory but are not likely to last for long. After days, people will be able to return to their houses unless severely affected or contaminated and start reconstruction (see *Recovery and Reconstruction After Disaster*). Earthquakes would require long-term stay in temporary shelters, whereas the crisis itself may last for a number of weeks. In this case, turnover among rescuers must be carefully planned and mechanisms for exchange of solutions and information must be set up.

Models of crisis management

According to common sense, crisis management requires the presence of a strong subject able to lead the team working on the disaster scene so as to achieve the best solutions in the shortest time. While this idea holds certainly some truth, particularly when the necessity to make decisions and to lead the event instead of just being at its mercy are considered, in general, some authors (Lagadec 1995; Reason 1997) contradict the idea that centralizing decisions and actions as well as making coping organization hierarchical actually improve response. In fact, the opposite has been demonstrated. Highly hierarchical organizations are not able to respond fast to changes and be flexible enough to react to surprises and unexpected situations. They require a long chain of orders and decisions to be followed and do not allow for much initiative to those in the field, who nevertheless have the direct grasp and perception of events, even though they lack a supervision of the entire scene and of the many interconnections among areas, resources, and systems.

A good balance must be sought between one person or restricted groups' ability to control and be in charge of the situation on the one side and the personnel who are at site and have a direct vision of the event on the other, so as to guarantee decisions and leadership and, in the meantime, allow for sufficient flexibility.

Often recalled in the crisis management field is also the opposition between improvisation and preparation. To a certain extent, this opposition is linked to the one discussed above between hierarchical and "democratic" organizations. In fact, hierarchical organizations tend to rely heavily on established plans, whereas local cells guaranteed enough autonomy may take fast decisions more tailored to the upcoming situation.

One way of combining the two needs, that is, take control of the entire crisis scene, particularly when the latter is complex and extended over large areas, and the need to be "close" to the site, where the incident or the natural event occurred, is constituted by a model of operation called "Incident Command System." The latter makes part of the recently reorganized "National Incident Management System" promoted within the US Homeland Security (2008) as a model for managing large emergencies. Such a model, already well established since the 1970s, has

spread beyond the USA and is currently adopted, though under different names, in many countries worldwide.

"The NIMS is based on the premise that utilization of a common incident management framework will give emergency management/response personnel a flexible but standardized system for emergency management and incident response activities. NIMS is flexible because the system components can be utilized to develop plans, processes, procedures, agreements, and roles for all types of incidents; it is applicable to any incident regardless of cause, size, location, or complexity. Additionally, NIMS provides an organized set of standardized operational structures, which is critical in allowing disparate organizations and agencies to work together in a predictable, coordinated manner" (Homeland Security 2008, p. 6). According to the model, local cells are sent to the scene with the capability to guarantee information exchange among those in the disaster scene and among the various organizations present on site and their respective operation centers. The incident command system is therefore constituted by an advanced group of technically skilled personnel who are also granted the capability to decide some immediate actions on site, coordinate the various organizations, and guarantee information and exact request of resources to each operational center and to the main emergency control room.

In the case of natural disaster, this organizational mode has to be adapted to the environmental and social contexts and to the characteristics of the hazard, particularly as far as the spatial features described above are concerned. Several challenges have to be met in adapting the NIMS to individual countries' characteristics and previous mode of operating. For example, the system requires the extensive use of technical terms and standardized documents. Both have to be "translated" linguistically and also semantically in newly produced documents and then a period of extended training must be foreseen. The transition from previous models to the new, even though more efficient structure, requires planning and the provision of additional resources.

In the case of a local hazard, an advanced command post may be enough; the same cannot be held for regional or multisite events, where clearly a net of advanced command posts must be coordinated so as to guarantee the correct treatment of each site where an event has occurred.

Civil protection and crisis management in a nutshell

In the previous section, the model of intervention, whether highly centralized or distributed, whether hierarchical or flexible, has been shortly discussed. In this section, the much more complex issue of how civil protection, as initially defined, manage crisis will be addressed.

Drawing upon Cherns and Bryant's (1984) work on the construction industry, it can be held that also crisis management requires inevitably the coordination of a complex temporary multiorganization that must achieve a unique goal (facing and exiting the crisis condition) in the shortest time and reducing as much as possible losses and errors. First, because crisis management requires the presence and the action of various agencies and organizations, ranging from the firemen, to the police, to the army, to the agencies in charge of environmental assessments, health indicators, etc. Those agencies and organizations share (or should share) a common objective, solving the crisis, but are characterized by their own culture, by their political and social mission, by their means and resources. Some of the organizations involved in the crisis are dealing with "minor" or "normal" emergencies everyday on a routine basis, for example, firemen or emergency doctors. Others are involved in crisis management only occasionally, depending on the event to be tackled, for example, lifelines managing companies, public health agencies, etc.

Those organizations do not generally meet on a routine basis, hardly know each other, both as organizations and as individuals, which makes coordination and management particularly challenging, among other reasons because the one who will be in charge of coordinating must get the approval and respect of all involved parties. What Cherns and Bryant (1984) say about the construction industry perfectly fits also the crisis management arena: "Relationships [among the various bodies] are formally governed by the contract [in the case of crisis management the contingency plan or other formal governmental arrangements and protocols can be considered], but are supplemented and moderated by informal understandings and practices which have evolved to cope with the unforeseen, sometimes unforeseeable difficulties that characterize [disasters]."

Unfortunately, few studies have been devoted to analyzing the difficulties and the solutions found by the temporary multiple organizations in charge of crisis management in given circumstances and under different crisis duration. Some work that can be quoted refers to organizations under stress, how they cope and how they can be brought to react better and even with success. A recent relevant work in this direction is provided by Comfort (2007) who suggests that beyond control, coordination, and communication capabilities, the real challenge "is to build the capacity for cognition at multiple levels of organisation and action in the assessment of risk to vulnerable communities." In her contribution, Comfort stresses the importance of cognition, as the capacity of multiple organizations to build a common understanding and interpretation of the evolving emergencies and act accordingly.

In general terms, it can be said that much more research has been carried out with respect to what happens within the same organization under stress, whereas little has been done with respect to the intercorporate dimension, that is, among distinct organizations. In general it can be said that difficulties encountered within the same organizations, for example, relatively to information exchange, decision making, identification of available resources, are exacerbated when a number of organizations must work together, particularly when such circumstance is temporary and not too frequent.

A specific point should be raised with respect to international crisis management, when aid is given to poor and developing countries. In fact, such intervention often sees the convergence of massive forces from a variety of countries in the affected place. Recent examples are the intervention on the occasion of the devastating tsunami hitting Southern Eastern Asia in 2004 (see Christoplos 2006) and of the earthquake in Haiti, January 2010. As it is already very complex to achieve coordination and cooperation among different organizations of the same country, one may easily imagine the almost insurmountable difficulties when the latter must be achieved among organizations pertaining to different countries. In this case, lack of coordination may be dramatic, producing overredundancy of some goods, complete lack of others, mismanagement in the form of goods supplied where and when they are least needed, tragic delays where they are urgent, etc. In addition to the multiple temporary organizations of different countries and speaking different languages, problems of logistics, understanding of the social, political, historic, and cultural context are also crucial, leading to a variety of mistakes, sometimes severe. There are not simple solutions to those problems; nevertheless, some elements may be considered to improve current practices. On the side of aiding countries, what can be asked is a higher understanding of the social and cultural context before providing help, building on experience to avoid errors already committed in the past, avoiding putting too much emphasis on fast results to be shown to donors, in favor of deeper analysis of actual needs, and identifying where resources can be invested so as to obtain the best results for the victims. On the side of recipients, what would be clearly ideal is the training of local responsible personnel able to direct materials and goods, to dispatch help to the most affected areas, and to provide guidance to international and external agencies. At the very least, local authorities should be able to interface with international agencies so as to avoid to be completely overridden, with the uncomfortable but almost inevitable outcome of money and resources spent haphazardly.

Main characteristics of crises today and potential challenges of tomorrow

Challenges can be grouped according to whether they are intra- or interorganizational, that is, whether they refer to problems arising within the same organizations involved in crisis management or among different agencies and organizations.

Within the same organization, the following can be mentioned:

- Ability to transfer information timely and effectively among the various members and subparts. Studies have shown that organizations relying on formal systems of communication are more likely to manage effectively crises particularly when technical disturbances in communication devices may occur (see McLennan et al. 2006).
- Level of preparation and preplanning. Regarding this particular point, a rather interesting literature exists (Lagadec 1993, 1995; Roux-Dufort 2000), depicting what works well, poorly, and not at all prepared organizations. Among other criteria, the most important is the behavior and attitude of responsible managers in facing crises, as in prepared organizations the latter tend to take the lead, whereas in the least prepared they tend to retire in their own shell and protect themselves from criticism. Equally relevant is the ability of organizations to learn from experience and to successfully interface with the public and the media.
- A specifically mentioned aspect refers to decision making, that is, the ability to make decisions (possibly sound ones) in the urgency of a disaster, under the tremendous pressure of the evolving event and the concerned public(s). Lagadec, Roux Dufort, and Weick all share the conviction that crisis management is a strategic not a reactive activity.

An example of decision which is particularly hard to make in the face of natural disasters is early warning in case of large uncertainties (see *Early Warning Systems*). Specific examples are in the field of seismic risk, where early signals may be particularly difficult to interpret correctly and, in any case, leave large room for false alarm (see *Earthquake Prediction and Forecasting*). Even though other hazards, like volcanic eruptions or floods, are in general more predictable than earthquakes, they all share some basic common aspects, like the sources of uncertainty, deriving from the quality of available data, the quality of scientific explanations and models. Other types of uncertainty intertwined with the latter refer to the societal and institutional backgrounds where the decision must be taken. As Sarewitz et al. (2000) convincingly showed, sometimes improvement in scientific understanding of a given natural phenomenon may even lead to larger and deeper uncertainties. Instead, the latter may be reduced by means of strong and sound decision making rather than better science or better data.

Larger difficulties arise when multiple organizations intervene in the same crisis scene:

- Communication among different organizations which does not only imply issues of language, jargon, secrecy, willing to keep information inside each organization, but also technical aspects, for example, different radio frequencies assigned to every agency and organization, a simple fact holding heavy consequences.
- Communication with the media, when multiple actors are in theory eligible to provide information. How to agree among the police, firemen, medical doctors, etc., about the opportunity to dispatch a unique information bulletin, particularly when stakes are high and uncertainty large?
- Need to share not only material resources but also the information about the actual availability of those resources and the way to obtain them from legitimate owners. Even though the civil protection is entitled to

ask for resources, conflicts among ministries and governmental agencies must be avoided; furthermore knowledge about existing resources must preexist if they are to be practically managed during the crisis.

A final word in this section must be devoted to the so-called lay or general public. Some of the latter may actually be part of the population who may be potential victim of the disaster. Social scientists have been producing thousands pages of studies describing and reasoning about the response of "people" to disasters under different circumstances and in different contexts (just as a reference, Barton 1970; Drabek 1986; Fischer 1996). Time has come to make those studies part of active crisis management, avoiding treating the public as pure recipients of somebody else's thoughts and decisions, recognizing the essential active role that the affected population actually plays in the majority of cases. Attempts to elude this reality have often turn crisis management into failure even in the presence of substantial means and well-prepared organizations. In this respect, the issue of informing the population before and during crises is clearly crucial. As Parker (1999) stated, there is often a contradiction between the requirement to keep it secret, in the fear of "panic," and the need to have the public act in an informed way (see *Risk Perception and Communication*). Considering again the example of early warning, Parker and Handmer (1998) have shown how any information, advice, or input from official sources undergoes a process of verification and analysis of costs and benefits implied in the suggested or required actions. The decision to comply with the latter depends, among other factors, on the familiarity with the hazard, on the familiarity with the authority issuing the alert, on the correspondence between the given message and the perceived threat, and, last but not least, on the tone and wording of the message itself.

Inter- and intraorganizational challenges mentioned above are limited to what is already known about past crises, emerging from experience and thinking about what happened in past events.

This is just one part of the problem at stake for today's crisis managers, the other one being future challenges, tomorrow's problems, and constraints that are not always that easy to identify and detect in advance. Scenarios of future and emerging hazards and risks must be first depicted in order to be able to answer the just asked question of how future crises will look like (see *Global Change and its Implications for Natural Disasters*).

In their book, *La fin du risqué zero*, Guilhou and Lagadec (2002) addressed those issues, pointing at two main concerns, referring to the emergence of surprises on the one hand and to the need to develop specific scientific expertise on the other. As for the first, the Authors hold that future crises will imply larger surprises and unexpected outcomes, the only way to be prepared for is training on scenarios and simulations, not because the future will be as drawn in the scenario, but because the latter helps those dealing with crises to prepare for the unexpected. As for the second, there is an increasing demand for scientific experts able to provide guidance on the basis of poor quality (and sometimes also quantity) data, making a guess informed by their knowledge and past experience in the field of concern (for example earthquakes or floods). This may be considered as a particular case of scientists advising policy makers (Jasanoff 1990), in a condition which is particularly stressful and delicate for both. As an example of tragic problems that may arise in the aftermath of a catastrophy one may recall the ongoing trial in Italy after the l'Aquila earthquake, in which scientists who worked as consultants for the civil protection are under trial for their failure in correctly communicating the risk and/or uncertainties implied in risk estimation and assessments capabilities (see Hall 2011).

In this contribution, little room has been devoted to technology, despite its omnipresence in all arenas of modern life, certainly in the field of emergency management. Computers, satellites, and cellular phones have changed substantially the conditions under which officers and civil protection servants are working (Harvard Humanitarian Initiative 2011). The increasingly extensive use of Internet has changed also victims' ability to get informed, to exchange feelings, problems, and sometime crucial information. Many technologies, starting from the GIS to several communication devices, have slowly shifted from military to civilian applications. In spite of such major influx of modern technologies, which certainly must be used to manage crises at best, a number of warnings must be raised, not with the aim to contradict the obvious potential of technologies, but rather to promote their most effective usage.

Quarantelli (1998) suggested for example that overreliance upon modern technologies should not divert attention from the need to provide backups, including manual backups, in case of technologies' failure; in any case, technologies should be looked for and developed to address actual needs rather than reshape crisis management to fit the technical features of existing devices offered in the market. Finally, the rather trivial but nonetheless important reminder of the fact that problems of interpretation and meaning cannot be solved by "more technology" (nor by more science as suggested by Sarewitz et al. 2000).

Conditions for successful crisis management: lessons learnt from successful and unsuccessful cases

There are a number of conditions that are commonly considered as keys to positive outcome of crisis management, including ability to govern complex and highly dynamic contexts and situations, ability to select the crucial information in the midst of flouring data and uncontrolled rumors, and ability to anticipate on the basis of understanding of the situation and thanks to a prior effort in designing scenarios and simulations helping to identify weak points and fragilities of both the exposed environment and communities.

One of the most crucial aspects refers to the capacity to learn upon experience, to capitalize past mistakes and successful results, and to rethink strategy and form of organizations. Well-organized agencies are able to face even failures so as to learn and question basic assumptions in an effort to be much more prepared for the next occasion; unprepared organizations do not even have the tools to analyze what went wrong and lack human, technical, and financial resources to recover in a resilient way. A resilient organization in this sense is not only able to recover after a failure but also to restructure itself so as to become stronger and take advantage of the lessons learnt. This is clearly a very demanding achievement, while most organizations tend to restore pre-event patterns, aiming at surviving, keeping the attention all focused on the specific aspects of the just occurred crisis, without questioning the entire set of organizational assumptions and fundamental beliefs.

Still the problem that remains open is how temporary multiple organizations can accomplish such learning which should not be only individual but also collective, that is, related to the entire set of different agencies, private companies, groups, and organizations making part or coordinated by civil protection and contributing to the solution of a crisis for the best or for the worst.

And even more challenging is the question of how to keep the memory of such learning, of the conditions that led to positive as well as to negative outcomes. Who should be responsible for keeping such memory and what form such memory can take. It can be suggested as a partial solution that emergency plans (see *Emergency Planning*) may be one of the material places where such memory can be kept, in the sense that the plan should constitute both a reminder of activities and procedures that proved to work well under given scenarios and may as well provide room for learning lessons from real events and simulations so as to revise the plan whenever the latter is being felt obsolete or requiring any kind of updating.

One unfortunate observation made by some authors (De Marchi 1996; Murphy 2009) is regarding the large amount of information, expertise, and know-how that is lost after some time has passed since the last crisis and several lessons must be learnt again and solutions found again, whereas they had already been achieved but not successfully transmitted in the past. In this regard, reports of emergencies that have been tackled in the recent past, in various developed and developing countries, are worthwhile reading and analyzing with the aim to build a reference archive at least for those problems and obstacles that arise over and over, which would deserve to become a common patrimony of all those in charge of crisis management at different stages and with varying levels of responsibility.

Summary

Civil protection is a term used in several countries to indicate the institution(s) that coordinates (or tackle) emergency and crisis management.

Crisis management is the set of activities aimed at facing a complex, unexpected situation originated by an accident, a war, a terrorist attack, or a natural calamity.

Crisis management is a particularly complex activity, which requires a number of qualities from those who are in charge of its solution. It is stated that crisis management as a definition holds an intrinsic contradiction in that crises are unmanageable by their very nature. They are characterized by a number of aspects, like difficulties in getting the right picture and extent of damage, disruption and resource needs, problems in communication at all levels, among stakeholders and with the public, rapid development, strong pressure on decision makers, and significant uncertainties about potential outcome of alternative decisions and consequent actions. Those and other features make the solution of crises particularly troublesome and questioning fundamental beliefs and procedures of the established organizations which are expected to deal with them effectively. Those organizations are generally grouped under the label of civil protection. The latter term may either refer to an individual organization which is in charge of coordinating the activity of the many others who intervene on the scene of a disaster or to the entire set of organizations entering in a disaster field. In both cases, crisis management often implies the establishment of a complex temporary multiorganization, comprising a variety of different agencies and organizations that meet on the occasion of a disaster and have to cooperate despite cultural, language, and mission differences. Findings of recent literature and deriving from practical cases are proposed to discuss what are the most agreed upon conditions that may lead to satisfactory crisis management solutions.

CLASSIFICATION OF NATURAL DISASTERS

Thomas Glade[1], David E. Alexander[2]
[1]University of Vienna, Vienna, Austria
[2]Global Risk Forum, Davos Platz, Switzerland

Introduction

The question of how to define a disaster and which criteria should be applied to classify it has been the subject of vigorous debate among practitioners of the field (MunichRE, 2006; Perry and Quarantelli, 2005; Quarantelli, 1998). For example, Berren et al. (1980) offer an independent and comprehensive classification that is not limited to natural disasters and is based on type and duration of disaster, magnitude of impact, potential for occurrence, and ability to control the impact. Other classification schemes consider the differentiation by magnitude of event or consequences, by the different scales (such as individual, family, community, and region), or by speed of onset and predictability. Hence, numerous classification schemes have been proposed, and little would be gained from reviewing them all here.

Despite these reservations, there is broad consensus that a disaster is an event or situation that severely disrupts normal socioeconomic activities and causes damage and possibly casualties. Attempts to quantify the definition, for example, in terms of monetary losses and numbers of people killed (Foster, 1976; Keller et al., 1992; Munich Re, 2006), have not met with universal acceptance. Nonetheless, it is clear those disasters there is a qualitative difference between disasters and lesser events, in that they require extraordinary responses in terms of resources and organization (Kreps, 1983). A common definition of a disaster is that the coping capacities of the affected individual, group or unit (local, regional or national governments, public institutions, social groups, etc.) are exceeded and external support is likely to be required. Hence, it may be appropriate to base the classification of the magnitude of emergencies and contingencies upon ability to cope with and respond to events of a given size (Table 1).

Three global data sources for natural disasters are available. Two are data catalogs compiled by insurance companies: the Sigma database of SwissRe and NatCatService of MunichRE. However, the most widely used data bank on disasters is the OFDA/CRED International Disasters Database (EM-DAT, refer also to www.em-dat.net), maintained at the Centre for Research on the Epidemiology of Disasters (CRED) of the Catholic University of Louvain in Belgium. Besides temporal information, all entries are arranged by continent, country, and theme, as requested by the UNISDR Secretariat.

It has long been noted that the term "natural disaster" is not particularly apt (O'Keefe et al., 1976). For example, although most earthquakes are entirely natural phenomena, the root cause of seismic disasters could be regarded

Classification of Natural Disasters, Table 1 A size classification of emergencies and contingencies (Partly after Tierney, 2008)

	Incidents	Major incidents	Disasters	Catastrophes
Impact	Very localized	Generally localized	Widespread and severe	Extremely large
Response	Local efforts	Some mutual assistance	Intergovernmental response	Major international response
Plans and procedures	Standard operating procedures	Emergency plans activated	Emergency plans fully activated	Plans potentially overwhelmed
Resources	Local resources	Some outside assistance	Interregional transfer of resources	Local resources overwhelmed
Public involvement	Very little involvement	Mainly not involved	Public very involved	Extensively involved
Recovery	Very few challenges	Few challenges	Major challenges	Massive challenges

as poor construction of buildings rather than the occurrence of ground shaking. Hence, there is a motive for regarding earthquakes as human-made disasters. In fact, because so much of the impact of disasters depends upon vulnerability, a predicament that mainly depends on human decision making, "natural" disaster can be regarded as a convenience term which distinguishes one class of phenomena from others. In this case the generating mechanisms stem directly from events in the geosphere, biosphere, atmosphere, and hydrosphere.

"Natural" disasters are caused by extreme events, in the sense of large departures from long-term mean values. For instance, sudden excesses of precipitation can cause floods, whereas long drawn-out shortages can result in drought. In this respect, *speed of onset* and *duration* are important criteria in classifying events. Earthquakes and rapid debris avalanches are examples of sudden-impact disasters, whereas drought and desertification or soil erosion are examples of slow-onset events. Most earthquakes have a main shock that will last from a few tens of seconds to a couple of minutes, but the sequence of aftershocks can stretch the emergency period to hours or days. This contrasts with a drought that may be prolonged for months or years and desertification that is essentially a permanent condition, i.e., one that is technically challenging and expensive to reverse. The typology suggested by the U.S. National Research Council's Committee on Disaster Research in the Social Sciences. (US NRC, 2006) is similar to the discussion presented here, but also includes the scope of impact.

Among extreme natural phenomena there is a wide variety of speeds of onset and duration, and in turn a large variation in predictability and potential for warning. For example, tsunamis are generated abruptly by the sudden displacement of a column of ocean water. Triggers may be earthquake activity, submarine landslides, or meteorite impact. However, the very long distances that tsunamis travel allow monitoring to take place and warnings to be issued to distant coastal areas in their path. This has been successfully applied, for instance, in the tsunami generated by the Chile earthquake on February 27, 2010, and the respective precautionary response along the Western Pacific coasts including Japan and New Zealand. For the Pacific basin warning lead times may exceed, at most, 17 h, but the main problems occur with "near-field" tsunamis (those that are generated locally) in which even instant detection does not allow more than a few minutes' warning to be issued to local communities. However, one should never forget that the population at risk from a local tsunami can often recognize earthquake shaking as an environmental cue indicating a need to evacuate to higher ground (McAdoo et al., 2009).

The prospect of short-term prior warning of earthquake main shocks has long been a goal for seismologists, but has proved consistently elusive, mainly because each earthquake involves some degree of complex uniqueness. Hence, most seismic disasters occur without prior warning, other than the long-term identification of areas at risk and recurrence intervals of earthquakes of a particular maximum size.

The predictability and warning potential of volcanic eruptions is highly variable. Heat fluxes, harmonic tremor, and gas emissions all indicate the rise of molten magma close to the Earth's surface, but the exact timing of eruptions tends to defy prediction. In the mid-1980s volcanic emergencies occurred in the Caribbean and southern Italy that lasted months without any actual eruptions. In contrast, many extreme events of an atmospheric or hydrological origin have a higher degree of predictability. The preparatory phenomena can be observed by direct measurement (e.g., rain gauges and streamflow monitoring) or remote sensing (synoptic views of storms), and numerical modeling can give forecasts of pending events.

Drought is the archetype of a slow-onset, or "creeping" disaster, a category that includes desertification (the degradation of land productivity) and accelerated soil erosion. This sort of phenomenon tends to be insidious. It may go undetected until the impact is chronic, and thus the state of disaster is defined by the cumulative sum of effects.

Recurrence interval and regularity are two further elements in the classification of natural disasters. Although many anthropogenic phenomena are nonrecurrent (for example, transportation crashes and catastrophic pollution

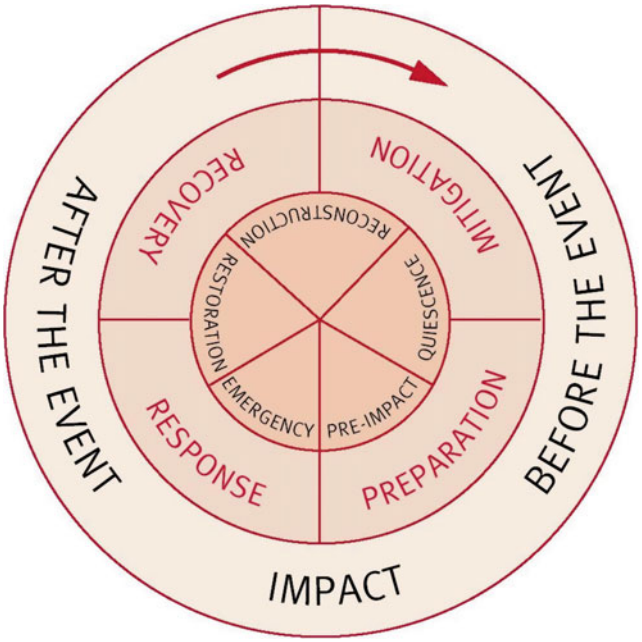
episodes), most extreme natural events are repetitive. The degree of regularity, or cyclicity, depends on the type and origin of the phenomenon. Meteorological and hydrological events tend to be the most cyclical on account of seasonality. In South Asia, monsoon-induced rains cause summer flooding; in the eastern central Atlantic Ocean the general circulation of the atmosphere leads to a hurricane season that extends from May to November; in the Pacific basin the El Niño-Southern Oscillation (ENSO) causes a 4-year cycle of floods and storms; and in the European Alps, large magnitude snowfalls often associated with temperature changes cause snow avalanches that tend to have their peak occurrence in particular months of the year (e.g., slab avalanches in deepest winter and slush avalanches in spring).

Many extreme atmospheric phenomena recur on complex cycles. Annual seasonality provides the shortest of these, whereas sunspot occurrence, fluctuations in the Earth's ionosphere, and trends in climate change provide others. Earthquakes tend to have definable cycles based on the gradual accumulation and sudden release of strain in the Earth's crust. On the San Andreas Fault the occurrence of high-magnitude earthquakes has been established by carbon dating of exposed faults, and other indications, as averaging once in 160 years. However, variations in the recurrence of seismic events can require confidence intervals that may be more than 50% as large as the cycle itself. The situation is even more indeterminate for volcanic eruptions, where the intervals between events may be very much longer than human timespans, in some cases as much as 10,000 years.

Regarding earthquakes, the picture may be complicated by other contributory factors. For instance, some research indicates that precipitation events may trigger large earthquakes (see Huang et al., 1979). The large amount of water made suddenly available adds weight to the earth's surface over a relatively short-time span. The stress–strain field in the Earth's crust can thus change very rapidly. If there are stable conditions, precipitation will have no influence on earthquakes, but if a region is already weakened then additional loading through precipitation may very well have an influence. The same is true of marine tides and "Earth tides" the pull of the Sun-moon system on the Earth's crust.

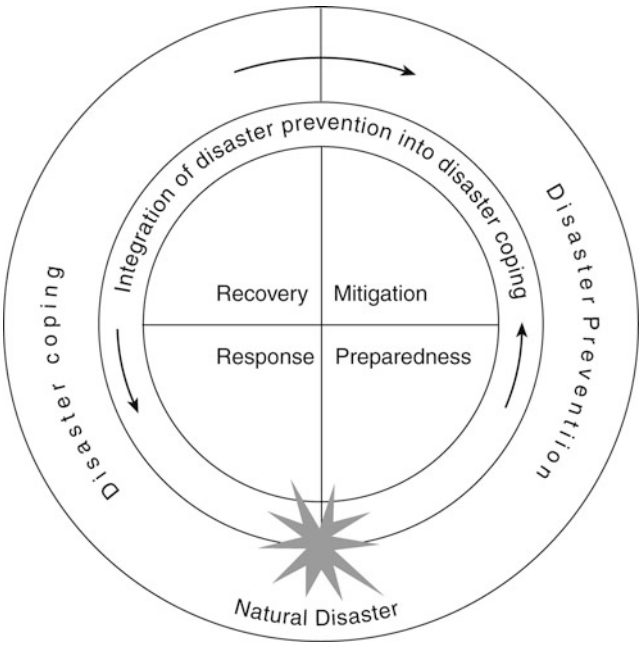
The case of river flooding illustrates the difficulty of using recurrence intervals in planning and preparedness. Following the practice in the USA, many countries use the 100-year flood as a benchmark. This is an event that has a probability of occurrence of 100% in a century and 1% in any single year. It usually corresponds to a defined floodable area and a set of depths of inundation, both of which can be expressed on maps. Convenient as the 100-year flood is, there is no guarantee that it will be the most significant or most disastrous event. Neither will it necessarily occur after a 100-year interval without major floods. The dilemma for land-use and emergency planners is what size of event should be used for preparation.

Probability distributions of diverse kinds of natural events were given by Hewitt (1970). Most of them were deemed to follow the magnitude-frequency rule, in which the larger the event, the smaller its probability of occurrence during any given interval of time. With normalization using logarithms, this can be reduced to a straight-line on a graph. However, the degree of predictability tends to fall with larger events for which there are limited or no data because the time spans are longer than those of existing measurements. Current thinking (Blöschl and Zehe, 2005) suggests that larger, less frequent events may be more significant than recognized in the past. This is the so-called "fat-tailed distribution" problem, in which large events are overrepresented in probability distributions, inducing major disasters to be more common than expected. This may be reinforced by the future tendency of climate change to increase the intensity, if not the frequency, of extreme meteorological events.



To some extent the complexity of extreme natural events defies classification. A good example of this is furnished by landslides (mass movements). Classifications (e.g., Cruden and Varnes, 1996) have commonly been based on the mechanism and speed of movement, with particular attention to flowing, sliding, falling, toppling, gliding, and creeping, and to a range of speeds that extends from infinitesimally slow to hundreds of kilometers per hour. Other classifications have considered the morphology of the phenomenon or its lithological setting, although perhaps with less success, and yet others have taken into account whether movement is primary, dormant, reactivated, or relict. Clearly, a perfect classification, if such were possible, would have to utilize sets of information on a wide variety of geological, mechanical, kinematic, and environmental factors. The first difficulty is to define boundaries on continuous phenomena, for instance, in speed of movement, which in most cases can only be arbitrarily divided up. Additionally, speed may vary within one large landslide body. The second, and overwhelming, problem is that the majority of mass movements in natural slopes are composite events, for example, flow-slides or avalanche-slide-falls. Slumps, in particular, may be reactivated paleolandslides, which further adds to the complexity. Moreover, many mass movements result from the underlying lithological complexity, particularly the juxtaposition of permeable and impermeable strata and the inclination of the respective layers. These factors tend to make classification somewhat artificial and to prevent it from being definitive.

In classification perhaps the broadest distinction is between natural disasters such as earthquakes and floods, technological disasters such as transportation crashes and toxic spills, social disasters (e.g., riots and crowd crushes), and intentional disasters (conventional and CBRN terrorism – see Showalter and Myers, 1994 and Steinberg et al., 2008). There is, of course, plenty of opportunity for overlap, as in the so-called "NaTech" disasters, which have natural origins and technological effects. For instance, reservoir dams can be affected by



floods, earthquakes, landslides, avalanches, or siltation. Indeed, as human impact is a prerequisite for an event to become a disaster, all natural catastrophes are to some extent NaTech events.

Like other forms of disaster, recurrent natural events can be considered in terms of the "disaster cycle" (Figure 1), with its phases of mitigation, preparation, emergency response, recovery, and reconstruction. The cycle has been criticized on various grounds. Not all events are cyclical, not all cycles are regular, and the phases may overlap or be superimposed, rather than be sequential (Neal, 1997). Three major issues are involved when dealing with the cycle. Firstly, mitigation and preparedness should be concurrent, not sequential as indicated in the figure. Secondly, some parts of the community may enter the recovery phase while others are still in response, leading to geographical discrepancies in the application of the cycle. Thirdly, mitigation is more likely to be undertaken if it is integrated into the recovery rather than constrained to follow it (Lindell et al., 2006). But despite these criticisms, the cycle has proved to be a robust and useful model, both in training and in the organization of disaster risk reduction (DRR) activities. Clearly, the duration of the cycle, and also the relative length of its phases, depends on the duration, geographical extent, and seriousness of the disaster impact. A major catastrophe may affect tens of thousands of square kilometers and hundreds of thousands of people. Recovery from it may take decades.

The "disaster cycle" has been lightly revised by Dikau and Weichselgartner (2005 – see Figure 2). In the new version countermeasures taken either in terms of supporting structures or land-use planning may alter or change the effects of the disaster impact.

Classification of Natural Disasters, Figure 1 The disaster cycle.

Classification of Natural Disasters, Figure 2 The revised disaster cycle (Revised by Dikau and Weichselgartner, 2005).

Summary

A natural disaster is an extreme event, caused by a natural phenomenon that has severe adverse impacts on human lives and livelihoods. Such events result from natural processes in the atmosphere, hydrosphere, biosphere, or geosphere. They can be characterized by their type of process, speed of onset (from instantaneous to long drawn-out), duration (from seconds to years), predictability, potential for warning, and scope of impact. A further element in classification is cyclicity and recurrence: events vary from unique to highly cyclic depending on their origin and on factors such as seasonality or the buildup of crustal strain.

The global sequence of natural disasters is irregular, but it shows a trend toward increases in the number and size of events of all kinds. It is dominated by natural processes such as floods, storms, and earthquakes, while others such as tsunamis or landsliding are increasing in importance as the vulnerability to them of human settlements and activities increases. Clearly, the impact of a natural event cannot be a disaster unless humans are affected. If a high-magnitude natural process develops into a disaster, this is not only an expression of its event characteristics, but also a reflection of the social context. Hence, any classification scheme for natural disasters should consider both the natural environmental and social dimensions.

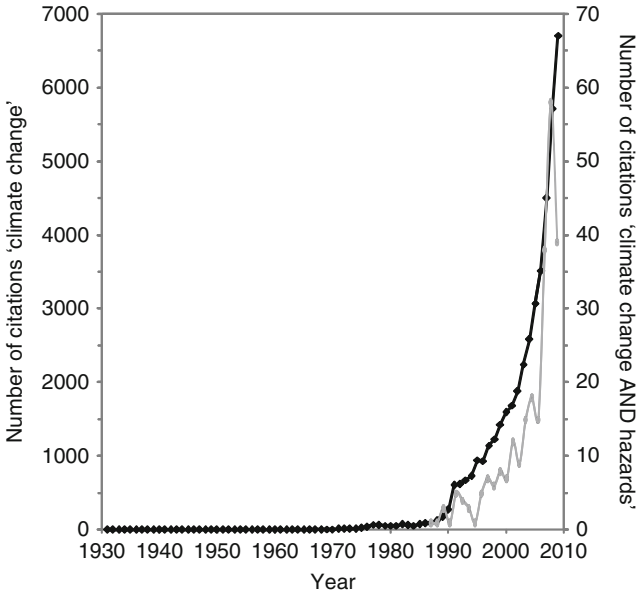
CLIMATE CHANGE



Jasper Knight
University of the Witwatersrand, Johannesburg, South Africa

Definition

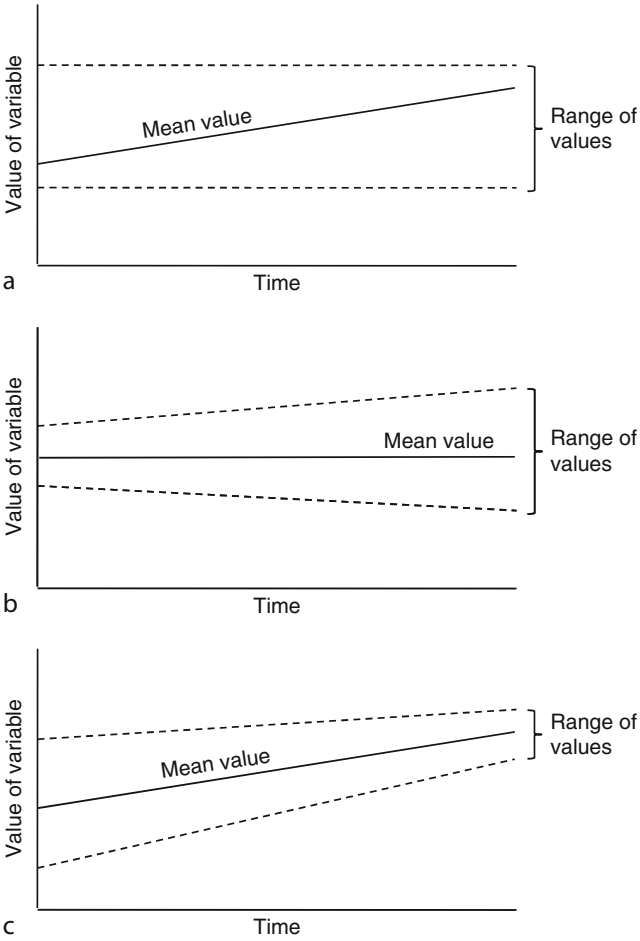
Climate change. (1) A statistically-significant change in the state of a particular climatic variable (commonly, mean annual air temperature; MAAT) that can be detected at a given place over a given timescale, and based on observed, instrumental data. (2) Article 1 of the United Nations Framework Convention on Climate Change (UNFCCC) defines climate change as that "which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods." (3) The Intergovernmental Panel on Climate Change (IPCC) has a slightly wider definition, inasmuch as it sees climate as a totality of different variables (precipitation, temperature etc.) and states that climate change can take place by a combination of natural and anthropogenic forcings (IPCC, 2007, p. 78).

Introduction

"Climate change" is an important and quickly-developing research area of the twenty-first century. It has spread from a relatively narrow and defined base in numerical modelling, meteorology and atmospheric physics to an all-embracing topic that spans the social and physical sciences, arts and humanities, and touches all areas of academic and applied research (Hulme, 2009). Figure 1 illustrates the increase in growth of research related to climate change. Moreover, "climate change" is now synonymous in the public sphere and mass media with "anthropogenic global warming," which fits with the UNFCCC (definition 2, above) but which is significantly different to its scientific meaning as given by the IPCC (definition 3, above). It is important to distinguish between these definitions because they imply the roles of different forcing factors on, in the context of this report, natural hazards. Although the IPCC definition of climate

Climate Change, Figure 1 Graph showing the increase in number of recorded citations on Web of Knowledge to year end 2009 (http://apps.isiknowledge.com, accessed January 23, 2010) with the keywords "climate change" (*black line*, left axis, $n = 43{,}297$) and "climate change AND hazards" (*grey line*, right axis, $n = 257$). Note the very marked recent increase in research on climate change and hazards although this is consistently two orders of magnitude smaller than work on climate change generally.

change is favoured over that of the UNFCCC because it considers both natural and anthropogenic processes, this contribution discusses the role of climate change in natural hazards within the context of specific climatic variables (definition 1, above) that correspond to present day climate change attributed to anthropogenic global warming. This approach is adopted because, in the real world, most natural hazards typically result from a particular type of climatic or meteorological forcing (such as very high precipitation or very strong winds), rather than from the sum of different climatic variables working together. Other direct measures of climate change that are related to MAAT include changes in albedo; sea surface temperature; seasonality of temperature range; radiative and sensible heat flux; and insolation receipt. These measures are in addition to changes in atmospheric composition (mainly CO_2) that is explicit in the UNFCCC definition, but also need to be considered within the wider context of climate change. Such alternative measures also suggest that "climate change" cannot simply be defined or parameterised using single measures alone: it can also be measured indirectly using other meteorological and associated climatic variables. These include, for example, relative humidity (which reflects latent heat flux); wind strength, direction and duration (which reflects the disposition of atmospheric pressure cells and gradients); sea ice area (which reflects sea surface temperature and freshwater flux patterns); and phenology and senescence of land plants (which mainly reflects MAAT).



In addition to the direct and indirect measures, climate also defines the context and boundary conditions within which geomorphological and ecological processes operate. Climate change can therefore also be evaluated indirectly through the dynamic behaviour of processes and landforms in different physical environments, including those occupied by rivers, glaciers and coasts. For example, increased precipitation usually results in increased river discharge, and it can also drive increased river bank erosion and sediment transport through the river system (see *Flood Hazard and Disaster*). These effects can be seen through the behavior of rivers at the present time, which enables relationships between precipitation, river discharge and sediment transport to be established. Furthermore, these processes can be linked directly to the dynamic behaviour of landforms and sediments, particularly on river floodplains, that evolve in response to changing river regimes over different spatial and temporal scales (Thorndycraft et al., 2008). Landforms and sediments that are preserved within river floodplains, at river mouths, and within river terraces provide evidence for past river responses to climate forcing.

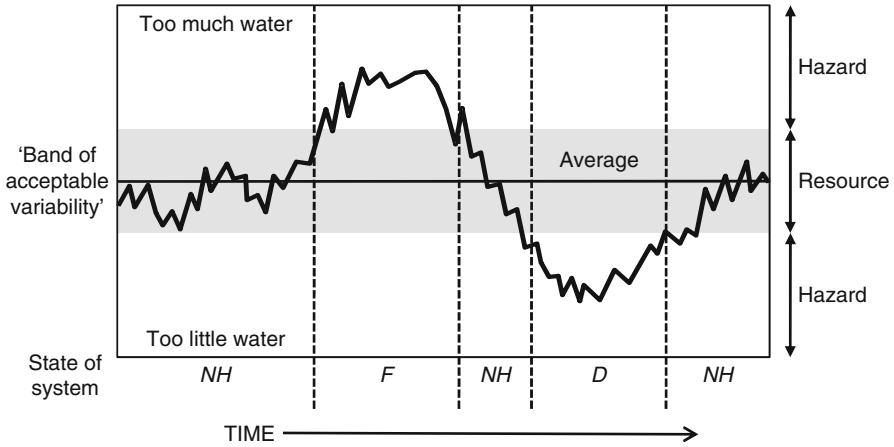
Analysis of past climate change deduced from proxy biological or geological evidence is best undertaken where this evidence has a stratigraphic (time) context, and where it unambiguously reflects a specific climatic forcing factor such as temperature or precipitation. Reconstruction of past climate change is the concern of the scientific discipline of palaeoclimatology (Cronin, 1999), and is not discussed in herein.

Climate change and climate variability

Both present-day instrumental and past reconstructed records of meteorological measures (mainly MAAT and precipitation) show that there is variability in these measures over all spatial and temporal scales. This variability arises as a result of both natural (including Milankovitch and sunspot cycles, El Nino, North Atlantic Oscillation, thermohaline circulation) and anthropogenic (including fossil fuel CO_2 and NO_x emissions, landuse change) factors in combination (O'Hare et al., 2005).

Much debate focuses on the degree to which present-day and projections of future climate change can be attributed to anthropogenic rather than natural factors (cf. Braganza et al., 2004). Fundamental to this debate, and its impact on natural hazards, is the relationship between climate change and climate variability. The term "climate variability" refers to the scatter or "spread" of values of certain meteorological variables (such as MAAT and precipitation) when they

Climate Change, Figure 2 Illustration of various scenarios of changes in the mean value and data range of a meteorological variable. (**a**) Mean value changes but the data range is the same, i.e., the distribution changes in skewness. (**b**) Mean value stays the same but the range increases, i.e., the distribution increases in variability with increased likelihood of extreme values. (**c**) Mean value increases but the data range changes (here, becomes narrower, indicating less variability and decreased likelihood of extreme values).



are measured systematically at a certain place over a certain time period. Measurement of these variables over time allows for a dataset to be constructed, which can then be examined statistically by calculation of its mean, standard deviation, trend etc. Change in the mean value over time is taken to be indicative of "climate change," which refers to a consistent directional trajectory (either upwards or downwards) of values of a certain meteorological variable that is measured at a particular place and over a particular time interval.

The IPCC (2007) uses specific terminology in order to help quantify the robustness of predictions of future climate changes. For example, the terms "likely" and "virtually certain" are used where there is a >66% and >99% probability of future occurrence, respectively. The distinction between climate variability and climate change is significant because it is related to the likelihood of occurrence of meteorological extreme values. For example, Figure 2a shows a consistent increase in mean value through the time period of the dataset, yet climate variability (given here by data range) has not changed. This suggests there is a change in shape of the frequency distribution from negatively to positively skewed. Figure 2b and c illustrate contrasting examples of changes in climate variability. In Figure 2b, the mean value is not changing but the variability is increasing over time, suggesting that the frequency of occurrence of more extreme values (relative to the mean) is also increasing (e.g., Schneider et al., 2007; Allan and Soden, 2008). Climate variability and climate change therefore have to be considered together in their implications for hazards.

Climate, resources and hazards

Many meteorological phenomena are associated with hazards that have the potential to impact directly on human activity. These commonly include floods and droughts (caused by variations in precipitation); heatwaves and cold snaps (variations in temperature); and hurricanes, tornados and typhoons (variations in wind speed). The unifying characteristic of these hazardous events is that they tend to occur most often when anomalously high or low values of the climate variable are received; for example, most lowland river floods take place when very high precipitation is received across the catchment. Floods can also occur, however, under conditions of more "average" precipitation but where other local environmental factors contribute, such as the ground surface being pre-saturated and unable to absorb any more water (see *Flood Hazard and Disaster*). This situation enhanced the devastating impacts of the August 2005 floods in the European Alps when prolonged rain reduced water storage capacity in high alpine areas, leading to very rapid water transfer into lowland basins with accompanying debris flows and landslides (Hilker et al., 2009).

Figure 3 illustrates the relationship between the amount of a meteorological variable, such as precipitation, and its value to human activity as a resource or a hazard. In the case of precipitation, a certain amount of precipitation is required over different time scales in order to sustain human activities, as for domestic, industrial and agricultural use, and to maintain the workings of land surface systems, including rivers and ecosystems. The amount required to sustain these activities is here termed the "band of acceptable variability." The width of this "band" is determined by the resilience of human and land surface systems to accommodate the natural variability in precipitation. As dams and irrigation schemes on river systems are developed, the capacity of the system to buffer temporary changes in precipitation amount is improved, and so the "band of acceptable variability" in precipitation amount will therefore increase in width. Outside of this

Climate Change, Figure 3 Schematic illustration of how changes over time in a meteorological variable (here, precipitation) are related to changes in perception of that variable as a resource or as a hazard (see text for detailed explanation). *NH* no hazard, *F* flood, D drought.

band, however, lies the flood (drought) hazards that are associated with precipitation amounts that are far above (below) the capacity of human and land surface systems to accommodate this variability (see *Drought*; *Flood Hazard and Disaster*). Changes in precipitation amount over different time and space scales therefore mean that hazard periods (as defined by meteorological factors alone) are episodic and evolve in intensity, location and impact over time (Schneider et al., 2007). In most real-world situations, a combination of natural and human factors contribute to the development of hazards, and are strongly conditioned by local scale factors and antecedent conditions.

The foregoing discussion highlights the fact that hazards may not always be identified or predicted based solely on statistical (e.g., standard deviation of a normal distribution) or magnitude-frequency relationships of time series of meteorological variables. This means that, by itself, a meteorological extreme may not be sufficient to produce a hazardous event, and that localised and/or antecedent conditions are often also required (Fuchs, 2009). As a result, future patterns of hazards may be difficult to predict based upon the distribution or timing of meteorological forcings alone.

Regional perspectives of climate change and hazards

The types of climatic hazards that impact most strongly on different physical environments or latitudes are shaped by prevailing synoptic-scale climate conditions related largely to atmospheric circulation patterns, including the vigour of the hydrological cycle (Hastenrath, 2007). For this reason the term hydrometeorological hazards is used (e.g., Lawford et al., 1995). Due to variations in atmospheric circulation patterns, there are therefore similarities between the hazards that affect different locations within the same latitudinal belt, and climate change is also having similar effects within these latitudinal belts. This enables locations within the same latitudinal climate zone to be compared to one another.

Low-latitude areas

Climate change in low-latitude areas is associated with changes in the hydrological cycle over both land and ocean (Lorenz and DeWeaver, 2007). At present, spatial variations in sea surface temperatures (SSTs) over low-latitude oceans drive atmospheric pressure gradients, leading to the seasonal development of deep low-pressure systems (cyclones) including hurricanes (Atlantic) and typhoons (Pacific). Shifts in hurricane intensity in the Azores-Caribbean region reflect climate changes over decadal to centennial scales (Mann et al., 2009), which are also recorded by spatial changes in hurricane tracks (Reading, 1990) (see *Hurricane (Typhoon, Cyclone)*). These variations reflect changes in open-Atlantic SSTs and positions of the intertropical convergence zone (ITCZ) and subtropical jet stream.

Temperature gradients between land and sea also drive seasonal monsoon circulation that is of critical importance in SE Asian agriculture (see *Monsoons*). Switch between summer and winter monsoon states is controlled strongly by heat balance over the Tibetan plateau. Presently, climate change is causing large-scale changes in snowcover extent and duration, glacier meltwater production, and vegetation distribution in the Tibetan plateau region (Bhutiyani et al., 2008; Kehrwald et al., 2008). These effects have major implications for the strength and duration of the blocking high pressure cell that controls the winter monsoon phase (Duan and Wu, 2005). Climate change is already affecting the strength, timing and location of monsoon rains, and leading to greater climatic variability, which has potential to decrease food security in the region (Mall et al., 2006). High precipitation in low-latitude areas, coupled to steep and

tectonically-active slopes and high rates of chemical weathering, also leads to slope weakening and high incidence of landslides, as in Hong Kong (Peart et al., 2009). These climatic conditions are also important in the transformation of mass movements and volcanic debris into highly dangerous landslides and mudflows (see *Mass Movement*).

More widely, significant future changes in low-latitude climates will be closely associated with changes in the position and dynamics of the ITCZ, which marks the equatorial convergence of trade winds. Changes in land-sea surface temperatures and moisture availability, particularly over large forest areas such as Amazonia (Huntington, 2006; Cook and Vizy, 2008), will have significant impacts on meridional energy fluxes, resulting in widening of the ITCZ and tropics with accompanying shifts in precipitation patterns and ecosystems (Seidel et al., 2008).

Mid-latitude areas

Mid-latitude areas tend to have high levels of urbanisation and population density, developed over long time periods, and as such are characterised by significant modification of landuse and water resources. Climate change impacts on the activity of the mid-latitude Ferrel cell are closely related to changes in the strength of surface ocean currents (including the North Atlantic Current (Gulf Stream), Kuroshio Current, Humboldt Current, Benguela Current etc.) that are important in meridional heat transport (Herwiejer et al., 2005). Mid-latitude oceans are also sensitive to changes in thermohaline circulation (deep water) and freshwater input from rivers and melting sea ice (surface water). As such, hazards that impact on mid-latitude coasts are linked very closely to variations in the dynamics of adjacent oceans. Strengthening zonal circulation in the North Atlantic region is associated with changes in frequency of strong westerly winds and wind gusts (Kaas et al., 1996) and with increase in mean wave height (Bacon and Carter, 1991). The net result of these is increased frequency and/or magnitude of coastal storm, storm surge, and related flood events, which is a likely outcome of climate change along these coasts (IPCC, 2007).

Other coastal impacts are a consequence of the Pleistocene glacial inheritance of many mid-latitude areas (see *Paraglacial*) which means that many of these coastlines are sediment-rich with well-developed sandy beaches, sand dunes and estuaries that are vulnerable to coastal erosion (Hansom, 2001). Enhanced coastal erosion can be related directly to climate change effects of sea-level rise and increased storminess (see *Coastal Erosion*). Coastal and river management has, in many areas, decreased sediment supply to nourish these coasts, thereby making them more vulnerable (Stive, 2004).

Inland, river engineering and management and the presence of historic settlements on floodplains make river systems vulnerable to variations in precipitation input and storage that may lead in turn to increased lowland flood frequency. This is seen clearly in some managed rivers worldwide (e.g., Wilby et al., 2008).

High-latitude areas

Climate change in high-latitude areas is causing increased glacier melt (Greenland, Antarctica) and permafrost warming (Eurasia, Canada), both of which are driven mainly by increased MAAT (Camill, 2005; Osterkamp, 2005). As a result, meltwater availability in these environments is increasing, with increasing volumes of fresh water being stored within proglacial or subglacial lakes (see *Jökulhlaups*). Increased glacier melt and ice retreat can also lead to slope instability, mass movement and land surface rebound that can contribute to increased seismicity (Hampel et al., 2010). To date, hazards associated with glacier retreat and permafrost melt in high-latitude areas have been relatively isolated in location, and subdued in magnitude (Gude and Barsch, 2005). For example, roads, buildings and oil pipelines in many high-latitude and high-altitude areas have been adversely affected by land surface subsidence as a result of permafrost melt, although some of this can be attributed directly to poor engineering practice (Harris et al., 2001; Khrustalev, 2001) (see *Cryological Engineering*). On shallow slopes, however, increased depth of the seasonally-thawed permafrost leads to meltwater pooling and mass flow hazard (including bog bursts) that decrease the stability of the land surface. More widely, permafrost melt is associated with secondary effects of increased CH_4 (methane) and CO_2 degassing where peatlands are undergoing aerobic decomposition (Schuur et al., 2009). Increased subsurface water mobility can also lead to increased contaminant transport through thawed substrates (see *Permafrost*). Hazards associated with ice retreat in mountain areas are more commonly observed (see *Paraglacial*).

Studies show that, as a result of changes in freshwater input and sea-surface warming, sea ice cover in the Arctic Ocean has decreased dramatically in recent years, continuing a trend that began in the 1970s (Serreze et al., 2007). Increased exposure of arctic coastlines due to sea ice retreat, and warming and destabilisation of coastal outcrops of permafrost, has led to a dramatic increase in coastal erosion rates across the entire Arctic Ocean, including northern Russia and Canada (Jones et al., 2009). In turn, sediment release into the nearshore zone increases turbidity and heat capacity of the water, leading to additional warming. This positive feedback effect is the basis for the arctic amplification of climate (Serreze et al., 2009). Long-term implications of climate change in the high-latitudes are likely to be significant but as yet are poorly understood, including CH_4 and CO_2 release (Schuur et al., 2009). More widespread permafrost warming will also increase the geographical area over which mass movement hazards operate, which will in turn become far more common than at present. This will be a major outcome of climate change in high-latitude areas over the next decades.

Driving factors linking hazards in different latitudes

Interrelationships between hazards that are most common in different latitudes are driven, largely, by the strength of the hydrological cycle (Huntington, 2006). This is manifested by both the vigour of macroscale atmospheric circulation patterns, including the strength and positioning of the low-latitude Hadley cell and high-latitude polar cell, and the detailed dynamical processes that take place within the atmospheric part of the hydrological cycle. This includes, critically, the role of latent heat effects which are related directly to the amount of energy (heat) moved through the system, and thus to climate change.

Water within the hydrological cycle can exist in solid, liquid and gaseous phase states. A change in phase between any of these stable states by processes of melting/freezing and evaporation/condensation is associated with the exchange of latent heat, as given by the Clausius-Clapeyron relation. Based on this relation, an airmass with a higher water vapour content and therefore associated with very vigorous evaporation/condensation processes generates a large amount of latent heat that, in turn, fuels atmospheric convection and instability (Willett et al., 2007). Increased SSTs particularly in low-latitude regions are actively contributing to increased rates of evaporation, leading to higher relative humidity and higher meridional heat flux as a result of macroscale atmospheric circulation (Lorenz and DeWeaver, 2007; Seidel et al., 2008). This process, driven largely by low-latitude warming, provides an atmospheric bridge to higher latitudes, and contributes to increased convective rainfall (thunderstorms) within the Ferrel cell. Furthermore, increased moisture content is also associated with changes in cloudiness, aerosols and atmospheric optical depth (Santer et al., 2007).

Surface and subsurface circulation patterns within the oceans are important in macroscale heat transport, and their paths depend on the three-dimensional evolution of density gradients within the oceans. As such, increased low-latitude SSTs have impacts on global temperatures: the globally-warm year of 1998 was due in large part to the strong El Nino event of that year associated with positive SST anomalies in the equatorial Pacific. Warmer surface waters have less capacity to draw down atmospheric CO_2, and are associated with lower levels of dissolved oxygen, reduced productivity where upwelling is suppressed by water stratification, and reduction in water quality, with impact on fisheries and other ecosystems. Studies of thermohaline circulation dynamics show that subsurface ocean current strength in the North Atlantic is variable spatially and temporally, which has implications for meridional heat transport (Cunningham et al., 2007). It also suggests that multiple factors can affect thermohaline circulation strength, with multiple outcomes for higher-latitude regions. Several studies discuss possible future changes in thermohaline circulation strength, including the likelihood of reversal or collapse (e.g., Vellinga and Wood, 2008), but most modelled predictions suggest that thermohaline circulation is likely to weaken rather than collapse fully (IPCC, 2007).

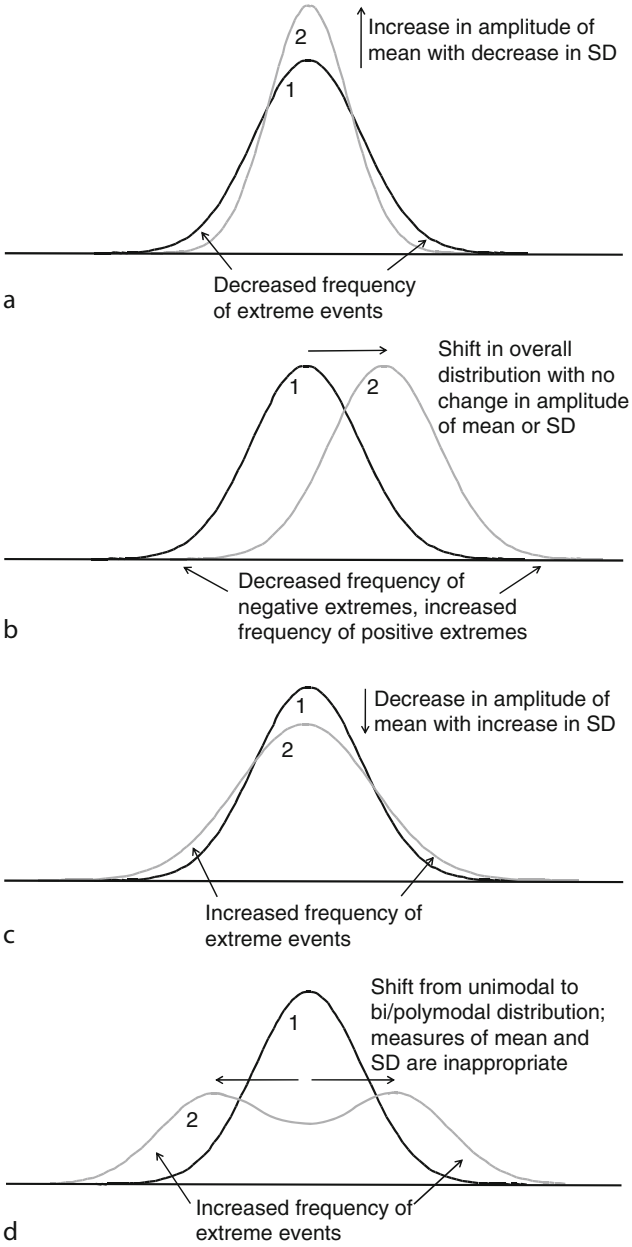
Impacts of climate change on the vulnerability of human systems to hazards

Climate change and climate variability give rise to changes in the frequency and magnitude of extreme events that can lead to hazards, as previously discussed. This relationship alone, however, cannot explain the impact of those hazards upon human systems (including agricultural production, socioeconomic impacts, cultural impacts, human health and wellbeing, etc.) (Hulme, 2009). The future climate changes that will frame the environmental conditions under which future hazardous events and processes will take place are considered explicitly by the IPCC (2007) (Table 1). These hazards operate over spatial and temporal scales that mean their impacts will be diverse, unpredictable, and multidisciplinary in nature. Table 1 shows that future climate change will impact in many different ways on almost all areas of human activity. Of particular concern is the role of climate change in the sustainability of food production. For example, Peng et al. (2004) show that, despite increased CO_2 which generally promotes plant growth, increased night-time temperatures will cause a decrease in rice yields.

Many natural hazards, where they impact upon human activity, have the capacity to lead to environmental or humanitarian "disasters" (see *Disasters*). The World Health Organisation-linked Centre for Research on the Epidemiology of Disasters (CRED) defines a disaster as "a situation or event which overwhelms local capacity, necessitating a request to a national or international level for external assistance; an unforeseen and often sudden event that causes great damage, destruction and human suffering" (Below et al., 2009, Annex II) (see *Casualties Following Natural Hazards*). The interlinkage of this definition to the capacity of local systems to deal with environmental variability is very similar in basis to that presented in Figure 3. CRED collates information on disasters of all types, but one such disaster category is hydrometeorological disasters that are related to floods, droughts, storms and storm surges, and landslides and avalanches (see *Hydrometeorological Hazards*).

Analysis of spatial and temporal trends in disasters and their impacts shows a very clear relationship to hydrometeorological variability (ISDR, 2009). In the period 1950–2007, two thirds of all disaster-related deaths and economic losses were caused by hydrometeorological disasters. Due to the dependence of floods, droughts and other events on atmospheric circulation patterns and local-scale factors, the disaster risk from hydrometeorological hazards is highly concentrated spatially, and disaster impacts are very variable depending on an individual country's infrastructure and wealth. For example, 75.5% of all expected global mortality from tropical cyclones (1975–2007) was in Bangladesh, but the entire south Asia region represents only 2.7% of total economic losses from these events over this time period. Patt et al. (2010) use a numerical model to predict how vulnerable developing countries will be to future climatic hazards. They show

Climate Change, Table 1 Summary of some of the major outcomes of future climate change for different aspects of earth systems (Summarised from IPCC, 2007), and their implications for hazards



IPCC subheading	Summary of likely changes (from IPCC, 2007)	Implications for hazards
Ecosystems	• Ecosystems will become more sensitive to environmental disturbance under future climate change • Ecosystems will contribute to changes in net carbon storage (to about 2050) and then outgassing (thereafter) • Increased risk of species' extinction under future climate change • Changes in ecosystem functioning, structure and biodiversity as a result of future CO_2 increase	• Risk of invasive species and pathogens that contribute to biodiversity loss and/or crop failure • On mountains, increased forest cover that will stabilise slopes • Increased CH_4/CO_2 outgassing from warming permafrost and desiccation of wetlands and peatlands
Food	• Spatial changes in agricultural productivity, with likely increase in mid-latitude areas and decrease in low-latitude areas, with impacts on food security in many regions	• Increased uncertainty in food and fibre production, particularly in agriculturally marginal areas in semi-arid regions and mountain slopes • Increased soil erosion and salinisation, loss of soil fertility • Reliance on irrigation in many areas, impacts on potable water quality; increase in water contamination/pollution and eutrophication
Coasts	• Increased risk of coastal erosion and flooding	• Increased frequency and height of flooding along coastal fringes, river estuaries and floodplains • Increased likelihood of storm surges and increased height of storm waves • Increased coastal erosion along all coastline types (including rock and sandy coasts) • Increased sediment mobility in some areas, implications for port/harbour access and navigation channel infilling
Industry, settlements and society	• Increasing vulnerability of industry, settlements and society to hydrometeorological events, particularly in low-lying and coastal regions	• Increased risk to all aspects of economic activity in coastal and low-lying areas from sea and river flooding • Increased risk of built and natural heritage loss in low-lying and coastal regions due to flood inundation and warmer sea temperatures, e.g. Venice, Great Barrier Reef
Health	• Increased risk of malnutrition and hunger as a result of variations in food production and hydrometeorological events • Increased risk of infectious and respiratory diseases and heat-related deaths, but fewer cold-related deaths	• Mass movement and flood events can cause groundwater and river water contamination
Water	• Increase in water-stressed regions, particularly in areas with high urbanisation • Reduced water availability from retreating mountain glaciers • Increased precipitation in mid-latitude areas, decreased precipitation in some low-latitude and semi-arid areas • Increased precipitation variability and seasonality, decreased water quality	• Increased mass loss from retreating glaciers, increased risk of downstream floods, jökulhlaups, landslides, mass and debris flows, rockfalls • Increased variability of precipitation at all latitudes with impacts on domestic, agricultural and industrial water supply and water quality, eutrophication

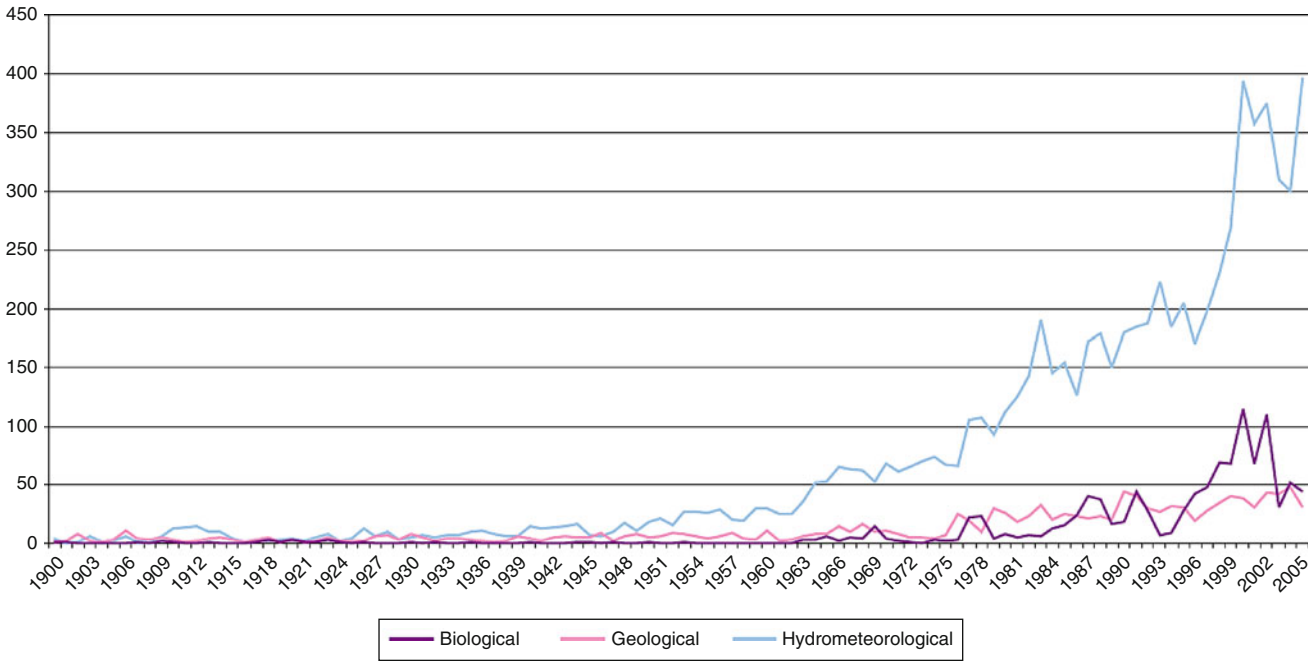
that increasing the country's resilience and adaptive capacity to such events, through socioeconomic development, is the most effective means by which hazardous impacts can be minimised (Figure 4).

Figure 5 shows that hydrometeorological disasters have increased disproportionate with respect to other types in recent decades, and are dominated by floods (30.7% of all disasters in the period 1970–2005) and wind storms (26.8%). This overall pattern is broadly similar irrespective of geographical region. The IPCC (2007) also confirms that hydrometeorological extremes are more likely under future climate change, therefore hazards of these types are likely to increase in frequency. Responses of the physical environment and human activity to these challenges are uncertain but are likely to be multidimensional and wide-ranging (McBean, 2004).

Hazards and the normal distribution

Present and future climate, in its totality, is headed on an upward trajectory, in which anthropogenic global warming is causing a directional shift in standard statistical measures of climate, for example in increased MAAT (IPCC, 2007). Other meteorological variables, however, are unlikely to show a comparable simple statistical response. For example, precipitation impacts are

Climate Change, Figure 4 Schematic distribution plots of a meteorological variable showing four possible changes in the nature of the distribution from time 1 to time 2. (**a**) Where the mean value stays the same but where standard deviation (SD) decreases. This leads to decreased frequency of extreme events. (**b**) Where the distribution stays the same but shifts to a higher (or a lower) value with no accompanying change in SD. In the example of precipitation this results in a decreased probability of droughts (floods) and increased probability of floods (droughts). (**c**) Where the mean value stays the same but where the SD increases, giving an increased probability of both positive and negative extreme events. (**d**) Where the distribution plot changes from unimodal (normal distribution) to a bimodal or polymodal distribution. In this case there may be an increased probability of extreme events, and that standard measures of mean and SD are inappropriate descriptors of the distribution.



more complex spatially and temporally, because they involve important feedback processes via ecosystems, humidity, and latent heat (Allen and Ingram, 2002). As a result, it is unlikely that under projected climate change precipitation will follow a normal distribution but rather will show a polymodal distribution in which the likelihood of both flood and drought hazards will increase (e.g., Figure 4d). Recent patterns of precipitation changes by latitude, season, and intensity suggest that these events are now beginning to take place (Zhang et al., 2007; Müller et al., 2009). Further evidence for the inapplicability of the normal distribution to some climatic variables comes from studies of changes in strength of thermohaline circulation over time that suggest this circulation can switch between one of two modes ("on" and "off") and over very short time scales and in response largely to changes in high-latitude freshwater input (Rahmsdorf, 2002). If this dynamic behaviour characterises thermohaline circulation under conditions of rapid climate change, then it confirms the importance of non-normality, nonlinear responses, and hysteresis (Rahmsdorf, 2002). These properties are not associated with simple shifts in the normal distribution, and highlight the role of spatial and temporal climate variability.

Changes in internal properties of the normal distribution, and shifts to other distributional types, show the importance of climate variability, for two reasons. First, it reveals the internal dynamical processes that are associated with changes in individual meteorological variables. Second, it impacts on the likelihood of occurrence of the extreme events that are most often associated with hazards.

Summary and outlook for the future

Anthropogenic climate change is causing unprecedented changes in physical and human systems that, together, are converging on increased frequency and magnitude of hazardous events related explicitly to changes in meteorological processes on different spatial and temporal scales. This suggests that earth systems are experiencing unprecedented rates of change and systems' organisation is responding dynamically to meteorological drivers.

One of the major areas of uncertainty in the prediction of future climate is related to climate sensitivity. This is defined as the equilibrium temperature response to a doubling of pre-industrial values of atmospheric CO_2 (Gregory et al., 2002) and is calculated, based on climate models that consider radiative forcing only, to be in the range +1.5–4.5°C (IPCC, 2007). Climate sensitivity is relevant to climate hazards because, if temperature reaches and maintains an equilibrium value, it can be inferred that other climatic variables such as precipitation must also be at equilibrium. However, much of the uncertainty associated with the calculation of climate sensitivity is due to the role of nonlinear feedbacks in the climate system, in particular atmospheric moisture content and cloudiness (Zickfeld et al., 2010). There will also be time lags and

Climate Change, Figure 5 Graph showing changes in number of disasters of different types, 1900–2005 (from http://www.unisdr.org/disaster-statistics/occurrence-trends-century.htm). Note the recent increase in hydrometeorological hazards relative to other hazards types, and individual peaks that correspond to strong El Nino events in 1982 and 1998.

feedbacks associated with the long-term response of earth surface processes (Lunt et al., 2010). In combination, these factors mean that long-term climate sensitivity could well be higher than predicted by radiative forcing alone (e.g., Pagani et al., 2010). There are a number of important implications of climate sensitivity for climatic hazards. The role of feedback processes means that future patterns of precipitation are unlikely to show the same speed or magnitude of change as that of temperature. It may also mean that temperature reaches equilibrium at a different time to other meteorological variables.

Many meteorological hazards yield secondary impacts which are predominantly negative, can be long-lasting, and which affect many earth systems and the human environment. Secondary impacts include, but are not limited to, changes in fluvial sediment budgets; coastal erosion; biogeochemical cycling; chemical weathering; biodiversity; food production; and renewable energy production. The precise nature and timescale of these impacts are often poorly-defined, and although they often arise from individual hazardous events such as a single flood, such events in themselves cannot be attributed with certainty to anthropogenic climate change. Rather, the events represent one aspect of climate variability that arises out of a set of ongoing directional changes to earth and human systems that have cumulative effect (i.e., climate change). Climate change therefore provides the hydrometeorological setting from which individual hazardous events can arise. In this way, climate change (sensu lato) has potential to impact in unexpected, complex and unpredictable ways on both human activity and the physical environment (Hulme, 2009).

Individual hazardous events cannot be predicted. General circulation models (GCMs) can, however, predict global to regional scale changes in some meteorological variables (temperature, precipitation etc.) that can in turn provide input to regional ecological, geophysical and geochemical models. None of these model types downscale very well to the local level where issues of land surface stability, earth surface processes and human activity are most significant, and where real hazards take place. As such there is a mismatch between our knowledge of future climate and our knowledge of future climate responses. Impacts of future climate change on hazard characteristics (type, location, magnitude) are therefore still unknown and, as such, cannot be predicted with any certainty. This is an important area for future research.

CLOUD SEEDING

Steven T. Siems
Monash University, Monash, VIC, Australia

Synonyms

Precipitation enhancement; Rain making

Definition

Cloud seeding is the practice of intentionally adding aerosols (e.g., silver iodide, common salt) or even ice itself (or dry ice) with the intent of changing the development of a cloud.

Discussion

Specifically the aim is to change either the phase of the cloud droplets/crystal (e.g., convert supercooled liquid water to ice for glaciogenic cloud seeding) or the size distribution (e.g., produce largely droplets that will coalesce more rapidly for hygroscopic seeding). Primarily cloud seeding has been used with the intent of enhancing the precipitation of a cloud, although efforts have been made to prevent precipitation, suppress hail, and burn off fog. The principles of cloud seeding have even been attempted for the suppression of hurricanes. Cloud seeding is perhaps the most common/vivid example of the practice of weather modification or weather engineering.

While cloud seeding is practiced in dozens of countries around the globe, it still remains a highly controversial practice primarily because of the lack of evidence supporting its effectiveness outside of fog dispersal. As stated in the World Meteorological Organisation Weather Modification Statement and Guidelines (2007): "Evidence for significant and beneficial changes in precipitation on the ground as a result of seeding is controversial and in many cases cannot be established with confidence." This lack of statistically significant evidence is even more apparent for the intent of hail suppression. These are the same conclusions reached the by committee established by the US Academy of Sciences in 2003.

COAL FIRE (UNDERGROUND)

Glenn B. Stracher
East Georgia College, University System of Georgia, Swainsboro, GA, USA

Synonyms

Burning coal; Coal combustion; Coal fire; Underground coal fire

Coal Fire (Underground), Figure 1 Surface manifestation of an underground coal-mine fire includes ground subsidence and smoke, as shown here along a former section of Pennsylvania Route 61 at the Centralia mine fire (Stracher et al., 2006). The asphalt road through the town of Centralia is subsiding into abandoned coal-mine workings, where anthracite is burning underground. A detour was constructed around this section of the highway. Coal fires emit dozens of toxic gases into the atmosphere including carbon monoxide, benzene, and toluene, in addition to green-house gases. Minerals and creosote (coal tar) that nucleate at the surface from coal-fire gas may serve as vectors for the transmission of bio-accumulated pollutants, including Hg and As, from water, soil, and wind-blown dust (Stracher, 2004; Stracher et al., 2005, 2009) (Photo by Janet L. Stracher, 2006).

Definition

An underground coal fire is defined as the combustion of coal below the Earth's surface accompanied by heat-energy transfer and the emission of gas, but not necessarily flames and consequently, the emission of light. Although "fire" implies flames, coal burning underground is seldom observed, and peer-reviewed publications about underground burning or even coal burning at the surface (Stracher, 2004, 2007; Stracher et al., 2010, 2012) do not consider flames and light as a necessary criterion when describing coal fires. When a coal fire is not accompanied by flames, the terminology "smoldering" is sometimes used in reference to such fires (Hadden and Rein, 2010).

Discussion

Underground coal fires may occur just beneath, many meters below, or as is commonly the case – at an unknown depth below the Earth's surface. They may occur in association with active or abandoned coal mines (Figure 1) and also in coal seams that were never mined. Combustion is supported by the circulation of atmospheric oxygen underground to the burning coal via joints, faults, intake vents, and coal-mine portals.

Origin: Underground coal fires are started by either anthropogenic or non-anthropogenic processes. The causes include (Stracher and Taylor, 2004; Stracher et al., 2009) (1) lightning strikes; (2) forest, grass, or brush fires; (3) landfill, coal-gob pile, or coal-storage-facility fires transmitted to underground coal seams; (4) mining activities such as the use of explosives, welding or electrical work, and short circuits; (5) arson; (6) spontaneous combustion promoted by "self heating" of the coal during exothermic oxidation of sulfide minerals in the coal (e.g., pyrite); (7) the illegal distillation of liquor in underground coal-mine tunnels; and (8) smoking or other activities that may accidentally ignite hydrogen or methane gas in an underground mine.

Extinguishing: Any attempt to extinguish or contain an underground coal fire is based on available funding, and some fires are cost-prohibitive to extinguish. Fire-fighting technology includes the use of compressed-air foam, inert-gas injection, fly-ash grout, water and mud or water and fly-ash slurries, fire breaks, burial of gas vents and fissures at the surface beneath soil, remote sensing technology, and excavating the fire either by hand or mechanical digging.

COASTAL EROSION

Wayne Stephenson
University of Otago, Dunedin, New Zealand

Definition

Coastal erosion. The net landward retreat of the shoreline, as measured relative to a given datum, over a given temporal scale that is longer than cyclic patterns of coastal variability.

Introduction

Coastal erosion is the net landward retreat of the shoreline, where the shoreline is represented by a datum such as mean high water spring or a mapped feature such as a cliff, beach or road (Figure 1). The landward retreat is persistent through time as distinct from shorter term (e.g., weeks, months) fluctuations in the position of the shoreline associated with storm erosion and recovery, typical of beaches. On cliffed coasts there is no recovery from erosion events because such landforms are wholly erosional in origin. Coastal erosion is a common condition of coastlines globally, with 70% of the world's beaches thought to be eroding (Bird, 1987, 1996) and 80% of the world's total shoreline composed of eroding cliffed and rocky morphologies (Emery and Kuhn, 1982). Coastal erosion is also associated with coastal hazards when infrastructure is built on an eroding shore, coastal erosion overtakes human use systems, or when erosion increases the exposure of infrastructure to processes such as inundation or direct wave attack.

Whilst coastal erosion is considered to be a hazard and is a significant issue for coastal managers, it is also a natural geomorphic process representing the adjustment of shorelines toward a new equilibrium, often in response to sea level rise, changes in sediment supply, wave climate, or a combination of these factors. Much of the world's shoreline is configured the way it is because of erosional processes. Coastal landscapes valued for their intrinsic beauty are often erosional in origin (e.g., cliffs, arches, stacks) and contribute to economic activity, particularly tourism. Paradoxically, coastal erosion management may involve allowing erosive processes to take place in order to maintain landscape values.

Causes

There are three first order controls of coastal erosion applicable to all coastal landforms, a rise in relative sea level, a deficit in the local sediment budget, and a change in wave climate. In addition to these fundamental causes, human activities introduce a myriad of interactions that can generate coastal erosion where there was none before or make existing coastal erosion worse. Human activity usually involves interference with local sediment budgets but can also change processes such as wave energy or wave driven longshore currents that transport sediment.

Sea level rise since the last glacial maximum is one of the most important long-term causes of coastal erosion, and many shorelines are still responding to this rise. The melting of glaciers and continental ice sheets since the last glacial maximum added vast volumes of water to the world's oceans causing very rapid sea level rise. The broad configuration of the world's coastlines and coastal erosion observed over historical time frames is in response to sea level changes that have occurred over the last 6,000–7,000 years. In addition to eustatic (changes in ocean water volume) causes of sea level rise, isostatic processes can also cause a relative rise in sea level through subsidence of land masses. Isostatic processes include the addition or removal of mass from the Earth's crust, such as ice sheets, sediment, or water, and cause the crust to sink under loading and rebound after the load is removed, such as when ice sheets melt during warm phases of Earth's climate. Tectonic processes may also cause subsidence of land masses giving the appearance of sea level rising. When there is no eustatic change in sea level in this scenario, the shoreline will respond as if sea level is rising. However, a rise in sea level does not always result in coastal erosion, and in some instances, shorelines can respond by advancing when there is a supply of sediment eroded from elsewhere or transported onshore from the continental shelf, generating a positive sediment budget.

Sediment budgeting offers a useful management approach to coastal erosion by accounting for inputs and losses of sediment from a defined length of coast known as a littoral cell (e.g., Komar, 1996; Bray et al., 1995; Patsch and Griggs, 2008; Mazzer et al., 2009). Sediment budgets are usually expressed as a volume of sediment gained or lost annually from a littoral cell. A negative sediment budget (where a littoral cell loses sediment over time) equates to coastal erosion whereas a positive budget results in shoreline progradation. Littoral cells are often delimited by natural features such as headlands, river mouths, and cliffs, or artificial structures such as harbor breakwaters. Some boundaries are fixed (e.g., headlands) while others can be transient such as river mouths that migrate alongshore or the seaward limit of sediment transport that changes as wave conditions change. Cell boundaries can also be absolute, in that no sediment crosses them, or partial in that they allow some leakage of sediment.

Importantly, a properly accounted sediment budget with well-defined boundaries allows the cause of sediment loss to be identified and the amount of sediment loss to be quantified. Determining why a cell is losing sediment and the amount of the deficient in the budget allows for a better assessment of appropriate mitigation techniques (e.g., Cooper and Pethick, 2005; Bezzi et al., 2009).

Coastal Erosion, Figure 1 Coastal erosion occurring on the North Otago coast of South Island, New Zealand. The management strategy has been to abandon the road after attempts to build protective rip-rap structures failed (source of debris on the beach) (Photo: Wayne Stephenson).

Increases in wave heights have been observed in the North Atlantic (Wolf and Woolf, 2006) and the northwest Pacific over recent decades and have been linked to evidence for enhanced beach erosion (Allan and Komar, 2002, 2006). Increases in wave height and frequencies of storms are also expected to increase the incidence of coastal erosion and shoreline retreat under climate change scenarios (Zhang et al., 2004).

In addition to natural changes in sea level, sediment budgets, and wave patterns, human activities can also

cause or exacerbate coastal erosion. Sea level rise from global warming will in many instances contribute to coastal erosion. Coastline development can remove, slow, or stop sediment delivery to coastal systems and prevent transport within or between littoral cells. The effect is often to shift neutral or positive sediment budgets into negative ones. Shorelines respond by eroding in order to restore the supply of sediment that has been lost. Dams on or extraction of sediment from rivers can cause coastal erosion by reducing sediment supply to the coast (Patsch and Griggs, 2008). Sediment extraction from dunes, beaches, reefs, or the nearshore for the purposes of construction may also cause coastal erosion. Seawalls built to stop cliff erosion may prevent sediment delivery to the coast and, where cliffs are important local sources of sediment for beaches, coastal erosion can result (Bird, 1987). Beach loss following the construction of a seawall is a widely recognized consequence. Wave energy is reflected by the wall, causing scour in front of the wall rather than dissipating wave energy as a beach would. Structures perpendicular to the shoreline such as groynes, built to intercept longshore sediment transport or retain sediment, may well accumulate sediment on one side (the up-drift side) but also cause erosion on the down-drift side, or farther along the shoreline by preventing sediment transport alongshore. Thus, many actions taken to prevent coastal erosion can make the situation worse or simply transfer the problem elsewhere along the coast. Breakwaters built for harbors can also inadvertently act as groyne and produce the same effects.

Measuring coastal erosion

Erosion rates are useful for planning and hazard mitigation purposes since they determine the amount of time remaining before infrastructure is overtaken or the rates at which land is being lost. Coastal erosion rates can be measured using a wide range of techniques, from regularly surveying of cross shore transects to aircraft using lasers known as LiDAR (Light Detection And Ranging). Maps, charts, and aerial photographs can be used to analyze shoreline change over longer historical time scales. Regardless of the method used, knowing the rate of shoreline retreat and/or the volume of sediment being lost from a coastal cell is critical for, first, determining that there is a real erosion problem and, second, deciding on the appropriate management response. Furthermore, the analysis needs to be over a sufficiently long timescale to remove short-term fluctuations associated with storm erosion and recovery in the case of sedimentary coasts, or noise associated with episodic failures common on cliffed coasts. Published rates of coastal erosion vary greatly, depending on shoreline type and geology and exposure. Erosion is also an episodic process both spatially and temporally. While erosion is commonly reported as a rate per year, this belies the highly episodic nature of the process.

Impacts

An obvious impact of coastal erosion is the permanent loss of land and infrastructure (Figure 1). Erosion of land can lead to loss of economic activity such as where beaches provide tourist amenity. Ecological function can also be lost as erosion progressively removes mangroves or salt marshes, and this is a significant issue when the coastal erosion is caused by human activity. Community vulnerability is increased as coastal erosion reduces the ability of shorelines to dissipate wave energy or to withstand barrier breaching. Vulnerability may also increase when artificial defenses (e.g., seawalls) are lost or damaged.

Response and mitigation

Approaches to erosion mitigation generally take one of two forms: retreat or defend. In the case of retreat, assets or activities can be abandoned or relocated to a safer position farther inland from the shore. However sociopolitical considerations work often to make this option difficult to employ. In many situations, this option is not viable because accommodation space behind the coast is unavailable to allow relocation. Defensive mitigation involves building a wide range of structures such as seawalls, breakwaters, groynes, and beach nourishment, where sediment is placed to recreate the natural buffer provided by beaches and dunes. Beach nourishment has become a popular and widely used method of erosion mitigation and is a useful approach since it addresses one of the fundamental causes of erosion – a deficit in the sediment budget. Psuty and Pace (2009) illustrate the use of sediment budgeting to better inform a beach nourishment approach to coastal erosion at Sandy Hook, New Jersey, USA. However, as with any response, it is not without problems, such as economic high costs, technical difficulties such as a lack of suitable sediment and negative ecological impacts (Grain et al., 1995; Speybroeck et al., 2006). For example, sand is often dredged from the sea floor disrupting or destroying benthic habitat and organisms. Sea turtle nesting success is known to be impacted when renourished sand is different to the original sand on the beach or when beach geometry is significantly altered (Brock et al., 2009). Alternatively well-designed beach nourishment could potentially improve nesting success by replacing lost beaches and nesting sites and restoring ecological opportunities. In situations where there is economic dependence on beach tourism, the cost (financial and ecological) of nourishment may be justifiable. Defensive structures are also expensive to build and maintain and often have detrimental impacts on shorelines, such as beach loss following seawall construction or down-drift erosion after a groyne is built. However, for high value assets, defensive structures are often necessary and beach loss is accepted. Importantly, there is no single response that is suitable for all coastal erosion problems and each case must be assessed on its own merits. The variety of responses to coastal erosion was reviewed by Pope (1997).

In situations where development has not occurred or is proposed, careful assessment of future erosion trends (based on measured or projected erosion rates) is necessary to avoid creating a new hazard. In such cases, planning schemes and zoning can be used to avoid creating erosion hazards. Predicting the position of future shorelines as sea levels rise is another approach and a wide variety of models are available for different shore types. A commonly used model to predict shoreline retreat in the face of sea level rise is the Bruun Rule, but the title is misleading since it is not a rule in a strict scientific sense but a rather simple model. The model requires a strict set of conditions to be met to successfully predict shoreline erosion, and more common than not these conditions are seldom meet (Cooper and Pilkey, 2004).

A common problem for coastal management is the view that shorelines should be rendered stable by erosion mitigation techniques, but this view is at odds with an environment that is naturally dynamic. Mitigation techniques that are also dynamic provide against current erosion problems and future climate change and sea level rise. Shoreline structures can be modified to return to dynamic behavior or built in such a way so as to allow dynamic behavior. For example, groynes can be constructed so as to be permeable to allow some sediment to continue to move alongshore (Nordstrom et al., 2007). Restoration of ecological function of mangroves, salt marshes, and coral reefs also provides protection from sea level rise, cyclones and tsunami, and hence coastal erosion. Such methods may be a more sustainable approach to erosion management than engineered structures.

Conclusions

Coastal erosion will continue to be a major hazard on coastlines into the future and in the face of projected climate change and increasing population pressure on coastal resources, it is likely to become an even more important hazard for coastal managers. Hazard management will need to come from adaptive strategies utilizing a wide range of mitigation techniques focused on managing human use systems.

COASTAL ZONE RISK MANAGEMENT

Norm Catto
Memorial University of Newfoundland, St. John's, NL, Canada

Definition

A coordinated strategy to cope with risks in the context of environmental, sociocultural, and sustainable multiple uses of the coastal zone.

Discussion

Risk management in the coastal zone requires an understanding of the evolving trends, particularly the desire for Integrated Coastal Zone Management (ICZM). A thorough understanding of the biophysical and ecoclimatic systems, using scientific principles and methods of investigation, is required. Socioeconomic concerns and maritime traditions must be incorporated into any management initiative. Management strategies must be practical, reflecting and respecting socioeconomic systems, demographic differences, existing political and regulatory systems, and biophysical conditions. They must also simultaneously respect the principles of conservation, stewardship, and sustainable development, and must acknowledge the human contribution to management.

In theory, ICZM requires:

- *Comprehensiveness* – all components of all systems must be included; all affected (or potentially affected) groups and individuals must be consulted and their views incorporated.
- *Coherence of elements* – the management plan as designed must "fit together," with individual components intermeshed; no overlapping jurisdictions or responsibilities, but perfect coordination between units with adjacent responsibilities; resource partitioning completely accomplished.
- *Consistency over time* – the plan remains in effect, not subject to political or regulatory change.
- *Cost-effectiveness of results* – the plan is economically (or socioeconomically) feasible, within the ability of the community or political jurisdiction to pay for its implementation.

In practice, this is unattainable. Not only is it impractical, but it also ignores the real nature of coastal systems: most significantly, by demanding consistency over time, it tacitly assumes that systems can reach a condition of stability. This is demographically and physically impossible. Although some degree of political consistency is desirable, any good plan must be suitably flexible to adapt to changing circumstances.

Applied specifically to risk management, this means that the hazard must be considered in the context of the coastal community or region. Coastal communities develop because they are adjacent to resources, such as fish species, convenient for transportation, attractive locations for humans to live and play, or for combinations of these reasons. Risks associated with waves and storms are inherent in any coastal setting. Some localities are also vulnerable to tsunami, slope failures, or terrestrial flooding. Communities are rarely settled in the complete absence of any perception of the hazards: although tsunami events may be rare, wave activity is a daily occurrence and is well known to maritime residents. The communities develop despite the known hazards, because the tangible benefits outweigh the hazards, both in visibility and frequency of occurrence.

Rather than thinking strictly of "cost-effectiveness" in terms of money, it is better and more productive to consider "effort-effectiveness." Does the risk management initiative make sense not only from a financial viewpoint but from the viewpoint of the amount of human effort required? Is the effort required to enforce a new regulation proportionate to the benefit? A risk management strategy in the coastal zone may affect demographic, sociocultural, or biophysical returns, in addition to fiscal ones.

These practical and conceptual issues and difficulties suggest that flexibility is the key to successful risk management in the coastal zone. The principles or theoretical ideals of Integrated Coastal Zone Management can be applied in a realistic way within the particular biophysical, political, and socioeconomic systems and subsystems.

COGNITIVE DISSONANCE

Jaroslaw Dzialek
Jagiellonian University, Krakow, Poland

Synonyms

Contradictory beliefs; Misperception

Definition

Cognitive dissonance is an unpleasant sensation that appears when someone is confronted with two contradictory facts or

ideas at the same time. People usually tend to keep consistency internalized and thus reduce the dissonance.

Overview

The cognitive dissonance theory is one of the most influential theories in social psychology. It was proposed and developed by Leon Festinger (1957). It states that people have some persistent beliefs about their physical and social environment, and try to behave in a self-consistent manner. When they encounter two cognitions (attitudes, beliefs, behaviors), which are relevant to each other, but dissonant at the same time, it generates an uncomfortable psychological tension. People are then motivated to reduce the dissonance by altering one of the causative cognitive elements. Consequently, it results in changing their attitudes, beliefs, and behaviors, or in attempts to justify or rationalize some of these. Dissonance reduction explains attitude and behavior changes of people, but fails in predicting what changes will happen in a particular situation (Glassman and Hadad, 2009). This human reaction can be interpreted as a kind of an irrational behavior as it prevents one from discovering real facts or in taking more appropriate decisions. From the psychological point of view, this mechanism serves to defend people's ego and keep a positive image of themselves (Aronson, 1979).

Cognitive dissonance processes help to understand the perception of natural hazards and disasters, and they especially explain why people living in hazardous areas tend to underestimate the risk and resign from undertaking appropriate mitigation actions. It results from misperception of natural hazards, particularly their frequency and intensity. People generally have difficulties in assessing the probability of rare phenomena and they usually think of disasters as something exceptional. They also feel they have limited control over such phenomena (National Research Council of the National Academies, 2006).

People living in hazardous areas may be confronted with dissonant ideas having both positive and negative consequences. On the one hand, they fear the eventuality that a disaster will happen that can cause losses and casualties. On the other hand, they may appreciate their living conditions or feel strongly attached to their neighborhood. Moreover, they might not have sufficient resources to move to a secure area. For example, inhabitants of volcanic slopes perceive higher benefits of living in a clean environment with opportunities to develop agriculture and tourism over the risk of eruptive and seismic activity (Chester et al., 2002). Understanding people's perception of natural hazards, particularly cognitive dissonance reduction, helps to improve hazard mitigation policies in cooperation with local population.

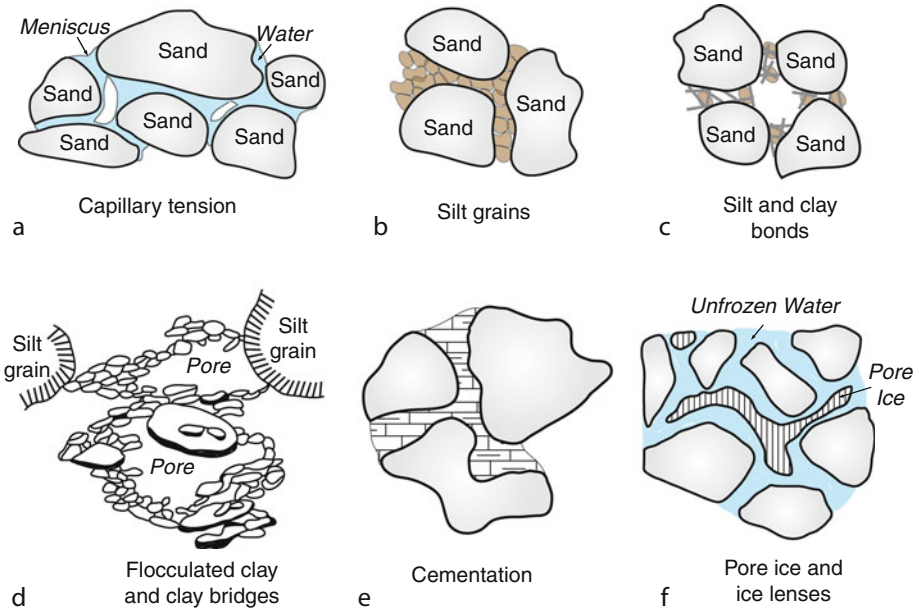
COLLAPSING SOIL HAZARDS

Andrew J. Stumpf
University of Illinois at Urbana-Champaign, Champaign, IL, USA

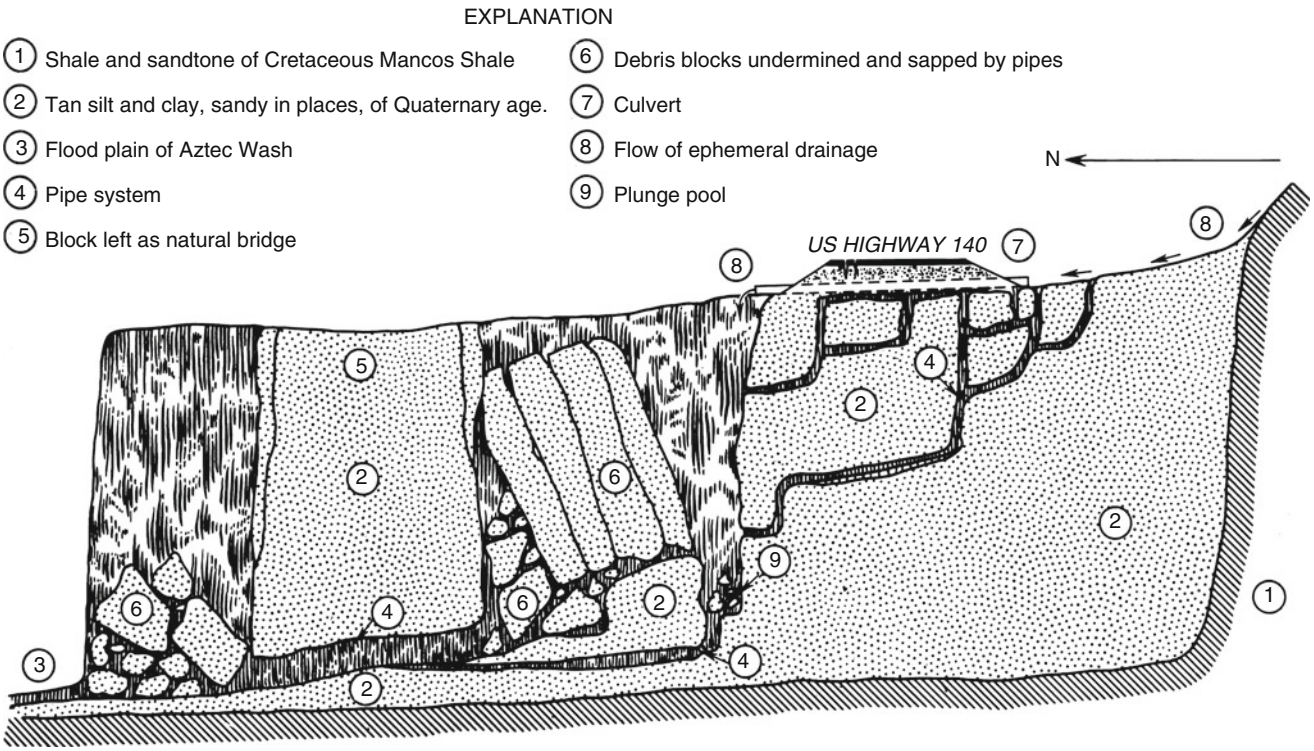
Synonyms

Hazards of collapsible or metastable soils



Definition

Collapsing soil hazard. A major hazard to natural land, disturbed ground, or engineered structures worldwide resulting from the structural collapse of constituents in soil. In most cases, collapse occurs following the wetting and loading of unsaturated materials (unconsolidated sediments), but soils with higher moisture content such as quick clays may undergo collapse as well. Collapsible soils also include those sediments that contain perennial ice or permafrost that has subsequently melted.



Introduction

Collapsing soils are not a local problem, but rather a worldwide phenomenon occurring on a variety of landscapes under different subsurface conditions. Soils may collapse catastrophically, but often signs of impending failure remain undetected especially in remote areas or on land modified by humans. The rate of collapsibility in soils depends on a number of factors such as their internal structure, moisture content and wetting history, degree of weathering or alteration, age, landscape position and mode of deposition, climatic conditions, mineralogy and shape of soil particles, presence of cementation, and compaction history due to loading (Dudley, 1970; Barden et al., 1973; Darwell and Denness, 1976; Rogers, 1995).

Alone, soil collapse annually results in hundreds of millions of dollars in damage to private and public property in the USA (Prior and Holzer, 1991). These collapse events may cause significant instability that engineers and

Collapsing Soil Hazards, Figure 1 Typical internal structure of collapsible soils. Soil particles and minerals are held together by: (**a**) capillary tension, (**b**) silt grains, (**c**) bonds containing silt and/or clay, (**d**) flocculated clay or clay aggregations, (**e**) mineral cements, and (**f**) pore ice or ice lenses (Modified from Collins and McGowan, 1974; Pavlik, 1980; Clemence and Finbarr, 1981; Holtz and Kovacs, 1981).

Collapsing Soil Hazards, Figure 2 Idealized north to south cross-section of Aztec Wash alluvium in southwestern Colorado, USA showing incipient piping system beneath US highway 140 (Figure 18 in Parker and Jenne, 1967). scientists must address in the design, construction, and maintenance of water distribution systems, pipelines, low gradient canals, power transmission lines, highways, railroads, buildings, and various aspects of land development and use (Curtin, 1973).

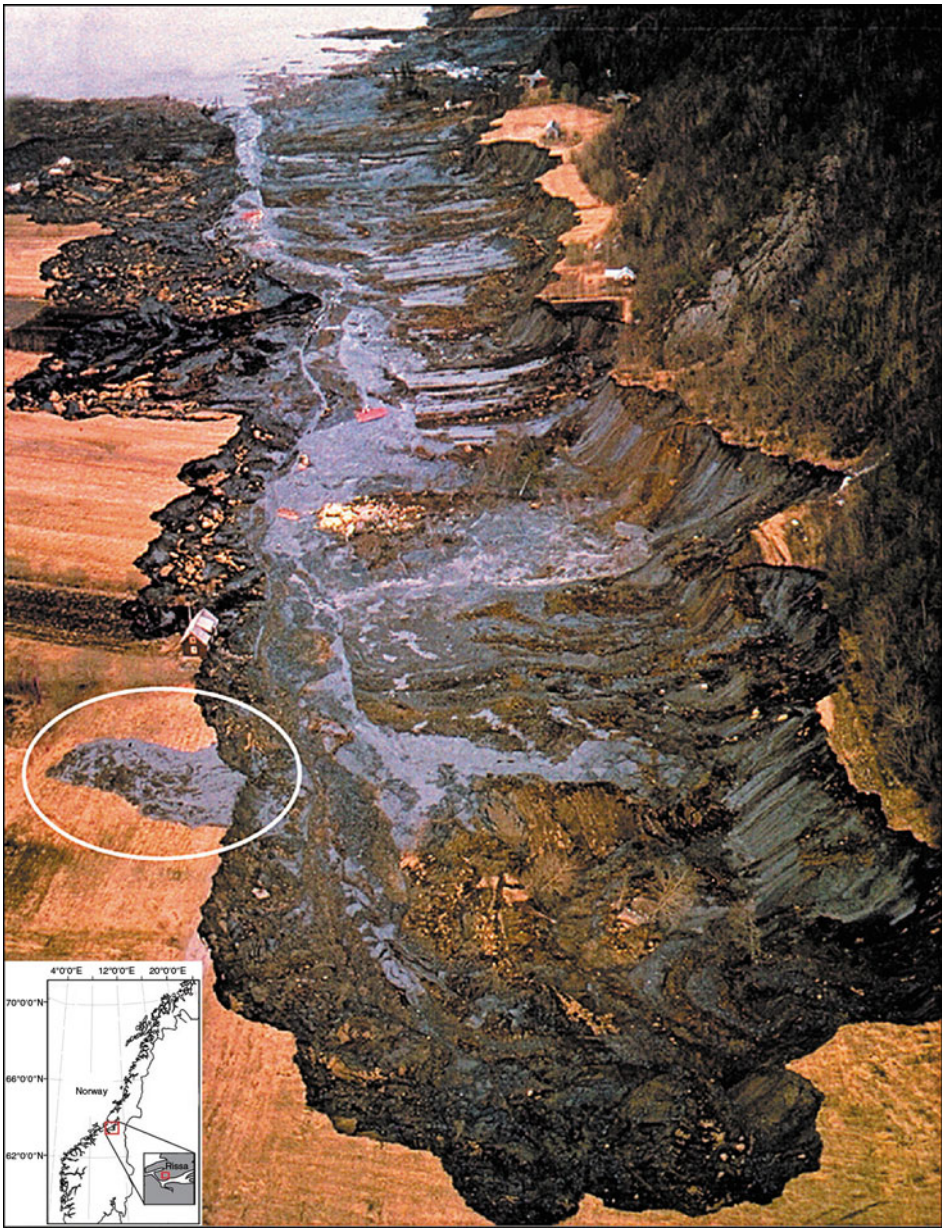
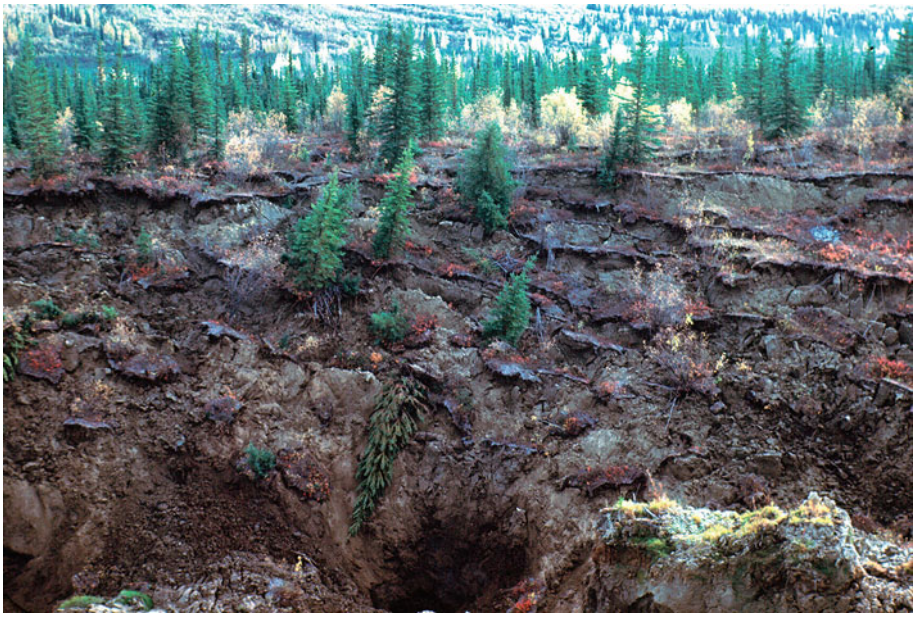
Properties of collapsible soils



Soils develop over a long period of time through a combination of physical, chemical, and biological processes that install distinctive internal structures and arrangement of soil particles. In situ compaction and wetting can further alter these soils. Collapsible or metastable soils are generally described as hard, dry, or partially saturated materials that have a low dry density and high porosity and will undergo an appreciable amount of volume change upon wetting, loading, or a combination of both (Sultan, 1969; Dudley, 1973; Handy, 1973; Jennings and Knight, 1975; Booth, 1977). These soils tend to be relatively young or recently altered, and have an open structure, a high void ratio, high sensitivity, and low interparticle bond strength (Derbyshire et al., 1995). Additional studies by Rosenqvist (1966), Czudek and Demek (1970), Mackay (1970), Torrance (1983), and MacKechnie (1992) provide additional information that show collapse may also occur in saturated soils, in transported or residual soils, dispersive soil, dispersive soil, and soils containing perennial ice. Soils overlying karst qv "*Karst hazard*" and soft bedrock may also collapse (Waltham et al., 2005), but these failures require the underlying rock be dissolved or fractured, processes not directly controlled by the overlying materials.

At the microscopic scale, collapse occurs when bonds between soil particles are broken and their internal structure weakened. Through this process, soil particles become further compacted producing subsidence that can be substantial and nonuniform (Barden et al., 1973; Clemence and Finbarr, 1981; Hunt, 2007). A soil is relatively stable when made up of uniform spherical particles that readily pack together to a near stable configuration reaching an optimum density (Rogers, 1995), whereas soils that contain much larger interparticle spaces between irregularly shaped grains, often of silt or fine sand size, are more prone to collapse (Clemence and Finbarr, 1981). Certain deposits containing flocculating clays may also collapse if the mineralogy and ion bonding are altered qv "*Dispersive soil hazard*" (Quigley, 1980).

Temporary strength in partially saturated, fine-grained cohesionless soils is provided through bonds between particles maintained by capillary tension, interlocking silt grains, silt and clay films and bridges, flocculated clay and clay agglomerations, chemical precipitates of iron oxide, calcium carbonate and gypsum, or pore ice and ice lenses as illustrated in Figure 1. Collapse in soil occurs once the bonds are broken particularly when: (a) water is applied increasing the degree of saturation; (b) loading exceeds the maximum strength; (c) cementing agents and salts are dissolved; and (d) permafrost is melted (Hunt, 2007; Muller et al., 2008).



Collapsing Soil Hazards, Figure 3 Complex retrogressive block collapse in thick loess on the fourth terrace of the Yellow River (Huang He) at Heifantai, ca. 60 km southwest of Lanzhou city, Gansu Province, China. Soil collapse has been accelerated by rapid growth of human settlement and resulting widespread irrigation of the terrace for agriculture. The river in the distance is the Huang Shui, here just above its junction with the Huang He. Photograph taken in 2006 (Reproduced with permission from E. Derbyshire).

Collapsing Soil Hazards, Figure 4 Photograph of the quick-clay slide at Rissa near Trondheim occurring in 1978. The largest quick-clay slide in Norway in the twentieth century, it covered a 330,000 m^2 area. The event began as a small failure in fill by a lake, but in a few hours approximately 6,000,000 m^3 of soil had collapsed by retrogressive sliding (Gregersen, 1981). The deposits of liquid clay that spilled over the edge of the scar during failure are encircled. Note the houses for scale (Reproduced with permission from Elsevier Limited).

When the support is removed, particles are able to move and slide past one another to fill the vacant pore space (Clemence and Finbarr, 1981).

Wetting that penetrates deeply into unsaturated, low-density soils often causes interparticle bonds to be broken and washing out of silt and clay particles. This creates open pore space that promotes the denser packing of grains that can result in subsidence. This process, hydrocompaction qv "*Hydrocompaction subsidence*", is commonly observed in fine-grained soils of arid and semiarid environments (Rogers et al., 1994). Some of these soils, once wetted, are prone to significant subsurface erosion by piping qv "*Piping hazards*", which may lead to further subsidence (Paige-Green, 2008). Water entering the soil through fractures formed by desiccation or subsidence carries suspended clay particles to discharge points on slopes or permeable layers at depth. Over time, the fractures enlarge, undercutting the overlying materials (Figure 2). Piping is most prevalent in dispersive

Collapsing Soil Hazards, Figure 5 Slumping at Ester Drain on Gold Hill near Fairbanks, Alaska, USA. Following the melting of permafrost in loess, a large piping system developed causing rapid subsidence. Photograph taken by T. L. Pewe on September 14, 1949 (Reproduced with permission from the United States Geological Survey).

soils qv "*Dispersive soil hazards*"; soils that have a higher concentration of soluble salts that are developed in alluvial clays, windblown fine sand and silt (loess qv "*Loess*"), flood plain deposits qv "*Flood deposits*", and residuum on marine claystone and shale (Sherard et al., 1977). Knight (1963) and Holtz and Hilf (1961) have shown that collapse occurs in saturated and unsaturated soils following loading, particularly when the moisture content exceeds the liquid limit of the soil.

Soils containing weakly cemented particles or dispersive clays are highly susceptible to collapse after wetting (Figures 3 and 4), especially when exposed at the surface or interstratified with higher permeability sediments (Handy, 1973; Torrance, 1987). Reports by National Research Council (1985) and Wang et al. (2006) suggest that ground motions from earthquakes and underground explosions may produce enough energy to trigger collapse in these soils.

At high latitudes and altitudes, melting of perennial ice in both fine-grained and permeable soils may cause significant subsidence of the ground surface (Figure 5). In finer textured soils where drainage is poor, the melting of ice creates supersaturated conditions causing the sediment to liquefy (Andersland and Ladanyi, 2004). In more permeable soils, however, subsidence of the ground surface occurs by consolidation after the loss of excess water by drainage or evaporation (Murton, 2009).

Distribution of collapsible soils

Collapse in partly saturated or saturated soil is a phenomenon recognized throughout the world posing significant problems to engineered structures and land management. As noted previously, collapse soils are geologically young and have not undergone significant compaction or weathering by natural processes. Collapsible soils are most commonly found in Upper Pleistocene loess of the North America, central Europe, China, Africa, Russia, India, Argentina, and elsewhere (Rogers et al., 1994 and therein; Trofimov, 2001) however other soils considered prone to collapse are developed in:

1. Weathered bedrock (Brink and Kantey, 1961; Rao and Revanasiddappa, 2002; Pereira et al., 2005)
2. Aeolian sand (Knight, 1963; Amin and Bankher, 1997)
3. Glacial lake silt and clay (Clague and Evans, 2003; Kohv et al., 2009)
4. Glaciomarine and marine clay (Egashira and Ohtsubo, 1981; Geertsema et al., 2006: Hansen et al., 2007)
5. Alluvial and flood deposits (Parker and Higgins, 1990; Psimoulis et al., 2007; White and Greenman, 2008)
6. Organic deposits (Wösten et al., 1997; Haeberli and Burn, 2002)
7. Perennially frozen sediment (Demek, 1996; Jorgenson and Osterkamp, 2005)
8. Volcanic ash and dust (Wright, 2001; Iriondo and Kröhling, 2007)
9. Cemented soil (Ola, 1978; Petrukhin and Presnov, 1991)
10. Saline soil (Loveland et al., 1986; Azam, 2000)
11. Man-made materials (Booth, 1977; Herbstová et al., 2007)

Summary

The large number of studies undertaken worldwide to identify and predict the distribution of collapsing soil suggests that their presence in geologic and man-made materials is more common than originally presumed (this point is set forth in Derbyshire et al., 1995). There has been much debate between the soil scientists, geologists, geomorphologists, and geotechnical engineers on definition of collapsible soils. It is expected that with continued discussion between these academic disciplines, along with additional characterization studies of soils prone to collapse, a comprehensive criteria for identifying collapsible soils will assist local- and regional-based practitioners in determination and mitigating their hazards.

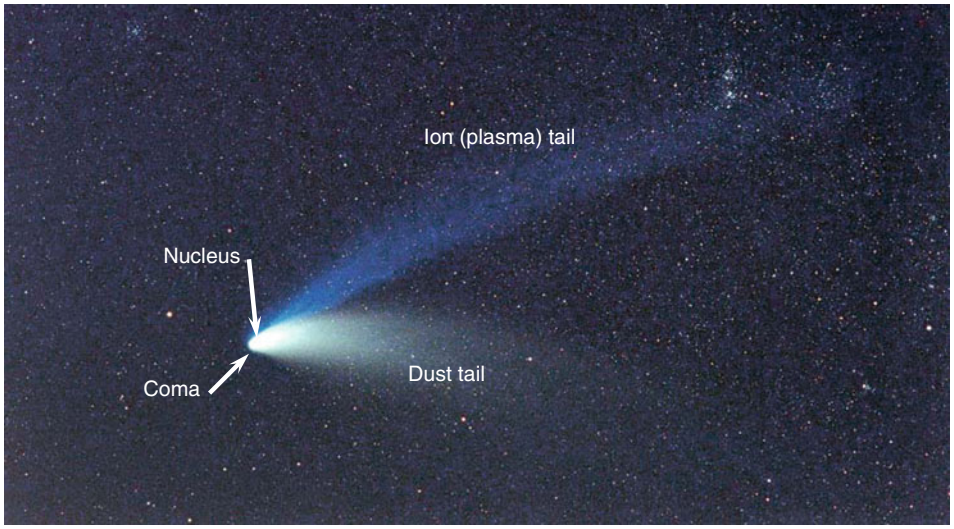
COMET

Paul R. Weissman
Jet Propulsion Laboratory/California Institute of Technology, Pasadena, CA, USA

Definition

Cometary nucleus – The solid, icy-conglomerate body that is the heart of the comet and the source of its activity.

Cometary coma – The freely outflowing atmosphere of dust and gas around the nucleus.



Comet tails – The coma materials separate and form two tails trailing behind the nucleus, one composed of dust and one composed of ionized gas molecules (see Figure 1).

Introduction

Comets are primitive bodies left over from the formation of the solar system. They were among the first solid bodies to form in the solar nebula, the collapsing interstellar cloud of dust and gas out of which the Sun and planets formed. Comets formed in the outer reaches of the planetary system where it was cold enough for volatile ices to condense. This is generally taken to be beyond 5 AU (astronomical units), or beyond the orbit of Jupiter. Because comets have been stored in distant orbits beyond the planets, they have undergone little of the modifying processes that have melted or changed most other bodies in the solar system. Thus, they retain a physical and chemical record of the primordial solar nebula and of the processes involved in the formation of planetary systems.

Cometary nuclei

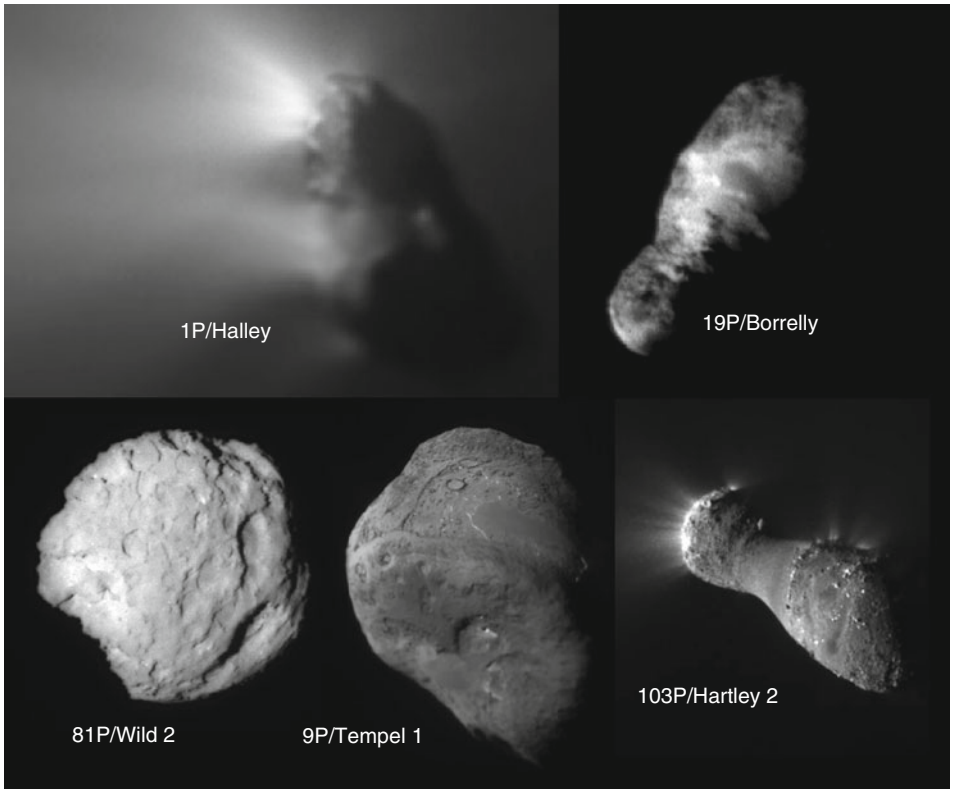
Cometary nuclei are small bodies, typically only a few kilometers in diameter, and composed of roughly equal parts of volatile ices, silicate dust, and organic materials. The ices are dominated by water ice (~80% of the total ices) but also include carbon monoxide, carbon dioxide, formaldehyde, and methanol. The silicate and organic mix is similar to that found in the most primitive meteorites, carbonaceous chondrites. These materials are intimately mixed at micron scales. Images of the five

Comet, Figure 1 Comet Hale-Bopp in 1997, showing the major components that make up a typical comet. The nucleus is embedded deep within the bright coma and is too small and dark to see in this image.

cometary nuclei visited so far by interplanetary spacecraft are shown in Figure 2.

The nuclei formed in the solar nebula as dust and ice particles settled to the central plane of the nebula. When these particles collided they tended to stick. Micron-sized particles grew through this process of agglomeration and accretion to meter-sized and then kilometer-sized bodies.

When cometary nuclei come close to the Sun, the ices in them sublimate, transforming directly from the solid to the vapor phase. The evolving gas molecules flow off the nucleus surface, carrying with them silicate and organic dust particles embedded in the ices. This outflowing mix of materials then forms the cometary coma, the comet's atmosphere. Because cometary nuclei are small, their gravity is too weak to retain this atmosphere and it flows freely out into space.



Because the different ices sublimate at different temperatures, gases are liberated from different depths below the surface as the solar heat wave penetrates into the surface. So the layers closest to the surface become progressively depleted in the most volatile ices. Also, a lag deposit of nonvolatile dust develops on the surface. These are typically particles too large to be lifted by the escaping gases. This nonvolatile layer can become so thick that it effectively insulates the icy component below it, preventing further sublimation.

Another feature of cometary activity is driven by the fact that the water ice in comets condensed at very low temperatures, <100 K. At these low temperatures, ice forms in the amorphous state, a random ordering of molecules. As the amorphous water ice is warmed above $\sim$115 K, it begins to transform to crystalline ice, first in the cubic form and then the normal hexagonal ice that we are most familiar with. This transition is complete at $\sim$153 K. It is an exothermic reaction, that is, it releases energy. This energy further sustains the reaction as it warms the ice around it, but dies out because it must also heat the nonvolatile dust components of the nucleus. The amorphous-crystalline ice transition may be one source of cometary outbursts, sharp increases in cometary activity that appear to occur randomly.

The internal structure of cometary nuclei is still an area of speculation. It is generally believed that as icy planetesimals came together at low velocity in the solar nebula, there was not enough energy to melt or compress them into a single solid body. The two leading explanations suggest that cometary nuclei are "fluffy aggregates" or "primordial rubble piles" with low binding strength and high porosity. Key data supporting these models are estimates of nucleus bulk density, ranging from 0.2 to 1.5 g/cm^3, with preferred values of $\sim$0.3–0.6 g/cm^3. This suggests a combined microscopic and macroscopic porosity of $\sim$64% or more, a very high value.

Additional evidence for the rubble pile model for cometary nuclei comes from observations of split (disrupted) cometary nuclei. Observations show that nuclei can randomly break apart, shedding a few or many pieces. These pieces have typically been estimated to be between 8 and 60 m in diameter. In some cases, the entire nucleus disrupts. Disruption can also occur if the nucleus passes too close to the Sun or to a large planet like Jupiter, where gravitational tidal forces tear the weakly bound nuclei apart. This has been observed for Sun-grazing comets, comets with perihelia within one solar radius of the Sun's photosphere.

A particularly interesting case of a tidally disrupted nucleus is that of comet Shoemaker-Levy 9. This comet was discovered in 1993 as a string of 21 separate but comoving, active nuclei. Observations showed that the

Comet, Figure 2 The five cometary nuclei imaged to date by flyby spacecraft: comet Halley (1986 by Giotto), comet Borrelly (2001 by Deep Space 1), comet Wild 2 (2004 by Stardust), comet Tempel 1 (2005 by Deep Impact), and comet Hartley 2 (2010 by EPOXI). The nuclei range in size from 16 × 8 km for Halley, down to 2 × 1 km for Hartley 2. Note the considerable differences in topographic features on each of the nuclei. These may be due to the surface features evolving as each comet makes more returns close to the Sun.

comet had been captured into orbit around Jupiter, and had passed so close to Jupiter on its last perijove passage, 1.3 Jupiter radii, that it was tidally disrupted. The nucleus appeared to have broken into thousands of separate "cometesimals." As this swarm of bodies moved away from Jupiter, their own self-gravity caused them to clump together. Interestingly, the number of final clumps was shown to be a function of the bulk density of the original nucleus, and the best fit was obtained for densities of $\sim$0.6 g/cm^3. Thus, comet Shoemaker-Levy 9 is another of the proofs of a low-density, rubble pile or aggregate structure for cometary nuclei.

Cometary atmospheres

Because of the small size and low gravity of the cometary nuclei, the evolving gases from sublimating ices expand freely into the vacuum of space. Entrained in the outflowing gas are fine dust particles, typically a micron in size, composed of both silicates and organics. Because the molecules are exposed to sunlight and the solar wind they begin to disassociate, breaking up into radicals and individual atoms. The most common case of this is the water molecule, which disassociates into H and OH. Organic dust grains appear to also release radicals into the outflowing coma, most common of which are CN, C_2, and C_3. These are known as "daughter" molecules and cometary spectroscopy is used to study the chemistry that goes on in the coma as the parent and daughter molecules, radicals, and individual atoms react with each other.

The observed composition of volatiles in cometary comae is very similar to that seen in dense, cold interstellar clouds where stars and solar systems are being formed. This reinforces strongly the belief that comets are frozen remnants of the primordial solar nebula, preserving unmodified volatiles from the formation of the planetary system, 4.56 billion years ago.

Cometary comae often show geyser-like structures, or "jets," which are taken as evidence of individual active areas on the surfaces of the nuclei. As noted above, lag deposits of large dust grains can shut down sublimation on the surface. Because the nature of the source vents for the cometary activity is as yet unknown, there is no good explanation as to why some areas remain active and others do not. It is known that this is likely an ageing effect, as the "active fraction" on the nucleus is large for long-period and Halley-type comets (see below), which have made relatively few approaches close to the Sun, and very low, typically only a few percent, for Jupiter-family comets, which have made hundreds of returns, on average.

Comets also can display "outbursts," which are large, sudden releases of dust and gas. The most famous of these is comet Holmes in 2007, which brightened by 15 magnitudes (one million times brighter) in less than a day. The explanation for outbursts, and their larger cousins, disruption events, is as yet unknown, though rotational spin-up due to torques from coma outgassing, has been suggested, and the amorphous-crystalline ice transition (see above) is also likely a factor.

Comet tails

The outflowing dust and gas in the coma also interacts with the solar wind and sunlight. The fine dust is blown away from the Sun by radiation pressure on the tiny grains. This forms a broad, curved sometimes yellow-colored tail following the comet in its orbit and pointed generally away from the Sun. This is known as a Type I tail. The molecules suffer a different fate as they are ionized by charge exchange with the solar wind. Once ionized, they are caught up in the Sun's magnetic field and flow away at high velocity in the solar wind. This process forms long, narrow, straight trails that glow blue in color due to the presence of CO^+ molecules. These tails point sharply away from the Sun and are known as Type II tails. Well before the first spacecraft observations of the solar wind in 1959, the existence of the solar wind was inferred from the appearance of cometary ion tails.

Dynamics

Comets are typically in more eccentric and more inclined orbits than other bodies in the solar system. In general, comets are classified into three dynamical groups: the Jupiter-family comets with orbital periods less than 20 years, the Halley-type comets with orbital periods between 20 and 200 years, and the long-period comets with orbital periods greater than 200 years. A more formal definition involves a quantity called the Tisserand parameter:

$$T = a_J/a + 2\sqrt{(a/a_J)(1 - e^2)}\cos i \quad (1)$$

where a, e, and i are the semimajor axis, eccentricity, and inclination of the comet's orbit and a_J is the semimajor axis of Jupiter's orbit. Jupiter-family comets have Tisserand parameters between 2.0 and 3.0 and Halley-type and long-period comets have T values less than 2.0. Asteroids have T values greater than 3.0. However, there are both some comets whose orbits have evolved to T values slightly greater than 3, and some asteroids with T values slightly less than 3.

Another important difference in the dynamical groups is their orbital inclination distributions. Jupiter-family comets typically have orbits that are modestly inclined to the ecliptic (the plane of the Earth's orbit), with inclinations up to about 35°. The Halley-type comets have much higher inclinations, including retrograde orbits that go around the Sun in the opposite direction, though not totally randomized. The long-period comets have totally random inclinations and can approach the planetary system from all directions. As a result, the Jupiter-family comets are also known as "ecliptic comets," whereas the long-period comets are also known as "isotropic comets."

The inclinations of the cometary orbits provide important clues to their origin. Dynamical simulations show that the great concentration of Jupiter-family orbits close to the ecliptic can only originate from a flattened source of comets. This source has been identified as the Kuiper belt, a flattened disk of icy bodies beyond the orbit of Neptune and extending to at least 50 AU from the Sun. The Kuiper belt is analogous to the asteroid belt and is composed of ice-rich bodies that never had enough time to form into a larger planet.

The exact source of the Jupiter-family comets is called the Scattered disk, Kuiper belt comets that are in more inclined and eccentric orbits with perihelia close to Neptune. Neptune can gravitationally scatter comets from the Scattered disk inward to become Jupiter-family comets, or outward, to the Oort cloud (see below).

The origin of the long-period comets with their random inclinations was a mystery until 1950 when Dutch astronomer Jan Oort proposed that these comets came from a vast cloud of comets surrounding the solar system and stretching to interstellar distances. The key to recognizing this was the distribution of orbital energies, which showed that a large fraction of the long-period comets were in very distant orbits with semimajor axes of ~25,000 AU or more. The orbits of comets in the "Oort cloud," as it is now known, are so distant that they are perturbed by random passing stars and tidal forces from the galactic disk. Again, dynamical simulations show that the Oort cloud is the only possible explanation for the number of comets with very distant orbits, but still gravitationally bound to the solar system.

But where did the Oort cloud comets come from? The solar nebula was too thin at those large distances for comet-sized bodies to form. Current thinking is that the Oort cloud comets are icy-planetesimals that formed in the region of the giant planets, between 5 and 30 AU, and were gravitationally ejected to distant orbits by the growing giant planets. This process is fairly inefficient and most icy planetesimals were ejected to interstellar space by the giant planets. If other forming solar systems are doing the same thing, then there is a vast swarm of comets in interstellar space. However, no comet has ever been observed entering the planetary system that was on an obviously interstellar orbit.

It is also possible that if the Sun formed in a cluster of stars, as most stars do, then it might have exchanged comets with the growing Oort clouds of those nearby stars. This could be a significant contributor to the Oort cloud population.

The source of the Halley-type comets, with their intermediate inclinations and eccentricities, is still a matter of debate. Both the Scattered disk and the Oort cloud have been suggested as sources. It may be that the explanation lies with a combination of the two cometary reservoirs.

The comet impact hazard

Comets pose a natural hazard to the Earth. This is because many of them are in orbits that cross the Earth's orbit and may collide with the Earth. Approximately 10 long-period comets, on the order of 1 km in diameter (or larger), cross the Earth's orbit each year. Because the Earth is a relatively small target and space is vast, the impact probability per comet is, on average, very low. A random long-period in an Earth-crossing orbit has an average impact probability of 2.2×10^{-9} per perihelion passage. This means that, on average, one long-period comet will strike the Earth for every 454 million comets that cross its orbit. Given the estimated rate of 10 long-period comets crossing the Earth's orbit per year, this results in a mean time between long-period comet impacts of 45 Myr.

However, because the long-period comets move on highly eccentric and highly inclined orbits, their mean impact velocities are much higher than for other celestial bodies, that is, asteroids. The average long-period comet will strike the Earth with a velocity of 51.8 km/s. If we weight the impact velocity by the probability of impact for a particular orbit, then the weighted mean impact velocity increases to 56.4 km/s. These values are much higher than that for Earth-crossing asteroids, which are typically only ~15 km/s.

An interesting case is that of Earth-crossing long-period comet Hale-Bopp (Figure 1), which passed closest to the Sun in 1997. Hale-Bopp was an unusually large and active comet, easily seen with the naked eye in evening skies. With a perihelion distance of 0.914 AU (the point in the orbit closest to the Sun), Hale-Bopp's orbit crossed inside the orbit of the Earth. Hale-Bopp was believed to have an unusually large nucleus, estimated to be 27–42 km in diameter. Taking a median value of 35 km and assuming a mean bulk density of 0.6 g/cm^3 results in an estimated mass of 1.3×10^{19} g.

The impact probability for Hale-Bopp on the Earth is 2.54×10^{-9} per perihelion passage, fairly typical for a long-period comet. Because of the comet's high orbital eccentricity, 0.9951, and inclination, 89.43°, the impact velocity would be 52.5 km/s. The resulting impact energy is equivalent to 4.4×10^9 megatons of TNT. This is ~44 times the estimated energy of the asteroid impact 65 Myr ago that killed the dinosaurs. Such an energetic impact may have the capability to completely sterilize the Earth, resulting in the extinction of all life on the planet! Fortunately, Hale-Bopp passed through the plane of the Earth's orbit on the far side of the Sun from the Earth, so there was never any possibility of an impact. Also, the average time between impacts of cometary nuclei as large as Hale-Bopp far exceeds the age of the solar system.

This illustrates an important point about the cometary impact hazard. Although asteroid impacts are far more frequent than comet impacts, some comets crossing the Earth's orbit are considerably larger than any of the known near-Earth asteroids. Thus, the largest and most devastating impacts on the Earth are likely to be of comets. Other known Earth-crossing comets with large nuclei include comet Halley, ~16 × 8 km in diameter, and comet Swift-Tuttle, ~23–30 km in diameter.

Also, the flux of long-period comets can vary over time. If a star comes close enough to the Sun to pass through the Oort cloud, in particular at distances less than 10,000 AU, then the star can cause a "shower" of comets to enter the planetary system. The rate of long-period comets crossing the Earth's orbit could increase by a factor of ~200 and the complete shower would last for about 2.5 Myr. Fortunately, such close stellar passages are rare, about one every 300 Myr.

For Jupiter-family comets, whose returns are predictable (once discovered), only 22 Earth-crossers are known (excluding the many small fragments of disrupted comet 73P/Schwassmann-Wachmann 3). Of these, four are lost, eight have only been observed on only one return, and one is no longer Earth-crossing. Their mean impact probability is 7.3×10^{-9} per orbit or 1.3×10^{-9} per year, and their mean encounter velocity with the Earth is 22.9 km/s, with a most probable encounter velocity of 19.9 km/s. The mean time between Jupiter-family comet impacts is 35 Myr

For Halley-type comets, whose returns are also predictable, another 16 Earth-crossers are known, of which 1 is lost and 6 have not yet made a second observed appearance. Their mean impact probability is 7.0×10^{-9} per orbit but only 0.16×10^{-9} per year because of their longer orbital periods. Their mean encounter velocity is 45.4 km/s, with a most probable encounter velocity of 52.3 km/s. The mean time between Halley-type comet impacts is 390 Myr. Note that the impact frequency for both Jupiter-family and Halley-type comets may be higher if there are yet undiscovered members of each group.

Summary

Comets are among the most interesting bodies in the solar system because they retain a cosmochemical record of the physical and chemical conditions at the time the planets formed. They have been kept in "cold storage" far from the Sun, during most of the solar system's history, and thus are essentially unmodified from their primitive state 4.56 billion years ago. Comets pose a small but significant part of the impact hazard to the Earth, and probably can account for the largest impacts on our planet over the last 3 billion years.

COMMUNICATING EMERGENCY INFORMATION*

John H. Sorensen
Oak Ridge National Laboratory, Oak Ridge, TN, USA

Definition and introduction

The empirical study of public communications in emergencies has been ongoing for almost 50 years (Perry and Mushkatel, 1986, 1984; Leik et al., 1981; Quarantelli, 1980; Baker, 1979; Mileti and Beck, 1975; Drabek and Stephenson, 1971; Lachman et al., 1961). These studies, when viewed collectively, have compiled an impressive record about how and why public behavior occurs in the presence of impending disaster or threat. For example, it is well documented that emergency warnings are most effective at eliciting public protective actions like evacuation when those warnings are frequently repeated (Mileti and Beck, 1975), are confirmatory in character (Drabek and Stephenson, 1971), make specific recommendations, and are perceived by the public as credible (Perry et al., 1981). Informal warning mechanisms (friends or relatives) are also at times very effective. In many evacuations, people leave the area at risk before an official warning is announced. Evacuation behavior is also influenced by other factors such as personal or family resources, age, and social relationships including social networks, level of education completed, experience with previous emergencies, social and environmental cues of immediate hazard, physical or psychological constraints to evacuating, as well as other more specific circumstances (such as time of day, weather conditions, etc.). Table 1 provides a list of those factors and how they have covaried with decisions to respond (Mailman School of PH @ Columbia, annual preparedness survey, focuses on why parents may not heed evacuation orders).

Studies that have used surveys of random samples of people living in or near-disaster areas have been conducted for a variety of hazard events. For hurricanes, these include Elena and Kate (Baker, 1987; Nelson et al., 1988), Eloise (Windham et al., 1977; Baker, 1979), Camille (Wilkinson and Ross, 1970), David and Frederick (Leik et al., 1981), Carla (Moore et al., 1964), Floyd (Dow and Cutter, 2002; HMG, no date), Andrew (Gladwin and Peacock, 1997), Bertha and Fran (Dow and Cutter, 1998), Georges (Dash and Morrow, 2001; Howell et al., 1998), Brett (Prater et al., 2000), Bonnie (Whitehead et al., 2000) Ivan (Howell and Bonner, 2005), and Lily (Lindell et al., 2005).

Studies of flood include Denver, CO (Drabek and Stephenson, 1971); Rapid City, SD; (Mileti and Beck, 1975); Big Thompson, CO (Gruntfest, 1977); Sumner Valley, Fillmore, and Snoqualmie, WA (Perry et al., 1981); Abilene, TX (Perry and Mushkatel, 1984); Clarksburg and Rochester, NY (Leik et al., 1981); and Denver, CO, and Austin, TX, (Hayden et al., 2007).

Studies of chemical accidents include Mississauga, Ontario, Canada (Burton, 1981); Mt. Vernon, WA; and Denver, CO (Perry and Mushkatel, 1986); Confluence and Pittsburg, PA (Rogers and Sorensen, 1989); Nanticote, PA (Duclos et al., 1989); and West Helena, AR (Vogt and Sorensen, 1999). Graniteville, SC (Mitchell et al., 2005).

Other protective action studies include the Hilo, HI, tsunami (Lachman et al., 1961); the Mt. St. Helens, WA, volcanic eruption (Perry and Greene, 1983; Dillman et al., 1984); the Three Mile Island nuclear accident, PA (Cutter and Barnes, 1985; Flynn, 1979); the World Trade Center bombing, NY, in 1993 (Aguire et al., 1998); the World Trade Center collapse, NY, in 2001 (Averill et al., 2005); SoCal wildfires in 2003 and Australian bushfires in 2005 (Proudley, 2008, AJEM) and in particular 2009 (Haynes et al., 2008, *J. Volc. Geotherm. Res*., on volcanic risk perception; Wray et al., 2008, *Am. J. Pub. Health*, on communicating with

public about health threats). The National Env. Health Assn published an excellent review of risk comm., risk perception, and loss of trust in "authorities" re post-collapse risk (Lyman, 2003, *Messages in the Dust*).

Excellent summaries of this research currently exist (Lindell and Perry, 2004; Drabek, 1986; Mileti and Sorensen, 1990; Tierney et al., 2003; National Research Council, 2006) and will not be repeated here.

Summary

Empirical studies and summaries have done much to further social scientific understanding of how people process and respond to risk communications in emergencies; it has also served to inform practical emergency preparedness efforts in this nation and abroad. Relevant research on human response to risk communications derived from the empirical research record can be summarized as follows.

Research indicates that people's decisions to respond to emergency communications are influenced by:

- The frequency and channel of communication of the warning. The most important dimensions of the warning frequency/channel are the number of different channels people hear the warning from, hearing from personal channels, and the frequency that people hear the warning.
- The content of the warning message. The most important dimensions of content are a description of the hazard and impacts, the predicted location of impacts, what actions to take, and when to take those actions.
- Observing cues. These include social cues (i.e., seeing neighbors evacuating) and physical cues (i.e., seeing flames or a smoke cloud).
- Aspects of individual status. These include socioeconomic status (i.e., income level and education completed), age, gender, and ethnicity.
- The role(s) an individual holds in society. These include having children at home, family size (i.e., larger vs. smaller), extent of kin relations, being a united family at time of the event, and greater community involvement.
- Previous experience with the hazard. People are inclined to do what they did in a previous situation.
- People's belief in the warning. Belief is not determined by the credibility of the source issuing the warning but by the frequency the message is heard.
- People's knowledge about the hazard. This includes previous information and data gained in the event or by cues.
- People's perceptions of risk. This includes perception of the threat before the event and perception of risk from the specific event.
- The extent of social interactions during the event. This includes efforts to contact others about the event, being contacted by others, and being able to confirm the message as accurate and credible.

COMMUNITY MANAGEMENT OF NATURAL HAZARDS

William T. Hartwell
Desert Research Institute, Nevada System of Higher Education, Las Vegas, NV, USA

Definition

Community management of natural hazards. Community-based participation in identification, mitigation, preparedness, response, and recovery and reconstruction activities related to potential and/or experienced natural hazards.

Introduction

Natural hazard management strategies typically include several broad categories of management. They include hazard identification and mitigation, preparedness (or planning), response, and recovery and reconstruction. These strategies can be viewed as a continuum, with recovery and reconstruction activities ideally resulting in increasingly effective mitigation strategies in advance of the next hazard event.

Historically, the management of natural hazards has been viewed primarily as one of response and recovery, with the responsibility resting largely on state or national government, and with direct planning and participation at the community level largely neglected (e.g., Laughy, 1991). However, as the Organization of American States has noted in its policy series on managing natural hazard risk, natural hazard risk management efforts are most effective when they are explicitly addressed at every level, including at the community level (OAS, 2004). The strengthening of stakeholder and community involvement is viewed by some as the greatest need in the evolving area of hazard management and mitigation (King, 2008). It has become increasingly clear that there is an ongoing shift from a response and recovery approach toward a mitigative approach in the management of natural hazards, which requires the integration of management practices at the community level in order to be successful and sustainable (Pearce, 2003).

There are many challenges to implementing successful community-based participation in the management of natural hazards. Among them is the influence of previous experience with a specific hazard (or lack thereof) on how local government and community members perceive risk from that hazard, which can determine the level of public participation in preparedness and mitigation strategies (Tierney et al., 2001). The effect of previous experience on how an individual responds to future participation in mitigative programs can often be counterintuitive, and has implications for the management of hazards (McGee et al., 2009). Another challenge is the difficulty of conveying concepts of hazard risk to the public, given the often very imprecise nature of the business of hazard prediction (Alexander, 2007). Additionally, individuals

may not participate in mitigative strategies due to a lack of accurate information, or the perception that a hazard is a political or ideological creation rather than a reality. They also may be moved to nonparticipation as a means to avoid unpleasant emotions about the issue or in the belief, especially in the case of global threats such as climate change, that there is really nothing they can really do about it (Norgaard, 2006). Studies showing relationships between individuals' risk-taking propensity and attitudes toward preparation for natural hazards (e.g., McClure et al., 1999), as well as the role that media portrayal of natural disasters has in influencing future social behavior and attitudes (e.g., McClure et al., 2001) have significant implications for how community management strategies may help alleviate fatalism and improve hazard preparedness. Drawing on community empowerment and engagement strategies can significantly enhance the ability of communities to promote and sustain participation in hazard preparedness (e.g., Frandsen et al., 2011).

Those living in the developing world as well as those living in poverty are particularly vulnerable to the effects of natural disasters (World Bank, 2001), largely as a result of the combination of underdevelopment, poor building construction and siting, and economic inability to adequately respond to and recover from a major disaster. The earthquake that struck the impoverished nation of Haiti on January 12, 2010 provided a stark example of the confluence of these attributes in the face of a major natural disaster. Well over 200,000 people had lost their lives as a result of this event, and at least 1.5 million were homeless. In the face of warnings from scientists as recently as 2008 that Haiti was at significant risk for a major earthquake (Manaker et al., 2008), mitigative measures to prepare were lacking, with economics likely a major factor in the lack of community preparedness for such a disaster.

Hazard identification and mitigation

Mitigation includes activities that eliminate or reduce the chance of occurrence or the effects of a disaster. Identification of potential hazards and potential vulnerabilities to hazards is the first step in this process. Communities' response to recommendations for mitigative measures may be predicated on previous personal experience with specific hazards (McGee et al., 2009). Community mitigation and preparedness for hazards that are perceived to be of low risk may not be implemented, in spite of the fact that occurrence of such hazards can result in very high consequence events (e.g., 2004 Indian Ocean Tsunami). Pre-hazard mitigation programs such as those offered by the Federal Emergency Management Agency (FEMA) in the United States have shown that, while communities may not necessarily be able to prevent disasters, they can take many proactive steps that can reduce the effects of hazards upon communities and their residents (e.g., Volunteer Florida, 2004). For example, requiring structural reinforcements to homes in areas prone to seismic activity will reduce property damage and loss of life from earthquakes. Similarly, the implementation of Early Warning Systems (e.g., Zschau and Küppers, 2003; Momani and Alzaghal, 2009) at the community level has the potential to save hundreds of thousands of lives in extreme cases, such as that which occurred as a result of the 2004 Indian Ocean Tsunami. Haque (2005) provides a range of experiences in the mitigation and management of natural hazards from an international perspective. It is important to distinguish between mitigation strategies themselves and a community's capacity to respond to them in a timely and effective manner. Assessing a community's ability to adapt and respond favorably to these strategies is key to effective implementation, whether in advance of or in response to a natural hazard (e.g., Paton and Tang, 2009).

Preparedness

Preparedness, the next aspect of hazard management, involves planning how to respond in the advent of a natural hazard, and how to activate community resources to respond effectively. Careful advance planning can help save lives and minimize property damage by preparing community members to respond in a prescribed manner when a hazard occurs. In a community-based approach, this phase involves significant public informational and educational components.

Ensuring public participation in the process of hazard management planning can be problematic at times for a variety of reasons (e.g., Chen et al., 2006). However, the importance of continued public involvement throughout the entire management cycle has direct bearing on whether or not mitigative strategies can be sustained until they are needed (e.g., Tanaka, 2009). Promoting community involvement in all aspects of preparedness can result in greater post-disaster resilience, particularly in segments of the population who are likely to be most affected by the occurrence of a natural disaster, such as children and their families (Ronan and Johnston, 2005). However, it is important to note the need to distinguish between providing information on hazards preparation and people's general ability to interpret and use such information. For example, Lindell et al. (2009) note that hazard experience, risk perception, and population demographics, among others, all can have effects on attributes related to hazard preparation adjustments. Additionally, community risk management strategies are to some extent socially constructed, and how people may act to manage their risk often encompasses both social and cultural issues (e.g., Paton et al., 2010). Finally, trust in the purveyor of the information related to hazard mitigation can influence how effective resultant strategies are (e.g., Paton, 2008).

Response

Response covers the period immediately prior to (if the hazard can be predicted in advance), during, and immediately following a disaster. Responders typically include

entities such as the fire and police departments, and medical services. Depending on the magnitude of the event, however, the usual responders and local government may be ill-equipped to manage the response phase without significant assistance from the state or national government, or the international community. Involvement of local community members in the aspects of disaster awareness training can influence hazard-related cognitions and preparedness behaviors (Karanci et al., 2005), resulting in the ability of the general community to participate in the response actions completely and in more beneficial effects (e.g., Paton et al., 2001).

Recovery and reconstruction

Recovery and reconstruction represent the final part of the management cycle, though it can also be viewed as the precursor to the improvement of mitigation procedures. Recovery and reconstruction continue until community functions have returned to normal. In the early part of this phase, critical community services are restored to minimum operating conditions. Depending on the severity of the hazard's impact, recovery may go on for months or even years, as in the case of disasters with major loss of life or property. Ironically, the impact of a major disaster on a community presents the opportunity for significant improvement of infrastructure and construction practices, resulting in the incorporation of features that are less likely to be affected by future events. While the process of recovery can provide opportunities to mitigate future disasters, successful implementation of such strategies requires an understanding of changes in community contributions to recovery and rebuilding efforts over time (Paton, 2006).

The recovery and reconstruction phase following a significant natural disaster often requires significant economical resources in order to succeed, and the resilience of a community may depend largely on the strength of pre-hazard mitigative strategies that are already in place at the time of the event. Just as important as the resources that contribute to the physical recovery of a community are the services that are in place to address emotional health needs, which can often be quite severe following a natural disaster. Psychiatric disorders such as post-traumatic stress disorders can be common, and while most people are resilient and will recover, some populations may be at higher risk for more serious mental health problems (Watanabe et al., 2004; Wickrama and Wickrama, 2008). A critical aspect of community management of hazards involves planning for both physical and emotional injury that could potentially result from a natural hazard, and communities can use methods such as the formation of innovative self-help groups to ensure recovery in both areas (e.g., Kuppuswamy and Rajarathnam, 2009). While the enabling of participatory planning after the occurrence of a natural disaster bears some beneficial aspects, earlier involvement of stakeholders in the mitigation process is indicated, since many may be ill-equipped emotionally immediately following a disaster (e.g., Ganapati and Ganapati, 2009).

The role of internet technology in community management of hazards

Just as radio and television in the earlier days, the Internet has become an increasingly important resource for communities marching toward active engagement in hazard management. The ability to provide near-real-time hazard-related data (Dimitruk, 2007) and interface with Geographical Information Systems (GIS) (Raheja et al., n.d.), Global Positioning Systems (GPS), and other communications technologies aid in all areas of hazard management. As early as 1998 following the advent of Hurricane Mitch's landfall in Central America, the Internet was used intensively to post regular updates on information such as epidemiological reports and public health guidelines on topics ranging from household water quality to the prevention of measles (Bittner, 2000).

For the community in the early stages of hazard management planning, the Internet is a tremendous source of ready information on all aspects of hazard management, with some sites functioning as warehouses for relevant links, such as a site hosted by Keele University in Britain (http://www.keele.ac.uk/depts/por/disaster.htm). The added benefit of being able to store relevant information and databases on computer servers far removed from the community that they will serve in the advent of a natural disaster means that the information will still be potentially accessible to communities, responders, and other critical parties even if communications infrastructure is initially disabled or destroyed at the site of the event. In the aftermath of Hurricane Katrina's landfall near New Orleans on the south coast of the United States in 2005, and also following the earthquake that struck Haiti in early 2010, the Internet was a critical resource in aiding community members at home and abroad to track down information on the status of missing loved ones (http://guides.library.msstate.edu/content.php?pid=16013&sid=107538; http://www.google.com/relief/haitiearthquake/). Finally, the Internet has become a critical component for the affected communities in the conduct of outreach to the global community to raise funds during the response and recovery phases following the advent of a natural hazard.

Selected examples of community management of hazards

The following are examples of different types of strategies of community management of various natural hazards:

Earthquakes

Tokai Earthquake Preparedness in Shizuoka Prefecture, Japan http://www.e-quakes.pref.shizuoka.jp/english/earthquakepreparedness_in_shizuoka.pdf

This entry discusses in detail the history behind, formation of, and plans for implementing highly integrated management of a potential earthquake hazard in Shizuoka Prefecture, Japan, including community education and participation.

A Novel Strong-Motion Seismic Network for Community Participation in Earthquake Monitoring

(Cochran et al., 2009) http://qcn.stanford.edu/ (Quake-Catcher Network).

This is an innovative approach to passive community-based volunteer participation in seismic data gathering and analysis through use of distributed computing techniques, with a goal of increasing the awareness of various aspects of seismic activity to aid with the aspects of earthquake preparedness planning.

Hurricanes, coastal erosion, and coastal flooding

Sustainable Coastal Communities and Ecosystems (SUCCESS) http://seagrant.gso.uri.edu/ecosystems/hazards.html

Based out of the University of Rhode Island in the United States, this program works with governments, the private sector, and community organizations to ensure that coastal communities face and recover from hurricanes, floods, and coastal storms. The goal is to help communities achieve economic growth while reducing the potential impacts of natural hazards and maximizing public safety and public access to the shore. The SUCCESS program works to help develop strategies to prepare for natural disasters, educate disaster preparedness and response professionals, enhance evacuation preparations, and plan for expediting recovery efforts.

Landslides

Landslide Management by Community-Based Approach in the Republic of Armenia (Mori et al., 2007) http://www.n-koei.co.jp/library/pdf/forum16_017.pdf

Report discussing community-based approach toward landslide hazard identification and management.

Natural radioactivity, radon hazard

The Community Environmental Monitoring Program http://cemp.dri.edu/

While this program concentrates on the potential of releases of man-made radioactivity as a result of the past testing of nuclear weapons at the Nevada Test Site, an understanding of the potential hazards of natural radioactivity, including radon, as well as concepts of dose, is an important component of the program. The program provides a hands-on role for community members in the monitoring process and equips them with the knowledge to communicate information on the subject to their neighbors (Hartwell and Shafer, 2011). This program also provides an example of how the Internet can be an effective tool for communication data dissemination.

Tornadoes

Tornado Tabletop Exercise: Engaging Youth in Community Emergency Management http://www.unce.unr.edu/publications/files/cy/2009/cm0908.pdf

An example of a classroom curriculum designed to educate students about community emergency management, including training them to use geospatial technology to create maps with shelter locations and evacuation routes, and simulating a tornado event.

Volcanoes

Maximizing Multi-stakeholder Participation in Government and Community Volcanic Hazard Management Programs: A Case Study from Savo, Solomon Islands (Cronin et al., 2004). Report on attempt at multi-level integration of volcanic risk management strategies and challenges of involvement of certain sectors of the community populations.

COMPLEXITY THEORY

William H. K. Lee
U.S. Geological Survey, Menlo Park, CA, USA

Synonyms

Systems theory

Definition

A complex system consists of many interacting parts, generates new collective behavior through self organization, and adaptively evolves through time. Many theories have been developed to study complex systems, including chaos, fractals, cellular automata, self organization, stochastic processes, turbulence, and genetic algorithms.

Introduction

The classical approach to study natural phenomena is to model them as *dynamical systems* governed by differential equations, which allow the temporal evolution of many *linear* phenomena (e.g., motions of a planet around the Sun, laminar fluid flow, etc.) to be predicted with considerable accuracy. A linear system is deterministic because its output is proportional to the input. However, most natural phenomena involve *nonlinear* processes. Jules Henri Poincaré analyzed the stability of the solar system and in 1890 discovered chaotic behavior in a three-body dynamical system. Since then, many new concepts and tools have been developed for solving nonlinear problems – some are successful, but many raise more questions than provide answers.

Chaos in dynamical systems

In 1963, Edward Lorenz discovered that simple computer models of weather were very sensitive to *initial conditions*, such that a slight change at the start would give very different results. Lorenz used a simplified version of the Navier–Stokes equations (formulated in the mid-nineteenth century) for his computer models. Lorenz's discovery led to the realization that our ability to predict weather is limited at best to several days, because small measurement errors in the initial conditions grow exponentially with time, leading to predictions that deviate significantly from the actual weather conditions in just a few days. This requires repeated updating of initial conditions to extend a useful prediction.

Fractals in geology and geophysics

About 1/3 of major natural catastrophes are caused by earthquakes (the other 2/3 are mostly due to hurricanes and floods); hence their occurrences have naturally drawn attention for millennia. A prominent feature of seismicity is the Gutenberg–Richter relation derived empirically from observations (Gutenberg and Richter, 1954). It is given as $\log N(M) = a - bM$, where M is the earthquake magnitude, $N(M)$ is the number of earthquakes with magnitude greater than or equal to M, and a and b are constants. It can be rewritten as $N = \alpha A^{-\beta}$, a power law that is characteristic of *fractals*, which possess scale invariance (Turcotte, 1997). As is the case with earthquakes, faults, volcanic eruptions, landslides, floods, and many other natural phenomena also exhibit scale invariance. A fractal is commonly defined as a collection of objects that have a power-law dependence of number on size. Fractals are observed in many physical, biological, and social systems, regardless of their underlying governing processes.

Discussion

The classical, deterministic approach enjoys great success in studying some natural phenomena that can be approximated as *linear* systems. However, many natural phenomena are *nonlinear*. Complexity theory has been developing to meet this challenge, but a unified theory is not yet available for universal applications. Existing theory indicates that deterministic prediction for many phenomena (e.g., weather or earthquakes) is inherently impossible but that probabilistic forecasts are feasible. Mitchell (2009) provides a "tour" of complexity theory, and an introduction to complexity in earthquakes, tsunamis, and volcanoes is given by Lee (2009).

CONCRETE STRUCTURES

Murat Saatcioglu
University of Ottawa, Ottawa, ON, Canada

Synonyms

Reinforced concrete structure

Definition

A structure constructed primarily of concrete reinforced with steel.

Concrete is a commonly used construction material that is locally available throughout the world. It consists of fine aggregate (sand), coarse aggregate (crushed stone), cement (usually Portland Cement), water, and air. Cement has the appropriate chemical composition as a binding material that hydrates in the presence of water, chemically binding fine and coarse aggregate particles together to form a rock-like material called concrete (Kosmatka et al., 2008; Neville and Brooks, 2008). The aggregates account for approximately 75% of total mix by volume. Air in concrete, purposely introduced through chemical admixtures, improves resistance to freeze-thaw cycles. Water-cement (W/C) ratio by weight is the single most important parameter that affects the quality of concrete. W/C ratio of 0.5 produces sufficient workability, good performance, and an average compressive strength of approximately 30 MPa. As the W/C ratio decreases, the strength and quality of concrete (durability, abrasion resistance, freeze-thaw resistance, permeability) improves drastically. Concrete mixtures may also contain chemical admixtures for improved quality and workability.

Concrete is strong in compression for use as a structural material. However, it is generally very weak in tension. Concrete cracks at approximately 10% of its compressive strength in tension, and further breaks into pieces unless properly reinforced. Therefore, concrete is often reinforced with a material that permits resistance to tension when used for structural applications. The resulting composite material is referred to as "reinforced concrete." The most commonly used type of reinforcement is a steel bar. Typical reinforced concrete structural elements consist of beams, columns, walls, slabs, and footings. The longitudinal reinforcing bars are often placed on the tension side to control cracks and resist tension, although sometimes they may be placed in the compression zone for additional compressive capacity. Transverse reinforcement is used to control diagonal tension cracks associated with shear, to laterally restrain compression bars against buckling or to confine concrete for improved inelastic deformation capacity. The resulting structural elements form a structural framing system, consisting of moment resisting frames, structural walls (shear walls), or the combination of the two. The primary objective in structural design is to provide resistance to gravity and lateral loads, including those caused by natural hazards. Concrete structures are built either as "cast-in-place" monolithic (continuous) structures, or "precast" structures that consist of prefabricated elements that can be assembled and connected on site. A special form of reinforced concrete is "prestressed concrete." This type of construction takes advantage of eliminating or reducing tension in concrete by imposing compressive stresses prior to the application of external loads (Nawy, 2006). The prestressing operation is often done by means of high-strength steel strands, cables, or bars that are pretensioned or posttensioned to compress concrete in regions of expected tension. Concrete structures are generally favored for providing resistance to natural hazards because of their inherent mass and rigidity, which provide stability and deformation control against extreme wind effects, storm surges, and tsunamis, while also providing fire resistance. They have to be designed for continuity and inelastic deformability for improved seismic resistance (Park and Pauley, 1975). Concrete structures are often designed to experience inelastic deformations under strong earthquakes to dissipate seismic-induced energy.

CONVERGENCE

Ilan Kelman
Center for International Climate and Environmental Research – Oslo (CICERO), Blindern, Oslo, Norway

Synonyms

Disaster tourism; Post disaster return

Definition

Convergence refers to the spontaneous movement of people, messages, and goods – organized and unorganized – towards a disaster area.

Overview

Following a disaster, a spontaneous movement towards the disaster-affected area of people for various reasons, messages bearing different forms of information, and goods including relief supplies are frequently observed. That movement combines organized and unorganized efforts. Such activity is termed "convergence" and is a topic in disaster research.

Fritz and Mathewson (1957) articulated reasons for what they termed "informal or unofficial convergers" to disaster sites within their theory of convergence behavior in disasters. They describe five categories – still relevant and used today, as they form the basis for ongoing convergence research – that are not mutually exclusive: the returnees, the anxious, the helpers, the curious, and the exploiters.

Returnees are disaster survivors, evacuees, or those who were away from home before the disaster and who come back to their homes, with or without official sanction. Reasons for returning include property recovery, property protection, grieving, and no other place to live. The anxious refers to those individuals with a close connection to the disaster-hit community but who do not live there and who converge on the disaster site out of anxiety for friends, relatives, or their previous home.

The helpers refer to volunteers or professional assisters who wish to provide post-disaster services. Examples are rescuing trapped people, body recovery, and meeting physical and psychological needs of on-site disaster survivors or other convergers. Some helpers self-deploy which is usually not recommended because that can interfere with post-disaster resources and coordination. Donations – of cash, time, goods, and services – is a form of helper convergence. Often, problems result from poorly considered donations, such as sending food or clothes that are culturally inappropriate for the affected area. The most effective post-disaster donations tend to be cash given to credible organizations that are familiar with the location.

The curious refers to people converging on the disaster site as sightseers or spectators.

The exploiters are subdivided into looters, pilferers or souvenir hunters, relief stealers, profiteers, each of which is self-defining. Although representatives of these categories are witnessed after many disasters, widespread and systematic looting, profiteering, and mob-related crime are not common. Instead, these tend to be isolated incidents that simply receive exaggerated publicity.

The Internet has permitted online convergence behavior. Examples are online memorials, scam artists trying to defraud disaster-affected people, and Web sites dedicated to specific disasters for memorials and/or voyeurism.

Research on convergence is principally, although not entirely, derived from sociological and American perspectives. Limited work covers convergence from other geographic, cultural, and disciplinary perspectives.

Myths and Misconceptions

COPING CAPACITY

Virginia R. Burkett
United States Geological Survey, Climate and Land use Change Mission Area, Many, LA, USA

Synonyms

Adaptive capacity

Definition

Coping capacity is the ability of a system (natural or human) to respond to and recover from the effects of stress or perturbations that have the potential to alter the structure or function of the system.

Discussion

The capacity of a system to cope with a natural hazard is determined by the ability of the system to adjust to a disturbance, moderate potential damage, take advantage of opportunities, and adapt to the consequences (Gallopin, 2006). The concept of coping capacity is often associated with extreme events whereas the concept of adaptive capacity generally alludes to a longer time frame and implies that some learning either before or after an extreme event or change in conditions has occurred (Smit and Wandel, 2006; Peltonen, 2010). The IPCC (2007, p. 869) defines "adaptive capacity" in relation to climate change as "the ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences." Turner et al. (2003) describe "adaptation" as a system's restructuring after exposure to a stress or perturbation.

Some natural hazards are considered "extreme events" because they are associated with the rapid restructuring of physical, biological, and/or societal systems. Storms, fires, volcanic eruptions, floods, landslides, avalanches, tsunamis, and other extreme events are all capable of stressing systems to a point that leads to a rapid shift from one state to another. Other natural hazards, such as subsidence of the land surface and erosion of the coastline, occur over a longer time frame. The cumulative effects

of such small-scale events can perturb natural and human systems, in some cases more severely than an "extreme event" such as a storm or earthquake.

The capacity of society to cope with a natural hazard is dependent upon many variables. The following factors are considered major determinants of coping capacity, based on a review of Yohe and Tol (2002), Gallopin (2003, 2006), Armas and Avram (2009), and Gaillard and others (2008):

1. The exposure and sensitivity of the system to direct or indirect impacts of the natural hazard and the related vulnerability of social systems and the environments on which they depend.
2. The ability of decision makers to manage information, the accuracy of information, the processes by which decision makers determine which information is credible, and the credibility of the decision makers themselves.
3. The range and availability of technological options.
4. The availability of resources and their distribution across the affected population.
5. The structure and efficiency of critical institutions and decision-making authority.
6. The stock of human and societal capital, including education, personal security, strength of livelihoods, and social networks.
7. The potential for risks to be shared or spread (e.g., insurance systems).
8. The public's perception of the natural hazard and the relative significance of exposure compared to other societal challenges.

Coping capacity is an attribute of a system that exists prior to the perturbation (Gallopin, 2006). In the context of human societies, changes in coping behavior can emerge spontaneously (unplanned) or proactively (planned). Proactive coping behavior is the outcome of deliberate policy decisions that are based on an awareness of the nature of the hazard and its potential impact, coupled with actions that are required to return to, maintain, or achieve a desired state. The enhancement of coping behavior is a necessary condition for reducing vulnerability, particularly for the most vulnerable regions and socioeconomic groups (Peltonen, 2010). Human coping behaviors and factors that determine the degree to which they increase societal capacity to cope with natural hazards are illustrated in the table below.

Natural hazard	Example of coping behavior	Factors that influence how the behavior enhances coping capacity (examples)
Tsunami	Early warning system	Availability of technology; effectiveness of evacuation; availability and distribution of resources to victims
Flood	Building codes that require elevation of structures above potential flood level	Public perception of risk; efficacy of enforcement; accuracy of flood level calculation; availability of flood insurance
Earthquake	Building codes	Availability of resources needed to for compliant building construction or retrofitting; confidence in vulnerability assessments; efficiency of institutions that regulate construction
Hurricane storm surge	Business continuity planning	Public perception of risk; speed with which utilities, transportation, and other infrastructure is restored; prior experience or simulations that reveal errors or omission in planning
Wildfire	Reduction of fuel load through prescribed fire	Public acceptance of fire as a management tool; training, skill, and availability of personnel experienced in the use of prescribed fire; presence of houses and other structures that prevent the use of fire as an option for hazard reduction
Subsidence	Control of human activity that contributes to subsidence – example: reduce rate of groundwater withdrawal	Geologic setting and other antecedent conditions; availability of alternative water resources

Summary

Coping is a behavioral capacity that can reduce the adverse impacts in a system that is exposed to an extreme event or a chronic natural hazard. The capacity for coping with a natural hazard is generally inversely related to vulnerability – the higher the coping capacity, the lower the vulnerability of a system, region, community, or individual. In some cases, however, even strong coping capacities do not necessarily reduce vulnerability. For example, transportation and sewage treatment facilities constructed in a geologic floodplain by a community with high institutional and financial resources may be as physically vulnerable to the impacts of flooding as facilities constructed by a community with low coping capacity. Coping behaviors that are based on a good understanding of both the hazard and its impacts can substantially increase the resilience of human settlements, infrastructure, and economies.

COST-BENEFIT ANALYSIS OF NATURAL HAZARD MITIGATION

Sven Fuchs
University of Natural Resources and Life Sciences, Vienna, Austria

Definition

Defined in its broadest sense, cost-benefit analysis (CBA) is a tool to estimate and sum up the equivalent monetary value of the costs and benefits of alternatives in order to establish a decision context for politicians (e.g., Mishan, 2006). CBA is used for a systematic comparison of all costs and benefits that arise over (a certain) time period; and it uses discounting to make costs and benefits that arise in future comparable. Regarding natural hazard mitigation, CBA is for the most part applied with respect to permanent technical mitigation measures such as snow-supporting structures in avalanche-prone areas or dams along rivers. Costs are usually defined as expenses needed for the respective mitigation measure, such as concrete and steel necessary to build a check dam, and the labor needed for construction works. Benefits are typically defined as prevented damage which will arise in the future due to the implementation of the planned mitigation measure. CBA allows comparing different given mitigation alternatives with each other. CBA is targeted at the socially optimum level of safety, which will be when risks have been reduced by mitigation measures up to the point where the extra cost of any risk reduction equals its benefits (Marin, 1992).

Background

Costs and benefits can be determined for any goods traded on perfect and therefore efficient markets by using existing market prices; these so-called private goods include almost everything that is available in everyday life, such as food, vehicles, realties, and flight tickets. Such private goods are characterized by rivalness and excludability (e.g., Mankiw, 2008); multiple consumers compete for the use of such goods, and if someone is not willing to pay for the good, he or she can be excluded from consumption. However, it has been repeatedly argued that some goods do not have these characteristics (e.g., Samuelson, 1954). When a person cannot be excluded from consumption even if he or she is not willing to pay (non-excludability), and the individual consumption does not detract from the ability of others to consume such goods (non-rivalry) the good is considered as a public good. Typical examples of public goods include national defense, uncongested nontoll roads, and permanent constructive natural hazard protection.

Taking the latter as an example, for an inhabitant of a settlement, the quality of hazard protection does not change by the utilization of the same good by another inhabitant (Fuchs and McAlpin, 2005; Fuchs et al., 2007). The marginal costs of the utilization of the hazard protection measure by an additional user are zero and, as a consequence, there is no market price for this good. As a result, consumption of the utility from this public good is not necessarily fully valued by the users. In turn, no user can exclude, independently of the individual willingness to pay, another user from utilization. Non-excludability creates incentives for free riding because people can attain the utility of a good without paying for it. Free riding is another source of market failure because, since people pay for less than the efficient quantity of a good, the market produces less than the efficient quantity of the good and, as a result, the private sector fails to provide this good at a sufficient level for economic efficiency (Fuchs and McAlpin, 2005). Therefore, the supply must take place via the public sector in order to meet the societal demand.

However, in some cases, due to the scarcity of protected areas for development within hazardous areas, potential users could be excluded from the utilization. This scarcity would make mitigation measures common (pool) resources, for which use by some decreases the potential utility to others (Fuchs and McAlpin, 2005; Mankiw, 2008).

To facilitate the optimal supply of mitigation measures, the public sector will need, among other information, evaluations of the costs and benefits of mitigation approaches (Musgrave, 1969). Due to the characteristics of public goods stated above, such an evaluation can be made by comparing the costs of the supply of the good with an indirect measurement of the benefit for the consumer. Whereas such an attempt is relatively robust with respect to tangibles, questions related to an evaluation of intangibles have been subject to continuous discussions for decades (e.g., Adams, 1974; Green and Penning-Rowsell, 1986; Bateman, 1992; Eade and Moran, 1996).

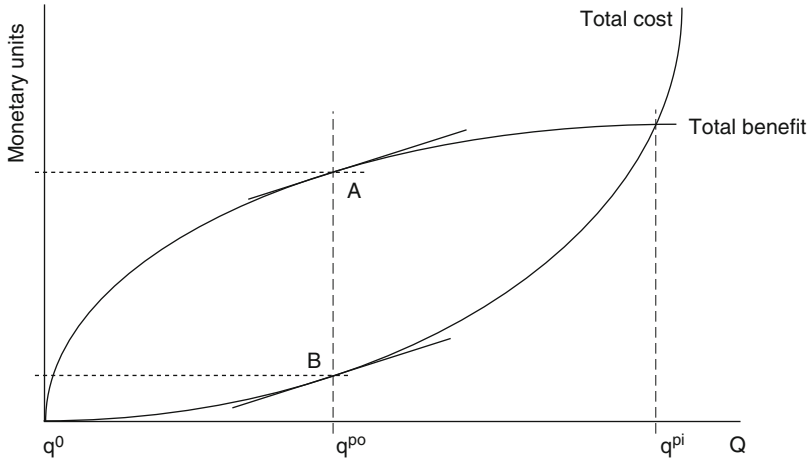
Methodology

It is necessary to consider all relevant costs and benefits when applying CBA, including indirect costs and those costs arising later in time. Sensitivity analysis allows coping with uncertainty by analyzing the sensitivity of the results obtained under the CBA to variations in the individual factors used. The net present value to be obtained during CBA is the discounted net benefit gained or the net cost imposed on the stream of costs and benefits over time. As a consequence, the planning horizon that is considered (e.g., with respect to a planned flood retention basin) matters for the outcome of a CBA.

From a theoretical point of view, the methodology is schematically illustrated by total cost and corresponding total benefit due to the implementation of mitigation measures in Figure 1. At the level of mitigation q^0, the marginal benefit of additional mitigation is higher than the cost. Thus, further investments produce net benefits. At q^{po}, the slope of total benefit (A) and the slope of total cost (B) are equal, the marginal benefit and marginal cost per unit of mitigation are equal, and the level of mitigation is optimal. As the level of mitigation increases beyond q^{po} up to q^{pi}, where the total costs are the same as the total benefits, the total supply of mitigation still provides positive net benefits but is greater than optimal because the marginal cost of each additional unit of mitigation exceeds the corresponding marginal benefit. Beyond q^{pi}, the total supply of mitigation produces negative net benefits (adapted from Russell, 1970, 386).

Determination of costs

Economic theory suggests evaluating the costs of mitigation measures in terms of opportunity costs, which is the alternative investment of resources in the next-best alternative available to someone who has to select between several mutually exclusive choices. These costs mirror the benefit that would have resulted from an alternative appropriation of the resources. From a practical point of view, the present value of investments in mitigation measures is taken instead since it is almost unfeasible to take into account all possible other alternatives. Apart from any material and labor force needed, the investments necessary for maintenance over the life time of the structures have to be taken into account. The present value of capital expenditures for permanent mitigation measures is calculated using Equation 1, based on the real interest rate, which takes into account inflation and therefore allows comparison of expenditures in different years. Therefore, discounting may change considerably the results of a CBA depending on the choice of the discount rate. From the perspective of society, the use of low discount rates is justified with considerations on intergenerational equity and sustainability. K_n is the present value of the total capital at the expiration of the validity in monetary units, p is the real interest rate in percent, s is the interest period, n the term, and K_0 the opening capital in monetary units. The real interest rate i_{real} is typically calculated on the basis of the nominal interest rate i_{nom} and the inflation J, using Equation 2. The corresponding nominal interest rate is derived from, e.g., the average rate of interest of government bonds in the countries were the study is located.



$$K_n = \left(1 + \frac{p \cdot s}{100}\right)^n \cdot K_0 \tag{1}$$

$$i_{real} = \left(\frac{1 + i_{nom}}{1 + J}\right) - 1 \tag{2}$$

Determination of benefit

The accuracy of CBA depends on how accurately benefits (and costs) are estimated and that all costs and benefits are accounted for. Principally, benefits of the impacts of an intervention are evaluated in terms of the public's willingness to pay for these impacts (benefits). The benefit related to mitigation measures can be determined in different ways. However, from a methodological point of view and focusing on the application of CBA in natural hazard risk management, the evaluation is either based on an evaluation of buildings and infrastructure lifelines exposed or with respect to protected human life. Both concepts are therefore separately described below.

- The utility can be defined in the sense of prevented damage to buildings and infrastructure, the so-called method of loss expenses. Because market processes (here for real estate within hazard-prone areas) are able to reflect the real costs, market values, from an economic point of view, are particularly suitable for the determination of possible damage. If, at the time of investigation, the market demand for the buildings is high, their current value may be above the replacement value. If, for example, due to a flood event, there is no demand on the market for those buildings, their value could be zero. The societal preferences of buildings in hazard-prone areas can therefore precisely be

Cost-Benefit Analysis of Natural Hazard Mitigation, Figure 1 Cost-benefit analysis of natural hazard mitigation.

measured, which is the overall aim of such economic methods. However, since the investigation is exactly focusing on buildings in endangered areas, there might be a bias with respect to the socially optimum level of safety. Thus, the replacement value can be used instead as an approximation, neglecting any risk-dependent change in the demand of buildings on the market. Following this method, data concerning the number of potentially affected buildings and their respective replacement value has to be collected. With respect to infrastructure lifelines, the evaluation usually takes place by multiplying their affected length by the value per unit length. These values have to be adjusted to take into account for inflation, and the obtained sums can be directly compared to the respective year of construction.

- In a second set of calculations, the benefit can be evaluated in terms of the number of lives protected (see *Economic Valuation of Life*). The number of persons in the endangered areas is thereby determined on the basis of census data, or the number of domiciles located within areas to be protected by the mitigation measure. Subsequently, a valuation of the number of persons is undertaken in order to place monetary units on human life to be able to calculate the cost-benefit ratios. This step is solely a technical necessity and does not imply that there is a however-defined "value" of human life (which would be an ethical issue that cannot be solved by CBA, compare Adams, 1974). One possibility to achieve such a value does make use of a human capital approach. This procedure can be traced back to approaches in the insurance business, where financial compensation is paid to the immediate family upon the premature demise of the policyholder. The value of human life is calculated as follows: In the study area, the annual gross earned income per working person is identified, for example, by using available statistical information. Subsequently, the average age of the population is achieved and compared to the mean average retirement age. By subtracting these two figures, a remaining average expectancy of working life and a corresponding expected gross income results. Equation 3 is applied to calculate the annuity value R_0 from the payment r, the factor q, and the term n. The factor q is derived summing up the rate of interest i with 1. The rate of interest is calculated by using information on the average rate of interest of government bonds in the countries where the study is located. Applying Equation 3, an annuity value with the interest paid at the end of the period results for the annuity value corresponding to the income of an average person during the remaining working life. This value is subsequently applied in the CBA in order to calculate the benefits resulting from a mitigation measure.

$$R_0 = r \cdot q^{-n} \cdot \frac{q^n - 1}{q - 1} \tag{3}$$

Discussion

Societal and political decisions about mitigation measures concerning natural hazards are generally based on a multiplicity of interests due to the variety of parties involved. Hence, there is a particular need for methodologies ensuring the consideration of all these interests and providing simultaneously a reliable basis for the final decision maker.

However, evaluations of the net benefits of natural hazard protection measures will vary as the local context changes. The relatively high property values in the densely populated regions of central Europe and the USA and relatively high incomes of persons produce net benefits that are higher than they would be

in other areas or countries with lower property values and incomes.

Although there may be potential gains in economic efficiency from changing the supply of hazard protection in some areas, the decision to supply more or less avalanche protection is a political one (Gamper et al., 2006). CBA can only inform, rather than answer, the question of how much risk protection the public sector should provide. The choice of how much to invest in mitigation measures depends on the political determination of a standard of protection. The standard may be set in terms of societal preferences such as risk reduction, the level of expenditures, as a target for the maximum number of lives lost, or in some other way. In addition to the need to incorporate CBA into a broader context of political decision making, there are still unresolved issues involved in using CBA as information for decisions about the level of protection against natural hazards. Firstly, most cost-benefit analyses assume that effects should be evaluated with respect to the preferences of individuals (Nash et al., 1975; Adams, 1993). However, since some people benefit more directly from mitigation measures than others, the preferences for the measures may be different among the group of people who live in endangered areas and among those who live outside those areas. Therefore, CBA is affected by whose preferences are used to determine the benefits of mitigation measures. In its traditional form, CBA does not consider the distribution of benefits and costs over individuals, and any increase in net benefits is desirable, regardless of to whom they occur. Secondly, while the utility from protecting property from natural hazards can be determined with relative ease and minimal debate, as the property values are already expressed in monetary terms, the valuation of protecting people from natural hazards requires placing a monetary value on each human life in the absence of objective rules for doing so (e.g., Adams, 1993; Pearce, 1998). The human capital approach presented above raises ethical issues, as it values old people less than young or middle-aged people. Thirdly, problems may arise in the aggregation of material assets and nonmaterial assets, such as an individuals' cognition of safety. Therefore, CBA seems to be an appropriate tool for a relative evaluation of different mitigation alternatives rather than for an absolute evaluation of one individual mitigation measure. CBA is simplified considerably when different alternatives attaining the same utility are evaluated against each other. This approach would apply in the situation where a level of risk acceptance has been set by the relevant community and the question is how to most effectively meet this standard. In order to determine the most competitive alternative, only relative comparisons of cost-effectiveness are necessary, which avoids the problems associated with valuing human lives.

Conclusion

Despite its limitations, economic analyses can contribute by providing information for the political choice of a standard of protection against natural hazards and on how to achieve the socially determined standard. CBA offers a tool for policy decisions because it allows for the comparison of monetary and nonmonetary factors. The comparison of economic costs and benefits is one consideration that may facilitate decision making about protection against natural hazards.

The optimal approach to natural hazards risk reduction depends on the particular hazard, the aims of the affected community, and relevant decision processes. Minimizing human fatalities may be the main priority, with an economic efficiency – thought of as a shift in welfare – as a secondary goal. Although there may be gains in economic efficiency from changing the supply of natural hazard protection, the decision to supply more or less protection is a political one. This decision is related to the society's level of risk acceptance, and should only be discussed on a participative basis.

The potential of CBA depends on its proper integration in the decision-making process as an equitable, transparent, and flexible instrument. Transparency as to assumptions used to calculate costs and benefits and the uncertainty contained in the results will increase the ability of decision makers to use findings of CBA. Decision makers have a responsibility to understand that CBA provides only part of the necessary information for natural hazards planning. Aims other than economic efficiency, such as alternative contextual factors or constraints, provide additional, necessary information for decision making.

COSTS (ECONOMIC) OF NATURAL HAZARDS AND DISASTERS

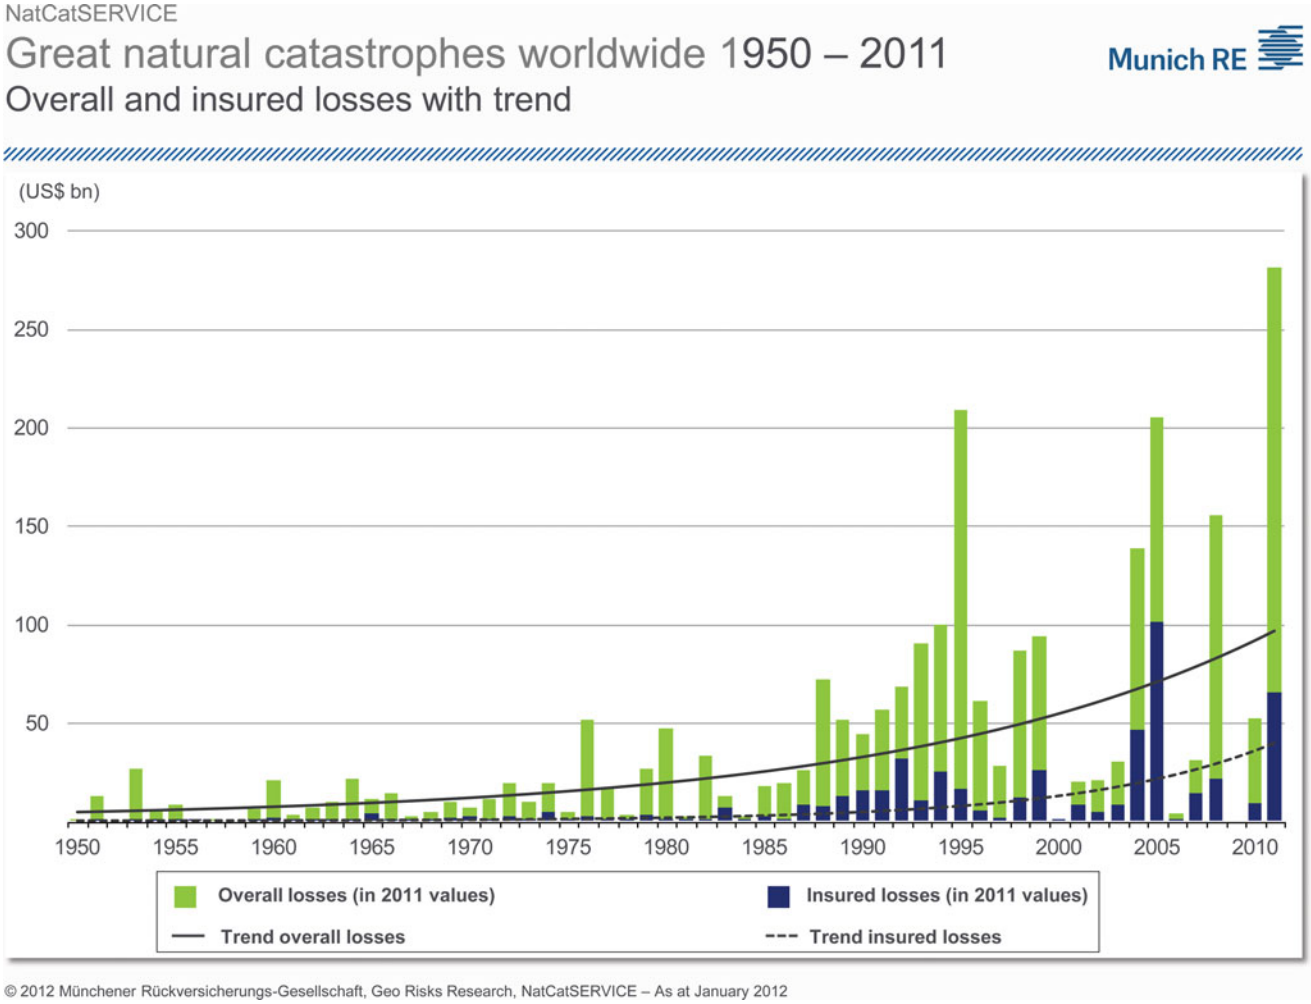
Howard Kunreuther, Erwann Michel-Kerjan
Risk Management and Decision Processes Center,
The Wharton School, University of Pennsylvania,
Philadelphia, PA, USA

Definition and introduction

Given the hundreds of billions of dollars in economic losses that catastrophes have caused in the USA since 2001, it is difficult to remember that when Hurricane Hugo hit the USA in 1989, it was the first catastrophe to inflict more than $1 billion of insured losses. But times have changed and there have been numerous large-scale natural disasters in the USA and other parts of the world in the past two decades that have been far costlier than Hugo both in terms of economic losses as well as fatalities and injuries due to the increasing concentration of population and activities in hazard-prone areas.

In Southeast Asia, the tsunami in December 2004 killed approximately ¼ million people residing in coastal areas. Cyclone Nargis, which made landfall in Myanmar in May 2008, killed an estimated 140,000 people, making it the deadliest natural disaster in the recorded history of the country. During the same month, the Great Sichuan Earthquake is estimated to have killed over 85,000, injured 374,000, and left almost five million homeless (Munich Re, 2008). Deaths from the Haitian earthquake in January 2010 are estimated at 230,000 (Insurance Journal, 2010).

Data reveals that the year 2011 is the costliest year the insurance industry has ever faced with respect to catastrophic losses. The Japan earthquake, tsunami, and nuclear power plant accident in March 2011 caused over US$210 billion in economic losses (not including nuclear-related damage), and insured losses in the range of US$35–40 billion (Munich Re, 2012). This disaster highlights the interdependencies between natural and technological accidents: the 9.0 magnitude earthquake that struck the Tohoku region of northeastern Japan caused a tsunami that hit the country's coastline within half an hour, taking the lives of nearly 20,000 people and destroying over 100,000 buildings, including the cooling system and the backup power generator of the Fukushima nuclear plant. The resulting meltdown of three nuclear reactors led to high radiation levels, which required the evacuation of more than 60,000 people (World Economic Forum Global Risk Report, 2012).



Although the USA has extensive experience with natural catastrophes and the resources to adequately prepare for them, loss-reduction measures and emergency-preparedness capacity are often inadequate to deal with large-scale natural disasters. Hurricane Katrina, which hit Louisiana and Mississippi at the end of August 2005, killed 1,300 people and forced 1.5 million people to evacuate the affected area – a historic record for the country. Economic losses from Hurricane Katrina are estimated in the range of $125–$150 billion (Munich Re, 2010).

Hurricanes in 2008 caused billions of dollars in direct economic losses along the Caribbean basin and in the USA. Hurricane Ike was the most expensive individual event in 2008, with privately insured losses estimated at $17.6 billion in addition to $2.4 billion in claims paid by the US National Flood Insurance Program for flood surge resulting from Ike (Swiss Re, 2009). Based on these figures, Hurricane Ike ranks as the third worst weather-related disaster in US history, after Hurricane Katrina and Hurricane Andrew, which hit southeast Florida in August 1992.

A new era of catastrophes

The economic and insured losses from great natural catastrophes such as hurricanes, earthquakes, and floods worldwide have increased significantly in recent years. According to Munich Re (2012), economic losses from natural catastrophes alone increased from $528 billion (1981–1990), $1.2 trillion (1991–2000) to $1.6 trillion over the period 2001–2011. During the past 10 years the losses were principally due to hurricanes and resulting storm surge occurring in 2004, 2005, and 2008. Figure 1 depicts the evolution of the direct economic losses and the insured portion from great natural disasters over the period 1970–2011.

Catastrophes since 1990 have had a more devastating impact on insurers than in the history of insurance before that time. Between 1970 and the mid-1980s, annual insured losses from natural disasters (including forest fires) were in the $3–$4 billion range. There was a radical increase in insured losses in the early 1990s, with

Costs (Economic) of Natural Hazards and Disasters, Figure 1 Natural catastrophes worldwide 1980–2011 – Overall and insured losses ($ billion) (Sources: Munich Re geo risks research).

Hurricane Andrew in Florida ($24.6 billion in 2008 dollars) and the Northridge earthquake in California ($20.3 billion in 2008 dollars). The four hurricanes in Florida in 2004 (Charley, Frances, Ivan, and Jeanne) collectively totaled almost $35 billion in insured losses. Hurricane Katrina alone cost insurers and reinsurers an estimated $48 billion, with total losses of $87 billion paid by private insurers for major natural catastrophes in 2005.

Table 1 reveals the 25 costliest insured catastrophes from 1970 to 2011 (in 2011 dollars). Of these 25 major events, 15 have occurred since 2001, 14 in the USA. With the exception of the terrorist attacks on September 11, 2001, all 25 of the costliest catastrophes were natural disasters. More than 85% of these were weather-related events – hurricanes, typhoons, storms, and floods –with nearly three quarters of the claims in the USA. Hurricane Andrew and the Northridge earthquake were the first two catastrophes that the industry experienced where losses were greater than $10 billion (designated "super-cats") and caused insurers to reflect on whether risks from natural disasters were still insurable. To assist them in making this determination, many firms began using catastrophe models to estimate the likelihood of, and consequences to, their insured portfolios from specific disasters in hazard-prone areas (Grossi and Kunreuther, 2005).

There is a very clear message from these data. Twenty or thirty years ago, large-scale natural disasters were considered to be low-probability events. Today, they not only are causing considerably greater economic losses than in the past but also appear to be occurring at an accelerating pace. In this context, it is important to understand more fully the factors influencing these changes in order to design more effective programs for reducing losses from future disasters.

The question of attribution

Several elements explain the increased costs of disasters in recent years. These include a higher degree of

Costs (Economic) of Natural Hazards and Disasters, Table 1 Twenty-five costliest insured catastrophes worldwide, 1970–2011

$ Billion	Event	Victims (dead or missing)	Year	Area of primary damage

urbanization, and an increase in the value at risk and insurance density. In 1950, approximately 30% of the world's population lived in cities. In 2000, about 50% of the world's population (six billion) resided in urban areas. Projections by the United Nations (2008) show that by 2025, this figure will have increased to 60% based on a world population estimate of 8.3 billion people.

In the USA in 2003, 53% of the nation's population, or 153 million people, lived in the 673 US coastal counties, an increase of 33 million people since 1980, according to the National Oceanic Atmospheric Administration. And the nation's coastal population is expected to increase by more than 12 million by 2015 (Crossett et al., 2004). Yet coastal counties, excluding Alaska, account for only 17% of land area in the USA. In hazard-prone areas, this urbanization and increase in population translate into greater concentration of exposure and hence a higher likelihood of catastrophic losses from future disasters. This new vulnerability is best understood in historical context – that is, compared to the cost of hurricanes in the past. It is possible to calculate the total direct economic cost of the major hurricanes affecting the USA in the past century, adjusted for inflation, population, and wealth normalization. Several studies have estimated how much previous hurricanes would have cost had they hit today. The most recent study by Pielke et al. (2008) normalizes mainland US hurricane damage for the period 1900–2005. Drawing on these data, Table 2 lists the 20 hurricanes that would have been costliest had they occurred in 2005. The estimate for each is a range based on the two approaches to normalizing losses used by the Pielke et al. study. The table provides the year when the hurricane originally occurred, the states that were the most seriously affected, and the hurricane category on the Saffir-Simpson scale. The data reveal that the hurricane that hit Miami in 1926 would have been almost twice as costly as Hurricane Katrina had it occurred in 2005, and the Galveston hurricane of 1900 would have had total direct economic costs as high as those from Katrina. We are very likely to see even more devastating disasters in the coming years because of the ongoing growth in values located in risk-prone areas.

There is another element to consider in determining how to adequately manage and finance catastrophe risks: the possible impact of a change in climate on future weather-related catastrophes. Between 1970 and 2004, storms and floods were responsible for over 90% of the total economic costs of extreme weather-related events worldwide. Storms (hurricanes in the US region, typhoons in Asia, and windstorms in Europe) contributed to over 75% of insured losses. In constant prices (2004), insured losses from weather-related events averaged $3 billion annually between 1970 and 1990 and then increased significantly to $16 billion annually between 1990 and 2004 (Association of British Insurers, 2005). In 2005, 99.7% of all catastrophic losses

Costs (Economic) of Natural Hazards and Disasters, Table 2 Twenty costliest Hurricanes, 1900–2005 (ranked using 2005 inflation, population, and wealth normalization)

Rank	Hurricane	Year	Category	Cost range in 2005 ($ billions)

worldwide were due to weather-related events (Mills and Lecomte, 2006).

There have been numerous discussions and scientific debates as to whether the series of major hurricanes that occurred in 2004 and 2005 might be partially attributable to the impact of a change in climate. One of the expected effects of global warming will be an increase in hurricane intensity. This increase has been predicted by theory and modeling, and substantiated by empirical data on climate change. Higher ocean temperatures lead to an exponentially higher evaporation rate in the atmosphere, which increases the intensity of cyclones and precipitation. An increase in the number of major hurricanes over a shorter period of time is likely to translate into a greater number hitting the coasts, with a greater likelihood of damage to a residences and commercial buildings today than in the 1940s – a trend that raises issues about the insurability of weather-related catastrophes.

Conclusions

Since the 1990s, a series of large-scale catastrophes have inflicted historic economic and insured losses. Fifteen of the 25 costliest insured catastrophes worldwide between 1970 and 2011 occurred after 2001, and all were natural disasters except for the 9/11 terrorist attacks. The USA has been particularly challenged because 14 of these disasters occurred in this country. The growing concentration of population and structures in high-risk areas, combined with the potential consequences of global climate change, are likely to lead to even more devastating catastrophes in the coming years unless cost-effective risk-reduction measures are put in place.

The task facing the USA and many other countries is ascertaining how to prevent the natural disaster syndrome. Even when risk-reduction measures are available and are cost-effective, many people still do not invest in them because they are myopic and misvalue the upfront costs of these measures as much greater than the expected benefits in reduced damage from disasters in future years. Many victims of Hurricane Katrina suffered severe losses from flooding because they had not undertaken loss mitigation and did not have flood insurance. As a result, an unprecedented level of federal disaster assistance – $81.6 billion (2005 prices) – was provided to these victims and the affected communities (Kunreuther and Michel-Kerjan, 2011).

CREEP

Piotr Migoń
University of Wrocław, Wrocław, Poland

Synonyms

Permafrost creep; Rock creep; Soil creep

Definition

Creep is defined as a semi-continuous, time-dependent deformation of solids which occurs at a low rate, under stress imposed by gravity. In Earth Sciences, creep of rock, soil, and frozen ground are distinguished. Not only are they different from the mechanical point of view, but they are associated with different types of natural hazards.

Overview

Soil creep is a very slow downslope movement of the near-surface part of the soil profile, at a rate usually decreasing exponentially with depth. At a depth > 50 cm, the effects of soil creep are hardly visible. It is a combination of different mechanisms, including pure shear, viscous laminar flow, expansion, and contraction. Frequent freeze/thaw and wetting/drying cycles contribute to the efficacy of creep. Creep rate, typically a few centimeters per year, is dependent on slope angle, cohesion of soil material, climatic conditions and biotic factors (vegetation cover, animal trampling). In the most favorable circumstances, e.g., on steep tropical slopes, rates approaching 0.5 m year^{-1} have been observed. Terracettes and bent trees (Figure 1) are noted as typical surface indicators of soil creep.

Creep, Figure 1 Bent trees are commonly viewed as an evidence of soil creep.

Rock creep is a unique behavior of solid rock and occurs under two circumstances. It may affect heavily fractured rock masses near the surface, which deform by joint opening and shearing along joint surfaces. Primary structural discontinuities bent downslope are the evidence of near-surface creep. Rock creep is also known to occur at great depths under considerable lithostatic stress, mainly in weak sedimentary rocks, particularly evaporates. Tunnel closures and excavation-wall buckling are typical manifestations of rock creep.
Permafrost creep is a term used to describe deformation of ice-saturated debris bodies, typically rock glaciers and protalus lobes, primarily under their own weight. However, doubts are expressed if this expression is correct, as permafrost is commonly understood as a thermal state of lithosphere.

Creep, being a deformation occurring at rather low rate, is rarely hazardous, although it may result in weakening of building foundations and tilting of trees and other vertical man-made structures (e.g., poles, masonry walls, gravestones) in the longer term, the latter leading to their collapse. However, creep may be a precursor to much more rapid deformations, in the form of either a mudslide (for soil creep) or rock slope failure (for rock creep). Rock creep may also cause severe problems in mine operations and transportation tunnels. Acceleration of creep usually occurs prior to a catastrophic yield. Therefore, in areas identified as potentially hazardous, the rate of creep should be monitored.

CRITICAL INCIDENT STRESS SYNDROME

Ann M. Mitchell[1], Kirstyn Kameg[2]
[1]University of Pittsburgh, Pittsburgh, PA, USA
[2]Robert Morris University, Moon Township, PA, USA

Synonyms

Acute stress disorder; Acute stress reaction; Post-traumatic stress disorder; Traumatic stress

Definition

Experiencing trauma is an essential part of being human, yet most people who experience critical incidents survive without developing psychiatric disorders. However, traumatic experiences can alter people's psychological, biological, and social equilibrium (van der Kolk et al., 1996).

Normal reactions

Most people exposed to critical incidents or traumas do not go on to develop psychiatric disorders; in fact, there is literature to support that there is the potential for post-traumatic growth following trauma (Linley and Joseph, 2004; Joseph and Linley, 2005; Paton, 2005). Natural disaster victims and their significant others who have been exposed to a sudden event that precipitates fear of injury or loss of life can respond to the traumatic event with a wide range of physical and emotional responses. Simply witnessing such an event can also produce psychological, social, and physiological dysfunction. Natural, technological, and other types of disasters (i.e., man-made, terroristic) expose innumerable people to scenes of destruction and human loss, and they can react with a classic set of symptoms similar to an acute stress reaction. Their emotional responses to disasters may be conceptualized as progressing through a number of phases. During the impact phase within the first few days, individuals often feel stunned and in shock. In these early days, individuals may also experience disbelief, numbness, fear, and confusion to the point of disorganization (Lubit, 2008). In the crisis phase, individuals may alternate between denial and intrusive symptoms with hyperarousal and may experience any number of somatic symptoms as well as irritability, apathy, and social withdrawal. Here, persons may become angry with caregivers who fail to solve problems and/or may be unable to be organized in the chaos of dealing with the crisis (Lubit, 2008). During the resolution phase, grief, guilt, and depression may be prominent and last through the first year as people continue to cope with their numerous losses, and finally, in the reconstruction phase, reappraisal, "meaning-making," and the integration of the event into a new self-concept occurs (Lubit, 2008).

Epidemiology

Epidemiological surveys of large groups of the general public have been done to determine exposure to various traumatic events. Researchers concluded that lifetime exposure to traumatic events may be as high as 73.6% for men and 64.8% for women (Solomon and Davidson, 1997). The lifetime prevalence of those individuals who will experience post-traumatic stress disorder (PTSD) at some point in their life varies from 7.8% (Kessler et al., 1995) for all to 5% of men and 10–12% of women (Solomon and Davidson, 1997). This figure jumps from 3% to 58% for "at risk individuals" (APA, 1994). Individuals may be at an increased risk for the development of PTSD if they witness an event that involves death, interpersonal violence, grotesque sensory images, or some natural disasters. It is also important to remember that critical incident stress may affect professionals (e.g., police, fire, healthcare professionals, and others) working in the field with victims of disasters (Paton and Violanti, 2011).

Complications

Two possible complications following exposure to a disaster include the development of acute stress disorder (ASD) and PTSD. Guidelines established by the Diagnostic Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) remain the gold standard for diagnosing ASD and PTSD. For both disorders, the individual must have been exposed to or witnessed a traumatic event that involved actual or threatened death, serious injury, or a threat to physical integrity in addition to responding with fear, helplessness, or horror. Additional symptoms seen in both disorders include reexperiencing the traumatic event, avoidance of stimuli associated with the traumatic event, and increased arousal. Reexperiencing the trauma may occur through intrusive recollections, nightmares, flashbacks, hallucinations, and psychological distress/physiological reactivity upon exposure to cues that symbolize the trauma. Symptoms of avoidance include efforts to avoid thoughts, feelings, or conversations associated with the trauma, inability to remember certain aspects of the trauma, reduced interest in activities, feeling detached from others, and a sense of a foreshortened future. Symptoms of increased arousal include difficulty with sleep, irritability/angry outbursts, poor focus, hypervigilance, and exaggerated startle response. Lastly, in both disorders, the symptoms cause significant distress or impair the individual's ability to function (APA, 1994).

Differences between the two diagnoses include the time frame and the occurrence of dissociative symptoms. The onset of ASD must occur and resolve within 4 weeks of the traumatic event. Additionally, in ASD, the individual experiences dissociative symptoms during exposure to the trauma or immediately following the trauma. In PTSD,

the duration of the symptoms exceeds 1 month. PTSD can also be classified as acute (duration of symptoms is less than 3 months), chronic (duration of symptoms is greater than 3 months), or delayed (duration of symptoms is at least 6 months after the stressor).

There is emerging evidence that there is a potential for positive outcomes following exposure to trauma. Paton (2005) and others (Tedeschi and Calhoun, 2003) have identified post-traumatic growth, enhanced professional capability, greater appreciation of family, and increased sense of control over significant adverse events as adaptive outcomes that may occur following a crisis. Factors that influence positive growth include personal resilience and vulnerability factors.

Treatment

Following exposure to a trauma, it is necessary to ensure a sense of safety. Provision of basic needs including food, clothing, and medical care must be met as well as ensuring that survivors are protected from reminders of the event, if possible; the onlookers; and the media. Mobilization of family members is critical, as social support networks may provide an important resource for coping with the aftermath of a traumatic event. It is also important to assist the survivor in reestablishing a sense of efficacy through education about stress responses and normal versus abnormal symptoms, as well as strategies to reduce anxiety.

Psychotropic medications should be used sparingly in the first 48 h following a natural disaster or trauma unless the individual is experiencing psychotic symptoms or their behavior is presenting a danger to themselves or others. If this is the case, a fast-acting benzodiazepine and/or an antipsychotic may be warranted as described in guidelines for managing agitation (Yildiz et al., 2003). Individuals who are experiencing acute panic symptoms and severe insomnia may benefit from a short-term (<1 week) prescription for benzodiazepines; however, early administration of benzodiazepines may be associated with a higher incidence of PTSD (Gelpin et al., 1996). According to the American Psychiatric Association (APA) practice guidelines, selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have shown superiority over placebo for noncombat-related PTSD (Benedek et al., 2009).

Conclusions

Exposure to a natural disaster or another traumatic event can disrupt an individual's physical, emotional, and psychosocial functioning. Besides providing emotional support, psychoeducation, improvement in coping skills, and reestablishment of a sense of resilience, a thorough assessment of the individual's symptoms and impairment in functioning is essential. There are numerous assessment scales available (Keane and Wilson, 2004; Norris, 1990) that can be utilized to assist in this process. In addition, screening the person for ASD and/or PTSD utilizing DSM-IV-TR diagnostic criteria is also necessary. Although medications should be used judiciously in the first days following a trauma, SSRIs have been found to be beneficial in the treatment of PTSD.

CRITICAL INFRASTRUCTURE

Susanne Krings
United Nations University, Bonn, Germany

Synonyms

Lifelines; Lifeline utilities

Definition

The term critical infrastructure is used to cover physical and organizational structures that provide services that are estimated to be essential to the functioning of society. Hence it is feared that the unavailability of critical infrastructure services may have severe consequences for basic societal needs.

The functioning of critical infrastructures depends to varying degrees on personnel and resources (material as well as information resources). The provision of critical infrastructure services in many cases involves the private sector. Public interest in their availability has frequently been articulated, e.g., in critical infrastructure protection policies (for an overview, see Brunner and Suter, 2008). Conventionally, concrete sectors, such as communication infrastructure or energy infrastructure, are listed in these policies. As most critical infrastructures are characterized by a high degree of (inter) dependencies, a failure in one sector is likely to affect others.

Among others, natural hazards are held to be threats for critical infrastructures and the services they provide. Destruction of critical infrastructure and service outages may initially cause severe problems and/or aggravate the situation in the course of events, most notably when services are needed to carry out relief measures to mitigate the immediate impact, and during recovery and reconstruction. Vulnerability and risk assessments as well as safeguards and risk-management measures may either focus on the level of single infrastructure components and/or opt for a system perspective.

CRYOLOGICAL ENGINEERING

Lukas U. Arenson[1], Sarah M. Springman[2]
[1]BGC Engineering Inc., Vancouver, BC, Canada
[2]Institut für Geotechnik/Institute for Geotechnical Engineering, Zurich, Switzerland

Synonyms

Cold regions engineering; High mountain engineering; Northern engineering; Permafrost engineering

Definitions

Cryosphere. That part of the earth's crust, hydrosphere, and atmosphere subject to temperatures below 0°C for at least part of each year.
Cryology. The study of materials having a temperature below 0°C.
Geocryology. The study of earth materials having a temperature below 0°C.
Engineering. The creative application of scientific principles to design or develop structures, machines, apparatus, or manufacturing processes, or works utilizing them singly or in combination; or to construct or operate the same with full cognizance of their design; or to forecast their behavior under specific operating conditions; all to meet an intended function, economics of operation, and safety to life and property (cf. American Engineers' Council for Professional Development). Additionally, the planning for, and maintenance of, a sustainable lifetime performance of the design object and its environment is essential.

Introduction

Generally, *Cryological Engineering* can be considered as the application of scientific principles to any design assignment that is subjected to temperatures below 0°C. The engineering disciplines that are most likely to be related to cryological engineering are civil, geotechnical, and mining, in particular when linked with projects in cold regions, such as northern and southern latitudes or high elevations. In recent years, engineering projects and developments in these cryospherical environments gained in importance due to access required to enable mining of natural resources (e.g., in the high Andes and the Arctic), resource transportation (e.g., pipelines), or in improving

infrastructure and accessibility (e.g., Qinghai–Tibetan railway and railroad). But also in the aviation and space industry and science, subfreezing conditions are of importance either for the design of aircrafts, space, Moon or Mars stations, or just for the study of extraterrestrial processes.

The cryosphere

The cryosphere may be divided into the cryoatmosphere, the cryohydrosphere (snow cover, glaciers, ice caps, ice sheets and river, lake and sea ice), and the cryolithosphere (perennially and seasonally cryotic ground). Some authorities exclude the earth's atmosphere from the cryosphere (e.g., UNEP, 2007); others restrict the term "cryosphere" to the regions of the earth's crust where permafrost, that is, perennially frozen ground, exists (Baranov, 1978). However, for engineering purposes, it is important to understand the physical differences in the materials that may be encountered and used as foundations or construction materials from the cryosphere, which include snow, firn, and ice in special forms, such as sea ice, glacier ice, pore ice, segregated ice, ground ice, ice shelves or ice bergs, just to name a few.

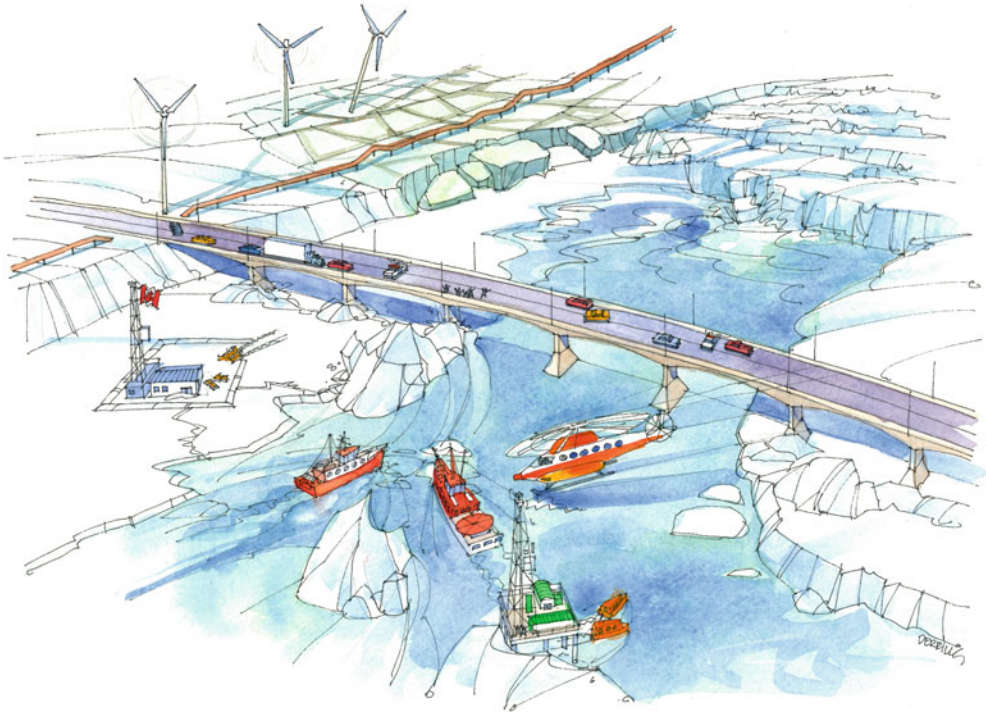
However, good knowledge about the special conditions that prevail in the cryosphere is required for the design of conditions that are artificially induced, such as artificial ground freezing used to increase the strength of the ground temporarily to build tunnels, caverns, or shafts (e.g., Harris, 1995).

Divisions of cryological engineering

Cryological engineering is complex and can, therefore, be seen as sub-categories in a series of engineering disciplines. Figure 1 illustrates some aspects of cryological engineering that demonstrates the variety of engineering disciplines involved. *Geotechnical* engineers design foundations and dams, and assess slope stability or general geohazards due to ground ice degradation. *Road* engineers design road surfaces that resist the harsh climatic conditions, which also affect the design of towers, buildings, and bridges that have to be designed by *structural* and *civil* engineers. *Mechanical* engineers have to consider the effect of subfreezing temperatures in their designs; in particular for moving elements where freezing water or the temperature-dependent material behavior may affect a machine's performance over its lifetime, which may also be reduced by repeated cycles of freezing and thawing. These examples are not exclusive and aspects of cryological engineering can probably be found in any engineering field.

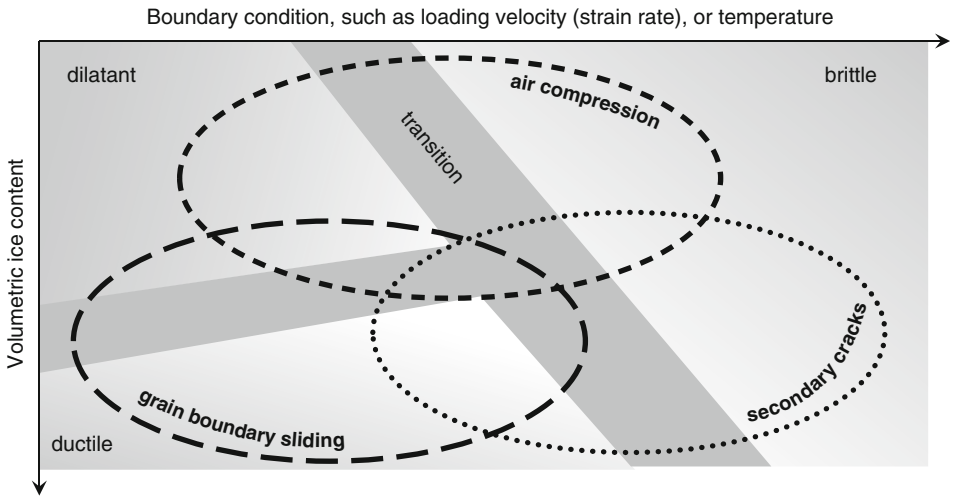
Although the engineering problems are diverse, the main challenge is similar for most disciplines, that is, the change in the mechanical behavior of unfrozen material versus frozen materials – in other words the differences in the physical response of a material containing fluid water opposed to ice.

Engineering challenges



The challenges associated with cryological engineering are as diverse as the projects. A good understanding of the *material properties* is essential. Phase changes (i.e., latent heat effects), thermal expansion, viscosity of ice, fatigue, and self-healing mechanisms as well as the temperature- and loading-dependent material stiffness are only some aspects that need to be considered. Andersland and Ladanyi (2004) or Paterson (1994) provide/provides valuable overviews on frozen ground and glacier physics. Figure 2 shows a diagram that illustrates schematically how the mechanical response of a frozen soil varies as a function of the loading conditions, temperature, and ice content. The differences in the mechanical response may result in variations of several magnitudes in the strength response and are, therefore, crucial for a sustainable foundation design. In addition, spatial variations and heterogeneities in the ground conditions pose problems in creating a standard design for linear infrastructure foundations, for example, and continuous in situ adaptations are often required in the field. Therefore, flexible engineering solutions are required.

The challenges from the material properties are, however, only one element to be considered in cryological engineering designs. Often more expensive are challenges related to the *logistics*, such as the remoteness of the construction site, available resources (e.g., gravel for concrete), or access in steep and high mountain environments. But also the effect of the harsh climatic conditions with cold temperatures and dark days at high latitude, or major diurnal air temperature variations and low oxygen levels in high mountain areas, are wearing on equipment and working crews. The logistical challenges and remoteness of some construction sites often result in limited information for the design, such as site investigation or historical climate data. The latter are important in predicting and designing for future climate change effects. Generally, the cryosphere is often found in environments that are ecologically very sensitive and it is, therefore, important to understand how a planned structure affects it and what adaptation strategies are required.



Not only local aspects are to be considered in the design process, but larger-scale effects may become important. For example, the cryogenic conditions of the surrounding landscape may change in the future, so that formerly stable, frozen slopes become unstable and transform into a potentially dangerous debris flow source zone. Hence it is important to familiarize oneself with the proximate surroundings, and with the general environment and landscape. A summary of these problems is presented in Bommer et al. (2010) for mountain permafrost environments.

Solutions

As with most engineering projects, in particular with civil projects, designs are typically prototypes, and no real testing is possible. Because of this unique situation, and the

Cryological Engineering, Figure 1 An overview of the diversity of cryological engineering (Illustration by Derrill Shuttleworth).

Cryological Engineering, Figure 2 Schematics of the dependency of the response mechanism of frozen soil on the boundary conditions (After Arenson and Springman, 2005).

challenges indicated above, special care is required during the design, construction, and operation of an engineered structure. Successful cryological engineering requires enough resources for planning in terms of time and financial means. It is important to have a good spatial representation of any data and long time series that allow for statistical trend analyses. Designs are to be favored that minimize the impact on the environment, notwithstanding the uncertainty about ongoing climate change over several decades. However, the environmental sensitivity and complex interactions between climate, foundation, and structure require designs to be adaptive, and the incorporation

of an observational approach is essential. Ongoing data evaluation and updating predictions should be a crucial part in the structure's operation and maintenance plan to monitor a structure's performance effectively. Redundancies, designed and implemented in time, help in minimizing any operational interruption in the future due to unforeseen changes in the boundary conditions. An estimation of project vulnerability, hazard, and associated risks is critical for the decision-making process and should also be carefully planned ahead of time.

Cryological engineering projects are, therefore, often expensive and require more resources for project management than similar projects in unfrozen environments. The project lifetime is often to be chosen shorter, or design re-evaluations are required at regular intervals (e.g., 20–30 years) and are to be accounted for in the original design process. In particular, the effects of climate change, including second- and third-order effects that are almost impossible to predict, have to be analyzed regularly, especially for sensitive structures and locations.

While the challenges of cryological engineering are substantive, various innovative solutions have been presented in recent years or are currently being evaluated. These include adjustable foundation designs (e.g., Phillips et al., 2007) or standardized protocols are in development to account for the potential impacts of climate change (e.g., CSA, 2007). Additional resources are listed in the bibliography to assist in cryological engineering designs.

Summary

Cryological Engineering implies the adaptation of multidisciplinary engineering processes to account for cryological conditions in subfreezing environments. When liquid water turns into ice, several physical processes change and this has to be considered in the design. However, the effect of the structure on its environment or climate change may result in current cryogenic conditions changing into non-cryogenic ones with time. The structural integrity or the serviceability of the engineered structures may be affected by such changes in the boundary conditions. It is, therefore, critical to consider such potential changes adequately in an adaptable design that has been developed on the basis of thorough investigations and historical data analyses.

CULTURAL HERITAGE AND NATURAL HAZARDS

Piotr Migoń
University of Wrocław, Wrocław, Poland

Definition

Cultural heritage is understood as the legacy of past generations which is maintained by the present one and intended to be passed on to future generations. It can be intangible (customs, beliefs) and tangible, the latter including various physical objects, from human-transformed landscapes (e.g., paddy rice fields on hillslopes) through places, buildings, monuments, to

movable artifacts. The significance of cultural heritage may be local, regional, or global. The most valued places are those with the status of World Heritage granted by UNESCO.

Natural hazards may adversely impact tangible cultural heritage, but in specific instances, the remains of an inhabited place, or a building, may become a valuable component of cultural heritage because of their destruction by natural forces at some time in the past. Likewise, stories of ancient catastrophes have become a part of the intangible heritage of many societies.

Introduction

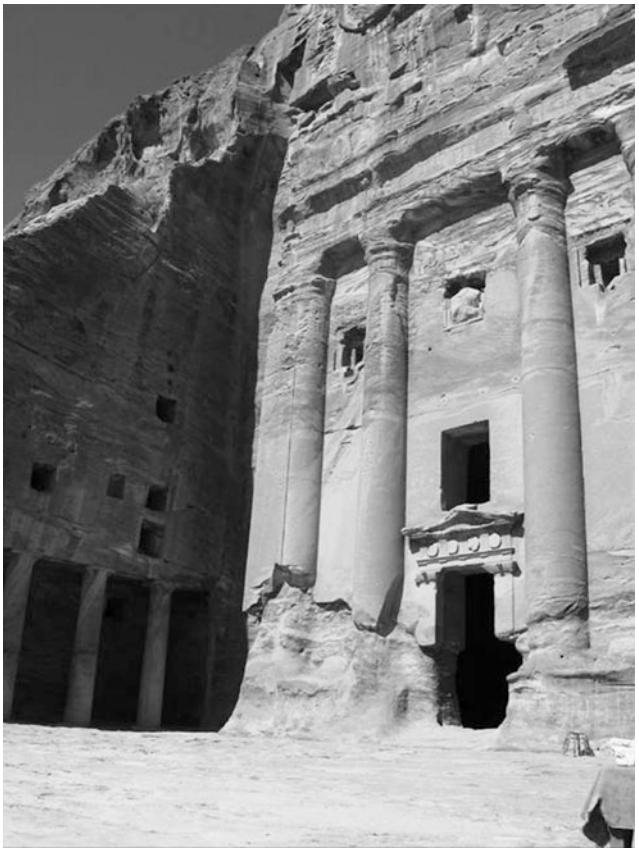
Relationships between cultural heritage of humankind and natural hazards are many and complex. Hence, many interrelating themes appear within the subject, including:

(a) Damage or destruction of cultural heritage due to natural catastrophic processes of various sorts
(b) Problems of adequate protection of cultural heritage sites against natural hazards
(c) The occurrence of globally or regionally significant representatives of ancient cultural heritage which have undergone catastrophic destruction by natural forces and have now become highly valued cultural properties because of their history of destruction
(d) The presence of natural hazards and catastrophes in oral folk traditions, hence a part of intangible cultural heritage

Natural hazards affecting cultural heritage properties do not form a specific category of hazards in terms of process or effect. Sites of cultural significance may become affected by catastrophic events of either endogenous (earthquakes, volcanic eruptions, tsunami) or exogenous origin (landslides, floods, ground collapses, wildfires, cyclones) (Smith, 1996), for which little or no warning has been received (particularly prior to the twentieth century). However, these sites may also suffer from processes which are not catastrophic in the conventional sense (i.e., have not appeared suddenly) but their cumulative effects in the long term may have a highly adverse impact. These include ground subsidence, especially in coastal settings, accelerated weathering of building stone, sandstorms, and recession of coastal cliffs.

Natural processes and loss of cultural heritage

Natural catastrophes have been known to affect and occasionally destroy material evidence of human activities since prehistory. Those from the most distant past are often shrouded in uncertainty and subject to scientific debate, such as the probable destruction of Sodom and Gomorrah located in the Dead Sea Graben due to an interaction of earthquakes, natural gas explosions, and fire. Volcanic eruptions were among the most devastating, able to wipe out island populations, as on the Aegean island of Santorini in the fifteenth century BC. At a more local scale, pyroclastic flows from Vesuvius were responsible for the total destruction of Pompeii and Herculaneum in 79 AD, whereas lava flows destroyed and buried the native American ceremonial center at Cuicuilco (present-day Mexico City) in the first century AD. Likewise, deteriorating environmental conditions in the longer term, particularly droughts, are often suspected as reasons for apparent declines of once mighty societies and political entities. It is widely believed that decreasing rainfall and diminishing river flows resulted in temporary or ultimate collapses of early "hydraulic" civilizations such as the Old Kingdom of Egypt around the twenty-second century BC or the great Harappan civilization of the Indus Valley, where channel changes may also have been important. More controversially perhaps, fragmentation of the Mayan states and an apparent decline of many Mayan cities in the eighth to eleventh century has been attributed to climate changes, mainly increasingly unreliable rainfall. More recent societies may also have been vulnerable, especially those living in marginal conditions. The demise of Nordic settlements in Greenland in the thirteenth/fourteenth century was influenced by climate cooling and the advent of the Little Ice Age.



The concept of cultural heritage was apparently present among ancient societies as early as the third century BC. In the Hellenistic world, its reflection was the list of Seven Wonders of the World, which was also the list of "must-see" places for ancient travelers. It included objects and sites, from Greece to Babylon, then considered absolute masterpieces of human genius. Only one of them – the Great Pyramid of Giza – has survived until today. Among the other six, three have been damaged by earthquakes. The Colossus of Rhodes tumbled down around 227 BC, the Pharos Lighthouse in Alexandria finally in the fourteenth century AD, whereas the Mausoleum in Halikarnassos (today Bodrum), destroyed by floods and earthquakes and rebuilt several times, eventually disappeared in the fifteenth century.

In recent decades, many significant sites of cultural heritage have suffered damage, occasionally irreversible, from natural processes. Mud-brick walls of an ancient fortress in Bam, Iran, largely crumbled during an earthquake on December 26, 2003, whereas numerous components of the famous Dujiangyan Irrigation System in the Sichuan province, China, dated to 256 BC, collapsed during the Wenchuan earthquake on May 12, 2008. Earthquake-induced ceiling collapse in the basilica of Assisi, Italy, in 1997 led to the destruction of unique frescoes from the thirteenth/fourteenth century. The revered pre-Columbian site of Chan Chan in northern Peru, built of dried mud brick, greatly suffered from several floods related to El Niño years. Widespread forest fires in western Peloponnese, Greece, in August 2007, put at serious risk the site of ancient games at Olympia, destroying parts of the surrounding landscape. Subsequent to fire, soil erosion from burnt slopes became an issue and a widespread erosion control project was undertaken. Floods tend to threaten historical cities located in the valley floors, late twentieth century examples being inundation of

downtown Florence (Italy) in 1966 and parts of Cologne (Germany) in 1993 and 1995.

For cultural heritage sites, slow-acting natural processes may be devastating too. However, it is useful to make a distinction between those processes which are an intrinsic part of the natural environment and those which have been induced, or accelerated, by human activities. This differentiation has considerable implications on the choice of remedial solutions toward preservation of sites under threat. Many ancient temples were located along shores, on exposed cliffs and promontories. Long-term transport of salts derived from sea-spray and its subsequent crystallization has affected building stones and caused disappearance of various fine architectonic details, particularly if these were built of easily weathered limestone (e.g., the megalithic temples of Malta, and the Poseidon temple at Cap Sounion near Athens). Salt weathering is also of considerable concern at the UNESCO site of Petra, Jordan. Both scarp-foot and mid-wall weathering, influenced by capillary rise and seepage respectively, have caused widespread damage to the finely carved facades of rock-hewn tombs (Figure 1). Rock/cave art is another highly valued legacy of past cultures that is highly susceptible to weathering and in many places suffers from rapid deterioration. In Calatayud, Spain, slow gypsum dissolution underneath the medieval city results in extensive ground subsidence and building destruction. Sea level changes affected the historic Serapis temple in Pozzuoli, Italy, as well as numerous other Mediterranean examples. In urban and industrialized areas, however, damage experienced by buildings of cultural significance can be often ascribed to anthropogenic sources of salt and air pollution (Goudie and Viles, 1997). In the context of aeolian processes, human impact has been suggested as the reason behind the damage of western sections of the Great Wall in Gansu province, China. In the last 20 years more than 40 km of this unique construction disappeared or was severely reduced by sand blasting during windstorms, and destructive farming methods with consequent enhanced dust production are considered responsible (http://www.msnbc.msn.com/id/20492488/ns/world_news-world_environment/t/sandstorms-eating-away-chinas-great-wall/(retrieved 2012-03-18)).

Coastal erosion is another process to impact building constructions located on cliffs and along beaches. Usually, the coast sections under threat are those undergoing slow long-term recession, but major damage is experienced during storm episodes, when wave energy is sufficient to induce cliff undercutting, leading to rock fall or retrogressive landslides. The southern coast of England hosts many examples of cultural heritage objects affected by cliff recession, from ancient Roman forts to remains from World War II (Bromhead and Ibsen, 2006), as do Mediterranean coasts. In Tanzania, beach erosion and wave inundation threat the integrity of ancient harbors of Kilwa Kisiwani and Songo Mnara. Coastal subsidence is of major concern too, the best known example being Venice, Italy. High floods, the famous *acqua alta*, have increased in frequency, causing weakening of building foundations and setting the stage for accelerated weathering.

Cultural Heritage and Natural Hazards, Figure 1 The unique cultural legacy of Petra in Jordan is under threat from various geomorphic processes, including salt weathering. The picture shows two zones of accelerated rock breakdown and deterioration, caused by capillary rise (near the bottom) and seepage (in the middle of the facade) (Photo P. Migoń).

Significant sites of cultural heritage: Evidence of ancient natural catastrophes

Our cultural heritage consists of objects and sites of various origin, context, and age. Many such objects are treasured because they have survived largely intact since the very distant past, occasionally even from prehistory. Their maintenance in a condition as close to original as possible is now the priority of conservation efforts and a significant constraint in access policy. Hence, any damage arising from any cause is considered highly detrimental for the integrity of a site. However, a considerable number of much valued cultural heritage sites, including many listed as UNESCO World Heritage properties, bear evidence of either natural catastrophes or slow deterioration. These natural processes once led to the abandonment of the sites, occasionally destruction, and their subsequent

Cultural Heritage and Natural Hazards, Figure 2 The ruined church tower rising from lava field north of the Paricutín volcano, Mexico, overwhelmed by lava in 1944, is already visited as a cultural heritage site (Photo P. Migoń).

disappearance from human memory. Much later archaeological work unearthed these sites as they appeared in ancient times, offering thereby unique insights into the past, not obstructed by subsequent societal and architectural developments. Examples come from different parts of the world, from the Mediterranean realm through the Middle East to the Far East, as well as from Central America.

Perhaps the best known example is Pompeii near Naples in Italy, the remains of a wealthy town buried by pyroclastic flow deposits from the eruption of Vesuvius in 79 AD. Excavations carried out since the eighteenth century, and more comprehensively since 1863, have revealed an astonishingly complete picture of daily life in the Roman Empire, with no parallels from elsewhere in the Mediterranean region. Interestingly, archaeological work has also shown evidence of earlier damage by a strong earthquake in 62 AD. Another important archaeological site is Akhrotiri on the Island of Thera (Santorini), likely abandoned just prior to the catastrophic explosion of Santorini volcano in the fifteenth century BC and then buried by many meters of pyroclastic deposits. Excavations, initiated in 1967, brought to light many details of the Minoan culture, including unique frescoes. Many ancient sites or buildings suffered from high-magnitude earthquakes, such as Kourion (Curium) in Cyprus in 365 AD, abandoned soon after. Archaeological work has not only revealed remnants of important buildings of the ancient city, but opened a window on the everyday life of this important, predominantly Christian settlement. The evidence of ancient earthquakes is common at archaeological sites in Asia Minor (e.g., Hierapolis) and along the Dead Sea Rift (e.g., Jericho). Patterns of building destruction are now used as important palaeoseismological tools (Hancock and Altunel, 1997).

River mouth siltation and channel changes have contributed to the decline and later abandonment of many important settlements of antiquity. Today many of these sites, excavated and partially reconstructed, are cherished sites of cultural heritage and important tourist attractions. They also tell instructive stories of how people interact with nature and how things can go wrong. Excellent examples are provided by ancient Greek-Roman cities in Asia Minor, along the Aegean coast, such as Miletus or Ephesus. Once important harbors and trading posts located at river/sea junctions, they declined concurrently with delta buildup, often considered a response to accelerated soil erosion in the hinterland.

Today, damage brought by natural events is usually repaired as quickly as possible. With current technological advances and international aid, the evidence of destruction may be obliterated in a few years and rebuilding sites of cultural heritage is often a priority. Very few places are left as standing memories of violent natural processes and these, over time, may join the family of cultural heritage sites. One such object is the ruined church at a site of the former town of San Juan Parangaricutiro in Mexico,

Cultural Heritage and Natural Hazards, Figure 3 The remains of a medieval church in Trzęsacz, northern Poland, atop a Baltic Sea cliff. The church was built in the fifteenth century about 1 km from the cliff edge, but long-term cliff recession resulted in a few successive collapses since 1900. Today the site is considered to be of special cultural importance and protected against further cliff erosion. However, erosion continues unabated next to the site (Photo P. Migoń).

the only survivor of a lava flow issued by the Paricutín volcano in 1944 (Figure 2). Others include sites near Pinatubo volcano in the Philippines.

Protection of cultural heritage against natural hazards

Natural hazards affecting cultural heritage properties do not form a specific category of hazards in terms of process or effect. It is the vulnerability and universal value of these properties which is decisive for the increasing risk experienced by cultural heritage sites. Mitigations and risk reduction strategies should consider characteristics of natural processes potentially affecting a site, particularly the likelihood of its occurrence in a specified period, the magnitude of expected damage, and the feasibility of preventive actions. Further, any potential human contribution to the hazard needs to be identified.

In many instances, hazards are simply unavoidable as the properties cannot be relocated to safer places. This applies to all cultural heritage sites in seismic zones and in the vicinity of active volcanoes. Many great heritage cities have been built along active fault zones and their cultural legacy is at particular risk from high-magnitude earthquakes (e.g., Istanbul, Athens, Mexico City, Kyoto). Construction strengthening is practically the only measure which can be undertaken. Others cities are located in zones prone to pyroclastic flows from volcanic eruptions (e.g., Naples, Mexico City). Large tsunamis can affect cultural heritage sites along seismogenic coasts of the Mediterranean Sea, southeast Asia, and the Pacific Ocean, as they did in Lisbon in 1755. Some sites, e.g., the Inca site of Machu Picchu, are located on hillslopes conducive to slope failures and these, if occur, may irreversibly damage the entire property.

Surface processes, such as shallow landslides, mudflows, or floods, can be predicted with more confidence and there is a choice of mitigation strategies. Landslide hazard and risk mapping is now routinely carried out and helps to identify the most vulnerable places. After these are identified, various methods of slope stabilization, depending on the type of mass movement likely to occur, may be used to protect a cultural heritage site. These include rock slope strengthening, reduction of slope angle, drainage diversion or improvement, bioengineering, and others (see Sidle and Ochiai, 2006). Flood hazard may be reduced by bank strengthening and dyke heightening adjacent to a site of concern, but these measures may not be sufficient during low-frequency, high-magnitude floods. It is also important to remember that for flood mitigation schemes to be effective, they should be designed for entire catchments and those for cultural heritage sites specifically need to be integrated within catchment-wide strategies. Valuable cliff-top sites may be protected by various coastal defenses, including sea walls, artificial boulder beaches, and concrete tetrapods (Figure 3). However, coasts are complex systems of mass transfer from one place to another and emphasis on preventing erosion and cliff recession in one locality may result in accelerated erosion in an adjacent locality. There are also different methods available to avert salt weathering and ground

salinization, such as the UNESCO attempt to rescue Mohenjo Daro, Pakistan, by reducing the water table and hence the capillary rise of salt. Any preventive action is bound to be very costly (e.g., plans to build protective barriers at the entrances to the Lagoon of Venice) and often there is no guarantee that the effects will be satisfactory.

An important part of disaster prevention and risk management programs at sites of cultural significance should be adequate preparedness (Spennemann, 1999; Taboroff, 2000). Ideally, it includes components such as hazard assessments for each natural process likely to occur, individual emergency plans integrated with disaster plans for wider areas, priority lists, detailed inventories of objects, and records of past dealings with natural events, and staff specialized training. There is no doubt that cultural heritage sites will continue to suffer from natural processes, which are largely beyond our ability to control them, but accumulated knowledge from past disasters can be of considerable help to reduce negative impact of any future event.

Summary

Cultural heritage is exposed to different types of hazards and potentially devastating natural events which may result in different degrees of damage or, less commonly, total destruction. Earthquakes appear to have most serious effects and many great heritage sites are located along major fault zones in Europe, Asia, and America. Other hazards include volcanic eruptions, gravitational mass movements, flash floods, and coastal erosion. Weathering and ground subsidence are slow-acting processes whose cumulative effects may nevertheless seriously affect the stability of structures and their visual quality. Perhaps the most important aspect of relationships between cultural heritage and natural hazards is that damage or loss of properties cannot be measured in monetary units only. Their value to the humankind can be hardly expressed in this way, and some are considered of outstanding universal value, protected by international conventions. In disaster-affected areas, if objects of cultural heritage are prioritized for rebuilding, they may be used as catalysts of renewed tourism interest and, thereby, as means to improve a shaken local economy.

DAMAGE AND THE BUILT ENVIRONMENT

Adriana Galderisi, Andrea Ceudech
University of Naples "Federico II", Naples, Italy

Synonyms

Losses; Urban areas; Urban environment

Definition

Damage: Losses, injuries, failures, or troubles which may occur in a given area as a consequence of the impact of a hazard on exposed and vulnerable elements and systems. Types and amount of damage depend on the features of both hazards and exposed elements and systems.

Built environment: The areas most modified by human beings, where people and all man-made structures are concentrated. It is generally opposite to the natural environment, even though close relationships between the built and natural environments are largely recognized. Built environments can greatly differ, in terms of spatial and functional patterns. The various types of built environments respond differently to hazards: that is, a densely built up historical city and a recent low-density urban area have a different susceptibility to damage from a given hazard.

Introduction

The damage due to natural hazards in built environments generally refers to the physical destruction to man-made structures and to the impacts on people. These types of damages are generally defined as direct damages and occur at the onset of a disaster or shortly thereafter. Direct damages can be due both to a primary hazard or to its impact on exposed vulnerable elements which represent, in turn, further hazard sources: for example, damages to buildings or people due to fires following an earthquake which causes, in turn, breaks in gas pipelines. Such damages are very common in the built environment, as clearly highlighted by several disasters that have occurred in the recent past. Nevertheless, in many cases, official reports do not distinguish the damages in relation to the different hazard sources.

Besides direct damages, indirect ones may occur and can result from physical damages affecting the functioning of some elements or systems (hospitals, lifelines, etc.) or inducing economic consequences (temporary unemployment due to physical damages to industries). Indirect damages may even occur over a long period of time after the event, affecting broader areas than that directly hit by the hazard. Permanent or temporary losses in relevant economic activities at local scale can reverberate on macroeconomic variables.

By their nature, indirect damages are harder to quantify than physical ones. The amount of indirect damages may constitute the majority of the total losses in large disasters affecting urban areas. Nevertheless, long-term indirect damages are frequently neglected, mainly in official reports often designed to provide governments with estimates of the amount of funds required to address emergency and reconstruction needs.

The overall damage is quantified in terms of economic losses, generally including direct damages and the most relevant economic effects, as well as distinguishing the insured losses within the overall amount. It is worth noting that in many cases, the evaluation of indirect damages is made even more difficult by the "nonmarket effects." Such effects are related to the loss in functioning of public equipment or infrastructure. Due to their public nature, such equipment provides services free of charge (Rose 2004); hence, damage cannot be easily assessed in economic terms.

Most of the available databases provide quantitative information related to damages to people (killed, injuries,

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

homeless, missing, or evacuated) and to structures (number of damaged or destroyed buildings) and qualitative information highlighting the most affected sectors (industry, transport, etc.).

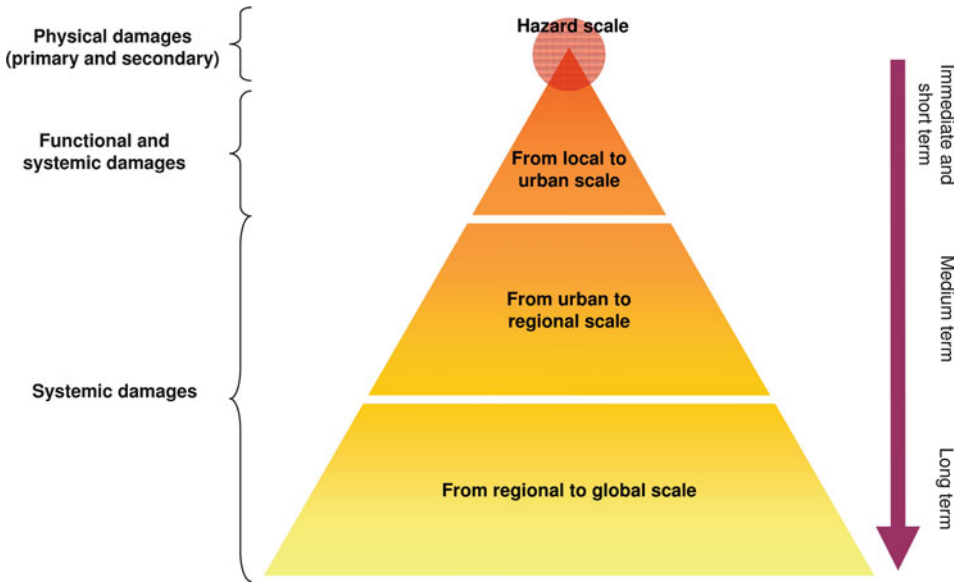
Typologies of damages

As previously mentioned, direct damages include physical damages and damages to people due to a primary hazardous event or to a secondary hazard triggered by the primary one. Since there is a close relation between hazard factors and physical damages, both the temporal and the geographical scale at which such damages generally occur are strictly related to the temporal and spatial scales of hazards themselves and may vary according to the type of hazard under consideration (earthquakes, landslides, or volcanic events induce different physical damages, over different temporal phases, and at different geographical scales).

A better understanding of the damages which can be classified as indirect requires a further distinction between "functional damages," meant as loss of efficiency or functioning affecting an element as a consequence of physical damages, and "systemic damages," meant as a loss of efficiency or functioning affecting an element or a system as a consequence of damages to other elements or systems.

Hence, systemic damages are generally due to the numerous interdependencies among elements or systems characterizing the built environment and are not directly related to the physical damages.

Given this distinction, functional damages are often taken into account due to their clear relationship to physical damage. For example, the most widespread methods for assessing damages have recently introduced parameters for the evaluation of functional damages linked to physical ones. In contrast, systemic ones are in many cases neglected, since they may reveal themselves in a medium or long term and can affect wide areas, even very far from the hazard source.



The pyramid of damages (Figure 1) shows the relationships among the different types of damages with respect to the spatial distribution of each type and to the time span in which they generally occur. The top of the pyramid represents the physical damages, occurring immediately after the hazardous event; the base represents the systemic damages. It is worth noting that there is a "fuzzy" boundary between functional and systemic damages, since functional damages are a direct consequence of physical ones and generally trigger ripple effects which reverberate on other elements, systems, or areas.

Finally, it is clear that since damages are "displaced, geographically and temporally, the narrower the time-space focus, the greater the likelihood that losses will be underestimated" (Cochrane 2004:39).

Chains of damages

A relevant challenge in analyzing and assessing damages derives both from potential chains of hazards and from physical damages inducing functional and/or systemic ones. Very often, it is difficult to distinguish in available databases such complex chains of causes and damages which characterize most of the large-scale disasters affecting urban areas.

As largely recognized in the current literature, disasters in the built environment are more and more "complex." According to McEntire et al. (2002), their growing complexity is due to changes of hazards, exposure, and

Damage and the Built Environment, Figure 1 The pyramid of damages highlights the correspondence among the types of damage, the geographical scales and the temporal spans at which they generally occur.

vulnerability of territorial systems and to the interactive mix of such changes.

As concerns hazard chains, they can have different levels of complexity, since a natural event can trigger one or more technological accidents and, in the interim, other secondary natural events. Additionally, a triggered technological event may induce, in turn, domino effects. In these cases, the phenomena have different features and the affected areas and targets will not necessarily overlap. Therefore, the damages may be due both to the effect of each hazard and to the synergies and overlapping among their impacts. Moreover, physical damages can result in losses of efficiency in different elements or systems which in turn, due to the interdependencies among them, may induce systemic damages.

Relationships between damage and built environment

Past disasters clearly highlight how much physical and functional characteristics of the built environment may affect the type and the amount of damage resulting from a hazardous event. The influence of physical features of the built environment on damages can be highlighted looking at the Kobe (1995) and the Northridge (1994) earthquakes. The two events had similar characteristics but very different outcomes. They had approximately the same magnitude; both of them occurred before the sunrise and affected metropolitan areas with high population density. However, the Northridge earthquake resulted in 57 dead, 1,500 injured, and 12,500 buildings seriously damaged, whereas the Kobe event caused about 5,500 deaths, 35,000 injured, and 180,000 buildings damaged. The overall damage caused by the Northridge earthquake was estimated at about 15 billion dollars, whereas the Japanese disaster cost approximately 147 billion dollars. Such a disproportion was due to several factors. First of all, the Northridge urban fabrics were regular and with high levels of accessibility, whereas in Kobe they were irregular and mostly developed along the coast. Moreover, the Japanese city is constrained between the sea and the mountains, with scarce cross-sectional roads and access from the outside. Consequently, the different urban morphologies created different conditions of accessibility for the rescuers in the emergency phase. For Kobe, the direct damages were significantly increased by fires due to breaks in gas pipelines caused by the earthquake. Such fires spread over a large area due to the structural typology of many old houses (wooden houses) as well as the interruptions in water supply which made the situation worse, thereby highlighting the role of systemic damages in large disasters.

Concerning the influence of functional features on damage, it is worth noting that areas characterized by social, economic, and functional weaknesses generally show high levels of physical damages. In contrast, large urban contexts, characterized by relevant activities (productive activities, mobility hubs, etc.), may show low levels of physical damages and high levels of functional and systemic ones which can expand over large areas.

Coupled human-natural environments

Even though damages induced by natural disasters on natural resources are in many cases negligible in the built environment, it is worth highlighting the need for taking into account the "vulnerability of coupled human-environment systems" (Turner et al. 2003: 8074) for a complete assessment of damage. Natural resources often represent the main target of secondary hazard due to the impact of the events on industrial plants or laboratories handling hazardous materials, gas pipelines, and so on. On the other hand, the everyday perturbations on natural resources due to human activities and to urbanization processes can cause or accelerate natural hazards or amplify their effects.

The twofold role played by natural resources was clearly highlighted during the Katrina hurricane, which impacted the city of New Orleans in 2005. In that case, the alteration of natural ecosystems before the hurricane contributed to the occurrence of the flood event, and the multiple damages due to the impact of flood on industrial plants induced relevant damages on natural resources, which had, in turn, short and long term repercussions on the social and economic systems. Moreover, in the Katrina event also the inadequate interventions undertaken during the emergency phase increased overall damage on environmental resources.

Measuring damages

The assessment of damage can be carried out after the hazardous event, to evaluate the dimension of the disaster, or before the event, to assess expected damage which represents a measure of the risk which a territory is prone to, with respect to a given hazard.

In both cases, the assessment is generally expressed in monetary or economic terms. For example, the European Union Solidarity Fund, established in 2002, is activated in cases of "major natural disasters," when the estimated cost of the direct damage is over three billion Euros or over the 0.6% of the GDP of the affected state. Such thresholds are defined taking into account only the cost of direct damages. The economic amount of the disaster is determined by the total amount of exposed assets.

Consequently, the lower values of damages reported for less developed or poor countries, if compared with those occurring in more developed nations, are ineffective and sometimes hide significant damage, although not in economic terms, for exposed people.

The damage assessment before or after the event is generally referred to populations, buildings, and infrastructures including economic and productive activities, taking into account all the direct and some of the indirect damages.

Concerning population, in pre-event damage assessment methods, damage is generally expressed in quantitative terms, through the number of dead and injured people determined as a percentage of the total involved population. At urban and territorial scales, this percentage is

generally obtained through statistical techniques, whereas at local scale it is specifically related to the expected damage level of building stock.

In the medium and long terms, the impact of the event on the population is expressed through the number of individuals that become homeless.

According to the close relationship between type and intensity of hazards and physical damages, natural hazard scales are based on the measure of damages produced in the built environment. For example, the Fujita Tornado Damage Scale was created to classify size and intensity of tornadoes in respect to the damages caused to man-made structures. Further examples are the Mercalli scale and the Parameterless Scale of Intensity (PSI) (Spence et al. 1991). Whereas the former is a discrete and subjective scale, the latter is a continuous one, based on curves which relate observed damage level in a given area to the intensity of the earthquake, for each structural type of building.

Generally, a damage scale classifies buildings into categories, ranging from complete destruction to no apparent damage. The scale of damage used by FEMA's HAZUS for earthquake, floods, and hurricane represents a widespread standard for post-event damage surveys. The HAZUS' damage models take into account both direct damages and some typologies of indirect ones, such as impacts on economic sectors over time, beds lost in hospitals, users not served by network services, and so on. The outputs are different for each type of hazard; for example, in case of earthquakes, direct losses in terms of repair costs, income losses, casualties, and shelter needs and indirect losses related to supply shortages, sales decline, or economic losses can be evaluated.

In the aftermath of disasters, damage assessment has been traditionally carried out through in-field surveys. Such surveys have some disadvantages, since the access to the affected areas is generally difficult in the immediate post event. Moreover, they require a long time to be applied, and although determined through analytic assessment forms, they can be influenced by the subjective judgments of the technicians. Some of the mentioned gaps can be overcome through remote-sensing damage assessment based on satellite and aerial images. These techniques allow the evaluation of the damage levels through quantitative methodologies based on remote-sensing characteristics observed from high-resolution optical imagery collected by satellites.

Furthermore, some techniques specifically addressed to evaluate functional damage have been developed, even though they are still in the early stages. These techniques are based on the assessment of the demand for activities and services arising after a hazardous event and the available supply in the impacted area. The balance between such components allows one to define the unsatisfied demand, which represents a measure of the functional damage (Galderisi and Ceudech 2009). These techniques can be helpful both for post- and pre-event assessment, mainly in relation to the loss in functioning of public equipments and infrastructures which, as mentioned above, is difficult to quantify in economic terms.

Conclusions

In summary, the different types of damages resulting from natural disasters in the built environment are at present largely recognized in scientific literature. Nevertheless, official reports and available databases generally focus on direct damages, whereas functional and systemic ones are mostly neglected. Furthermore, available techniques for the post-event assessment of physical damages are still mainly based on in-field surveys; damage assessment models based on remote-sensing techniques are however in development. With respect to medium and long-term systemic damages, data and standard assessment models are not currently available, even though some models are available in scientific literature.

Finally, the need for shifting from the couple hazard/physical damages towards the complex chains of hazards/physical, functional, and systemic damages, as well as for taking into account the role of the environmental resources into reports and data-bases on damage has to be emphasized.

Definition

A debris avalanche is a large volume, extremely rapid, and, therefore, highly destructive *mass movement* involving unconsolidated material.

Introduction

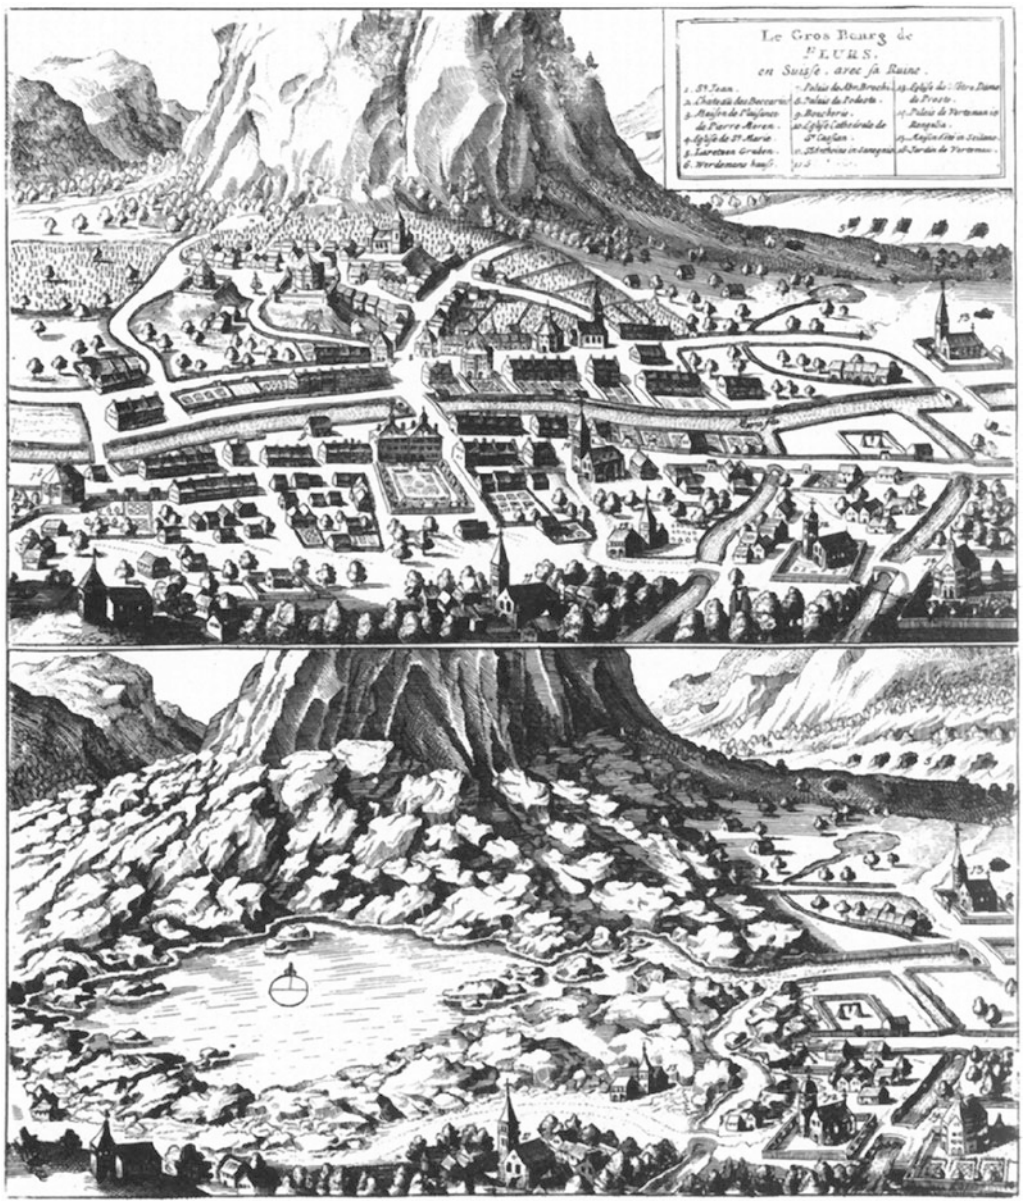
Historical occurrence of catastrophic landslides in the European Alps during the nineteenth century animated early popular interest in *natural hazard* phenomena and fostered the development of scientific studies on *slope stability*. Thanks to eyewitness accounts and precise landslide reports, well-known Swiss *sturzstroms* of Rossberg (A.D. 1806) and Elm (A.D. 1881) described by Heim (1932) offered some basic knowledge for interpreting previous historical cases (such as Piuro; Figure 1) and identifying distinctive characteristics of these sudden failures of mountain slopes: the large dimensions of the displaced mass (volume $> 10^6$ m^3), the long runout (L = horizontal movement: up to 20–30 times greater than H = vertical drop), and high velocity (up to 100 m/s). Later comparisons between historic and prehistoric case studies (Eisbacher and Clague, 1984) allowed for a better distinction between *sturzstroms* of granular or rocky materials (i.e., distinction between *debris* and *rock-avalanches*). Recurrent geomorphic features and sedimentological characteristics of debris avalanches were then used for characterizing slope instabilities throughout the world, either in mountain environments (Hsü, 1975) or volcanoes (Siebert, 1984), and even the submarine environment. Recent advances in planetary science reveal debris avalanches also affect other bodies in our solar system (Shaller and Komatsu, 1994).

Geo-environmental contexts and typology

Debris avalanches, as defined by past and present classifications of slope instabilities (Sharpe, 1938; Varnes, 1958, 1978; Cruden and Varnes, 1996), are large, extremely rapid, and often open-slope (non-channelized) landslides. They act as important agents in geomorphological landscape evolution of both mountain ranges and volcanic areas, where they may result either from earthquakes, volcanic activity, heavy rainfall, or snow melting.

Rugged mountains, like the Alps, are prone to large slope instabilities because of the widespread occurrence of oversteepened slopes, particularly where rock masses and surficial deposits are unstable due to recent glacier debuttressing and retreat, and to *permafrost* degradation. Debris avalanches are also frequently and extensively activated by gravity-induced slope failures in active volcanic areas where they can be related to magmatic or phreatic eruptions, or also can be triggered by earthquakes or precipitation.

Due to the broad environmental distribution, and, therefore, different expertise and approaches being applied in their study, debris avalanches have sometimes undergone inconsistent classifications with respect to distinctive features, styles of movement, and to rheologic behavior of involved material. So far, major apparent discrepancies are related to the thickness of deposits and the water content of debris avalanches, which have been defined either as "shallow flows of partially or fully saturated debris (. . .) without confinement in an established channel" (Hungr, 2005), or as "the products of large scale collapses of a sector of a volcanic edifice under water-undersaturated conditions" (Ui et al., 2000). The following geomorphological and sedimentological notes are useful to describe distinctive features of debris avalanches deposits of both volcanic and nonvolcanic contexts and to interpret their characteristic transport mechanisms as flows or complex slides according to the categories of Cruden and Varnes (1996).



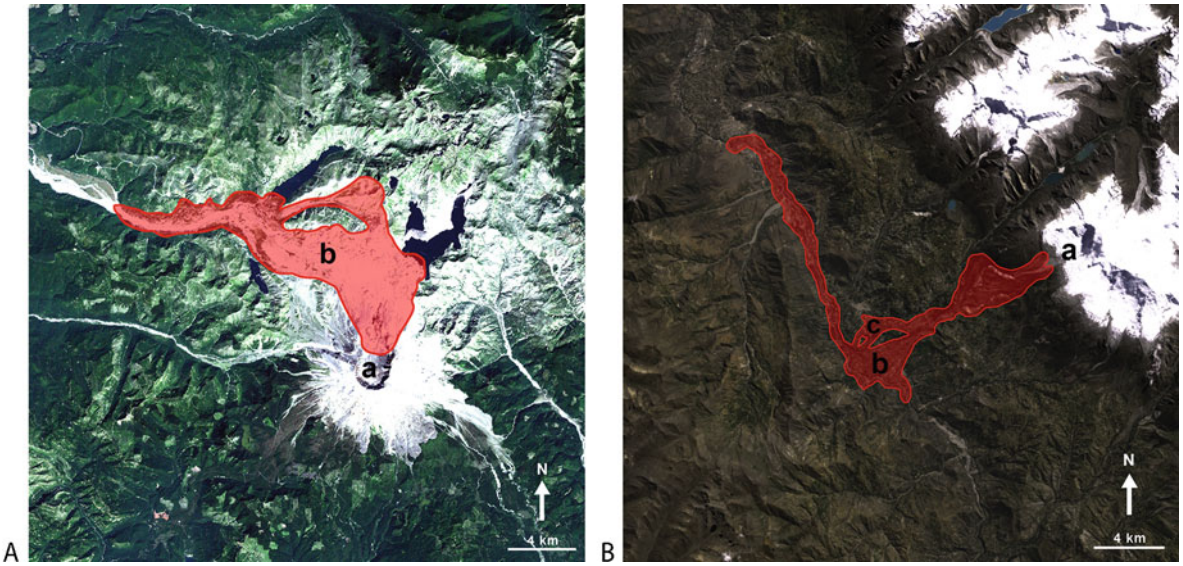
Geomorphological and sedimentological characteristics

Analysis of erosional and depositional features along the depletion, transport, and accumulation zones of debris avalanches allows outlining similarities and differences between types of volcanic and nonvolcanic environments (Figure 2).

As a general scheme, depletion zones of both types of slope instabilities are characterized by concave landforms, volcanic detachment scarps ("amphitheaters") being more arcuate in plan and gentler in profile than the nonvolcanic ones ("headscarps"). Arm-chair shaped volcanic amphitheaters can be strongly remodeled either by magmatic processes (i.e., new lava dome growth) or later gravitational instabilities. In all cases, initial detachment scarp height and slope steepness can be reduced by debris fall and accumulation.

Debris avalanche deposits from both types of environments are characterized by a hummocky topography, with hills and depressions, discontinuous drainage, steep-sided distal and lateral edges. If compared to the area covered by debris, thickness of the displaced mass is relatively shallow, but dimensions differ largely between different environments. It is a matter of scale: Volcanic debris avalanches may reach magnitude orders of 1 km^3 in subaerial conditions and > 10 km^3 in submarine conditions, maximum thickness of deposits exceeding 100 m. Debris avalanches in nonvolcanic mountain environments have been reported at smaller dimensions, up to 0.1 km^3. These relatively shallower deposits (average 10 m) can spread over the slope with no established channels.

Texture of debris avalanche deposits can be defined as that of a diamicton, whose unsorted materials include (coarse) clasts and (fine) matrix. Dimensional separation between these two phases is related to the size of debris avalanches: Clasts of large volcanic debris avalanches may reach hundreds of meters in diameter, average size of nonvolcanic ones being metric. As for the height of



Debris Avalanche, Figure 1 Historical illustration of an ancient sturzstrom: pre- and post-event of the Piuro landslide (September 4th, 1618; Central Alps, Italy; modified from the original illustration by J.J. Scheuchzer, Itinera per Helvetiae alpinas regions, Lugduni Batavorum, 1723).

hummocks, the size of volcanic debris avalanches clasts ("blocks") tend to decrease toward the distal part of the deposit. Internal structure of blocks often shows distinctive irregular fracture patterns (jigsaw cracks), a common characteristic also reported in nonvolcanic case studies. Debris avalanche matrix includes relatively finer deposits: usually sand or finer, but also gravel or larger, when smaller than the average dimension of clasts.

Granulometric heterogeneities and their distribution throughout the accumulation zones are distinctive features for interpreting overall kinematic characteristics of debris avalanches. Matrix abundance is larger at the base of the deposit, close to the contact with not-displaced material. Surficial abundance of highly fractured blocks, larger clasts concentrations along hummocks, and their topographical contrasts with flat, matrix-rich areas indicate progressive disintegration of materials during flow-like motion of debris avalanches.

Deposits are usually chaotic and heterometric, and usually do not display well-organized internal fabric. On the contrary, the deposits of the sturzstrom of Flims (Grisons, Swiss Alps) in the Rhine valley upstream of Chur show

Debris Avalanche, Figure 2 Outlines of debris avalanche runout: (**A**) the Mount St. Helens debris avalanche (WA, USA; May 18, 1980). a) volcanic detachment scarp ("amphitheater"); b) area of hummocky topography. the presence of a well-preserved fabric in areas that were not disorganized during the transport.

Type of movement

Used by itself, the term "avalanche" to describe landslide movements does not make specific reference to a particular material type or a single transport mechanism. It only relates to the overall kinematics of the displaced mass. Several dynamic emplacement models of debris avalanches have been proposed for interpreting different characteristics and distributions of the movement of loose materials through involved slopes.

Some authors invoked "air fluidization" phenomena to explain the long runout of debris avalanches of the coherent type and their peculiar features, such as frontal and lateral bulldozed edges, and internal preserved primary stratigraphy. A "hovercraft"-like mechanism was first proposed by Shreve (1968) in the case of Sherman Glacier, Alaska, where the rock/debris avalanche was interpreted to move over a cushion of trapped air. As an alternative view, progressive incorporation of air in the avalanching debris was postulated by Kent (1966). Also mechanisms of "pore fluid vaporization" due to frictional heating are able to increase gas pore pressure at the base of the debris avalanche, thus lowering the angle of friction and enhancing velocity. This is the case of Flims, Switzerland, where CO_2 gas, dissociated from carbonate rocks, provided lubricant for early movement of the landslide mass. The "air-controlled" emplacement modes appear to be not applicable to extraterrestrial and subaqueous debris avalanches, for which other mechanisms should be invoked.

The emplacement models by "mechanical fluidization" (Davies, 1982) refer to momentum exchanges between the particles of the debris avalanche, due to their collision. Cruden and Varnes (1996) interpreted the debris motion to be dependent on turbulent granular flow with dispersive stresses. Hsü (1975) pointed out the role of interstitial dust suspension in lowering effective normal pressure between flowing blocks, therefore reducing frictional resistance of dry debris. Also snow and ice can be incorporated into the debris avalanche to enhance fluidization, thus contributing to mobility of the displaced mass, such as in the case of Huascaran, Peru (May 31, 1970), where peak velocities over 100 m/s were reached (Plafker and Ericksen, 1978).

Mountain debris avalanches are mainly generated under water-undersaturated conditions. Greater mobility and larger volumes of debris avalanches in volcanic areas seem to be related to more frequent and widespread conditions of altered and water-saturated materials. In such an environment, larger spreading debris avalanches are generated due to direct proportional relationships between volume of the displaced mass, area covered by the debris, and runout length. Bingham plastic flow models have been proposed for several debris avalanches on volcanoes. They are comparable to viscoplastic materials behaving as rigid bodies at low stresses. By increasing stress they approximate a threshold to a viscous fluid behavior. The sequence of activated movements usually starts with sliding phenomena followed by plug flow.

When the behavior of a rock/debris avalanche during transport is not homogeneously characterized by strong interactions between particles, the granular flow can approximate a nonturbulent type. Here, clasts can be very angular in shape and original fabric of slope material

Debris Avalanche, Figure 3 Effects of the Huascaran debris avalanches (Perù), event of May 31, 1970. (**a**) hummocky topography; (**b**) devastated buildings and (**c**) bus at Yungay; (**d**) damaged tree stump, and debris avalanche deposits (photo by W. Alberto, 2008).

somehow preserved, as suggested by Schneider et al. (1999) for the cases of Flims, Switzerland, and Blackhawk, California. In other cases, grain-size segregation during granular flow causes pseudo-stratification of debris avalanches deposits (Fineberg, 1997). Flow transformations are particularly evident in distal and lateral parts of the deposits, where the internal structures of debris accumulation disappear.

The role of basal lubricant for debris avalanches also can be achieved by other fluidized materials; sand or finer materials can be "trapped" beneath the avalanche debris after having been eroded by the moving landslide mass.

Hazards and risks

Spatial and temporal occurrences, and magnitude of instability events, are key factors controlling hazards and risks derived from debris avalanches. Hazards assessment studies should also address the recognition of possible emplacement modes and triggering mechanisms related to specific environmental contexts. As shown elsewhere large-scale volcanic debris avalanches are of higher magnitude than nonvolcanic ones. Larger mobility and volume of mobilized materials lead to wider affected areas that can be assessed by using H/L diagrams, showing the relationships between the maximum collapse height and the runout distance. By analyzing volcanic instabilities, attention has to be paid also to the evidence of transformed flows, that is, from debris avalanches to debris/mud flows or to lahars. The collapse of the north side of the volcanic edifice of Mount St. Helens during the cataclysmic eruption of the May 18, 1980, caused a massive 2.8 km^3 rock-slide/debris avalanche that traveled 28 km from its source (Voight et al., 1985). Associated debris flows (*lahars*) and muddy stream flows traveled farther, extending the damaged area northwestward, when the water-saturated parts of the massive debris avalanche deposits began to slump and flow.

Other intensity parameters, such as velocity and flow depths, should be also estimated in order to assess derived parameters such as run-up of mass from instable slopes and area of possible impacts on structures. In the case of the Huascaran debris avalanches (Perù), a first event (January 10, 1961) had limited damaging impacts due to lower magnitude and thanks to the protective effect of a 240 m-high ridge near Yungay; the subsequent event (May 31, 1970) of higher magnitude (3,800-m total height, 16-km runout; Figure 1b), overtopped the ridge, and Yungay and Ranrayrca were devastated (Figure 3a–d). Casualties were up to 18,000 people, associated debris flows filled Rio Santa and flowed 160 km downstream to the Pacific Ocean.

DEBRIS FLOW

Oldrich Hungr
University of British Columbia, Vancouver, BC, Canada

Definition

Debris flow is an extremely rapid, flow-like mass movement, traveling in a steep, established channel and involving a saturated, unsorted mixture of granular soils, organics, and other debris (Hungr et al., 2001).

Most steep natural slopes are mantled by varying thickness of colluvial soils, disturbed by surficial phenomena known collectively as soil creep, as well as small-scale landslides. Colluvium naturally accumulates in depressions and near the thalweg of steep low-order drainage channels, where it is likely to become saturated during high infiltration periods. During the same period of high near-surface groundwater pressures, a local slope instability such as a debris slide from a steep gully headwall or an erosion-undercut side slope above the channel can occur. The moving debris impacts the steep floor of the channel, instantly increasing total stresses on the saturated colluvium, or poorly sorted channel deposits accumulated there. Given the rapid occurrence of such loading, even pervious granular materials cannot drain quickly enough, and excess pore pressures are generated. As a result of this "rapid undrained loading" mechanism, the colluvium on the gully floor is destabilized. It joins material already in motion, and a translating wave of liquefied debris continues downslope (e.g., Johnson, 1970; Sassa, 1985).

In addition to debris slides, initiation can occur as a result of rock fall impact, or by the spontaneous shear failure of the steep bed of the channel, carrying heavy flood flow. Because the initiation typically occurs during a period of unusually intensive precipitation or snowmelt, multiple, near-simultaneous initiation in several branches of a steep drainage system often takes place (Figure 1).

As the resulting flow-like mass movement progresses downslope, the rapid loading cycle is continuously repeated, as long as the slope remains sufficiently steep

Debris Flow, Figure 1 Multiple debris flow initiation points and converging channels in a Rocky Mountains, Alberta, Canada, mountain drainage.

Debris Flow, Figure 2 Bouldery levee created by a debris flow surge in Kyrghistan. The boulders in the center of the photo are approximately one meter in diameter.

and loose saturated material is available. Often, the entire length of the steep segments of zero and first- or second-order channel is scoured of loose material, and the debris flow "surge" grows to a volume far exceeding that of the initial slide (Hungr et al., 2005). While entraining saturated solid material, the debris flow surge also overtakes and incorporates surface flow from the channel, becoming progressively more diluted.

Flow of saturated liquid debris in a steep channel is not a stable process. Surges form either by longitudinal sorting and accumulation of coarse clasts (Iverson, 1997) or by increasing turbulence where the flow depth is large (Davies, 1986). Either process leads to the development of "surges," characterized by a steep front consisting either of a concentration of boulders ("a moving dam") or a zone of highly turbulent flow. The passage of a bouldery front often creates a ridge-like "levee" deposit along the margins of the channel (Figure 2). Behind the front, the surge attains a shorter or longer region of maximum depth, containing fairly dense liquefied material and often flowing in a macroscopically laminar regime and a tapering "tail" or "intersurge flow," where the flow becomes more highly diluted and turbulent (Pierson, 1980).

The surge building process is the most important aspect of debris flows, as it magnifies the flow depth and thereby peak discharge. While a debris flow surge may not travel much faster than an extreme water flood flow in the same steep channel, its peak discharge may be several tens of times greater than the peak discharge of a flood. Typical flow parameters of debris surges in the coastal region of British Columbia are peak discharge of 300–500 m^3/s, velocity of 10–15 m/s, and flow depth of 2–5 m. Thus, debris surges are capable of vastly greater impact and potential damage than even the most extreme water floods.

Due to the presence of multiple initiation points and contributing channels, as well as the erratic time development process of surge building, many debris flow "events" consist of multiple and sometimes periodic surges, separated by periods of flood flow.

Heavy water floods in steep channels can also transport large quantities of sediment, often in the form of bulk channel instability driven by the tractive forces of overflowing water. Some writers suggested using peak discharge as a criterion to distinguish between a "debris flood" and "debris flow" (Aulitzky, 1980; Hungr, 2005). A debris flood has a peak discharge of the same order as a hydrologic flood wave. It may transport large quantities of sediment but is limited in its ability to transport very large boulders and inflicting damaging impacts on trees and structures. A debris flow at peak discharge is much deeper, can transport boulders several meters in diameter, and destroys objects in its path (Figure 3). Many events contain individual surges that can be classified as debris floods, in addition to those that are true debris flow surges. Usually, the latter dominate in terms of resulting damage.

Debris surges traverse and erode material from steep channels and then gradually deposit on "debris fans." Debris fans can be recognized and distinguished from alluvial fans by high steepness, extremely poor channel stability, and the presence of very large clasts in the deposits (Figure 4).

Debris flows are ubiquitous in mountain drainages and on steep slopes everywhere, particularly where concentrated periods of high precipitation occur and good supply

Debris Flow, Figure 3 A large boulder deposited by a debris flow in Taiwan.

Debris Flow, Figure 4 A debris fan in the Coast Ranges, British Columbia, Canada.

of unconsolidated colluvium exists. Because it is such a common process, debris flow is responsible for considerable losses in terms of fatalities, destruction of structures, and, most often, interruption and damage to infrastructure such as roads and railways. This type of damage exacts a steady toll in all regions with steep slopes. Sometimes, juncture of unfavorable circumstances, especially in terms of extreme rainfall, creates clusters of debris flows that can devastate an entire region. For example, the 1999 debris flows on the northern slopes of the Aquila Range in the Venezuelan state Vargas claimed approximately 30,000 fatalities among the inhabitants of several debris fans in the area (Larsen and Wieczorek, 2006).

DEEP-SEATED GRAVITATIONAL SLOPE DEFORMATION

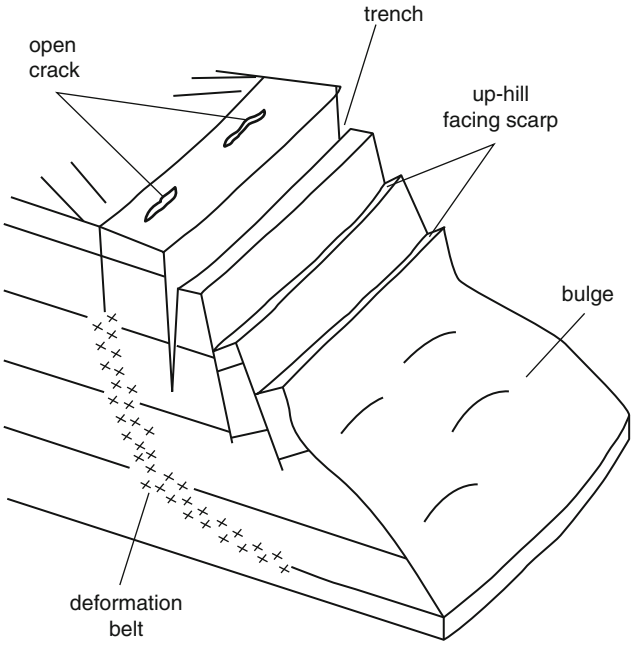
Mauro Soldati
Università degli Studi di Modena e Reggio Emilia, Modena, Italy

Definition

A deep-seated gravitational slope deformation (DGSD) is a gravity-induced process affecting large portions of slopes

evolving over very long periods of time. A DGSD may displace rock volumes of up to hundreds of millions of cubic meters, with thicknesses of up to a few hundred meters.

Introduction

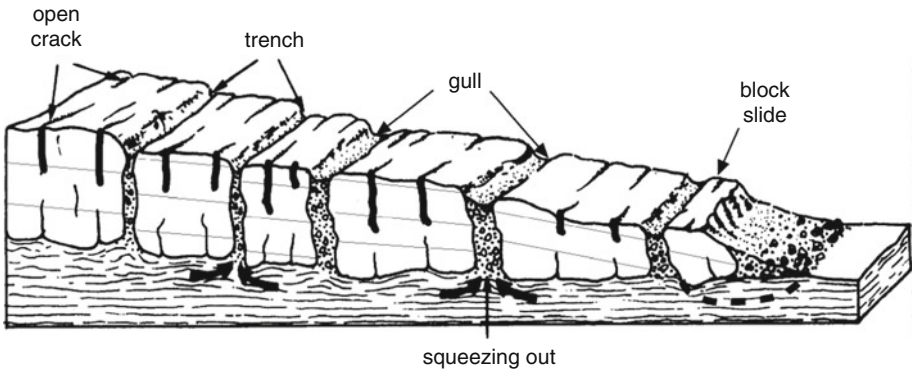


Deep-seated gravitational slope deformations (DGSDs) are not considered hazardous phenomena because they evolve very slowly. However, they must not be neglected when defining slope instability in a territory and the related hazard implications. Despite their slow deformation rates, DGSDs may cause damage to surface and underground (e.g., tunnels) structures. In addition, they may evolve into faster mass movements or favor collateral landslide processes.

Causes

Deep-seated gravitational slope deformations are often recognized in formerly glaciated valleys and in seismically active mountain regions. The occurrence of DGSD is generally related to tensional stresses induced by gravity in steep-sided valleys which can be linked to (1) unloading of oversteepened slopes due to glacier retreat or fluvial downcutting, (2) presence of discontinuities of tectonic origin (joints, fractures, etc.), and (3) seismic activity (Kostak and Avramova-Taceva, 1981; Dramis and Sorriso-Valvo, 1983, 1994; Bisci et al., 1996; Pasuto and Soldati, 1996; Agliardi et al., 2001; Gutiérrez et al., 2008). Displacements related to DGSDs occur due to the presence of deformation belts at depth, where the rock mass is affected by micro-fractures (Radbruch-Hall, 1978). The main feature that distinguishes DGSDs from landslides s.s. is the absence of a continuous or well-defined sliding surface.

The term "deep-seated gravitational slope deformation" was firstly used by Malgot (1977). Alternative definitions for DGSD include *sackung* (Zischinsky, 1966), *gravity faulting* (Beck, 1968), *depth creep of slopes* (Ter-Stepanian, 1966, 1977), *gravitational slope deformations* (Nemčok, 1972), *deep-seated creep deformations* (Mahr and Nemčok, 1977), *gravitational block-type movements* (Pasek, 1974), or *gravitational spreading* and *gravitational creep* (Radbruch-Hall, 1978).

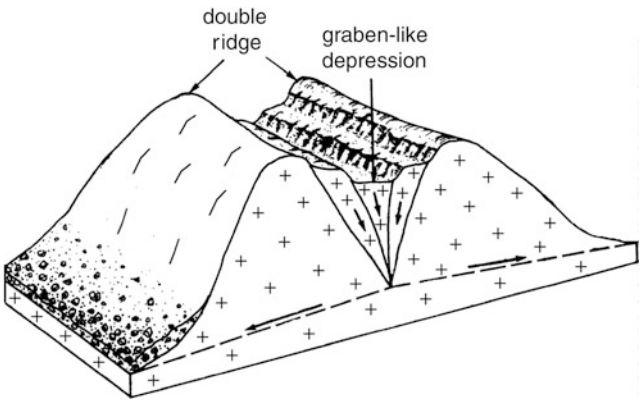


It is worth mentioning an earlier contribution to the definition of the processes involved in DGSDs by Terzaghi (1950), who showed the difference between "landslide" and "creep." According to Terzaghi, a "landslide" occurs along a well-defined sliding plane when the stress conditions for failure are satisfied, whereas "creep" is a continuous process characterized by undefined boundaries between stationary and moving material. This implies that the deformation/creep phase may be naturally followed by a sliding and much quicker phase. Though the temporal evolution from a deformation phase to a sliding phase is generally hard to predict, and possibly extremely long, the hazard implications become clear. Furthermore, as far as hazard is concerned, it should be noted that the presence of deep-seated gravitational deformations within a rock mass also favors the onset of collateral slope movements (e.g., rock falls, rock topples, block slides, etc.), which are likely to occur suddenly. If this takes place in inhabited areas, risk issues may have to be faced.

Deep-seated Gravitational Slope Deformation, Figure 1 Sackung (After Bisci et al., 1996; modified).

Types

Two main types of DGSDs can be outlined: *sackung* and *lateral spreading*. Sackung (or rock flow, according to the landslide classification by Cruden and Varnes, 1996) refers to the sagging of high and steep slopes due to visco-plastic deformation occurring at depth (Zischinsky, 1969; Bisci et al., 1996). Homogeneous and jointed or stratified rock masses, characterized by a brittle mechanical behavior, are generally affected by this type of DGSD. As a result of the deformation, typical sackung morphological features are twin ridges, trenches, gulls, and uphill-facing scarps in the upper part of the slopes as well as bulges in the medium and lower parts of the slopes (Figure 1). In addition, subhorizontal joints can be found at the lower edge of the slopes. In spite of a general agreement on the morphological features which characterize a sackung, there is still some uncertainty and dispute on the kinematics of the process. However, the development of deep-seated deformations is generally referred to the rock mass behavior at depth which is different from that at surface, owing to the higher confining pressure. Two main displacement models have been proposed. One the one hand, it is assumed that a high confining pressure does not allow the formation of well-defined shear surfaces at depth (Mahr, 1977), enabling only viscous deformations to take place (nonshearing model). This generally occurs



Deep-seated Gravitational Slope Deformation, Figure 2 Lateral spreading affecting brittle rock masses overlying ductile terrains (After Pasuto and Soldati, 1996; modified).

at the central parts of the slope, whereas at the top and toe of the slope, shear surfaces may still develop due to lower confining pressures. On the other hand, it is stated that the deformation zone is indeed interrupted along a shear surface located at the base of the unstable rock mass (plastic failure model) (Savage and Varnes, 1987).

Lateral spreading (or rock spreading) consists of lateral expansions of rock masses occurring along shear or tensile fractures. Two types of rock spreading can be distinguished which occur in different geological conditions (Pasuto and Soldati, 1996).

The first type refers to lateral spreading affecting brittle rock masses overlying ductile terrains. It may extensively affect rock plateaus, the effects being most evident at their edges. The spreading process is generally caused by the deformation of the underlying material and favored by slope or cliff downcutting. The deformation takes place through horizontal displacements along tensile fractures or subvertical tectonic discontinuities (Conti and Tosatti, 1996). Trenches, gulls, grabens, karst-like depressions in the brittle rocks and bulges in the weaker material are typical morphological features of lateral spreading (Figure 2). The overburden of the rock slabs is generally assumed as the cause of long-term deformation affecting the underlying terrains. As a result, squeezing out of the weaker rock types and rock block spreading due to tensile stresses take place. The process may be accelerated by water percolation through the fissures and consequent softening of the weaker materials. Lateral spreading phenomena are often accompanied by collateral slope movements occurring at the edges of the plateaus, such as rock falls and topples, block slides, and earth flows. Downcutting of valleys may favor the onset of these movements. The process may continue for long periods and cause progressive spreading and dismembering of rock plateaus.

The second type of lateral spreading occurs in homogeneous, and usually brittle, rock masses and has mostly been recognized in mountain areas with high relief energy. The spreading process generally occurs without a well-defined basal shear surface or zone of visco-plastic flow. As a result of the deformation process occurring at depth,

Deep-seated Gravitational Slope Deformation, Figure 3 Lateral spreading in homogeneous rock masses (After Pasuto and Soldati, 1996; modified).

double ridges, uphill-facing scarps, ridge-top depressions, and infilled troughs can be found at surface (Figure 3). The presence of joints in the rock mass is considered as a predisposing factor, but the mechanics of the deformation has not yet been well defined.

Hazard implications

Sackung and lateral spreads may evolve into faster mass movements due to various causes (e.g., earthquakes), and therefore, their presence should be adequately taken into account in landslide hazard assessment (Coltorti et al., 1985; Hewitt et al., 2008). As a matter of fact, sackung may evolve into rotational/translational slides or into rock/debris avalanches, inducing possible risk situations due to the potential high velocity of these mass movements. On the other hand, lateral spreads tend to evolve in slower movements, such as block slides occurring at the edges of the areas affected by the spreading. Nevertheless, the possible occurrence of collateral landslides favored by the lateral spreading (e.g., rock falls, rock topples, earth flows, and slides) should not be overlooked when landslide hazard has to be assessed;

these phenomena are likely to be connected with the modifications of the groundwater flow net and the stress conditions related to the active deep-seated deformations.

The awareness of the role that DGSDs can play on slope instability is fundamental when stabilization and monitoring of single landslides are to be planned. If the influence of deep-seated deformations is not considered, mitigation measures may result incomplete and noneffective in long terms. It is clear that resolving interventions aiming at the mitigation of the effects of deep-seated gravitational deformations are hard to envisage due to the large size of these phenomena. However, the application of new methods for the detection, survey, and monitoring of DGSDs is very important to understand the kinematics of the movements and foresee possible evolution scenarios. In this respect, a geomorphological survey, accompanied by high-precision topographic measurements (e.g., by means of the GPS technique), LIDAR surveys, and interferometric analyses of radar images, may provide significant outputs with respect to the areas affected and volumes involved in DGSDs, as well as on the displacement rates and trends. Structural and geomechanical analyses of the rock masses are also very important to understand the lithological and tectonic control on DGSD onset and development.

Recently, the importance of the recognition of DGSDs morphological features, especially those related to sackung, has been acknowledged in paleoseismic investigations. Actually, sackung features may represent natural archives of the recurrence of high-intensity paleoearthquakes, providing useful information for seismic hazard assessment (Gutiérrez-Santolalla et al., 2005; Gutiérrez et al., 2008). The causal and chronological relationship between sackung features and earthquakes has been shown in terms of generation and/or reactivations of sackung scarps during historic earthquakes (McCalpin and Hart, 2003; Moro et al., 2007). Therefore, timing of sackung features caused by earthquakes, as determined by trenching and radiocarbon dating of sediments, can improve existing paleoseismic catalogues. The use of this technique can be particularly important where seismogenetic faults are buried, blind, or have scarce geomorphological evidence which makes conventional paleoseismic investigations difficult. It should be added that geomorphological features generated by DGSDs, such as double ridges and scarps, are frequently interpreted as of tectonic origin. This may lead to seismic hazard overestimations with significant economic implications (Bovis and Evans, 1995) and proves the importance of detecting the role of gravity in shaping these features for a correct and reliable hazard assessment.

DESERTIFICATION

Nicholas Lancaster
Desert Research Institute, Reno, NV, USA

Synonyms

Land degradation; Loss of productivity

Definition

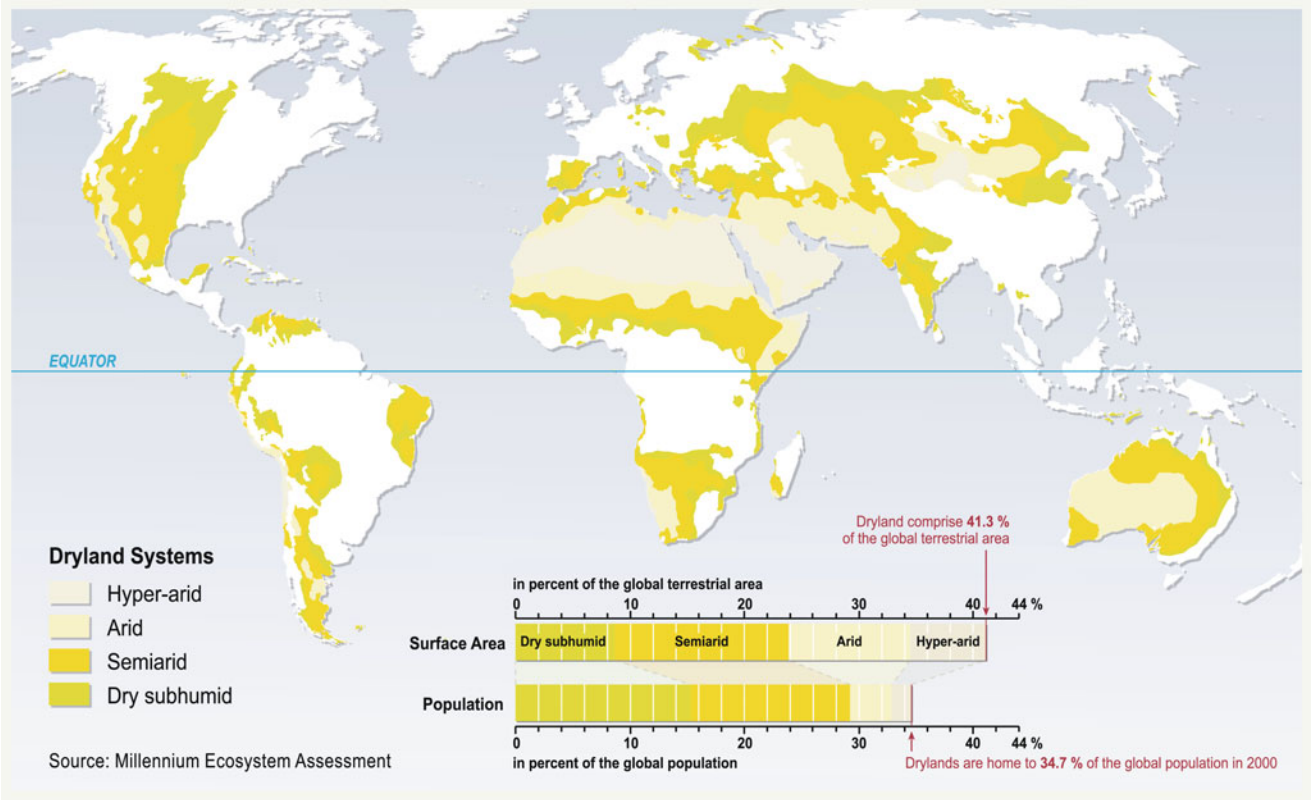
There are many definitions of desertification, but the most widely used is that adopted by the United Nations Convention to Combat Desertification (UNCCD) http://www.unccd.int/, which defined desertification as land degradation in drylands (arid, semiarid, and dry subhumid areas) resulting mainly from adverse human impact and climate variability (Safriel and Adeel, 2005).

Introduction

Drylands, defined as areas in which the ratio between precipitation and evapotranspiration is less than 0.75, cover as much as 47% of the world's land surface (Figure 1) and are home to over one billion people (Ezcurra, 2006). Following the UNEP definitions, drylands include areas classified climatically as hyperarid to dry subhumid. Drylands are fragile environments that experience great natural variability in climate and are easily affected by natural disturbance and anthropogenic stressors. In many areas, they are being impacted by a rapidly growing and increasingly urban population. One manifestation of natural and environmental stress in drylands is the phenomenon of desertification, a term originally used by French colonial scientists to describe environmental degradation in dry areas of West Africa. Although land degradation in drylands has been occurring locally for millennia, the problem gained prominence and recognition by the international community in the 1970s following severe drought in the Sahel region of Africa and with the United Nations Conference on Desertification held in Nairobi, Kenya, in 1977. Desertification is, however, a concept that encompasses a variety of physical and biological processes, none of which are restricted to drylands, but which take on a particular form in such areas (Thomas and Middleton, 1994).

Causes of desertification

Desertification involves the degradation of ecosystems by a combination of natural disturbance (e.g., droughts) and human stress (e.g., overgrazing, inappropriate land use). The result is a persistent reduction in the level of productivity and ecosystem services over an extended period. Desertification occurs when the natural resilience of dryland ecosystems to disturbance is impaired by anthropogenic stressors, so that it is unable to revert in the short term to its prior state when the stresses are relaxed (Whitford, 2002).



In their natural state, dryland ecosystems are resilient to natural disturbances such as drought and fire. Likewise, traditional land-use practices such as nomadic pastoralism, hunting of wildlife, and localized rain-fed agriculture have evolved to cope with a highly variable environment. Socioeconomic changes, including population growth, settling of previously mobile populations, imposition of political borders, commercial (often export-oriented) agriculture and livestock raising, provision of permanent water sources (wells and boreholes) together with poor land-use practices, such as overgrazing, fuel wood extraction, excessive irrigation, and cultivation of marginal land, impose stresses on ecosystems such that their resilience to disturbance is impaired. The result is loss of biologic and economic productivity (Adeel et al., 2005).

Occurrence of desertification

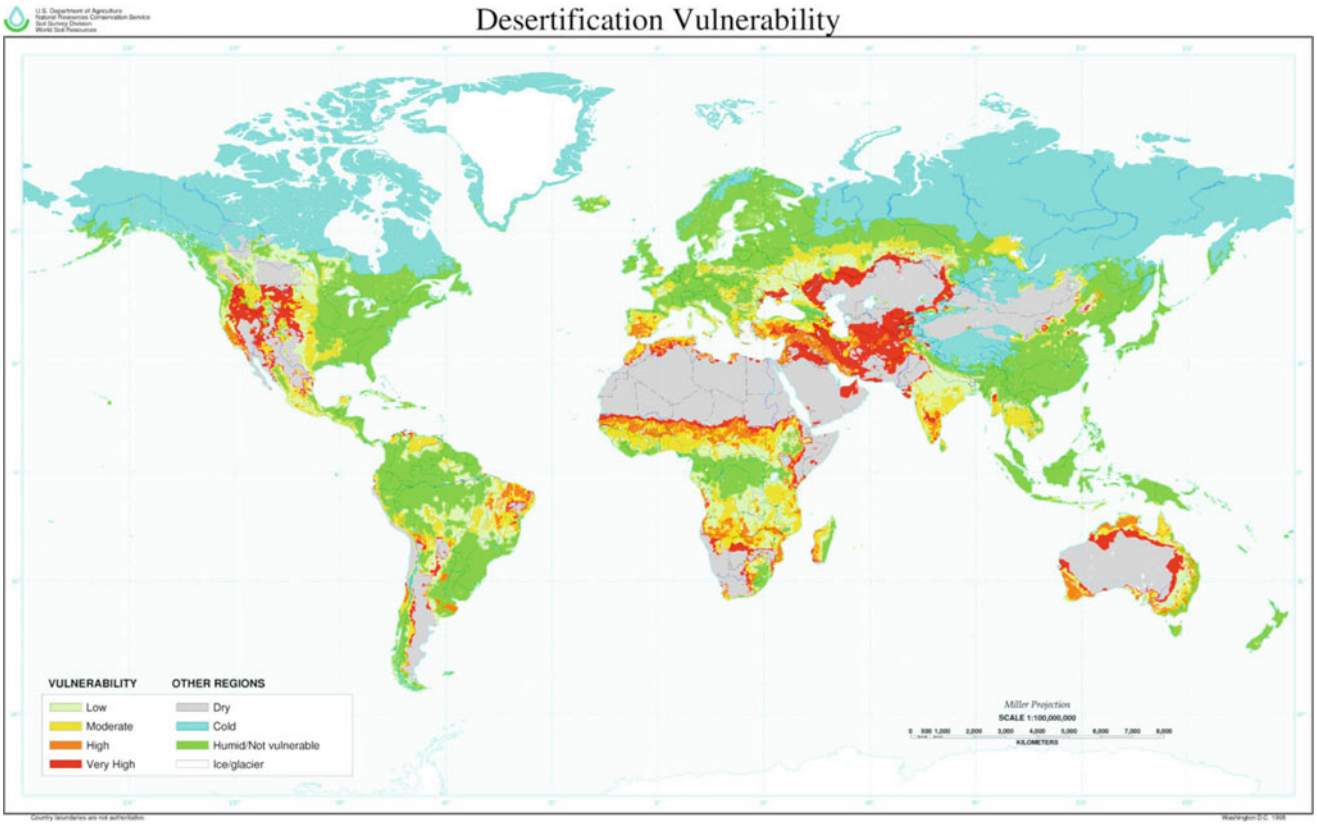
According to the UNEP, 70% of the world's drylands (excluding hyperarid deserts), or some 3,600 million hectares, are estimated to experience varying degrees of desertification. The most vulnerable areas occur where human pressures combine with fragile ecosystems and soils, and tend to be concentrated in semiarid or desert margin areas (Figure 2). Over 250 million people are directly affected by desertification. In addition, at least one billion people in over 100 countries are at risk. These people include many of the world's poorest, most marginalized, and politically weak citizens.

Ecological effects of desertification

Land degradation in drylands takes many forms, manifested by physical changes such as reduction in vegetation cover, changes in the types of plants, loss of soil

Desertification, Figure 1 Global extent of drylands From http://www.maweb.org/documents/document.355.aspx.pdf.

by wind or water erosion, and changes in plant nutrient distribution. Some of these changes can result in loss of primary productivity. In many areas, lower productivity is measured by reduced carrying capacity for livestock as a result of changes in the amount and composition of vegetation. For example, perennial grasses may be replaced by unpalatable or inedible shrubs, as documented in the Southwestern USA, southern Africa, and parts of Australia. Replacement of grassland by shrubs, partly as a result of overgrazing, may lead to a progressive and irreversible reorganization of soil and water resources at a landscape scale (Figure 3). Formerly widely distributed nutrients and water are concentrated into a series of "islands" of productivity nucleated by shrubs (Schlesinger et al., 1990). The intervening bare areas are subject to increasing erosion by wind and/or water, so creating a series of positive feedback loops that lead to a highly degraded and functionally different ecosystem.



This process is well documented from the southwestern USA, where in the Chihuahuan Desert, grasses have been gradually replaced by mesquite shrubs over the past 50–100 years, with important consequences for ecosystems and geomorphic processes (Okin et al., 2001). In the Jornada area of New Mexico, the mesquite shrubs anchor coppice dunes separated by "streets" of high sand transport rates (Okin, 2008).

Grazing also damages or destroys the biological soil crusts that are important in stabilizing soils, reducing wind and water erosion, and fixing nitrogen in many desert regions. In southeastern Utah, even after 30 years without grazing, soils in areas that have been historically grazed have much lower contents of organic matter and primary nutrients, compared to areas that have never been grazed, suggesting that livestock grazing promotes increased wind erosion which reduces soil productivity in native grasslands (Neff et al., 2008).

Land degradation as a result of fire and grazing pressure may also lead to replacement of native species by invasive or exotic species. In the Great Basin of the USA, the perennial sagebrush steppe is being invaded by exotic annual grasses such as *Bromus tectorum* (cheat grass), which leads to an increase in fire frequency and inhibits recolonization by native grasses and shrubs after fires (Smith et al., 2000).

Physical effects of desertification

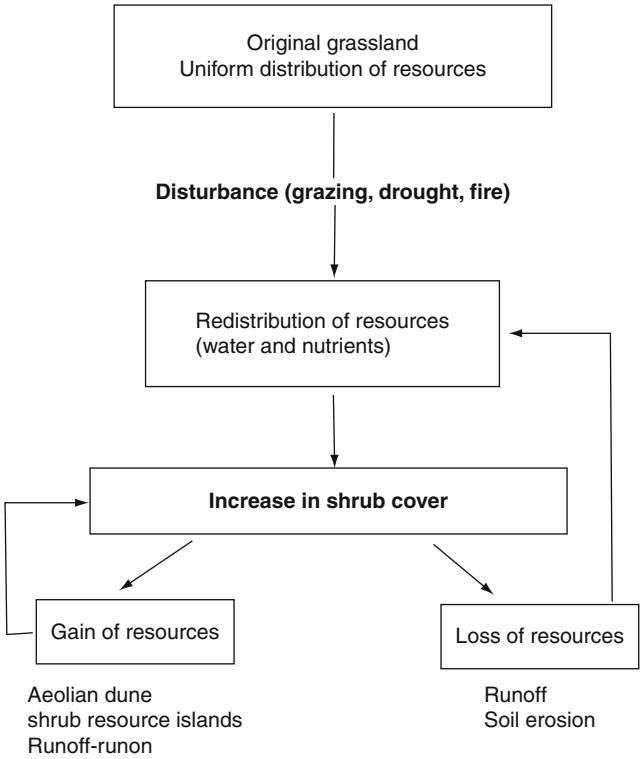
Desertification rarely involves the expansion of existing deserts, represented most dramatically by encroachment of active (mobile) sand dunes. Despite reports of "spreading deserts" in the Sahel region of Africa and western China, there is little scientific evidence to support such assertions (Thomas and Middleton, 1994).

Desertification, Figure 2 Global extent of desertification vulnerability – after NRCS 2003: http://soils.usda.gov/use/worldsoils/mapindex/desert.html.

Overgrazing and fire may combine with drought to reduce vegetation cover on sand dunes so that sand transport becomes more active and more widespread. Localized reactivation of vegetation-stabilized dunes has been documented from western China (Wang et al., 2008) and the Sahel region of Africa (Niang et al., 2008).

Increased sand transport, mainly as a result of a sparse vegetation cover, may also increase the occurrence of dust storms, as saltating sand grains impact fine-grained soils. An increase in the frequency of dust storms was observed during the Sahel droughts of the 1970s (Prospero and Lamb, 2003). Areas of fine-grained soils that are subject to rain-fed agriculture are particularly susceptible to wind erosion, as in the Dust Bowl of the USA in the 1930s (Goudie and Middleton, 2006) and further in the 1970s (Lee and Tchakerian, 1995).

In many areas, reduction of vegetation cover, or replacement of grasslands by shrubs on hillslopes, reduces infiltration of rainwater and leads to increased surface runoff and loss of soil (Abrahams et al., 1995). In extreme cases, extensive networks of gullies may result.



Salinization of soils is a further physical expression of desertification, resulting mainly from poor irrigation practices. Excessive application of water leads to accumulation of salts in the soil to levels that are toxic to plants. Leakage from unlined irrigation canals contributes to a rise in the water table unless countered by drainage systems.

Social dimensions of desertification

It is widely assumed that desertification is a consequence of human activities. Reduction in the productivity of drylands has many adverse effects on the populations of these areas, leading to widespread and far reaching social, economic, and political repercussions (Adeel et al., 2005; Reynolds et al., 2007). Reduced productivity of drylands leads to lower food production, competition for scarce resources, and an increase in poverty; subsistence agriculture and cattle raising are no longer viable, so people are forced to migrate to urban areas. Lack of opportunities may lead to political instability and emigration to more developed countries. A cycle of increasing poverty and loss of livelihood ensues. Even in developed nations such as the USA and Australia, land degradation and loss of agricultural productivity in drylands have serious economic consequences.

Climate change and desertification

Hydroclimatological observations show that changes in seasonal and annual temperature, precipitation, runoff,

Desertification, Figure 3 Conceptual model for progressive degradation of arid ecosystems (After Whitford, 2002).

groundwater recharge, and evapotranspiration are occurring today in most deserts and models predict that they are likely to continue in the future. Many drylands are already experiencing significant increases in temperature and a reduction in rainfall over the past two decades, manifested in extended droughts. Climate models differ in their predictions for drylands: Some may enjoy increased rainfall as monsoon circulations are enhanced, but this effect is offset by higher temperatures. Increased variability of climate will likely result in more frequent and severe drought conditions. Because human pressures in many areas are increasing, dryland ecosystems will be less resilient to natural disturbance in the future, resulting in an enhanced vulnerability to desertification and its physical, biological, and human consequences (Safriel and Adeel, 2005).

Disaster-conflict nexus; Disaster politics; Disasters and political change

Definition

Disaster diplomacy examines how and why disaster-related activities (e.g., mitigation, prevention, response, and recovery) do and do not reduce conflict and support peace.

Overview

Disaster diplomacy research and application (see http://www.disasterdiplomacy.org) examines how and why disaster-related activities do and do not reduce conflict and support peace. Disaster-related activities include pre-disaster actions, such as prevention, mitigation, preparedness, and planning. Disaster-related activities also include post-disaster actions, such as response, recovery, and reconstruction. The range and scale of investigation and use is wide, including countries at war with each other to communities suffering internal conflict.

This field is investigated mainly through scientific research seeking policy recommendations, but practitioners have also advanced and used disaster-diplomacy knowledge (e.g., Renner and Chafe, 2007). Approaches take mainly two forms: specific case studies and overall analyses seeking patterns and predictions.

Case study examples include India-Pakistan after the 2001 Gujarat and 2005 Kashmir earthquakes, collaboration across the Middle East on seismic building codes, the internal conflicts in Sri Lanka and Aceh (Indonesia) after the 2004 tsunamis, and Cuban and American scientists collaborating on hurricane prediction and monitoring.

The case studies examined indicate that disaster-related activities do not create new approaches to conflict resolution. If, however, ongoing connections amongst antagonists exist on a solid basis, disaster-related activities in the short term can be the catalyst to turn those connections into hopes for peace. Examples of connections are peace negotiations, the desire for trade links, or a topic of common concern such as pollution or another enemy.

Over the long-term, non-disaster factors tend to overtake any disaster-related influences on peace. Examples are leadership changes, prominence of an historical conflict or grievance, or continuing distrust. As a result, disaster-related activities can exacerbate conflict, especially when a disaster has raised expectations of peace immediately following the calamity.

Work on disaster diplomacy also covers theories and patterns underlying the case study observations. Such work helps to understand why case studies do not yield disaster diplomacy. It further contributes to attempts at predicting what could occur in instances or circumstances under which disaster diplomacy might be more successful.

Explanations include why governments, organizations, or people involved in disaster diplomacy select specific pathways that try to promote or inhibit disaster-related reconciliation. Other approaches to developing typologies and explanations for disaster-diplomacy case studies cover the proximity of those involved in disaster diplomacy (e.g., if countries are involved, do they border each other?) along with their aid relationships (e.g., a donor-recipient situation or mutual aid).

The reason why disaster-related activities usually fail to support peace are complex, often involving the long histories of the parties involved and the personalities and personal interests of the current leaders. Overall, the evidence suggests that dealing with disasters appropriately and seeking peace are not always the first priorities of those involved. Consequently, disaster diplomacy has good intentions but is not likely to succeed often.

DISASTER RELIEF

Jane Carter Ingram
Wildlife Conservation Society, Bronx, NY, USA

Synonyms

Disaster assistance; Disaster response

Definition

Disaster relief refers to interventions aimed at meeting the immediate needs of the victims of a disastrous event. Disaster relief commonly refers to aid that can be used to alleviate the suffering of national or foreign disaster victims. It often includes aid or assistance in the form of humanitarian services and transportation; the provision of food, clothing, medicine, medical services, beds, and bedding; temporary shelter and housing; and making repairs to essential services such as electricity, water supplies, and phone lines.

Discussion

Disaster relief, often commonly referred to as disaster response, is an intermediate phase of several phases in disaster management, which include (1) mitigation, (2) preparedness, (3) relief, or response, and, (4) recovery (the longest phase). Relief in this context comprises the range of actions that are necessary during the critical period immediately following a disaster when infrastructure has been damaged, communication lines have been destroyed, access to services such as electricity and water has been compromised, people have been injured and/or

separated from their families, and victims' homes, assets, and/or livelihoods have been lost or damaged. Disaster relief entails ensuring that people's immediate needs such as food, shelter, and medical assistance are met, first and foremost. Relief efforts also include reconnecting severed social networks through helping people locate their family, friends, and/or loved ones if they have been separated from one another. In order to meet these basic physical and social needs, disaster relief operations may involve clearing rubble from damaged infrastructure, extinguishing fires, repairing damaged electrical lines, or reducing other potential hazards that have resulted from the disaster so that vital resources and services can be delivered efficiently to affected populations.

A major challenge during the disaster relief phase is ensuring that vulnerable people are kept safe, which often requires external support because local police or security forces may have been fragmented during a disaster. Security during the relief phase is of special concern in temporary shelters. For example, following the Indian Ocean tsunami of 2004, many people in Sri Lanka were housed in temples that were converted into temporary shelter for multiple families or were given tents in which to live until more permanent structures could be built in safe locations. Following Hurricane Katrina, thousands of people were temporarily housed in the Super Dome. While these locations may have provided relief from natural hazards, in both cases, the temporary housing options where men and women from different families were living in close quarters with each other presented security risks for vulnerable populations in society, particularly the elderly, women, and children. Furthermore, in the absence of police and security forces, looting, and other crimes may increase during the relief phase as people deal with anguish over their losses and are desperate to meet their basic needs. Thus, it is critical that relief efforts, especially those that place women, children, and the elderly in new housing situations are developed with a consideration of preexistent and new safety concerns that have arisen as a result of the disaster so that people's needs are met and their safety is not worsened by temporary conditions.

While the disaster "recovery" phase would ideally start as soon as immediate needs are met, the relief phase often lasts for quite a while due to funding delays or other constraints that hamper the recovery phase.

Definition

Disasters are not new phenomena. Disasters have affected humans throughout history and, consequently different forms of research (that evolved into the modern scientific method) as well as policies have been applied to deal with them. Overall, these approaches have moved from assuming a lack of control over disasters, to blaming external forces such as the "hazard" along with people affected by "hazards," to more recent approaches accepting that humans are responsible for creating the conditions that lead to disasters. To fully tackle disasters, research shows that policies should focus on reducing vulnerability which is created by humans, usually affecting others.

Introduction

Disasters have long been viewed principally as natural hazards through physical science disciplines such as seismology, volcanology, climatology, geomorphology, hydrology, and meteorology. Up until the mid-twentieth century, the responsibility for the occurrence of disasters that include physical phenomena (e.g., earthquakes or tornadoes) was therefore attributed to external natural forces or the whims of angry, vindictive, or inebriated deities.

In a 1756 letter to Voltaire regarding the 1755 Lisbon earthquake and tsunami, Rousseau was the first person known to attribute humanity's responsibility in disasters (e.g., Dynes, 1997). However, it was not until the 1940s that the human dimension of disasters began to be widely accepted. Two major research and policy paradigms developed, and were often opposed in their understanding

of disasters and in the way that disaster risk should be reduced. The contemporary emphasis on climate change is a step backward in the approaches taken.

The hazard paradigm

The paradigm which has long dominated scientific studies of disasters emphasizes the importance of nature's threats, called natural hazards. This approach has been spearheaded by White's (1945) pioneering dissertation on people's adjustments to flooding in the USA. This paradigm is known as the hazard paradigm. Burton and Kates (1964, p. 413), two of White's students, define natural hazards as "*those elements in the physical environment, harmful to man and caused by forces extraneous to him*." Frampton et al. (2000) further stress their "*uncontrollable dimension*." Many more definitions of natural hazards similarly emphasize extreme (function of magnitude) and rare (function of time) natural phenomena that exceed humanity's ability to cope with them.

The "extraneous" and extreme dimension of natural hazards leads disasters identified with these natural phenomena to be considered out of the regular social fabric (e.g., Kates and Clark, 1996). Scientists, institutions, governments, and media thus often mention "extra-ordinary," "un-controllable," "in-credible," "un-predictable," and "un-certain" phenomena along with "un-expected" disasters and "un-scheduled" and "un-anticipated" damage (see Hewitt, 1983 for a critique). Regions affected are claimed to be unable to face such forces of nature and are often considered to be "under-developed," "over-populated," "un-informed," "un-prepared," and "un-planned" (again see Hewitt, 1983 for a critique). Therefore, a clear border is delineated between regions of the world which are often struck by disastrous events and those that are supposedly safe (see Bankoff, 2001 for a critique).

In this context, earth and climate scientists and engineers tend to focus on monitoring, predicting, and calculating probabilities and parameters for extreme natural events. In contrast, social scientists are interested in how people and societies perceive the potential danger and how they adjust to possible threats. Individuals and societies said to have a low perception of risk allegedly adjust poorly to possible threats. People and societies considered to have a high risk perception are assumed to adjust well to natural hazards (Kates, 1971; Burton et al., 1978; Fischhoff et al., 1978; Slovic, 1987). Factors that affect people's perception of risk are hazard related too (i.e., hazard magnitude, duration, frequency and temporal spacing, plus the recentness, frequency, and intensity of past personal experiences with hazards). Kates (1971, p. 441) underlines this held belief that those factors are independent from the socioeconomic environment.

In many countries, disaster policies and practices reflect the influence of the hazard paradigm. These policies are primarily geared toward the extreme dimension of natural phenomena and often reflect war strategies (Gilbert, 1995). In many countries, disaster policies are handled by the army or civil protection institutions, relying on military chains of command, and treating natural hazards as enemies to fight against (Alexander, 2002). Risk reduction strategies consequently tend to focus on technocratic, command-and-control measures such as engineering structures, technology-based warning systems activated only after a natural event, hazard-based land-use planning, and hazard-based risk awareness campaigns.

Internationally, disaster risk reduction policies have long relied on contrasting safe, affluent countries with dangerous, poor countries. That fits into wider development policies which foster top-down transfers of knowledge, technology, and experience from the rich to the poor, because the poor countries are allegedly unable to cope without external assistance (Bankoff, 2001; de Waal, 1997).

The vulnerability approach

In the 1970s, there was a critical evolution in the way disasters have been considered and faced (Waddell, 1977; Torry, 1979). Drawing on cases from around the world, scholars such as O'Keefe et al. (1976), Wisner et al. (1977) and Hewitt (1983) increasingly emphasized people's vulnerability in the face of natural hazards, an approach referred to as the "vulnerability paradigm."

Vulnerability in facing natural hazards reflects people's marginalization within society. Disaster-affected people disproportionately include those who are chronically marginalized in daily life (Wisner, 1993; 2004). These people are marginalized geographically because they live in hazardous places (e.g., informal settlers); socially because they are members of minority groups (e.g., ethnic or caste minorities, people with disabilities, prisoners, and refugees); economically because they are poor (e.g., homeless, underemployed and jobless); and politically because their voice is disregarded (e.g., women, non-heterosexuals, children, and elderly). People's vulnerability varies in time and space and is determined by mainly hazard-independent, structural constraints that are social, cultural, economic, and political (Watts and Bohle, 1993; Wisner et al., 2004; Gaillard, 2007).

Disasters thus most affect individuals with limited and fragile incomes (low wages, informal jobs, lack of savings), reducing their capability to deal with natural hazards (e.g., location of home, type of housing, knowledge of mitigation measures). Vulnerability and marginality also result from inadequate social protection (e.g., health insurance, health services, construction rules, prevention measures) and limited solidarity networks.

That does not necessarily indicate that means of protection are unavailable locally. In many instances, such as for famines (Hartmann and Boyce, 1983; Sen, 1983), the lack of access does not reflect the availability of food, knowledge, technologies, or financial capital, but rather an unequal distribution of available resources and the nature, strength, and diversity of people's livelihoods. Assets and resources essential in the sustainable or unsustainable livelihoods are conversely crucial in defining vulnerability.

Such an intimate relationship between livelihood and vulnerability supports the justification that many people have no other choice but to face natural hazards to sustain their daily needs. The difficulty of accessing sustainable livelihoods may further lead to environmental degradation, which often manifests in increasing natural hazards. For instance, the need for firewood may accelerate deforestation that in turn exacerbates the effects of landslides and floods.

People's incapacity to safely endure "natural hazards" therefore results from their inability to control their daily life and to choose the location of their home and their livelihoods (Blaikie, 1985). In that context, disasters highlight or amplify people's daily hardship and everyday emergencies (Baird et al., 1975; Maskrey, 1989). Thus, disastrous events cannot be considered as "accidents" beyond the usual functioning of the society (Hewitt, 1983; Wisner, 1993). Instead, disasters generally reflect development failures where the root causes of vulnerability have origins in other, usually contextual, development-related crises.

Some of the central ideas of the vulnerability paradigm have been progressively integrated into some, but not all, international policy documents such as United Nations strategies (United Nations, 1995; United Nations International Strategy for Disaster Reduction, 2005). Numerous NGOs focusing on development and disaster risk reduction have also adopted aspects from the vulnerability paradigm, translating them into sound policies (e.g., Global Network of Civil Society Organisations for Disaster Reduction, 2011). Conversely, some more powerful institutions like the International Monetary Fund (IMF) have not yet integrated the basic concepts of the vulnerability paradigm (Freeman et al., 2003), while other organizations such as the World Trade Organization (WTO) downplay the negative effects of disasters (World Trade Organization, 2006).

Community-based disaster risk reduction

Despite the advantages of the vulnerability approach, no single solution can address every situation. However, a general concept does seem to apply universally; reducing disaster risk requires increasing participation of local communities, a concept that has for a long time been encouraged in development research, policy, and practice (e.g., Chambers, 1983; Wisner, 1995). The actions of local communities are nearly always the first line of defense in reducing disaster risk. A wide consensus acknowledges the capacities of local communities in dealing with natural hazards on their own, as long as they are empowered with adequate resources (e.g., Quarantelli and Dynes, 1972; Delica-Willison and Willison, 2004). Community-Based Disaster Risk Reduction (CBDRR) fosters the participation of threatened communities in the evaluation and reduction of risk (including hazards, vulnerabilities, capacities, and resiliencies).

CBDRR empowers communities with self-developed and culturally, socially, and economically acceptable ways of coping with and avoiding crises related to natural hazards (e.g., Anderson and Woodrow, 1989; Maskrey, 1989). CBDRR enhances endogenous resources which prevent people from resorting to exogenous means that are often hard to access and which often create a cycle of dependency. CBDRR further aims at strengthening people's livelihoods to enable local communities to live with risk on an everyday basis (Benson et al., 2001; Cannon et al., 2003; Twigg, 2004), thus favoring the integration of disaster risk reduction into development policy and planning. It is often impossible to prevent people from settling in hazardous areas because these same locations provide resources to communities on a daily basis, such as fertile agricultural land that lies on floodplains and low-lying coastal zones with fisheries. Focusing on livelihoods simultaneously when considering disaster risk reduction will address people's ability to sustain their daily needs and their capacities to face natural hazards and other development threats.

CBDRR is also increasingly promoted among local governments and scientific communities in order to strengthen the links between top-down and bottom-up disaster-related measures (Kafle and Murshed, 2006) and to facilitate their integration into wider development policy frameworks. Top-down responsibility is not absolved by CBDRR, but instead should support, rather than substitute for, the capacities of communities. Local communities should indeed be externally assisted when large-scale measures are required, such as massive evacuations over long distances, regional settlement and infrastructure planning, and considerable debris cleaning. CBDRR accepts external assistance when appropriate on the *community's terms*, thereby also assisting in avoiding one community's measures creating or exacerbating problems for other communities.

CBDRR and other locally driven measures are crucial for development policy; however, these should be backed by a strong commitment from national and international institutions, especially those which have not yet incorporated the central arguments of the vulnerability paradigm (e.g., IMF, WTO). Too many disasters are rooted in governance issues, for instance, disobedience of laws such as building codes, corruption, the misuse of available resources, and the looting of natural and economic resources to benefit the most powerful (e.g., Lewis, 2008). In most cases, simple, affordable, and locally available measures as part of development policy would remediate such concerns and avoid disasters (Lewis, 1999; Hewitt, 2007).

Climate change and conceptual regressing?

The dominant hazard paradigm now seems to be regaining ground, fuelled by the media, political, and scientific discourse on climate change (Kelman and Gaillard, 2008). Uncertainties around the evolution of climate conditions constitute a powerful argument for the proponents of the hazard paradigm for considering Nature as the major

threat (e.g., White, 2004). Uncertainties are frequently associated with the probability of occurrence of rare and extreme natural hazards which should be addressed through scientific models and statistical probabilities. The contemporary focus on climate change thus reinforces a paradigm where Nature is the danger source (even if exacerbated by human activity, as with climate change and many other hazards).

The recent interjection of climate change into disaster research is evident in the latest report of the Intergovernmental Panel on Climate Change (IPCC) (International Panel on Climate Change, 2007). In this IPCC document, vulnerability is defined as "*the degree to which a system is susceptible to, and unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude, and rate of climate change and variation to which a system is exposed, its sensitivity, and its adaptive capacity.*" This definition emphasizes extreme events and dependence on the climate systems, especially the magnitude of change to be experienced, which are both characteristics of the hazard paradigm.

In the face of such changing threats, people must change to deal with them. The analogy with the hazard paradigm is obvious. The vocabulary has shifted from adjustment to adaptation, but the meaning and scientific justification are the same as emphasized in the definition of adaptation provided in IPCC (2007): "*adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.*" As for the hazard paradigm, people's ability to cope with changes in climate patterns have largely been overlooked, even though their response is constrained by the same development-related factors underpinning vulnerability (Bohle et al., 1994).

Such a scientific discourse on climate change and other disasters, highly emphasized by some media, distracts national governments and international institutions from the root causes of vulnerability, making climate change a perfect scapegoat for disasters and lack of development (Kelman and Gaillard, 2008). Pinpointing a phenomenon with global scale and diffused responsibility enables governments to evade their own responsibility in addressing the root causes of vulnerability.

Therefore, there is no surprise that climate change policies and practices have reintroduced most of the actions that have failed to mitigate the occurrence of disasters over the last 60 years.

Outlook

Beyond the different, often opposing paradigms on the origins of disasters and actions to be undertaken to reduce disaster risks, there is a crucial need for increasing dialogue between the proponents of all approaches and those most affected by disasters. The top-down approach of the hazard paradigm has obviously failed to mitigate the occurrence of disasters. Consequently, it is unlikely that the similar paradigm emerging from the discourse on climate change will achieve better results.

Conversely, bottom-up actions rarely suffice to tackle the root causes of vulnerability on a large scale. Therefore, a need exists for better integration of top-down and bottom-up approaches into a single paradigm that involves working collaboratively toward the same goal, to prevent disasters (Hewitt, 2007).

DISASTER RISK MANAGEMENT

N. Nirupama
York University, Toronto, ON, Canada

Definition

Disaster risk management is a comprehensive approach involving the identification of threats due to hazards; processing and analyzing these threats; understanding people's vulnerability; assessing the resilience and coping capacity of the communities; developing strategies for future risk reduction; and building up capacities and operational skills to implement the proposed measures.

Introduction

Disaster risk cannot be eliminated completely, but it can be assessed and managed in order to reduce the impact of disasters (Smith and Petley, 2009). The management of disaster risks has attracted much attention since the 2005 initiative of the International Strategy for Disaster Reduction (ISDR, 2004) that defined the Ten Essentials in order to empower local governments and other agencies

to implement the Hyogo Framework for Action until 2015. In the twenty-first century, our understanding of disasters that are caused by natural, technological, and/or human sources has improved significantly. Both the developing and the developed worlds have made considerable progress, within their capacity and limitations, toward the development of policies and mitigation measures to reduce future disasters. However, disasters continue to harm millions of people each year worldwide. A disaster can affect, or be affected by our natural environment, social processes, psychological elements, cultural issues, historical information, and political and economic ideologies. Certain risks are often inherent within a social system or physical location, but they can also be created due to certain natural or technological hazards (Alexander, 1999). The consequences, however, can be similar in that they wreak havoc in communities and destroy social and economic systems. In order to effectively and efficiently manage disaster risks, our focus should be on addressing vulnerability (The conditions determined by physical, social, economic and environmental factors or processes, which increase the susceptibility of a community to the impact of hazards (ISDR, 2004)) and improving the resilience and coping capacity of populations (Nirupama, 2009, 2012; Twigg, 2007; Canton, 2007; Cutter, 2001).

Risk identification is a measure of individual perception – how those perceptions are understood by society as a whole, as well as an objective assessment (Cardona, 2006). The holistic approach of disaster risk management would involve risk identification and risk reduction components, a disaster management component, which is about response and recovery; and a financial protection piece that will account for institutional support, financial resources, and risk transfer tools. The shaping of risk identification, risk reduction, and risk management strategies, policies, resource allocation, and operational plans should, ideally, engage all the stakeholders in the process. A risk management team must have adequate information and understanding of high-probability/low-consequences versus low-probability/high-consequences events. A number of risk management strategies, such as education, awareness, economic incentives for individual mitigation measures, as well as legal, and legislative requirement can be considered. The process can be challenging as transfer of knowledge from science to politics is not easy (Schneider et al., 2006).

Understanding risk

Risk is defined as a function of probability of occurrence of hazardous event, and potential loss to people, property, and/or the environment (Smith, 2004; Wisner et al., 2004; ISDR, 2004; HRVA, 2004) as shown in Eq. 1. Historical records of past disasters provide reasonable estimates of the probability of occurrence of hazards, hence risk is considered to be quantifiable using probabilities and consequences (Helm, 1996; Green, 2004; Smith and Petley, 2009). Information on vulnerable populations and elements that are particularly exposed to risk can be assessed using a variety of indicators and criteria (Birkmann, 2006; Armenakis and Nirupama, 2009, 2012). Risk perception also plays a significant role in how disaster risk management is carried out in various societies and cultures (Slovic, 2000). Therefore, perception becomes a noteworthy factor to be accounted for in risk management, and risks can vary with geographic location and local conditions. Figure 1 demonstrates various perceptions of risk.

The standard risk formula is expressed as:

$$R = H \times V \tag{1}$$

Here, R = risk; H = hazard, determined as a probability (or likelihood) of the occurrence of hazard; V = vulnerability (also loss, impact or consequences).

Several variations of standard risk formula have been proposed by experts (Table 1) and are as much practiced as the standard risk formula given in Eq. 1.

Key elements of disaster risk management

Key elements of a comprehensive disaster risk management system are shown in Figure 2. Each element is briefly explained below.

Threat recognition – risk and vulnerability identification

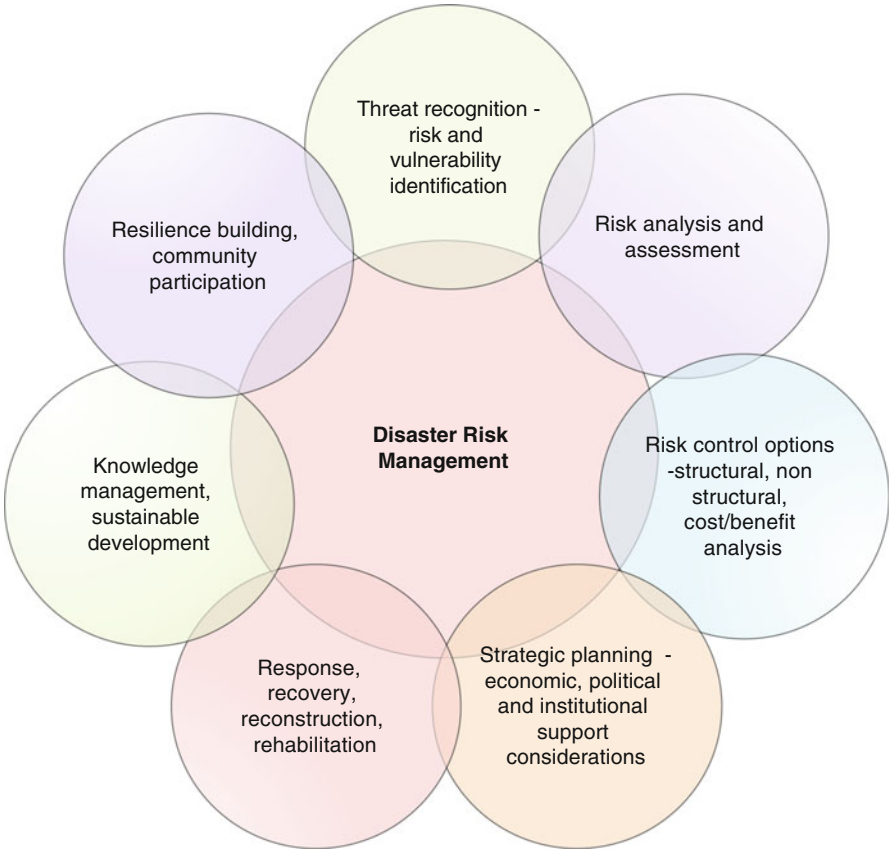
Identifying potential risks from natural, technological, or human-induced hazards; and recognizing vulnerable populations, such as very old, very young, single parents with young children, low income earners, unemployed, those facing language barriers, and physically and emotionally challenged people.

Risk analysis and assessment

Understanding the magnitude, frequency of occurrence, and severity of consequences and prioritization of risks. The standard risk formula is given in Eq. 1. A few risk evaluation methods are discussed here.

Qualitative and quantitative frameworks and methods have been developed to understand and evaluate disaster risk. Qualitatively speaking, all individual/institutional perceptions of risk carry equal weight as they choose to respond in a certain manner to a certain threat in certain circumstances (Nirupama and Etkin, 2009). Among the qualitative models, *Pressure and Release* (*PR*) *and Access to Resources* (*AR*) models (Wisner et al., 2004) are widely used. The *PR* is a static model, founded on the concept of progression of vulnerability by looking at how underlying causes create an environment that allows for some dynamic pressures (e.g., lack of education, land degradation, population growth) to translate into unsafe conditions (e.g., exposure to risk, lack of social network) in a given timeframe. Unlike the *PR*, the *AR* model is dynamic and community based. It focuses on access to

Disaster Risk Management, Figure 1 Various perceptions of hazard/disaster risk.



Disaster Risk Management, Table 1 List of disaster risk assessment approaches that are similar to the conventional approach as given in Eq. 1. Here, commonly known variables are: *R = risk*; *p (or H) = probability*; *L = loss*; *V = vulnerability*; *I = impact*.

Proposed risk evaluation equation	Variable other than probability and impact	Expert(s)
$R = p \cdot L^x$	$x\ (>1)$ = people's perception	Whyte and Burton (1982)
$R = P \cdot S$	S = severity	Government of Michigan (2001)
$R = p \cdot V \cdot n$	n = social consequences	Ferrier and Haque (2003)
$Risk = \frac{H \cdot L}{preparedness(mitigation)}$	Preparedness or mitigation are measurable measures	Smith (2004)
$R = p \cdot L \cdot f(x)$	$f(x)$= risk aversion factor	Schneider et al. (2006)
$R = H \cdot V \cdot M$	M = manageability or ability of humans	Noson (2009)
$R = H \cdot Elements\ at\ Risk \cdot V$	*Elements at risk = physically exposed assets*	Smith and Petley (2009)
$R = H \cdot (V \cdot cp)$	cp = community perception	Nirupama (2012)

income opportunities, and the development of coping strategies during and after a disaster.

In most quantitative risk assessment methods, two variables – probability of the occurrence of hazards and their potential impact – are commonly used. A few methods are discussed here. The HRVA (Hazard, Risk, and Vulnerability Analysis) method (HRVA, 2004) of BC, Canada evaluates disaster risk based on event likelihood; assessment of vulnerability (social, physical, economic, and environmental) and severity of consequences (fatality, injury, damage, and disruption of essential services – water, electricity, communication networks, physical, and economic impact). Although the HIRA (Hazard Identification and Risk Assessment) (HIRA, 2011) of Ontario, Canada follows similar steps: Hazard identification, risk assessment, risk analysis, and monitoring/review for future revisions, it accounts for psychosocial factors, such as panic and hoarding behavior, in assessing disaster impacts.

The FEMA (Federal Emergency Management Agency) model (FEMA) was developed in the USA to provide guidance to the nation for planning and decision making

Disaster Risk Management, Figure 2 Elements of comprehensive risk management.

during disaster management through the use of mitigation. The model accounts for threat identification and rating, assessment of assets, vulnerability, risk, and mitigation options. NOAA (National Oceanic and Atmospheric Administration)'s Geographic Information System (GIS)-based vulnerability assessment tool identifies opportunities beyond the existing built environment for reducing future hazard vulnerability and identifies the large tracts of undeveloped land in communities that can be used for future land-use planning for sustainable growth.

The SMUG (Seriousness, Manageability, Urgency, and Growth) (CDEMG, 2005) model was developed by the Civil Defence Unit of Chatham Islands Council of New Zealand. The model describes the prioritization of potential hazard risks based on four criteria: Seriousness (number of lives lost, potential for injury; physical, social, and economic consequences), Manageability (ability to mitigate, both hazard and vulnerability), Urgency (measure of capability to address the hazard), and Growth (rate at which hazard risk will increase through either an increase in the probability of occurrence, in the exposure of the community, or combination of the two); and four R's (Reduction, Readiness, Response, and Recovery).

In less developed regions such as Latin America and the Caribbean and Asian countries, national governments and NGOs usually play a pivotal role in managing disasters. The concept of risk evaluation, however, is similar to that of shown in Eq. 1 and risk assessment methodologies are similar to the ones used in developed world. In an ideal disaster risk management, a hazard and vulnerability analysis would be carried out and then appropriate action would be taken based upon the analysis (NDM, 2012).

Risk control options – structural, nonstructural, cost/benefit analysis

These considerations are based on feasibility, effectiveness, and cost/benefit analysis. Structural measures may include the building of dykes, dams, and other protective structures. Nonstructural measures may include land-use planning, hazard risk zoning, early warning systems, education and awareness campaigns, affordable disaster insurance, and legal and regulatory policy. Market-like tools, such as reinsured catastrophe funds (Mexico) and mitigation-focused insurance schemes (Barbados), have been implemented in a few countries (Freeman et al., 2002).

Strategic planning – economic, political, and institutional support considerations

Financial commitment and political will are fundamental to any successful disaster management program. The allocation of resources, the building of institutional support, the creation of social programs, and community-based initiatives toward individual and collective protection measures are most important. In North America, Europe, and other developed countries, disaster risk management programs are well established, structured, and fairly funded. These regions also have great early warning systems in place, remarkable disaster preparedness, and response and recovery capabilities. In the developing world, however, the focus has shifted to knowledge dissemination, disaster preparedness awareness, and community-based programs. For example, in India, the authorities at the state level take the main responsibility for disaster relief with financial assistance from the central government. A small Calamity Relief Fund, constituted with both state and central government contributions is managed by the Disaster Management Authority of India, under the Ministry of Home Affairs (Freeman et al., 2002). In case of a major disaster, the central government provides predetermined reimbursement sums for loss of life, limb, and partial and total loss of housing and productive assets.

Response, recovery, reconstruction, and rehabilitation

Response capability and mutual agreement with neighboring regions (depending on the size and type of the event), assistance with recovery, and reconstruction would be extremely important for the impacted communities to deal with their loss and remain optimistic about their future. The rehabilitation phase provides a rare opportunity to reassess the situation, consider various options to relocate or build a better, stronger, and more resilient community. Disaster aid – internal and/or international, bilateral (government to government or through NGOs) or multilateral (through the UN agencies) must be in place to reduce the impact of a disaster. The Government of India, in partnership with the United Nations Development Program (GOI-UNDP, 2008, 2010), has developed a Disaster Risk Management Programme through disaster preparedness and vulnerability reduction. Their goal is to strengthen institutional capacity with specific emphasis on women and other marginalized groups. They have adopted a multi-hazard approach with an objective of achieving a sustainable disaster risk reduction in some of the most hazard-prone districts in selected states in India. Another example is from Fiji, where exposure to cyclones, floods, droughts, earthquakes, and tsunamis is widespread. Fiji has been able to develop a good disaster preparedness, response, and recovery plan in which NGOs are encouraged to actively participate in all the functions of disaster risk management (Freeman et al., 2002).

Knowledge management and sustainable development

Institutional knowledge must be preserved for better learning and understanding. An approach of sustainable development would allow for the use of local resources (human, social, environmental) and thus contributes to local economy. Interestingly, in developing nations, NGOs play an active role in risk reduction activities in the region. The so-called "knowledge network" involving civil society, the scientific community, and to some extent, the market is gaining popularity among people in India.

An approach suggested by Cardona (2006) for the Americas, and which can also be applied to other regions, is to use a system of indicators to measure a country's risk management performance. As shown in Eq. 2, the Risk Management Index (RMI) is based on a set of indicators that represent organization, development, capacity, and institutional actions taken to reduce vulnerability and losses, to prepare for crisis, and to recover efficiently from disasters.

$$RMI = \frac{(RMI_{RI} + RMI_{RR} + RMI_{DM} + RMI_{FP})}{4} \quad (2)$$

where

RMI_{RI} = risk identification, includes objective and perceived risks
RMI_{RR} = risk identification, includes objective and perceived risks
RMI_{DM} = measures of response and recovery
RMI_{FP} = governance and financial protection measures

Resilience building and community participation

The final element in the cycle of disaster risk management is to work toward building resilient communities with community participation and community owned programs. For an effective and helpful risk management program, it is critical that communities make risk-based choices to address vulnerabilities and mitigate disaster impact. Resilience building must become the foundation of future risk management programs. A well-designed communication strategy can be instrumental in the successful implementation of policy and other measures. In Asian countries, a communities based holistic approach is gaining popularity as people feel responsible for their safe future (Padmanabhan, 2008).

Summary

Disaster risk management involves overall understanding and realization of potential hazards, identification of vulnerable people and property, risk evaluation, institutional support, and the adoption of a culture invested in preserving institutional knowledge. Various qualitative and quantitative methods can be used for risk assessment for the purpose of the development of a disaster risk management framework. The use of indicators to capture a sense of the central components in a holistic risk management process

is worth examining. It is, however, safe to say that in recent years, most nations have shown an increasing trend toward developing comprehensive disaster management programs. They have broadened their national disaster management programs to encompass risk assessment, risk control, mitigation, preparedness, political will, economic feasibility, response, recovery, resilience building, and strategic and sustainable development activities. The success of such a framework or program may depend on the commitment of stakeholders such as communities, professionals, academics, and policy and decision makers.

Definition

Disaster risk reduction (DRR) refers to a wide range of opportunities for risk abatement and disaster management. Risk reduction includes prevention, preparedness, and part of the recovery process, and it gives particular emphasis to the reduction of vulnerability, which is defined as "the conditions determined by physical, social, economic and environmental factors or processes, which increase the susceptibility of a community to the impact of hazards" (UNISDR, 2005) Disaster management includes warning, alert, emergency response, and part of recovery. It includes a focus on methods of increasing resilience. DRR aims to limit risks – assuming that they cannot be completely avoided – and concentrates on minimizing the adverse impacts on disasters. This needs to be accomplished within the broad context of sustainable development.

Introduction

The increasing world population, coupled with globalization and urbanization, has greatly increased the risks and impacts of disasters. Climate change and land degradation aggravate the situation in terms of intensity, occurrence, and complexity. Recent disasters, such as the Asian tsunami, Hurricane Katrina, the earthquake in Haiti, and influenza pandemics confirm the global reach of disasters and the tendency for their impacts to increase over time. Trends in risk management confirm that the world we live in today is more complex, more vulnerable, and more interdependent than at any time before in history (UNISDR, 2012). When settlements or infrastructure overlap with major hazard zones, natural events can cause significant damage. Natural hazards limit the availability of living space and thus incur social costs. Studies by the World Bank (World Bank, 2005; Global Facility, 2007) show that more than 3.5 billion people are located, and about 80% of the world's gross domestic product is produced, in areas exposed to at least one natural hazard with a significant probability of occurrence.

Over the last few years numerous catastrophes have drawn attention to the fact that the extent to which life, limb, and property can be protected is limited. The protection of life is certainly the primary concern, but also economic damage has to be reduced in order to protect vital economic growth, especially in developing countries, in which large disasters can absorb more than 10% of GDP. Sustainable development and poverty reduction go hand in hand with disaster risk reduction strategies to achieve the UN Millennium Development Goals (UN MDGs). Disasters and risks should no longer be seen as a purely humanitarian affair but as an integrative part of sustainable development and adaptation to climate change (UNISDR, 2009). In fact, adaptive capacity is considered a core characteristic of a resilient socioeconomic system (CRN, 2011, p. 39).

The World Conference on Disaster Risk Reduction held in Kobe, Japan, in January 2005 (WCDR, 2005) brought consensus that to achieve risk-resilient, sustainable societies, extreme events – such as natural hazards, climate change, diseases (including pandemics), man-made hazards and terrorism – have to be managed in an integrative way. As a result, the "Hyogo Framework for Action 2005–2015: Building the Resilience of Nations and Communities to Disasters" HFA (UNISDR, 2005) was approved by the 168 government representatives gathered in Kobe. Under the Hyogo Framework, governments committed themselves to the following five priorities:

- Make disaster risk reduction a priority: ensure that it is a national and local priority with a strong institutional basis for implementation. The creation of national platforms and national focal points is strongly encouraged.
- Know the risks and take early action: identify, assess, and monitor disaster risks, as these tasks are essential components of risk reduction that will enhance early warning.
- Build an understanding of awareness: use knowledge, innovation, and education to build a culture of safety and resilience at all levels.
- Reduce risk: identify those variables latent in society and the environment that contribute to risk and ways to mitigate them.
- Be prepared and ready to act: strengthen disaster preparedness for an effective response at all levels.

Subsequently, the UNISDR produced assessment reports on disaster risk reduction (e.g., UNISDR, 2011) and a policy discussion document on the way forward after the Hyogo initiative ends in 2015 (UNISDR, 2012). DRR is clearly going to benefit from integration with the Millennium Development Goals and the Rio + 20 resolutions. At the time of writing it is unclear what instruments will replace the five Hyogo goals and whether the succeeding initiative will be merely an extension of the current one or will involve new legal and administrative instruments to induce governments to reduce the risk of disasters.

Disaster risk reduction (DRR)

Disaster risk reduction has two components:

- *Risk reduction* refers to efforts to limit risks due to hazardous situations. This can be achieved by good prevention.
- *Disaster management* signifies the need to reduce or limit the resulting damages caused by a disaster. This can be achieved by good preparedness, an efficient disaster or crisis management system and an effective recovery process.

DRR is thus a process of both, risk reduction and disaster management and is sometimes called integrative risk management (IRM–Ammann, 2006). Besides risks due to natural hazard, which is aggravated by climate change, IRM includes numerous other risks to be considered simultaneously such as those of a technical, biological, and chemical nature; pandemics, terrorism, and financial risks.

DRR requires an approach that not only tackles multiple risks, but also involves multiple stakeholders. Although the HFA recognizes that governments have the primary responsibility to guide and implement measures for achieving DRR, to create the necessary political will at the national level, a wide group of risk management experts, practitioners, scientists, and key players from civil society and other sectors with a strong emphasis on implementation at "the last mile" has to be involved and has to interact with key players from line ministries and disaster management authorities. Practice, science, policy, and decision making have to be closely linked in the search for sustainable solutions to the complex risks society is facing today. Only an interdisciplinary approach can bridge the gap between problems and their main causes on the one hand, and governance and technology perspectives for problem solving on the other. Demand-driven, practical application has to supplant purely supply-driven scientific knowledge. The task of protecting people and private and public goods has to be the central focus of this knowledge development process, and it has to be achieved in a sustainable manner.

As climate change is aggravating the meteorological hazards in terms of frequency, intensity and interdependency, measures for *climate change adaptation (CCA)* have to be closely linked to programs for DRR (UNISDR, 2009). The *harmonization of DRR and CCA* measures is already a crucial issue. This must take place through a common process of adaptation to both the effects of climate change and the increasing impacts of disasters. Common strategies of vulnerability reduction are needed. For instance, in tropical coastal areas, settlement and livelihoods need to be made resistant not only to hurricane storm surges and tsunamis, but also to potential sea-level rise and the intensification of storms that climate change may bring. Coasts are very attractive areas for settlement and are in many cases the most economically buoyant parts of countries, rich and poor alike. However, it may be necessary to manage a retreat from the coast if the worst hazards are to be avoided or reduced. This will involve both costs and economic sacrifices.

Dealing with natural hazards is not just complex, but also contradictory when technical, social, economic, and ecological aspects have to be balanced. It is no longer adequate for risk management professionals to focus solely on risk within a particular realm. Rather, in a world with interdependent systems of rapidly growing complexity (such as critical infrastructures and interdependent processes and services), risk management must have a new vision that overcomes boundaries between subject areas, one that reaches across specialisms and departments. Safety and security have to be seen as a holistic means of enabling better planning, response, and reduction of the most pressing risks.

Integrative risk management, risk culture, and governance

The key questions are: How do we create a safer world and how can our developing knowledge support this process of change? The approach must be that of integrative risk management across subject areas, professions, and sectors, encompassing natural sciences, social sciences, and engineering. Scientific understanding must be placed at the service of business, policy responses, and citizen participation. Among the risk management communities, stronger ties have to be built with private-public partnership models, and approaches need to be devised to move toward a more truly integrative way of thinking about risk: a holistic approach to risk reduction with safety, security, and sustainability at the center. This is an approach that will help policy makers and business people, risk managers and civil society to address the complex risks around them more effectively.

To be able to take effective and efficient decisions for disaster risk reduction and climate change adaptation measures, which lead to transparent and comparable results in different risk situations, a consistent and systematic risk management approach has to be followed. Hereafter, this approach will be called "integrative risk management," a process that embodies a systematic framework for risk analysis and assessment procedures, that leads eventually to consistent decisions and to the optimized, integrative planning of risk reduction measures. A consistent risk concept provides a substantial base and allows the comparison of various risk scenarios at different locations and originating from different natural disasters. Hence, the key to the future is risk-based management, rather than an approach based solely on hazard management. A significant driving force for this paradigm shift is the demand for accountability and improved effectiveness of the risk reduction measures.

The public perception of natural hazards differs from the perception of ecological, technical, and social risks leading to conflicting security philosophies, which hinders consensus on integrative measures. Different ways

in which people perceive risks have an important effect on how they may or may not accept any measures that are imposed. A strategy for protection from natural disasters has to find a way to put the various risks onto a common scale to allow for comparability and that serves as a platform from which measures can be agreed upon. Any risk to humans and the environment has to be considered within the context of social, financial, and economic consequences and increased interdependencies between the various risks. The way a society handles questions of safety and security may be summarized with the term "*risk culture*." This means that security can only be gained by risk-oriented thinking.

Risk governance looks at how risk-related decision making unfolds when a multitude of stakeholders and actors is involved, requiring coordination and possibly reconciliation between a profusion of roles, perspectives, goals, and activities. Good risk governance stands for transparency in decision making, effectiveness and efficiency of the measures, accountability, a strategic focus, sustainability, equity, fairness, respect for the law, and the need for the solution to be politically attractive and legally permissible, as well as ethically and publicly acceptable.

Integrative risk management and good risk governance are complicated by the fact that in today's society many risks are not isolated, single events with limited extent, but are trans-boundary risks that affect countries with different political systems and coping strategies.

Framework for DRR and CCA

The concept of integrative risk management (i.e., DRR) is shown in Figure 1. Integrative risk management starts with the process of identifying and analyzing risks in order to answer the question "What can happen?," followed by risk assessment, which should answer the question "Is what happens acceptable?," which leads in turn to the planning of risk reduction measures. The ultimate objective is to create protective measures. The main criterion for choosing the correct protective measures is cost-effectiveness. However, DRR (and CCA) have to overcome a number of problems and obstacles:

- The risk-oriented approach and the methodology of dealing with uncertainties may determine the solution rather than the risk itself. This applies both to the analysis and the assessment of risk.
- Measures designed to promote safety may have limitations that are greater than the expectations of safety held by civil society.
- The various points of view, attitudes, and values of all stakeholders involved and affected by the risk may differ and possibly conflict.
- Disaster risk prevention and mitigation measures have to take the whole set of pre- and post-disaster measures into consideration, as well as measures during a crisis itself, and measures to transfer risk using insurance (Figure 4).

Disaster Risk Reduction, Figure 1 Framework for integrative risk management (Source: author).

- All solutions have to fulfill the criteria of sustainability, that is, a sustainable approach to disaster risk management has to be a socially, economically, and environmentally balanced and acceptable approach.
- Integrative risk management also needs a strategic and systematic process of control, including the periodic evaluation of the risk situation and a comprehensive dialogue on risk between all stakeholders.
- When setting limits for the protection and defining the processes of decision making, there is a need for dialogue and communication in order to ensure the participation of all stakeholders. Risk communication can have a major impact on how well society is prepared to cope with risks and how people react to crises and disasters.
- A balance is needed between acceptable residual risk and the economic costs of risk reduction measures.

Risk concept

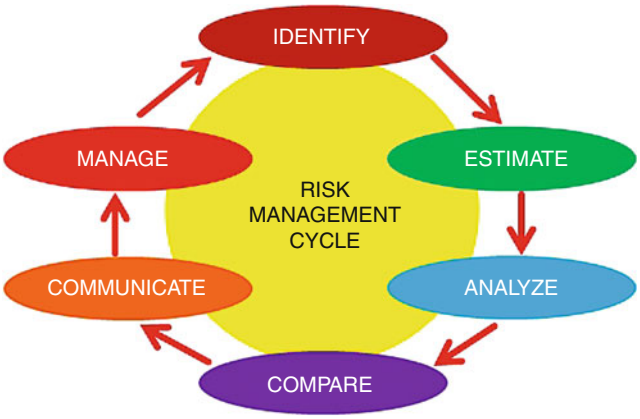
To be able to compare different types of natural hazards and their related risks and to design adequate risk reduction measures, a consistent and systematic approach has to be used (Figure 1). The risk concept represents the methodological basis of several elements: integrative risk management, the decision-making process in risk reduction and mitigation, and disaster management. It serves to aid transparency in risk dialogue between all stakeholders (Ammann, 2006). The basic principles of the risk concept are represented in Figure 2 and can be summarized by the following key questions:

- How safe is safe enough?
- What can happen?
- What is acceptable (to happen)?
- What needs to be done?

The question "What can happen?" has to be answered by risk analysis, whereas the question "What is acceptable?" needs the assessment of risks. The necessary steps

Disaster Risk Reduction, Figure 2 Basic questions and elements of the risk concept (Source: author).

Risk Anaysis	Risk Assessment	Planning of Measures
▪ Hazard Analysis – Event Analysis – Effect Analysis ▪ Exposure Analysis ▪ Impact Analysis (Vulnerability Analysis/ Robustness) ▪ Risk estimation and Risk de-scription/Visualisation	▪ Protection Goals – Life Risk - Individual Risk - Collective Risk – Assets/Material Damage ▪ Risk Categories ▪ Risk Aversion	▪ Risk- Cost- relationship ▪ Marginal Costs ▪ Integration of all possible measures ▪ Comprehensive Assessment of all measures



Disaster Risk Reduction, Figure 3 Necessary steps in risk analysis, risk assessment, and the integrative planning of risk reduction measures (Source: author).

are summarized in Figure 3. The goal of a risk analysis is to achieve the most objective possible identification of the risk factors for a specific, damaging event, object, or area. The question "What can happen?" has to be answered by considering a variety of factors that influence it.

Risk assessment aims to give an explicitly subjective answer to the question "What is acceptable?". Thus, it asks how big a residual risk is acceptable. Risk assessment is by nature very complex and has to deal with the fact that risk is a mental construct but not a fully rational one. An important aspect is risk aversion, as practiced in relation to catastrophic events: people's wish to prevent large, spectacular, or particularly frightening events may be disproportionate to the event's real consequences. The acceptance of a risk also depends on whether it is given by active choice or not. Risk categories are defined to the extent that self-reliance and autonomy are possible.

Risk assessment is closely linked with the protection goals that people want to achieve. A protection goal is a set of criteria for the implementation of the primary goals of all efforts to improve safety. It represents the acceptable risk level and thus defines how far the measures should go. A protection goal has different meanings as it has to cover individual and collective perspectives. An individual's protection goal is often defined in terms of the probability of dying. The marginal costs of safety measures (Ammann, 2006) have proven to be the most useful means of defining protection goals in terms of the collective perspective of society. The marginal costs represent certain expenses per fatality avoided or per human life saved. The safety measures can be increased until the desired level of risk reduction is achieved.

Determining the marginal costs of avoiding a fatality can lead to the misunderstanding that a price can be allocated to a human life. The criterion of marginal costs

Disaster Risk Reduction, Figure 4 The risk management cycle (Source: author).

should be seen as the optimization of safety measures in terms of lives saved within the limitations of available means and resources.

Planning helps identify measures that are necessary and appropriate in order to reach the protection goals. The main function of the planning of integrative measures is to achieve the intended level of safety in the most cost-effective way. Organizational, technical, and biological protective measures must be planned, checked for effectiveness, and undertaken in concert, while keeping in mind that prevention, intervention, and reconstruction are all equally valid risk management measures (Figure 4). Whereas preventive measures serve primarily to reduce vulnerability, preparedness and intervention measures primarily serve to strengthen resilience. Further criteria such as sustainability, acceptability, feasibility, and the reliability of solutions have also to be kept in mind.

Safety measures are always accompanied by side effects. The most obvious of these is financial; however, aspects of ecology, landscape protection, and land-use planning can be of equal importance. The optimal coordination of all measures has to bear in mind that all relevant aspects and activities in the field of disaster risk reduction have to be sustainable. Measures need to be environmentally sound, to consider societal preferences and to be cost-effective. Disaster risk reduction has also to integrate with the sustainable use of natural resources and with sustainable development. This is why it is considered a cross-cutting issue.

The sociopolitical aspects of sustainability are a question of development and welfare priorities and have to be seen in context of other targets such as education and health care. Especially in developing countries, a reallocation of resources is often needed after major catastrophes for recovery purposes – resources which have been allocated originally to be used for investments in, for example, education, health care, or welfare. What is needed is a political balance between long-term investments for prevention and short-term measures for disaster response and recovery.

Risk dialogue and strategic controlling

Integrative risk management not only dictates that the measures are planned, assessed, and applied in accordance with the risk concept, but also that all those who are involved and affected are included in a comprehensive risk dialogue, and in the processes of planning protection measures. Risk communication and risk dialogue with all stakeholders have to start promptly at an early stage. They will be dominated to a greater extent by questions than by answers, and by processes rather than solutions. A continuous, comprehensive risk dialogue is therefore of vital importance, as it will help ensure that risk management becomes a transparent, understandable affair of public trust.

Active information supply and communication play a dominant role in crisis situations. A well-informed public will weather a catastrophic situation much better than an ill-informed one, and the risk of panic and long-term damage can thus be reduced.

Strategic controls should be used periodically to check the risk situation and monitor the costs and benefits of measures. It is also necessary to monitor residual risks. Integrative risk management enables the overarching aims to be reached using protection measures that can be justified in technical, economic, societal, and environment terms.

Numerous factors can increase future risks and thus create additional uncertainty. Among the most important factors to be taken into consideration, monitored, and periodically checked are globalization, mass mobility, vulnerability, the spread of urban areas, the increase in fixed capital investments, sensitivity (through increasing economic interdependencies), international leisure activities, sociopolitical changes, and changing climate and weather patterns. Developments in hazard and risk management must be followed carefully and the potential for optimization exploited. In the future, the challenge will be to understand and cope with constant change; new risk scenarios, new hazards, climate change, new sociopolitical conditions, and so on. This means that strategies for dealing with risks due to natural and anthropogenic hazards will have to undergo constant adaptation.

Conclusions

Disaster risk reduction is embodied in the combination of risk reduction and disaster management. It addresses the whole risk cycle of prevention, intervention, and recovery. In coping with natural hazards, most countries still focus on reactive disaster management, whereas proactive risk reduction using preventive measures is politically more difficult to justify and implement. To cite Kofi Annan, former Secretary General of the United Nations, "The benefits of prevention are not tangible; they are the disasters that did not happen." To strengthen prevention is only possible with a risk-related approach that needs a paradigm shift from hazard-oriented reaction to risk-related preemptive action. The benefits of prevention can only be made clear with a strict risk controlling process, and political support for prevention and climate change adaptation can only be gained with continuous activities designed to raise public awareness.

Introduction

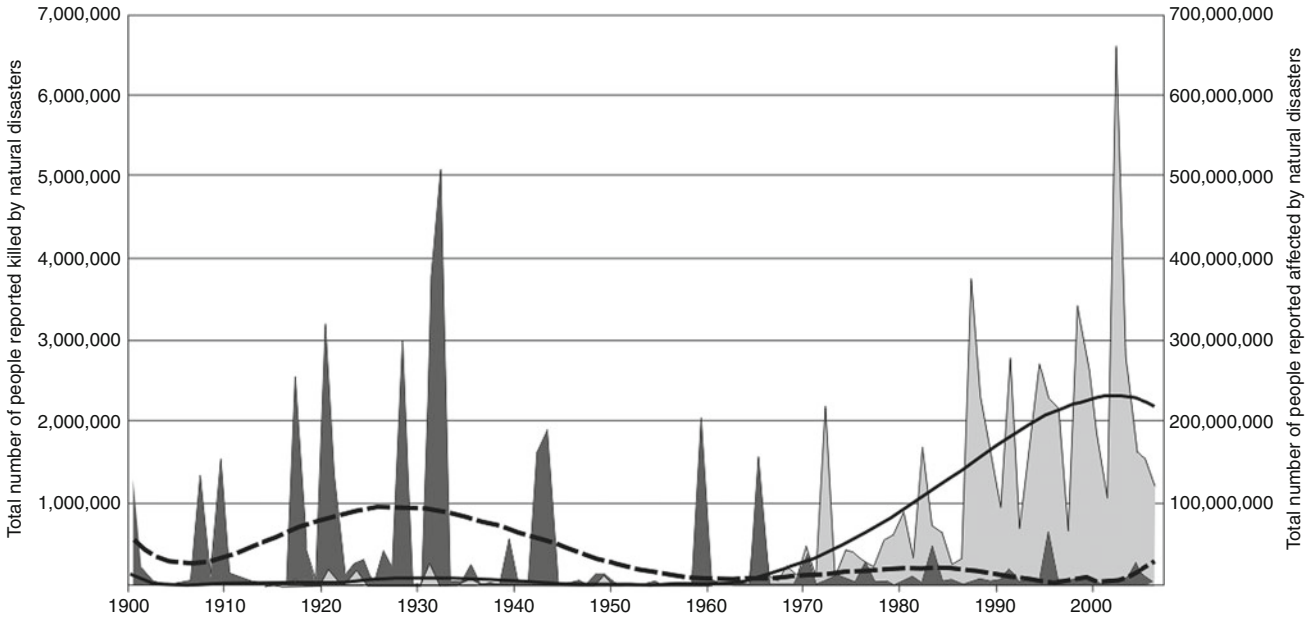
In the novel Candide by Voltaire (1759), two characters debate the roots of a great earthquake that had just leveled one of Europe's greatest and most religious cities, Lisbon (Figure 1). To one, Candide, the calamity – which struck on All Saints' Day 1755 when all the pious were in church – was clearly the day of final judgment; to the other, his tutor Pangloss, it was simply Lisbon's location above a subterranean seam and an inconsequential event in what was otherwise the best of all possible worlds. The authorities of the city, a powerhouse of the inquisition, tolerated no such debate: for his sins in not recognizing divine retribution as the cause, Pangloss was rapidly hanged, whereas Candide was administered a hundred lashes for listening and watching.

Disasters, Figure 1 The cathedral in Lisbon was one of many that collapsed during the 1755 earthquake in which many of the city's inhabitants perished. The result was a cathartic reinterpretation of natural hazards as acts of God or physical nature and also the emergence of a social science paradigm that viewed disasters as the consequence of human culpability.

Voltaire's international best seller may have been parodying the new religious optimism of the Enlightenment which saw the best in everything, but the Lisbon disaster would turn out to be a turning point in the recognition that events like earthquakes were not the result of

divine wrath or an unmerciful God but instead were natural phenomena. However, amid the theological fires that the quake ignited among major Enlightenment thinkers, one of them, the philosopher Rousseau, drew attention to human culpability. After all "...nature did not construct 20,000 houses of six to seven stories there, and that if the inhabitants of this great city had been more equally spread out and more lightly lodged, the damage would have been much less and perhaps of no account" (Rousseau, translation in Dynes, 2000, p. 106). What is more, Rousseau pointed out that if the population had evacuated promptly at the first tremors, they would have been safe, but instead, "How many unfortunate people have perished in this disaster because of wanting to take his clothes, another his papers, another his money?" For Rousseau, human beings were responsible for risk because their actions, not the actions of an unmerciful god, brought consequences.

Today, the 1755 Lisbon earthquake is regarded as the world's first modern natural disaster (Dynes, 2000). But two and a half centuries on, those same questions concerning the "naturalness" of disasters, and of the competing significance of their human and physical roots, remain. At the heart of contemporary hazards, research is a clash between two broad schools of thought (Alexander, 1993). The first is fixed in the pioneering US flood hazard research of Gilbert White in the 1940s, which spawned a generation of scientists – the so-called Chicago School – convinced that scientific and technological solutions could protect society against natural disasters (Burton et al., 1978). Their belief that we can adapt to destructive natural forces and reduce their adverse impacts through engineering and planning was a mainstay of the International Decade of Natural Disaster Reduction. IDNDR strategy, developed in the 1980s, sought to transfer this knowledge on disaster reduction as practiced in developed nations to hazard-prone developing countries (Press and Hamilton, 1999). Around this time, however, an opposing school of thought was emerging, gaining ground particularly among social scientists working in the field of development studies, who saw Western technocratic methods as being inadequate for tackling the root causes of most disasters, namely, underdevelopment and the marginalization of people in poor communities. The so-called radical critics increasingly argued that if an individual or a community was already economically or ecologically marginalized, a transfer of technology would not alleviate disaster (O'Keefe et al., 1976; Hewitt, 1983).



Today, the science of natural disasters is underpinned by a broad acceptance of the paradox that while the causative events (hazards) emerge from nature, the consequent disasters are made in society (Alexander, 1993; Varley, 1994; Hewitt, 1997; Pelling, 2003; Wisner et al., 2004). In other words, although an understanding of the dynamics of the physical environment is crucial for anticipating the incidence of hazardous phenomena, equally important is an understanding of the social, economic, political, and cultural dynamics within a community or society that transform a particular hazard event into a specific disaster. In the contest between the physical and human framing of natural hazards, the latter has arguably now gained the upper hand as the dominating disaster paradigm. As the prominent hazard geographer Kenneth Hewitt (1997, p. 141) notes, "...society, rather than nature, decides who is more likely to be exposed to dangerous geophysical agents."

Modern disaster science, consequently, attempts to fuse an interdisciplinary perspective in which geoscientists and engineers seek to improve their understanding of the frequency and intensity of potentially damaging physical events (the "hazard"), and social scientists reveal the characteristics of a community or society to anticipate, cope with, resist, and recover from such events (the "vulnerability") (Smith, 2001; ISDR, 2004; Wisner et al., 2004). Taken together, analysis of both the physical hazard and the social vulnerability constitutes an assessment of "risk" – the probability of loss resulting from a specified hazard event affecting a particular societal target. It is the realization of this threat that turns a "natural hazard" into a "human disaster." An event that seriously disrupts the functioning of a community or a society (causing widespread human, material, economic, or environmental losses which would exceed the ability of the affected group to cope using it own resources) is designated a "disaster" (Smith, 2001; ISDR, 2004).

The statistics of disaster

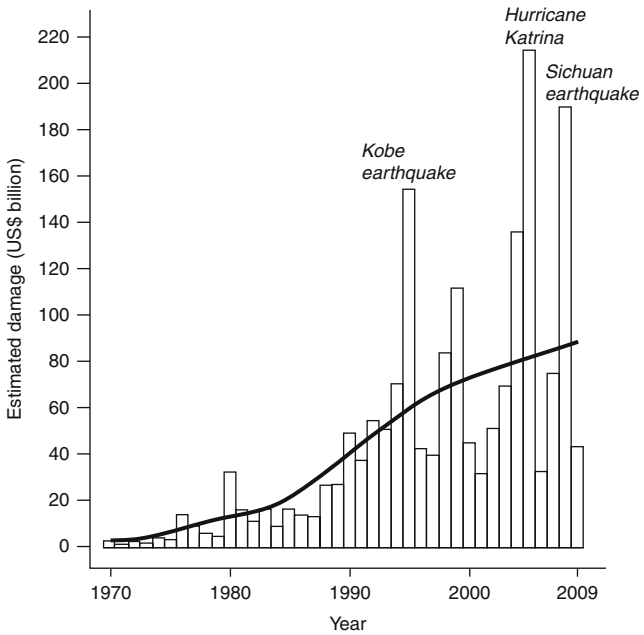
The emergence of vulnerability-oriented disaster perspectives has reflected the perceived failure of technocratic approaches to stem the swelling tide of disaster. In 1978, when Gilbert White and colleagues ushered in modern disaster science with the classic text "Environment as Hazard," they did so with opening remarks that lamented how "... the global deathtoll from extreme events of nature is increasing. Loss in property from natural hazards is rising in most regions of the earth, and loss of life is continuing or increasing among many of the poor nations of this world" (Burton et al., 1978, p. 1). Despite three decades of scientific efforts, including an international decade – the 1990s – devoted to natural disaster reduction (Press and Hamilton, 1999), the world still confronts a soaring toll of natural crises.

The raw statistics show that the past four decades have witnessed a fourfold increase in the number of reported natural disasters, from fewer than 100 per year in the mid-1970s to around 400 in the period 2000–2007 (Guha-Sapir et al., 2004; Rodriguez et al., 2009). Since the 1990s, something of the order of 1.5 million people have been killed in natural crises, with the annual death toll averaging around 55,000–65,000 fatalities. In years blighted by major catastrophes, the toll is far greater, such as in 2008 when Cyclone Nargis killed 138,366 people in Myanmar and the Sichuan earthquake in China caused the deaths of 87,476 people, producing mortality estimates more than three times the recent average. In terms of

Disasters, Figure 2 Human losses due to natural disasters, 1900–2006. *Dark shading* indicates fatalities reported due to natural disasters (scale on *left*) and *light shading* indicates total number of people affected (scale on *right*). *Dashed line* shows the smoothed trend for fatality numbers and *solid line* shows smoothed trend for number affected (Source: EM-DAT – the OFDA/CRED International Disaster database, http://www.em-dat.net, Université Catholique de Louvain, Brussels, Belgium).

those affected by disasters, the situation is even more perilous – in recent times (1994–2003), more than 255 million people have been annually affected by natural calamities (EM-DAT, 2006) (Figure 2).

Such crude numbers obscure an underlying geography to disaster fatalities. For the period 1980–2004, the number of disasters and the at-risk populations of high-income and low-income countries are broadly similar (Stromberg, 2007). However, the numbers killed in disasters are over an order of magnitude lower in the wealthier nations – around 75,000 fatalities compared with over 900,000 for poorer nations. This reflects the fact that high-income countries have invariably have invested substantially in a wide range of preparedness and mitigation measures (Figure 3): buildings can be constructed of stronger and more durable materials or elevated above flood levels, farmland can be irrigated to reduce losses during droughts, warning systems for certain natural disasters, such as hurricanes, can save lives, and after a disaster strikes, mass evacuation and emergency medical care and food can limit the human toll of the disaster. Lacking the wealth, infrastructure, and institutional capacity to afford adequate protection, it is no surprise to find that over 90% of the hazard-related deaths are in less-developed nations.



The headline message of the economics of disaster is simple: the costliest collateral losses are incurred by wealthy industrialized nations, but the greatest fiscal burden of disasters (as a proportion of a country's gross domestic product) is inequitably borne by the least economically favored nations (Dilley et al., 2005). Moreover, the financial costs are rising (Figure 4). Current economic losses are up 14-fold compared to 1950s levels, and in the mid-1990s, natural hazards in the USA alone were estimated at US$54 billion per year – or a staggering US$1 billion per week (van der Vink et al., 1998). Currently (2000–2007), the annual global average loss is thought to be around US$82 billion. Again, a contagion of disasters make some years more expensive than others. 2008, for example, was especially costly with the Sichuan earthquake in China (US$85 billion) and hurricane Ike in the USA (US$30 billion), contributing to economic losses more than double the recent average (Rodriguez et al., 2009). As the global economy grows and the number of at-risk assets swells worldwide, the cost of natural disasters in both monetary and human terms is expected to spiral higher still.

The changing face of disasters

Despite the rising incidence of disasters over recent decades, there is little sign that the physical environment that we occupy is becoming intrinsically more dangerous. There is no appreciable increase detected in the frequency or magnitude of major geophysical phenomena such as earthquakes, volcanic eruptions, and tsunamis. It is possible that anthropogenic climate change ("global warming") is invigorating the incidence and severity of tropical storms and other hydrometeorological hazards (Mitchell et al., 2006; Knutson et al., 2010; Lubchenco and Karl, 2012), but even if a heightened level of some hazardous

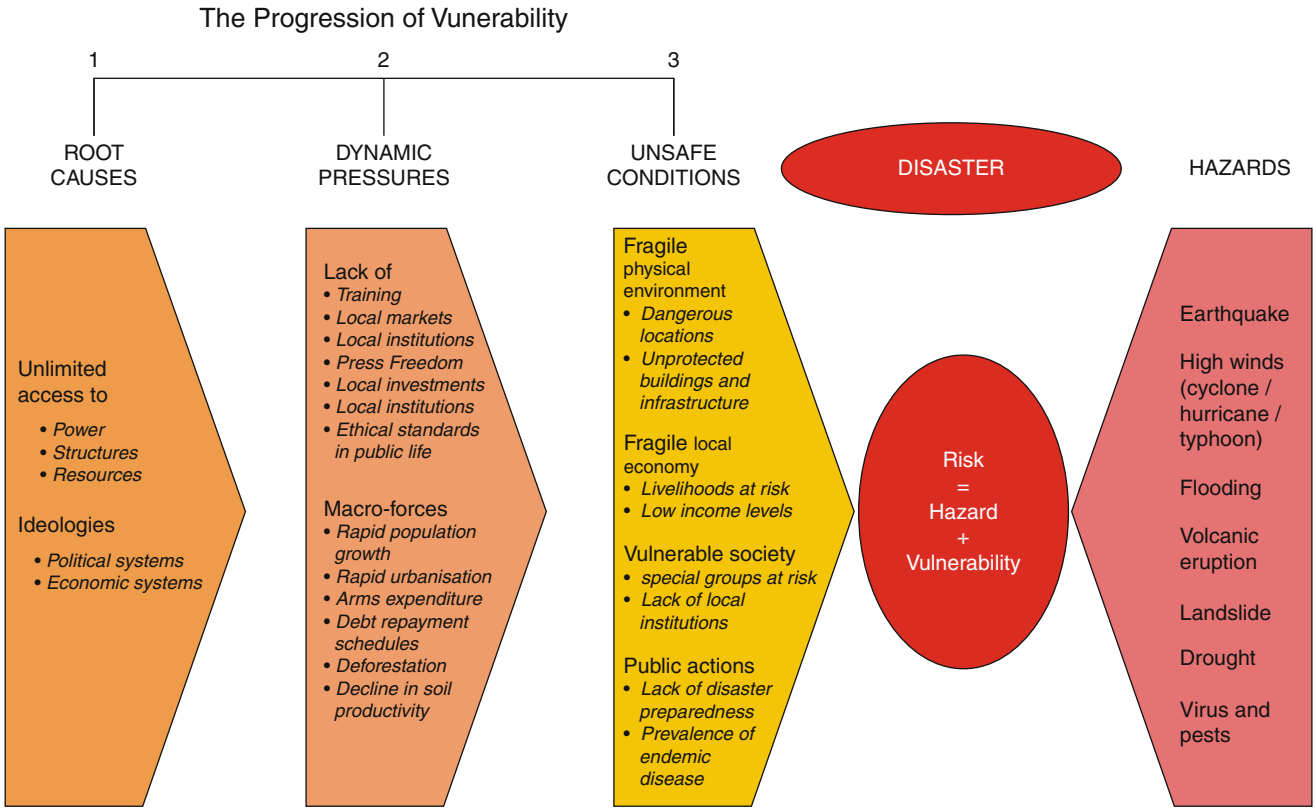
Disasters, Figure 3 Two contrasting views of how urban settlements face up to the earthquake threat. (*Left*) In wealthy industrial nations considerable effort has gone into engineering buildings to withstand earthquakes, evident in this Tokyo skyscraper. However, in major cities in lesser developed nations, such as Istanbul, Turkey (*right*), it is the weakly assembled building stock that is the main threat to live and livelihood in future seismic disasters. Although engineers have the technical knowledge to design buildings to withstand moderate earthquake strikes, in many countries the implementation of good construction practices and effective planning measures is hampered by weak regulatory controls and political corruption.

Disasters, Figure 4 Estimated damages (US$ billion) caused by reported natural disasters, 1970–2009 (Source: EM-DAT – the OFDA/CRED International Disaster database, http://www.em-dat.net, Université catholique de Louvain, Brussels, Belgium).

processes is real, it is insufficient to account for the dramatic increases in natural disasters over recent times.

Instead, for many disaster scientists, the root of our more perilous predicament lies not in the physical domain but in the human one. Specifically, it lies in the increase in the world's population, its concentration in large conurbations, the high vulnerability of modern societies and technologies, and the social and economic consequences of development in highly exposed regions, such as coastlines (Smolka, 2006). Coastalization is a trend recognized worldwide whereby more and more population, property, and infrastructure squeezed along shorelines facing rising sea levels and threatened with saltwater intrusion into groundwater aquifers and inundation from storm surges and tsunamis (Figure 5). Drawing attention to the preferential migration of the most affluent sectors in US society to the popular retirement destinations of the earthquake-prone shores of California and Washington and the hurricane-prone Gulf Coast, for example, van der Vink et al. (1998, p.537) asserted "We are becoming more ulnerable to natural disasters because of the trends in our society rather than those of nature."

Along with a move to the coast, the global shift to urban living has made many cities as dangerous as the natural environments they replace. With the rise of supercities (>2 million people) and megacities (>10 million people), human settlement has been forced into marginal,



Disasters, Figure 5 The concentration of people, infrastructure and economic development along tsunami-prone shores has changed the nature and extent of vulnerability in many coastal zones. The 2004 Indian Ocean earthquake and tsunami, for example, affected 14 Asian and African countries and killed people from 48 nationalities, 34 representing foreign tourists from around the world. Expensive beachfront tourist complexes, such as one destroyed here in Khao Lak (Thailand), greatly contributed to the human and economic losses of this calamitous event.

dangerous places, sometimes within the sprawling metropolitan areas. Alongside the physical marginality of such areas is the acute social and economic marginality of the people who must inhabit them (Wisner et al., 2004). Such a situation is tragically exemplified by the slide of solid waste from the Payatas rubbish dump in central Manila (Philippines) in July 2000 which killed 300 people in the contiguous squatter settlement (Gaillard and Cadag, 2009). Such an event illustrates how, although hazard typologies have in the past made a clear separation between "natural disasters" produced by geophysical agents and "human disasters" that arise from technological failures or human conflict, such a distinction is ever more difficult to sustain in the real world. In the real world, disasters are increasingly messy amalgams between natural processes acting on human environments.

For all their unnaturalness, disasters retain a clear natural geography to their incidence. That is because the hazard processes that underpin them tend to strike repeatedly in the same places. The hazard "hot spots" are familiar: droughts have been occurring in the Sahelian region of Africa for millennia, monsoonal storm surges annually inundate the deltaic plains of Bangladesh, hurricanes seasonally batter the Atlantic and Gulf coasts of the USA, and earthquakes and volcanic eruptions routinely plague the tectonic plate boundaries like the Pacific Ring of Fire (Dilley et al., 2005). Because geophysical phenomena are, by and large, persistent offenders, knowledge of their past incidence can provide a reasonable expectation of the physical exposure to hazard in any particular geographic area. Of course, monitoring the nascent signs of impending hazards and forecasting the likely location, size, or style of their impact remain fraught with technical difficulties and scientific uncertainties. The 2011 Tohoku (Japan) earthquake provided a telling reminder of those difficulties; the giant ($M > 9$) earthquake and its accompanying tsunami were not unexpected based on geological evidence, but that data was overlooked in subsequent hazard assessments, leading to inadequate mitigation measures (insufficiently high seawalls). Nonetheless, gauging the physical exposure to floods, hurricanes, earthquake, volcanic eruptions, and the like is often more readily constrained than assessing a hazard-prone community's capacity to resist such events (e.g., Wisner et al., 2004).

The nature of vulnerability

A fundamental challenge of disaster reduction is to anticipate the intrinsic vulnerability (or lack thereof) of communities at risk? The notion of vulnerability has been confronted by disaster researchers for decades, but it is only in the past few years that it has become an issue that is explicitly addressed, and it remains a concept that is difficult to define and quantify (Bankoff, 2004; Wisner et al.,

Disasters, Figure 6 Pressure and Release (PAR) model of Blaikie et al. (1994) showing the progression of vulnerability. The diagram shows a disaster as the intersection between socio-economic pressures on the *left* and physical exposures (natural hazards) on the *right*.

2004; Cutter, 2006). As disasters lie at the intersection of socioeconomic pressures and physical exposures, different kinds of vulnerability prevail (Figure 6). Physical vulnerability (exposure to hazard threats) is the easiest to determine, identifying those that live in perilous places as being potential victims of disaster. Less easy to determine are those whose situation is made perilous because they are socially excluded, economically disadvantaged, and/or politically marginalized. Social, economic, and political vulnerability ensures that access to hazard mitigation measures and disaster reduction strategies are often unevenly distributed across and among at-risk communities. These different facets of vulnerability operate dynamically during hazard events, as is evident in this account of Bangladesh floods:

> On the eve of Bangladesh's massive floods in August 1988, this relatively powerless group (landless squatters] was living in an economically marginal situation but close to the city, on low-lying land prone to flooding. Their economic and political marginality meant they had few assets in reserve. It also meant that their children were unusually malnourished and chronically ill. This channelled the dynamic pressure arising out of landlessness and economic marginalization into a particular form of vulnerability: lack of resistance to diarrheal disease and hunger following the flooding in 1988. Factors involving power, access, location, livelihood, and biology mutually determined a situation of particular unsafe conditions and enhanced vulnerability. (Blaikie et al., 1994, p. 27)

For most practitioners, the first "line of defense" against vulnerability to disaster is livelihood – ensuring that individuals have appropriate assets to grow food themselves or make earnings (Cannon, 2008). Higher incomes and stable employment enable households to have livelihoods that are buffers against hazards. Livelihood presets a person's basic nutritional state, their baseline status, and their general health and welfare. Individuals with poor nutrition are generally less resistant to disease and less capable of making a good recovery when stressed by a hazard impact; morale and personal resilience, stress and general mental health are all factors that are likely to affect the ability to overcome the impact of a hazard. An individual's income determines their capacity to build a home that is safe from endemic hazards and their ability to site that home somewhere out of harm's way. Many people remain vulnerable precisely because they do not have the financial resources to live sufficiently above the regular flood levels or away from steep marginal slopes prone to landslides, excluded from safer areas by high land prices.

"Self protection" from hazards requires knowledge or skills that may be available from the local community or from outside agencies. Equally, for some vulnerable groups like children, the elderly, sick, or disabled, adequate protection from hazards can only be provided at a community or society level. Much of this "social protection" is conferred by local, regional, and national authorities, in the form of hazard-awareness programs, warning systems, emergency plans, and regulations to do with land-use management or engineering and building controls.

Yet ill-judged or inadequate social protection measures can also instigate human disasters, such as through inappropriate policies, weak infrastructure, poor governance and corruption, ineffective monitoring and communication, bad development decisions, injustice, and discrimination. Inaction, in the form of authorities not carrying out their expected regulatory functions, also aggravates disaster. For example, a failure to deal effectively with land squatting and irregular construction fuels vulnerability in the environs of many hazard-prone cities. In Istanbul (Turkey), for example, many people ignore mandatory requirements to live in homes approved as conforming to stringent earthquake design standards, preferring instead to illegally self-build. Yet they do so in part because of a suspicion that the formal approved building stock is "unsafe," having been built by people and using materials unknown to them and signed off as safe by potentially corrupt engineers or officials, all chronic failings of endemic construction practices exposed by the 1999 Izmit earthquake in which tens of thousands of people lost their lives through the collapse of improperly constructed buildings (Green, 2008). Given this deep distrust of the Istanbul's authorized, commercially built housing stock, Green (2008) suggests that bolstering the city's unauthorized self-built housing might actually be an effective means of providing protection against the future earthquake threat.

Regardless of levels of self- and social protection, in landscapes of chronic vulnerability like urban squatter settlements, disasters in some form are probably inevitable. As noted by Hewitt (1983), *"In most places and segments of society where calamities are occurring, the natural events are about as certain as anything within a person's lifetime*." The point here is that although Western disaster discourse typically depicts "disasters" as abnormal occurrences, in communities in many acutely marginalized parts of the world, vulnerability emerges from the "normal" order of things – hazards simply compound the struggles that are part of people's daily lives. Hazards are, in effect, the ordinary, not the extraordinary. Communities living on the margins will have a very low capacity to withstand even small damaging events. For that reason, basic capacity-building measures are a fundamental part of disaster reduction.

In less acute situations, vulnerability (and its alter ego, resilience) is difficult to track, being a dynamic that changes through time as individuals, groups, and institutions adapt to internal and external pressures (Oliver-Smith, 1999a; Turner et al., 2003; Berkes, 2007). Communities can become less vulnerable to hazards if they have a range of options for coping with external shocks and stresses. The key to reducing vulnerability, therefore, is to increase "resilience," a concept defined by the United Nations Strategy for Disaster Reduction as "the ability of a system, community, or society exposed to hazards to resist, absorb, or recover from the effects of a hazard in a timely and efficient manner." Most strategies for growing resilience involve reducing risks by spreading them out, thereby increasing opportunities in the face of hazards (Paton and Johnson, 2006). Ultimately, however, a measure of the success of a community's adaptations to anticipated threats is only apparent after the event (Cannon, 2008). Prior to acute environmental crises, the manifestations of vulnerability – social, economic, institutional, and infrastructure – may be hidden from view. Only when a hazard strikes do the societal and technical bonds of an at-risk community become truly tested and often found wanting (Oliver-Smith and Hoffman, 2002).

A potent example of the revelatory power of disasters was provided by Hurricane Katrina in 2005. The likely impact of major hurricane making landfall in the low-lying Mississippi delta was well known (e.g., Fischetti, 2001), and the landfall of the destructive Katrina storm in New Orleans was accurately forecasted and emergency evacuation plans were put in motion (McCallum and Heming, 2006). What surprised few was that the aging infrastructure of the Mississippi coast's flood protection levees – designed for a category three storm surge – failed under the onslaught of the storm, allowing widespread inundation of the city. What stunned many was the resulting institutional meltdown, which for several days left evacuees with no power, no drinking water, dwindling food supplies, understaffed law enforcement, and delayed search and rescue activities (Cutter et al., 2006).

Events like Hurricane Katrina throw into question how resilience is fostered in social systems. It has long been assumed that governments, from the federal to the municipal, comprise the backbone of emergency management, but increasing community organizations are shown to have a major role to play in the face of disaster (King, 2007). Community resilience takes the form of networks of strong and weak ties – families, churches, local volunteer and relief groups, hobby clubs, even neighborhood and crime watch organizations – that is referred collectively as "social capital" (Dynes, 2002). Through social capital, citizens assume roles as active agents rather than passive victims since they are able to draw upon collective strengths, assistance, and resources to deal with disasters, thereby being more proactive in decision making and effecting a more speedy recovery.

Cultures of catastrophe

While considerable attention has been devoted by hazard practitioners to elucidate and quantify the factors underpinning social vulnerability (Cutter, 2006), some argue

Disasters, Figure 7 The narrow streets, multi-story houses and tiled roofs of many Andean towns are a cultural import from Spanish Andalucia, transforming earlier Inca settlements into places of heightened seismic vulnerability.

that the whole concept of vulnerability is itself a Western ideological construct that fails to acknowledge how natural hazards are themselves a cultural driver, shaping community adaptations in ways that allow disasters to be incorporated into daily life. Bankoff (2003) recognizes this effect of the "normalization of threat" in Philippine culture, seeing it in "…the design and construction of buildings, in the agricultural system, in the constant relocation of settlements and in the frequency of migration. Filipino society has evolved certain 'coping mechanisms' to come to terms with the constancy of hazard and to mitigate the worst effects of disasters. Often, too, in the way in which people deal with emotional and psychological requirements of living with uncertainty may influence what are seen as 'Filipino' beliefs and character traits."

The loss or removal of such cultural coping mechanisms can expose communities to heightened hazard threats, even when that transformation happened decades or centuries before. According to Oliver-Smith (1999b), the calamitous May 31st 1970 Peru earthquake (M 7.7) in Peru had its roots five centuries before when local Andean resilience was replaced by imported Spanish practices; the dispersed design of Inca towns was replaced by the Andalucian-inspired new towns favoring narrow streets with multistory houses pressed close together. Sturdy monumental stonemasonry and anti-seismic wall ties were abandoned, and thatched roofs were replaced with heavy ceramic roof tiles, all of which made houses into earthquake death traps (Figure 7). For these reasons, Oliver-Smith (1999b) argues that the 1970 earthquake – an event which saw 70,000 people killed, 140,000 injured, and half a million homeless – was a calamity 500 years in the making.

Where indigenous cultural practices have persisted alongside recurrent hazard experiences, they are often in stark tension with Western scientific and social dialogues of hazards as interactions between extreme natural events and vulnerable human populations (Chester, 2005). Local knowledge, customs, and traditional beliefs can motivate a community's actions during a crisis, including their propensity to evacuate; in some cases, the cultural ties between community and hazard can have lethal consequences. In 1963, Bali's Mt. Agung erupted during the once-in-a generation Hindu rite killing 1,200 people, many of them waiting patiently and clothed in ritual dress within their temples and resisting attempts by officials and even priests to evacuate them. On the neighboring island of Java, spiritual ties with Mt. Merapi are part of the reason why communities on the perilous upper slopes have resisted efforts to evacuate during repeated volcanic crises, although socioeconomic factors also exert a strong control (Donovan, 2010) (Figure 8). Across many hazard-prone developing regions "…the battle against natural forces is often fought in the cultural arena – with religion as a backdrop" (Svensen, 2009).

Although indigenous cultural traits can at times undermine hazard science approaches to disaster reduction, traditional cultures can also reduce vulnerability by strengthening resilience and providing effective mitigation techniques (Cashman and Cronin, 2008). Perhaps

Disasters, Figure 8 (**a**) The fertile environs of Mount Merapi on the Indonesian island of Java is a hazardous high-population environment where lethal volcanic crises recur every few years. (**b**) Scientific studies of the volcano through monitoring of ground deformation, seismicity and summit gas activity give rise to early warning alerts and lead to mandatory evacuation orders by local authorities. However, routinely at-risk communities on the volcano's upper flanks refuse to evacuate, sometimes with lethal consequences. (**c**) During the 2006 eruption crisis, a pyroclastic flow killed 60 people attending a wedding ceremony in Turgo, a settlement located inside the high-risk exclusion zone. Reluctance to follow volcano emergency management plans reflects a complex combination of socio-economic and cultural factors.

the most dramatic example of this was the self-evacuation of coastal communities on Simeulue and Nias Islands during the 2004 Indian Ocean tsunami. Despite being close to the epicenter of the earthquake and experiencing considerable wave heights, oral traditions of calamitous tsunamis from more than a century before motivated them, at the onset of the initial tremors, to evacuate to higher ground and hardly any lives were lost (Sieh, 2006).

Along the adjacent tsunami-stricken shores of Sumatra, such cultural memories have been largely lost, eroded by economic and tourist development, and with them, have gone traditional practices that long protected communities (McAdoo et al., 2006; Gaillard et al., 2008). According to Sieh (2006, p.1947), disaster reduction in such areas "...does not necessarily involve hugely expensive or high-tech solutions such as the construction of coastal defences or sensor-based tsunami warning systems. More valuable and practical steps include extending the scientific research, educating the at-risk populations as to what to do in the event of a long-lasting earthquake (i.e., one that might be followed by a tsunami), taking simple measures to strengthen buildings against shaking, providing adequate escape routes and helping the residents of the vulnerable low-lying coastal strips to relocate their homes and businesses to land that is higher or farther from the coast."

The politics of disaster

Local disaster cultures exist because communities, and in some cases, whole societies, have coevolved with perilous nature. Strengthening or reestablishing indigenous practices may provide the means by which such communities can confront their hazard threats, but equally, the solutions may come from outside. The technical ability to construct buildings and defenses that can withstand modest hazard shocks exists, as does the scientific knowledge to identify and delineate hazard threats (e.g., Bilham, 2009). But embedding those good building practices and good land-use planning into local environments does not just require an appreciation of cultural sensitivities. Safe construction and effective planning protocols are also underpinned by robust regulatory control. Here, a very different culture can arise – a culture of ignorance, incompetence, and corruption within the authorities charged with emergency planning. With disaster reduction obligations invested in the hands of political authorities, it is the role and efficacy of the state itself that becomes the ultimate element in where and when disasters happen.

According to Berkes (2007), for example, the same hurricane striking Samoa and neighboring American Samoa in the Pacific produced markedly different results: the former was prepared and capable, whereas the latter, much less affluent and used to outside aid for disasters, had weaker institutions for response. Political environments in which there is strong linkage from local to national levels tend to withstand disasters better; Wisner (2001) has argued that so few people died when Hurricane Michelle hit Cuba severely because of the existence of strong organic links between government and people. It has also been argued that emergency crises may be less severe in countries with democratic governments (Sen, 1981), where disaster reduction measures can be more effectively monitored and made accountable through firm civil liberties and a free press (Besley and Burgess, 2002). Of course, as recent disasters in Japan and the USA testify, active democratic systems do not provide immunity from natural emergencies.

Disasters themselves are political instruments. In some cases, they can be a pretext for international political and economic "engineering," and disaster recovery is the impetus for institutional reform (Klein, 2005). In this way, governance – the manner in which power is exercised in the management of a country's economic and social resources for development – exerts a powerful influence on national and international disaster policies. After Hurricane Mitch in 1998, for example, afflicted countries in Central America agreed to a set of principles

with international aid donors that included promotion of democracy and good governance, political decentralization and economic debt reduction (Wisner et al., 2004).

The realization that disasters can be significant agents of societal change leads to the paradoxical question as to whether they might, in any sense, bring positive benefits. One benign facet of natural disasters might be in aiding international diplomacy. The earthquakes that struck Istanbul and Athens, in August and September 1999, respectively, opened communication channels between feuding Greece and Turkey, whereas the Bam (southern Iran) earthquake of December 2003 prompted offers of aid from 40 countries, including the USA – the "Great Satan" – which had broken off diplomatic relations with Iran 20 years before. What patchy evidence there is on this notion of disaster diplomacy suggests that while disaster-related initiatives can be catalysts for diplomatic interchanges that have already started, they rarely cement political rapprochement, with a possible exception being the peace deal reached in Aceh after the December 26, 2004, earthquake and tsunami (Kelman, 2006).

Although natural hazards may offer up opportunities for "disaster diplomacy," they can also stir cross-border tensions. During the 2000 and 2004 floods along the India-Bangladesh border, Indian border security forces breached river embankments to allow the water to spill out, thereby ameliorating its downstream impacts in West Bengal (India) but exacerbating destruction of life, crop, and property in Bangladesh (Ali, 2007). In this instance, there was no cross-border conflict, but disasters can trigger political action. It has been argued, for example, that the cyclone and storm surge in East Pakistan in 1970 contributed to the development of the Bangladesh independence movement, while the revolutionary movement in Nicaragua from 1974 to 1979 derived some of its impetus from the effect of the Managua earthquake of 1972 (Wisner et al., 2004). Disasters striking politically peripheral regions can catalyze regional tensions, especially where existing regional deprivations are worsened by post-disaster governmental responses (Pelling and Dill, 2006). Disasters can enhance or even regain the popular legitimacy of political leaders, and many political regimes might interpret spontaneous collective actions by afflicted communities in the aftermath of a disaster as a threat and thereby respond with repression.

Overall, fractured or contested political landscapes often promote a heightened risk to disaster specifically because they sustain an inequitable distribution of resources. But economic resources too can be redefined by disasters; emergency crises can bring direct monetary gain in the form of disaster relief funds that are injected into the local economy. Following the earthquake that killed 80,000 people in China's Sichuan Province in May 2008, for example, funds allocated to rebuilding outweighed the economic loss caused by the quake, enough to raise national economic growth by 0.3% (Hewitt, 2009). Disasters may be economic catalysts at the regional level too. It has been argued that the reconstruction activities following the 1994 Northridge earthquake boosted Los Angeles economy in a similar way to Miami that benefitted after the 1992 Hurricane Andrew (Romero and Adams, 1995; Cochrane, 1997). Following the 1991 volcanic eruption of Mt. Pinatubo in the Philippines, financial resources, investment, and infrastructure poured into the area, turning Luzon into an economic hub. However, although reconstruction efforts may contribute positively to an economy (as measured by gross domestic product or GDP), the loss of productive capital may reduce it. As a result, the financial balance sheet of natural crises shows that the growth in real incomes is not significantly different in years when disasters strike than in an average year (Stromberg, 2007).

The recognition that the financial costs of natural disasters typically have comparatively little effect on most national economies is arguably less applicable to the fiscal fate of less-developed nations. Many developing nations will be hard pressed to develop economically due to recurrent hazard losses, and for many countries, probable economic losses over the next century exceeds their current financial resources (Cardona, 2005). Average losses from disasters in low-income countries (e.g., Sri Lanka, Bangladesh, Nicaragua) can be 10–20 times greater than in disasters in high-income nations (Haas et al., 1977). Whereas floods and droughts typically claim about one tenth of 1% of the GDP of industrialized countries, they cost up to 20 times more (up to 2% of GDP) in less-developed nations (Alexander, 1993).

In such a context, it is difficult to appreciate a silver lining of disasters. Indeed, most disaster scientists would contest the notion that natural calamities can be "good value" at all. A recent e-discussion on the question of whether disasters can help a country's economy drew these remarks (Hewitt, 2009): "*To say that disasters help the economy is a materialistic view. . .as well as loss of life, disasters entail a loss of investment in those who are killed, and have a long-term psychological impact on those who survive, affecting their capacities and capabilities, and resulting in a loss of productivity, opportunity costs, and more. Therefore, the indirect cost of a disaster is much larger than the direct cost. A loss is a loss and cannot be turned into an investment and produce income or benefits. In addition, losses are not limited to lives, materials, and animals, but also include traditional wisdom and knowledge, making future settlements more prone to natural disasters.*"

DISPERSIVE SOIL HAZARDS

Andrew J. Stumpf
Institute of Natural Resource Sustainability, University of Illinois at Urbana-Champaign, Champaign, IL, USA

Synonyms

"Dispersive" soils (Volk, 1937; Fletcher and Carroll, 1948)

Definition

Some natural clay-rich soils are highly erodible by flowing water both at and below land surface. These soils contain an abundance of clay particles that disperse (slake) and deflocculate when relatively pure water is added. Such "dispersive soils" have clays with a higher exchangeable sodium percentage – the proportion of sodium cations to the total of other soluble cations (e.g., calcium and magnesium). Because of the mineralogy of their clay particles, these soils are distinct highly susceptible to erosion by gulleying, tunneling, and piping when cultivated or when disturbed to some depth below land surface.

Soil characteristics

Dispersive soils were first recognized over 120 years ago, but were not studied in depth until over 50 years later by Volk (1937) and Richards (1954), and later by Australian engineers (e.g., Aitchison and Wood, 1965). These soils contain a high proportion of clay particles that have weak electrochemical attraction to adjacent particles. These bonds are affected primarily by the type of clay minerals present, however pH, amount of organic matter, temperature, water content, thixotropy (viscosity change), and chemistry of pore water (Bell and Maud, 1994) also can affect dispersion. These soils have higher percentage of exchangeable sodium (expressed by the exchangeable sodium percentage – ESP) than most soils. Dispersive sodic soils in Australia have ESP > 6 in the top meter of the soil horizon (Northcote and Skene, 1972; Raine and Loch, 2003). Commonly, dispersive soils contain little organic matter content and have alkaline pore waters with a pH > 8.5. More recent studies have found these soils in humid tropical climates where the pore water may be acidic (Sherard et al., 1977). Often, little or no evidence of their associated instability are exposed at land surface, because the soil is covered with silty or sandy material (containing no dispersive clays) or a continuous layer of topsoil and vegetation. Since many traditional laboratory index tests, including specific gravity and Atterberg limits, fail to differentiate dispersive soils collapsible soil hazards (see entry *Collapsing Soil Hazards*) from non-dispersive soils (Sherard et al., 1972), a number of specialized experiments have been developed to measure the erodibility of dispersive soil, (Reilly, 1964; Sherard et al., 1976b, and Emerson, 2002).

Process

Erosion occurs by a process in which individual clay particles are electrochemically suspended in water ponded at the land surface or in the subsurface in soil pores. The particles are transported when the water flows. This process is significantly different than erosion taking place in other soil types, where a considerable velocity is needed for water to erode clay particles (Sherard et al., 1976a). More specifically, as water wets the soil clay particles interact with the water to weaken interparticle sodium bonds. Eventually, these bonds are broken, the sodium cations disperse, and the individual clay particles begin to deflocculate (Knodel, 1991).

Distribution

Many early studies indicated that dispersive soils form exclusively in arid and semiarid climates in alkaline soils. In alluvial floodplain deposits, slope wash, lake bed deposits, and Loess (see entry *Loess*). Some dispersed soils have been identified in residuum on marine claystone and shale, granites, and sandstone (Sherard et al., 1977; Clark, 1986). More recent field work has extended their distribution to humid climates and are now identified in United States, Venezuela, Australia, South Africa, Iran, Tasmania, Mexico, Trinidad, Vietnam, South Africa, Thailand, Israel, Ghana, and Brazil (Knodel, 1991).

Hazards

The breakdown in the internal structure of dispersive soils has led to problems such as surface crusting, reduced water infiltration, and retarded plant establishment and growth (Rengasamy et al., 1984). Dispersive soils are prone to gully erosion and piping hazards (see entry *Piping Hazard*). Damage due to subsidence has occurred in existing earth embankment dam built with dispersive soil, and in new reservoirs and buildings constructed on these soils. In the United States, the most notable failure in dispersive soils occurred at Teton Dam (Sherard, 1987). Some studies have shown that the failure of structures built on dispersive clay soils occurs after the first wetting (Knodel, 1991).

Summary

The study of dispersive soil has a long history, and a worldwide effort has been undertaken to identify and characterize them through rigorous testing, in order to develop a comprehensive classification scheme. Ancillary research has utilized this data to develop products (i.e., filters and chemical additives) used to mitigate their affect on agriculture and water-retaining structures. In many countries, major outreach programs have been developed to educate landholders, planners, and engineers to draw awareness toward the problems associated with dispersive soils.

DOPPLER WEATHER RADAR

Rodger A. Brown
NOAA/National Severe Storms Laboratory, Norman, OK, USA

Synonyms

Doppler frequency shift

Definition

Conventional weather radar. A conventional weather radar transmits a narrow pulse of electromagnetic radiation (centimeter wavelength), and then listens to see if any energy is scattered back from distant targets before the next pulse is transmitted (e.g., Rinehart, 2010). The targets of meteorological interest are hydrometeors (raindrops, hailstones, ice crystals). The time delay between the transmitted and returned pulse determines the distance to the hydrometeors and the amount of energy received (called radar reflectivity) is proportional to the size and scattering characteristics of the hydrometeors within the pulse volume. Owing to random fluctuations of hydrometeors within the pulse volume, tens of consecutive pulses are averaged together to obtain a representative measurement.

Doppler weather radar. A Doppler weather radar is a conventional weather radar that has the additional capability of detecting a slight frequency shift (Doppler shift) in the returned pulse (e.g., Rinehart, 2010). The frequency shift is caused by *the component of hydrometeor motion toward or away from the radar.* The three basic quantities measured by a Doppler radar are radar reflectivity, Doppler velocity (the mean Doppler velocity component of hydrometeor motion within the series of returned pulses), and spectrum width (the standard deviation of the velocity components within the series of pulses).

Overview

During the mid-1950s, a few research organizations around the world started to apply Doppler radar techniques to study weather phenomena (e.g., Rogers, 1990). The first radars were pointed vertically because updrafts and downdrafts in storms could be uniquely identified. However, by the late 1960s and early 1970s, researchers began to scan radars horizontally through thunderstorms. They discovered that – even though a Doppler radar measures only the single component of flow toward or away from the radar – there are unique Doppler velocity signatures of rotating and divergent/convergent flows that have warning implications. With coordinated measurements from two or more nearby Doppler radars and a few assumptions, researchers can estimate the full three-dimensional components of airflow within storms.

During the 1980s and 1990s, based on the existence of single Doppler velocity signatures, it was becoming apparent to national weather services in various countries that they could improve the timeliness and accuracy of hazardous weather warnings by replacing their conventional radar networks with Doppler radar networks (e.g., Whiton et al., 1998). With many such networks now in existence, Doppler radar data are beginning to be assimilated into numerical weather prediction models with the goal of producing more accurate short-term (1–6 h) forecasts of evolving hazardous weather conditions.

DOSE RATE*

Cathy Scheib
British Geological Survey, Nottingham, UK

Synonyms

Radiation absorbed

Definition

Dose rate is the quantity of radiation absorbed per unit time (Gy s^{-1}).

Overview

The *absorbed dose* is the amount of energy deposited by ionizing radiation in a unit mass of medium, such as tissue.

*©British Geological Survey

This dose is expressed in units of joule per kilogram (J kg^{-1}), which is called the "Gray" (Gy). The unit Gray can be used for any type of radiation, but it does not describe the biological effects resulting from different radiation types. Absorbed dose rate in air (nGy h^{-1}) is commonly used to express gamma ray intensity in the air from radioactive materials in the earth and atmosphere. *Equivalent dose* relates the absorbed dose in human tissue to the effective biological damage and is expressed in the unit Sievert (Sv) (The International System of Units, 2008). To determine equivalent dose, the absorbed dose is multiplied by a quality factor that is unique to the type of incident radiation in question (e.g., alpha particles, 20; beta particles, 1; gamma and x-rays, 1). To take account of the susceptibility of organs and tissues to radiation doses, weighted equivalent doses in all the tissues and organs of the body are summed to determine the *effective dose* (Sv) (Wrixon, 2008; US Department of Health and Human Studies).

Sources and effects of human exposure to ionizing radiation

Natural radiation contributes over 80% of the average radiation dose received; approximately half the overall dose occurring due to exposure to radon gas and its decay products (Eisenbud and Gesell, 1997). Terrestrial gamma radiation – which is largely controlled by geological variation of naturally occurring radioactive materials in rocks, soils, and building materials – and cosmic radiation, which varies with altitude and latitude, contribute on average 13% and 12%, respectively of the average annual dose to the UK population (Hughes et al., 2005). The average global annual effective dose from natural radiation is approximately 2.4 mSv. This level of exposure varies around the world, usually by a factor of 3, although at some locations it can be exceeded by more than a factor of 10 (UNSCEAR, 2000).

Anthropogenic sources of exposure to ionizing radiation include medical screening and therapeutic procedures, nuclear weapons testing, electricity generation, and accidents such as the one at Chernobyl in 1986, although the contribution to dose from these sources is small in comparison to that from natural radiation (UNSCEAR, 2000).

Damage to DNA in the nucleus is the main initiating event by which radiation causes long-term damage to organs and tissues of the body (UNSCEAR, 2006). There is no convincing scientific evidence that cancer risk from radiation exposure disappears at very low doses, and this is currently the focus of major research (e.g., US Department Of Energy – Low Dose Radiation Research Programme).

DROUGHT

Suzanne Hollins, John Dodson
Australian Nuclear Science and Technology Organisation, Lucas Heights, NSW, Australia

Definition

Drought is a severe natural hazard that affects more people than any other natural disaster. It is usually only recognized as a natural hazard when social, economic, or environmental impacts become apparent. Drought is different from many other natural hazards in that it lacks easily identified onsets and terminations (Maybank et al., 1995). It is also unusual in that it is a hazard of scarcity rather than one of excess. Drought is a natural, recurring pattern of climate that occurs within nearly all climatic regions. However, it is not just a physical phenomenon or natural event caused by changes in climatic conditions. Rather, drought results from a connection between the natural event of lower than expected precipitation, and the demand of human usage on water supplies (Wilhite, 2000). Anthropogenic activities can exacerbate the severity and impacts of drought, but within a natural variability range.

Drought does not have a universal definition; rather it has hundreds, as Wilhite and Glantz (1985) discussed in their classification study. Despite the number of definitions, many are not useful to policy makers or scientists. This causes some uncertainty in declaring whether a region is suffering from drought, and its degree of

Drought, Figure 1 The relationship between types of drought and duration of drought events (Figure modified from Wilhite, 2000, p. 10.).

severity. There are three major characteristics of drought – intensity, duration, and spatial extent. Drought is never small scale or short term (by definition). The effects of drought can build up over lengthy periods of time, and these effects may be felt for years after the drought has "broken," making the onset and conclusion of drought difficult to define. "Seasonal" droughts are frequent and predictable, as distinguished from "supra-seasonal" droughts, which are aberrant and unpredictable (Bond et al., 2008). It is generally accepted that drought can be divided into four categories based on disciplinary viewpoints: meteorological, hydrological, agricultural, and socioeconomic (Wilhite and Glantz, 1985). Figure 1 (modified from Wilhite, 2000) shows the relationship between the various categories of drought and their durations. Each discipline incorporates different physical, biological, and/or socioeconomic factors in its definition (Wilhite, 2000), but common to all these is inadequate precipitation.

A working definition of meteorological drought is "an extended period (season, year, or several years) of deficient rainfall relative to the statistical multiyear mean for a region" (Druyan, 1996a). A lack of rainfall does not necessarily constitute drought. It must be distinguished from aridity, which occurs in areas where there is a high probability of low rainfall for indeterminate periods of time (Druyan, 1996b). Meteorological drought must be defined on a regional basis, as deficiencies in precipitation are specific to local atmospheric conditions. Once meteorological drought establishes itself, both agricultural and hydrological drought usually follows.

Hydrological drought is associated with the effects of a persistent scarcity in rainfall on the capacity and

availability of surface water (e.g., rivers, lakes, reservoirs) and groundwater supplies. The frequency and severity of hydrological drought is often defined on a catchment or basin scale. The commencement and finishing of groundwater drought both usually lag well behind that of surface water drought (Bond et al., 2008), and both are usually out of phase with meteorological and agricultural drought. As a lack of expected rainfall continues, water levels in temporary water bodies decrease, and they eventually dry up. The drought also decreases water levels in "perennial" surface water bodies, and if it continues long enough, these may also disappear. As surface waters are depleted by ongoing drought, groundwater levels may also decrease over time in those aquifers influenced by modern recharge. This can exacerbate the effects of drought in surface water systems in which groundwater forms the base flow. After a return to normal rainfall conditions, surface water drought usually breaks well before groundwater drought.

Agricultural drought is associated with a shortage of available water for plant growth. It is assessed as insufficient soil moisture to replace evapotranspiration losses, and links meteorological and hydrological drought to impacts on agriculture. Most regions can be affected by agricultural drought, but its duration and intensity varies greatly between climatic zones (Wilhite, 2000). There are many definitions of agricultural drought, but in general they account for the varying susceptibility of crops during development to deficient topsoil moisture.

Scientists tend to frame the broad social dimensions of droughts into a general category called "socioeconomic drought" (Kallis, 2008). Socioeconomic drought associates supply and demand of economic goods with at least some elements of meteorological, hydrological, and agricultural drought (Wilhite, 2000). It can result when the demand for economic goods exceeds supply because of a shortfall in water related to variations in climate. It can also occur when the demand for goods increases due to population increase and/or per capita consumption.

Drought indices

Measurements of the frequency and severity of droughts are important in the development of mitigation strategies and preparedness plans. As in drought definitions, it is generally agreed that there can be no universal drought index or operational definition (Kallis, 2008), and so numerous indices have been developed to monitor and measure drought. Droughts differ in three major ways: intensity, duration, and spatial coverage (Wilhite, 2000). Intensity is related to the precipitation deficit, and several indices measure how precipitation has deviated from historical norms. The duration of drought is a discerning characteristic, which along with intensity and timing, is closely related to the level of impact. The spatial characteristics of drought also differ as the degree of severity evolves across areas and through seasons.

Drought and its severity can be numerically defined using indices that integrate temperature, precipitation, and other variables that effect evapotranspiration and soil moisture (IPCC, 2007a). The simplest of these assess meteorological drought using a measure of the precipitation deficit over a particular time period, whereas those more complicated use models that incorporate soil moisture conditions and land-use parameters (Oladipo, 1985).

One of the main difficulties with using indices that measure precipitation deficiency is setting the threshold below which the onset of drought is defined (Wilhite, 2000). The Palmer Drought Severity Index (PDSI; Palmer, 1965) is one of the most extensively used meteorological drought indices across the world, and particularly in the USA. PDSI is a reflection of how much soil moisture is currently available compared to that for normal or average conditions (Cook et al., 2007). The PDSI was one of the first methods to successfully quantify the severity of droughts across different climates. The index is based upon a primitive water balance model which accounts for the difference between precipitation required to maintain a water balance and the actual precipitation. The PDSI also incorporates calculations that attempt to account for climatic differences between locations and seasons of the year (Wells et al., 2004). Despite its popularity, the PDSI has been widely criticized for its empiricism (Keyantash and Dracup, 2002). It does not incorporate variables such as wind speed, water vapor, or solar radiation into its calculation of potential evapotranspiration. Commonly, it is said that calculated PDSI values are not comparable between diverse climatological regions. This led to the development of a self-calibrating version of the PDSI by Wells et al. (2004) to ensure consistency with the climate at any location. A relatively new precipitation deficit index used in the USA is the Standardized Precipitation Index (SPI) developed by McKee et al. (1993, 1995) in recognition of the impacts that precipitation deficit has on groundwater, soil moisture, streamflow, and other water resources. It was designed to quantify precipitation deficit for multiple timescales, allowing for the determination of the rarity of drought as well as the probability of precipitation necessary to break a drought. In Australia, the drought definition is based on the Rainfall Deciles method (Gibbs and Maher, 1967), chosen because it is relatively simple to calculate, and requires fewer assumptions than the PDSI (Smith et al., 1993).

Similar to the PDSI is the Palmer Hydrological Drought Severity Index (PHDI), with the primary difference being stricter criterion for the ending of a drought (or wet spell). This is considered more appropriate for hydrological drought assessment, as it is much slower to build up than meteorological drought (Keyantash and Dracup, 2002). Shafer and Dezman (1982) developed the Surface Water Supply Index (SWSI) to account for snowpack and delayed runoff, and it is useful in providing a measure of hydrological drought in areas where snow makes up a significant component of the hydrological budget.

Agricultural drought is specifically related to cultivated crops rather than natural vegetation (Keyantash and Dracup, 2002), and it is characterized by short-term changes to volumetric soil moisture in the root zone. The Crop Moisture Index (CMI) was developed by Palmer (1968) and uses a meteorological approach to monitor agricultural drought. The CMI was developed from procedures within the PDSI, but it was designed to measure short-term moisture conditions across crop-producing regions, rather than monitoring long-term meteorological drought like the PDSI (Hayes, 2009).

Many parts of the world have not adopted clear indices for agricultural drought and hydrological drought, making attempts to compare the impacts of drought between places and between times difficult (Bond et al., 2008). In the context of climate change and increasing land degradation, it is becoming increasingly important to be able to calculate drought impacts if the consequences of climate change are to be understood (Vicente-Serrano, 2007).

Impacts of drought

Drought, as one of the most complicated yet least understood natural hazards, is associated with many other kinds of hazard, and these play out in impacts on economic, social, and environmental systems (Kallis, 2008). The onset of drought is difficult to identify or even recognize, although predictive capabilities are increasing. The study of past droughts can indicate what onset might look like, how drought develops and the kinds of impacts that follow. The palaeo record shows that severe droughts of the last century were greatly eclipsed by megadroughts in the past (Maybank et al., 1995; Woodhouse and Overpeck, 1998). These will occur again, and are likely to be exacerbated by greenhouse warming.

There are methodological problems in assessing the impact of droughts due to the difficulty of defining it. However, the most obvious first-order impacts are through drought impact on agricultural production, water supply, and forestry. Forests are usually less sensitive to drought as they tend to occur in wetter regions.

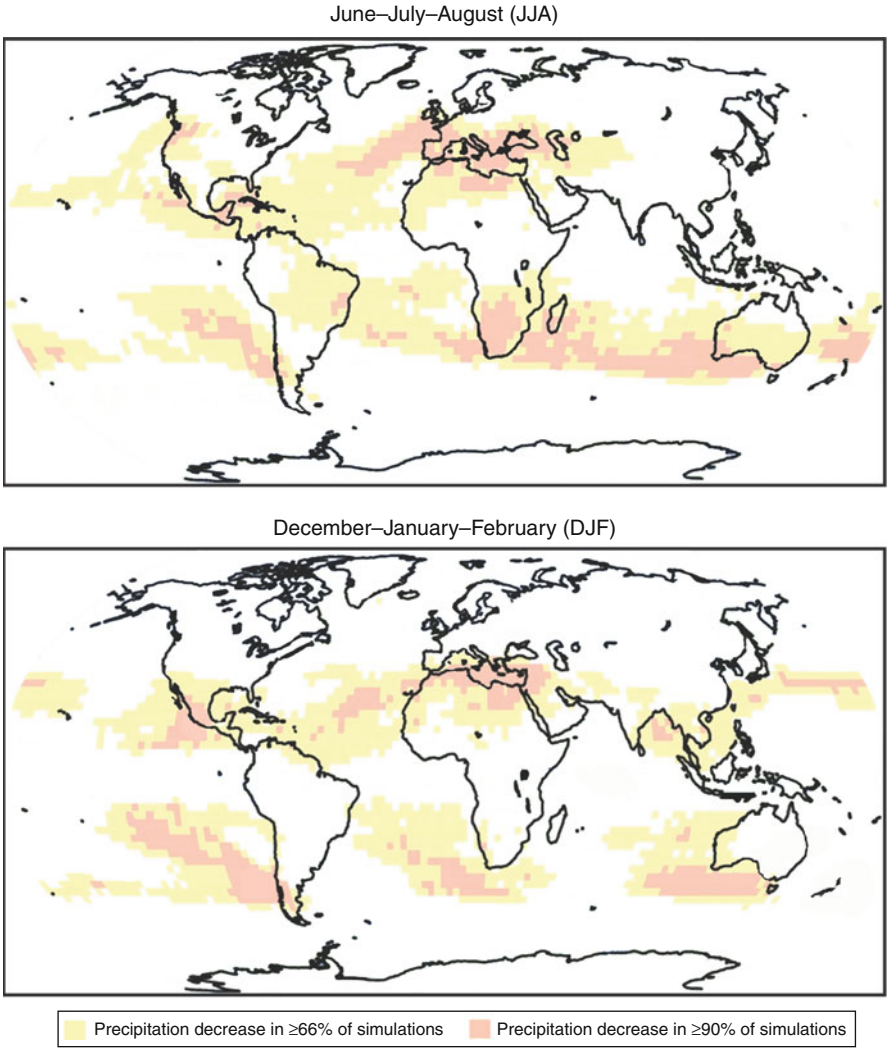
Reduction in crop and animal production has secondary affects on food prices and may feed through to global markets and consumer demand (Kallis, 2008). Reduction in river flows may have consequences for water supply, hydroelectricity generation, and the amount of potable water. Poor quality water can have significant negative health outcomes for affected populations.

Drought takes a heavy toll on life in Africa, causes social disruption in Asia, and has economic impacts in Western countries. Exposure and vulnerability have strongly regionalized patterns; where drought coincides with war, poverty, or recession, the impact is magnified and exposed population are made more vulnerable (Kallis, 2008).

There is a significant difference between aridity and drought. Deserts occur in areas where there is extreme heating of the surface, and/or lack of moisture. These are created when subsiding air, which becomes compressed and thus heated, forms subtropical high-pressure zones. The deserts of Australia, Peru-Chile (Atacama), southwestern USA, Namib, Sahara, and Kalahari are of this type. Additionally, deserts occur in the lee of major mountains: Patagonia, Middle East, central Asia, Ethiopia, and the Thar (India) are examples of these.

Deserts are naturally dry most of the time, and thus drought is not a hazard in them in the strictest sense. However, droughts can be a normal weather pattern in all regions.

Projected precipitation anomalies estimated from regional climate models depend heavily on the scenario applied for the simulations. The IPCC (2007b) has applied a relatively large number of simulations (21) and these show a high degree of consistency. Drought conditions will be exacerbated whenever simulations suggest a decline in precipitation, especially outside the natural regions of aridity. Figure 2 (modified from IPCC, 2007b) shows that the main areas of predicted precipitation decrease are:



1. Annual decrease in the Mediterranean region, northern Africa, Central America, and SW USA.
2. Winter decrease in SW Australia, eastern French Polynesia, southern Africa.
3. Winter and spring decreases in southern Australia.
4. Decrease in snow season length and likely snow depth in Europe and North America.
5. Summer decrease in the southern Andes, southern SE Asia, SE South America, central Asia, central Europe, and southern Canada.

The effect of decreased precipitation will be enhanced with higher temperatures. The main regions of impact are outside the tropics and high latitude zones, and areas with winter and spring dominated rainfall patterns will be particularly disadvantaged, as will midlatitude areas dependent on snow melt for water supply. The burden of enhanced drought will fall quite unevenly across the nations of the world. These same regions will need to develop robust adaption and mitigation strategies to reduce future vulnerability to drought.

Historical impact of drought

Severe drought can have serious consequences for exposed societies. The degree of exposure depends on the kind of drought and the resilience of the society. All but the least resilient of societies can weather single seasonal droughts when they occur at some kind of recurring interval. They often do this by building reserves that can be drawn upon in times of need. Societies meet the most challenging of situations when long sequences of unexpected drought conditions occur. These may be due to rare and essentially unanticipated sequences or due to a shift in climate pattern. It is expected that climate change will, as it always has, alter the geographical patterns and severity of droughts.

In the past, many societies have encountered unexpected enduring drought conditions and they have had to adjust and adapt, migrate, or they collapse. One can wonder at

Drought, Figure 2 The fraction of 21 atmosphere–ocean global climate model simulations that predict a decrease in mean precipitation in a model grid cell (comparing the period 2080–2099 with control period 1980–1999) (Figure modified from IPCC, 2007a, p. 859.).

the thought processes that accompanied these circumstances. Initially, a poor season would have placed strains that would have been endured with the expectation that "normality" would return the next season. After all, this was what experience shows to be the case. A string of poor seasons challenges this experience, and the longer the sequence the more challenging this becomes. When do societies accept that conditions have indeed changed and adjustments must be made? This dilemma has been met before and will be visited upon many societies in the future.

An example of how this occurred in the past concerns the Classic Maya Civilization. The Maya occupied the Yucatan Peninsula region of Mesoamerica from 250 to 850 AD. The Late Classic culture (550–850 AD) was known for being a highly stratified society; there were vast trade networks, and widespread construction of urban centers and monuments. Complex language, belief systems, sports, and mathematics were embedded as elements of society. This all came to a sudden end when society seemed to be at its peak. Many potential factors have been cited for the collapse and include deforestation, overpopulation, warfare, and social upheaval for political reasons.

Recent research suggests prolonged drought was at least a contributing factor. Lake sediments reveal substantially lowered water levels and changes from freshwater to saline conditions (Hodell et al., 2001), reduction in forest cover according to pollen diagrams (Mueller et al., 2009), and increased soil erosion is recorded in marine sediments (e.g., Gischler et al., 2008). These indicate substantial environmental change, which coincides with the main phase of collapse of the Maya in terms of buildings and the desertion of urban centers. In the latter phase of

the Maya, Sun God worship was evident, and this may have been an attempt to appease the Sun as the cause of ongoing drought.

Similar fates are thought to have transpired to the Harappan people of NW India as an arid phase developed over the region and made extensive irrigation systems become dysfunctional, and the base which supported a huge urban population was swept away (Staubwasser et al., 2003).

In some cases, human activities have appeared to exacerbate the impact of drought. In northern China, there is an environmental boundary between the loess and desert. Loess is windblown dust deposited by the Westerlies and is a highly productive soil where there is sufficient rain or irrigation that can be applied to it. In the northern region the loess gives way to desert sand-dominated soils, these are mobile and rarely watered by the monsoon rains which sweep in from the Pacific Ocean. The border region of the Northern Loess Plateau and Chinese deserts west of Beijing supported many Neolithic villages in the mid-Holocene. It appears that monsoon rain reached the region and provided sufficient water for millet-based agriculture and animal husbandry. By about 3,000–4,000 years ago villages were abandoned as desertification set in (Zhou et al., 2002). This may have been due to drought resulting from failure of the monsoon rains reaching the region, perhaps in concert with anthropogenic driven land degeneration. In any case, the desert sands shifted some hundreds of kilometers south, and so did the villages.

The observational record of drought

Observations of drought based on meteorological records indicate that they have become more intense, of longer duration, and occurred over wider areas of the tropics and subtropics since the 1970s (IPCC, 2007a). Reliable meteorological records for much of the world only exist for the last 100 years or so, but they provide a basis to investigate possible causes for drought.

Since the 1950s, the number of heat waves and warm nights has increased. These have contributed to the area under drought, although the drivers of changes in precipitation are also very important. While increases in continental temperatures are important for some regions, changes in snowpack and sea surface temperatures related to phenomena, such as El Niño–Southern Oscillation, are also strong drivers for climate in other regions. Extreme events such as the drought for western North America (Canada to Mexico) in 1999–2004 seem to be strongly related to a diminished snowpack and hence runoff (McCabe et al., 2004; Stewart et al., 2004). These in turn may be driven by sea surface temperatures in the tropical Pacific (Herweijer et al., 2007). Recent Australian droughts correlate well with higher continental temperatures, and the 15% decline in precipitation for southwestern Australia since the 1970s (mostly a failure of early winter precipitation) is related to sea surface temperature variation in the tropical Indian Ocean (Samuel et al., 2006).

Drought in the Sahel is due to failure of rainfall. Simulations have been good at reproducing the decadal variations in Sahel rainfall (Held et al., 2005) and these suggest sea surface temperatures of the Indian Oceans and Mediterranean are significant drivers of this, as is sulfate aerosol concentration (Rosenfeld et al., 2008).

Overall, the increased risk of drought, as measured by the Palmer Drought Severity Index suggests that the anthropogenic fingerprint is there, but simulations have this as a weaker component than the observed occurrence of drought (IPCC, 2007b).

Future vulnerability to drought

Observations show drought has already increased. Models can be used to simulate possible future drought intensity, frequency, and extent. In general, these suggest that the trends already seen can be expected to intensify, and the increase will be between 1% and 30% of land area in the next few decades – with greatest increase in midlatitude areas. The Mediterranean, western USA, Southern Africa, and northeastern Brazil are all expected to see intensification of drought. Russia, Mongolia, China, southern SE Asia will see drought intensification due to higher temperatures in the summer and drier months and due to changes in ENSO (IPCC, 2007b), and poleward migration of annular weather modes (Yin, 2005; Menéndez and Carril, 2010).

The impact of drought will be intensified due to human population increases. About one sixth of the world's population relies on meltwater, and reduced snowfall and snowpack will result in a reduction in delayed runoff. People in Bolivia, Ecuador, Peru, and the Hindu Kush – Himalaya are particularly vulnerable to this (Barnett et al., 2005). Soil moisture deficits will reduce pasture growth in the eastern South Island and Bay of Plenty regions of New Zealand (Mullan et al., 2005). There will be increased fire danger in seasonal environments of the midlatitudes (Gonzalez et al., 2010).

The high cost of drought, for example, in Australia in 1982–1983 ($2.3b), 1991–1995 ($3.8b), and 2002–2003 ($7.6b) (IPCC, 2007b), has already driven measures for adaption. A range of options have been used or are being considered for vulnerable areas. These include increased rainwater harvesting, adjustment of silvicultural techniques, channel and pipe leakage reduction and modifying crop planting dates, and choosing varieties which are more drought resistant.

Models also suggest precipitation extremes will be more prevalent, but the gaps between high magnitude events will increase, and so will the likelihood of drought. Of course the scale of these changes will depend on the willingness of nations to reduce the size of the anthropogenic fingerprint on global warming.

Mitigation

As a natural element of climate, the recurrence of hydrometeorological drought is inevitable. However, drought

can also be exacerbated by anthropogenic influences such as rapid population growth, excessive water demand, and land degradation, and vulnerability to these impacts can be mitigated by appropriate drought plans (Rossi et al., 2005).

The uncertainty about drought definition leads to uncertainty about its characteristics and impacts, which contributes to poor drought management and mitigation across many parts of the world (Wilhite et al., 2007). A key element in any drought plan is a set of indicators that characterize drought conditions, and location-specific triggers (indicator values) which prompt some kind of response. Unfortunately, drought plans often contain ad hoc indicators and triggers that lack scientific validation or operational relevancy, and this can weaken the effectiveness of the mitigation plan (Steinemann and Cavalcanti, 2006). Other factors contributing to the difficulty of developing an effective drought plan include the changing spatial and temporal scales of drought impacts, the unique characteristics of each region or watershed, and changing societal structures and demands, to name just a few. Even though an existing drought may be of similar intensity and duration to one that has occurred in the past, changes in socioeconomic structures and environmental conditions can result in strikingly different impacts, and therefore changing vulnerability (Wilhite et al., 2007).

According to Wilhite (2000), drought mitigation is "short and long-term actions, programs, or policies implemented during and in advance of drought that reduce the degree of risk to human life, property, and productive capacity." These measures can be classified as either proactive or reactive. The proactive measures are prepared according to a planning strategy rather than in an emergency situation (Rossi et al., 2005). The most effective actions are long-term measures taken in advance of drought, such as building infrastructure to increase the reliability of water supply under increasing demand and drought conditions (Dziegielewski, 2003). Short-term measures are taken after the onset of drought, and these are aimed at mitigating impacts within existing infrastructure and management policies. An effective mitigation strategy will contain an appropriate mix of long- and short-term actions to reduce the vulnerability of human life, property, and production to future droughts.

Mitigating agricultural drought

Vulnerability, and therefore appropriate mitigation actions, differs significantly between the developing world, where drought can lead to livelihood loss, famine, and even death, and the developed world, where impacts are usually economic or asset losses. Numerous mitigation measures have been formulated to reduce the impacts of drought, and especially that of agricultural drought because of its huge environmental, economic, and social costs (Maybank et al., 1995).

Approximately, 80% of the world's agricultural land is rainfed (Rockström, 2003), so developing mitigation strategies to build ecological resilience in drought-prone and semiarid agricultural land is very important for food security. To a certain extent, water harvesting through small-scale systems such as farm ponds and subsurface tanks, can help mitigate the impacts of drought or dry spells in these areas. The building of ecological resilience to drought also requires strategies such as conservation farming (minimal or no tillage), improved crop varieties, and soil fertility management.

Decreases in agricultural production can have a roll-on effect leading to financial disaster for farmers and higher food prices for all consumers, unemployment, and even migration. Water is frequently wasted in agriculture practices through over-irrigation, poorly designed canals, and inefficient irrigation systems, and this waste can be reduced through adoption of improved channeling and irrigation practices (Le Houerou, 1996). A multidisciplinary approach of genetic improvement and physiological regulation to increase crop water productivity is another way to help achieve efficient and effective use of water (Cattivelli et al., 2008). Combining these biological water-saving measures with engineered solutions (e.g., water-saving irrigation methods) and agronomic and soil manipulation will contribute to an effective drought mitigation strategy for agriculture (Ali and Talukder, 2008).

Mitigating hydrological drought

Mitigation of hydrological drought primarily involves optimal water supply management under drought conditions, that is, making water more productive. This requires a contingency plan that includes a systematic evaluation of drought conditions with associated responses.

Traditionally, mitigation has focused on increasing water supplies through the construction of dams and reservoirs to capture and store increasing fractions of surface runoff. High levels of surface storage can effectively buffer against low runoff periods, especially in regions that experience high interannual variability in river flows (Bond et al., 2008). This practice was carried out with little analysis of how water was actually being used or of the impacts of this practice on the aquatic ecosystems. As new fresh surface water supplies for exploitation have dwindled, governments have turned to groundwater to augment supplies, especially during drought. However, the increased dependence on groundwater resources is leading to dwindling reserves and/or quality degradation. More and more countries are turning to nonconventional water sources to boost supplies. Desalination and waste water treatment and recycling are usually more expensive options than traditional water sources, but the associated environmental benefits can compensate for some of the costs.

Summary/Conclusions

Drought is a severe natural hazard that affects more people than any other natural disaster. It is difficult to define and

recognizing its onset and termination is also difficult. It can be expressed in meteorological, hydrological, agricultural, and socioeconomic terms. The severity and extent of drought has increased in recent decades, and regional climate models suggest these will increase further in the future. The burden of dealing with drought will be unevenly distributed. Midlatitude regions and those heavily dependent on snow melt will have the greatest challenges. Multidisciplinary approaches will need to be developed to mitigate the extreme impacts of drought.

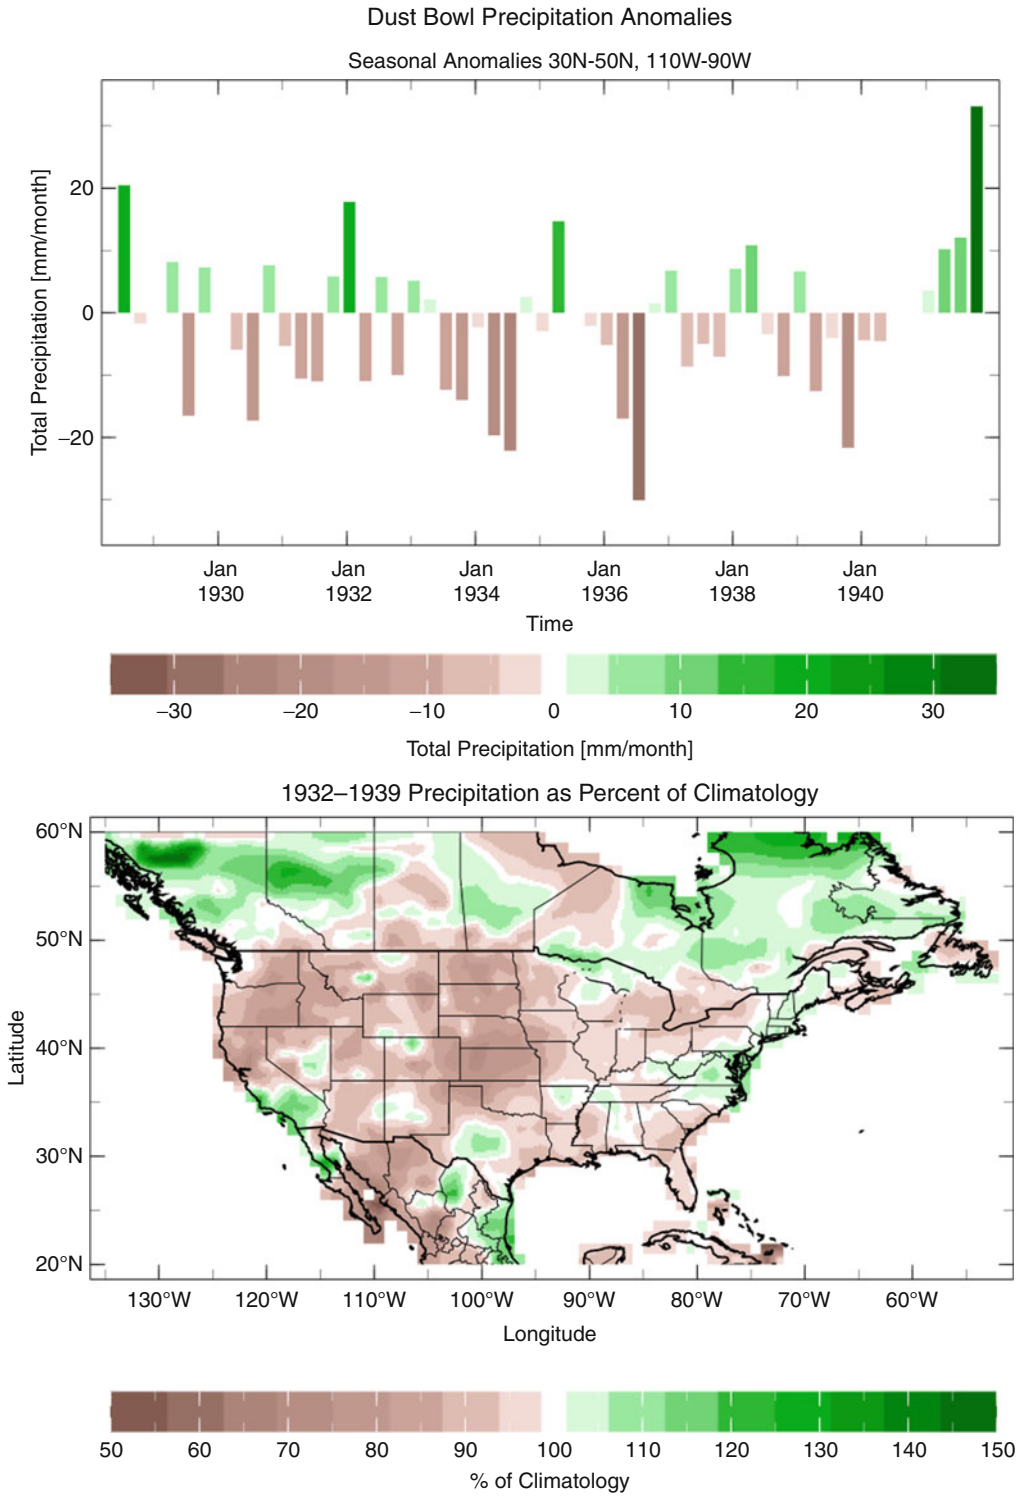
Definition

Dust Bowl. A period of drought, soil erosion, and intense dust storms that impacted the Great Plains of the United States during the 1930s.



Introduction

The Dust Bowl refers to the years of drought and dust storms that affected the Great Plains of the United States during the 1930s. The term "Dust Bowl" was proposed by a reporter writing an article 1 day after "Black Sunday" – April 14, 1935 – which was one of the worst days of dust storms. The term originally referred to some of the worst affected regions in Texas, Oklahoma, Colorado, and Kansas. "Dust Bowl" is now used to refer more generally to the entire catastrophe in the 1930s comprising drought, crop failure, soil erosion, dust storms, economic collapse, and human migration.

Meteorological origins of the dust bowl

The Dust Bowl began with drought. Rain gauge data show that average precipitation over the Great Plains was less than normal for two thirds of the seasons between 1932 and 1939. Averaged over the core years of the Dust Bowl, 1932–39, the precipitation was less than 80% of normal in most of the Great Plains (Figure 1). Droughts of this length and severity are normal features of the climate in the Plains and several had occurred since European settlement with the most recent occurring in the early to mid-1890s. What made the Dust Bowl different from these earlier droughts was the widespread soil erosion and dust storms. In the period after World War I, the Plains were transformed by the expansion of agriculture (primarily wheat, much of it for export to Europe) and the removal of drought-resistant prairie grasses (Worster, 1979). During the 1920s, adequate rains allowed for bountiful crops, thereby encouraging more new planting. When the drought struck in the early 1930s, the non-drought-resistant strains of wheat that had been planted died, exposing bare soil that was easily eroded from the surface by the wind, creating the dust storms that were characteristic of the period. The scale and magnitude of wind erosion and dust storm activity during the Dust Bowl was fairly unique and did not occur during the earlier droughts.

In the mid-2000s, computer simulations with atmosphere models forced by ship-observed historical sea

Dust Bowl, Figure 1 The precipitation anomaly (mm/day), relative to a 1900–2007 climatology, averaged over 30–50°N and 110 to 90°W, by season for the decade of the 1930s and adjacent years (*top*). The 1932–39 averaged precipitation over North America as a percent of climatology (*bottom*). Data are from the Global Precipitation Climatology Centre.

surface temperatures (SSTs) demonstrated that small variations of tropical Pacific and Atlantic SSTs forced the sequence of multiyear, persistent droughts over the Plains and Southwest North America, including the Dust Bowl drought (Schubert et al., 2004a, b; Seager et al., 2005). North American drought is particularly common when the tropical Pacific Ocean is colder than normal (referred to as a La Niña-like state) and the tropical North Atlantic is warmer than normal. This was the case during the 1930s, and again during the early to mid-1950s when a separate drought struck southwest North America (Seager et al., 2008). These SST anomalies arise naturally from ocean-atmosphere interaction and cause drought over North America through changes in the circulation and thermal structure of the atmosphere. The end result is subsidence (sinking air) over the Plains, suppressing precipitation.

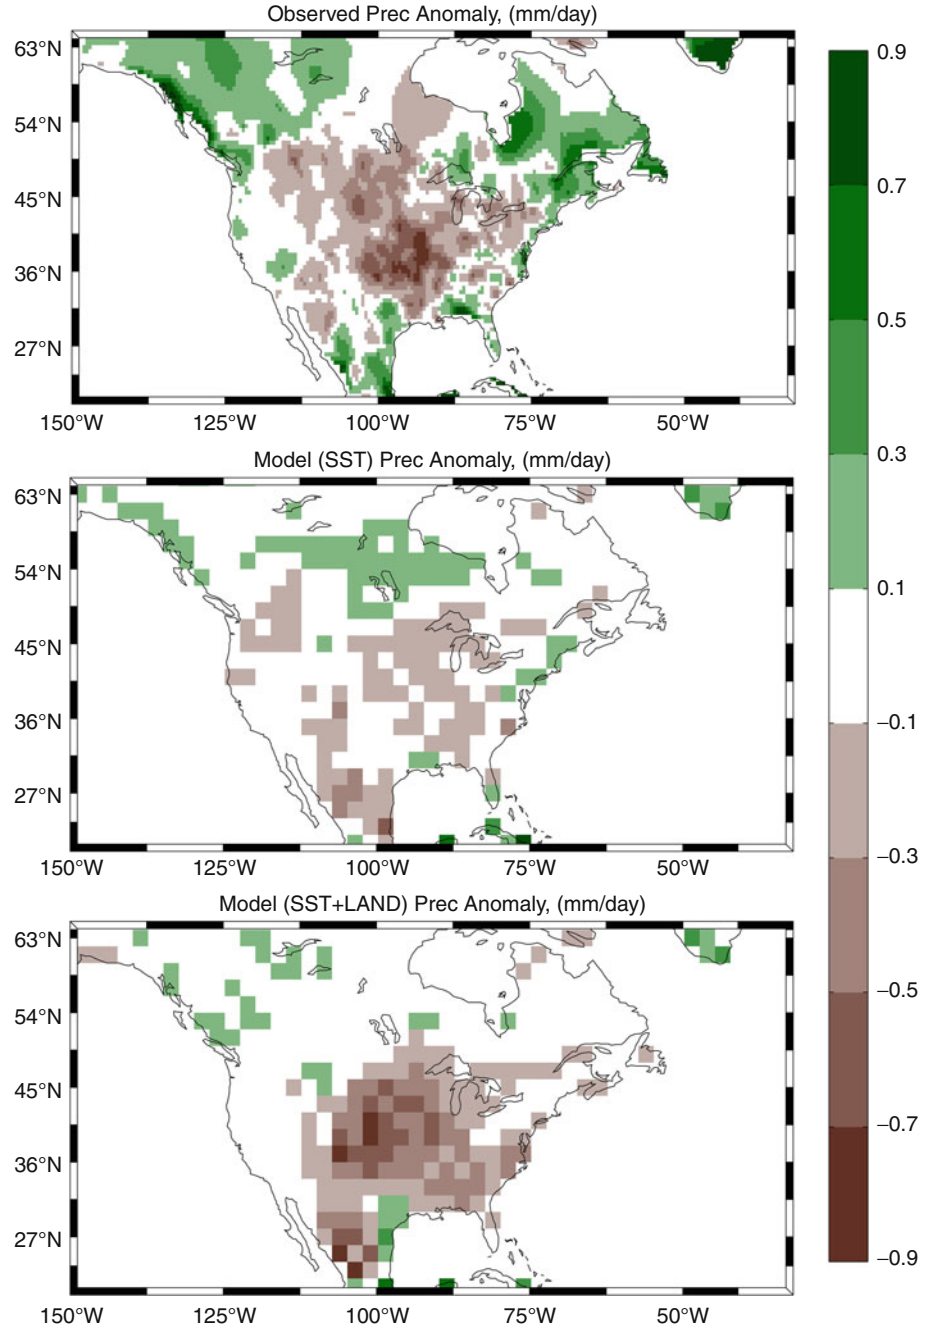
The role of dust storms in modifying and intensifying the drought

Typical SST-forced droughts, however, tend to be centered in the southern Plains, southwest USA, and Mexico, whereas the Dust Bowl drought extended up into the northern Plains and the Canadian prairies. Because of this, some researchers have argued that the Dust Bowl drought was largely forced by internal atmosphere variability and not related to anomalous SSTs (Hoerling et al. 2009). An alternative theory is that the dust storms were so frequent, widespread, and intensive that they actually altered the regional climate. Climate model simulations have been performed in which an atmosphere model was forced by observed 1930s SSTs but also with bare soil placed at the surface where contemporary maps indicated wind erosion occurred. The model created dust storms that interacted with the solar radiation. By reflecting radiation to space, the dust storms induced subsiding air and suppressed conversion of water vapor into precipitation and intensified the drought (Figure 2). Since the dust transport was north and east from the Plains, the modeled drought center also shifted north with the dust, bringing the spatial pattern of the Dust Bowl drought into better agreement with observations (Cook et al., 2009).

Impacts of the Dust Bowl drought and efforts to control the soil erosion

At the peak of dust storm activity, the Plains were emitting dust at a rate equivalent to current dust emissions in the most productive areas of the Sahara (Cook et al., 2008; Laurent et al., 2008). Dust was transported eastward to coastal cities and the Atlantic Ocean, creating widespread health problems related to dust inhalation and choking of the lungs. This became known as “dust pneumonia” and led to an uncertain number of deaths (Egan, 2005). In 1935, after the wind erosion and dust storms had been ongoing for several years, the Soil Conservation Service was created specifically to address the problem of soil erosion. In 1936, the Service completed a map showing the full extent of wind and water erosion during the Dust Bowl, an area extending through the Great Plains from the Gulf of Mexico to Canada (see Hansen and Libecap, 2004).

Soil Conservation Service scientists diagnosed the cause of wind erosion to lie in a combination of drought and poor cultivation practices (i.e., lack of fallowing of land and strip cropping and the absence of shelterbelts and vegetative residue to protect soils) (e.g., Chepil, 1957). Consistently, soil erosion from cultivated land in the 1930s greatly exceeded the erosion from pasturelands (Chepil, 1957). Hansen and Libecap (2004) also noted that the small size of Dust Bowl farms encouraged farmers facing drought to plant as much area as possible to compensate for reduced yield, instead of instituting erosion control measures that would reduce erosion risk but also take land out of cultivation. In many cases, eroded soil from one farm would be transported to neighboring farms, causing a chain reaction of crop failures and wind erosion within an area. To counter such destructive practices, the Soil Conservation Service created Soil Conservation Districts that, through a mix of incentives and coercion, encouraged farmers to cooperatively practice soil conservation techniques. In addition, some marginal lands were purchased by the Federal government and allowed to return to natural grasslands. Soil conservation techniques achieved some gains against erosion, but by 1941, rains were above normal and the drought and Dust Bowl had ended.



Crop failure put many farmers into debt and forced farm sales and abandonment. According to Worster (1979), by the end of the Dust Bowl, about three million people had left their farms and about 0.5 million migrated entirely out of the affected areas, with about half of those moving to California.

Legacy of the Dust Bowl

The Dust Bowl permanently altered the agricultural economy and farming of the Plains and directly led to the widespread adoption of soil conservation techniques in the United States. Out-migration led to farm consolidation. When drought returned to the Great Plains in the 1950s, the soil erosion and dust storms were more limited than in the 1930s and the social disruption was minor by comparison. Federal farm support policies and the beginning of irrigation also helped alleviate the impact of the 1950s drought on farmers (Hansen and Libecap, 2004; Worster, 1979).

Summary

The 1930s drought was, by meteorological standards, a multiyear drought of the kind the Great Plains had experienced previously and thereafter. It was forced by a combination of cold tropical Pacific and warm tropical Atlantic sea surface temperature anomalies that in turn generated changes in atmospheric circulation that suppressed precipitation in the drought region. Poor agricultural practices, such as expansive cropping of non-drought-resistant plants with little regard for soil erosion

Dust Bowl, Figure 2 Observed (*top panel*) and climate model simulated warm season (April–September) precipitation anomalies for the Dust Bowl period (1932–1939). When the model is forced with observed SSTs only (*central panel*), a weak drought is simulated that is centered too far south. If the effect of the dust storms is integrated into the model in addition to the SSTs (*bottom panel*), the drought intensifies and moves northward into the central Great Plains.

potential, turned the drought into the Dust Bowl as crops failed, bare soil was exposed, and wind erosion led to dust storms. The dust storms intensified the drought and moved its center northward. In response, the Soil Conservation Service was created and put in place conservation measures to limit the erosion. The drought ended when normal levels of rainfall returned in the early 1940s. The Dust Bowl led to a permanent transformation of Plains agriculture in terms of farm size, farming practices, and farm support policies. Subsequent droughts have not led to the same scale of soil erosion because of these changes and the introduction of irrigation.

Definition

Warm-core vortices, normally less than 100 m high formed at the base of convective plumes often appearing as a well-defined dust funnel.

Overview

Dust devils are low-pressure, warm-core vortices with typical diameters ranging from 1 to 10 m, and heights of less than 100 m (Figure 1). However, occasionally, they can be larger or taller by more than an order of magnitude. Dust devils form at the bottom of convective plumes. Since their sources of angular momentum are local wind shears, caused either by the convective circulation itself or by larger scale phenomena, they can rotate clockwise or anticlockwise with equal probability. A distinctive feature of intense dust devils is their well-defined dust funnel. Theory indicates that dust is focused around the funnel by a dynamic pressure drop caused by increases in the speeds of the air spiraling toward the vortex.

Like waterspouts, tornadoes, and hurricanes, dust devils can be idealized as convective heat engines. They are the smallest and weakest members of this class of weather phenomena. The intensity of a dust devil depends on the depth of the convective plume and the transfer of heat from the ground into the air. When the surface is composed of loose particles, they might become airborne and make a dust devil visible. Dust particles are indirectly lifted from the surface by a process known as saltation. In this process, the larger particles are forced to move by the wind and bounce along the surface, lifting the smaller, harder to lift (because of strong cohesion forces) dust particles into the air. When loose particles are not present, intense vortices may exist and may not be visible to the observer. When a dust devil crosses a cold terrain, the dust column is cut off, and the vortex dissipates.

The abrupt increase in wind speed around dust devils is what creates a hazard; more than 10% of the accidents with light airplanes and helicopters are caused by visible or invisible dust-free dust devils. However, the abrupt reduction in visibility caused by them can also be a hazard.

Dust devils are more frequent in hot desert regions, but they also have been observed in colder regions such as the subarctic. Dust devils move with the ambient wind and slope with height in the wind shear direction. When the wind is strong, their diameters are biased toward large values.

The occurrence of dust devils increases abruptly from nearly zero at around 10 am to a maximum value at around 1 p.m. Then, dust devil activity slowly decreases toward nearly zero at the end of the afternoon. The abrupt increase at around 10 a.m. is due to increases in the solar radiation and abrupt increase in the depth of the boundary layer. The decrease to nearly zero at the end of the afternoon is due to the decrease in solar radiation and therefore convective activity.

Charge transfer occurs when sand and dust particles collide with each other and the surface. In this process, the smaller particles charge negatively and the surface and large particles positively. Then, the convective updrafts cause charge separation by carrying the smaller particles upward and electric fields of the order of 10,000 V/m can be generated. There are suggestions that

Dust Devil, Figure 1 Large dust devil photographed in the Nevada Desert in USA, July 2009 (Credit: University of Michigan).

these electric fields affect dust transport and, that on Mars they can even affect atmospheric chemistry.

Dust devils have been observed on Mars by almost all orbiters and landers that visited the planet. On Mars, they are ubiquitous, can form almost anywhere on the planet, and can have diameters of more than 1 km and heights of more than 10 km. There is evidence that dust devils play an important role on the global aerosol budget of both Earth and Mars.

DUST STORM

Nilton O. Rennó
University of Michigan, Ann Arbor, MI, USA

Synonyms

Haboob; Sand storm

Definition

Dust storms are weather systems that lift large quantities of dust particles into the air causing extremely low visibility.

Overview

Dust storms form when the wind speed exceeds the threshold value necessary to move sand particles over plowed fields and arid terrains. Particles of diameters between about 50 and 500 μm (sand-sized particles) are the first to move as the wind speed increases. When these sand particles move, they bounce along the surface in a process known as saltation. The impact of saltating particles on the surface consequently ejects smaller, hard to lift (because of large ratio of cohesive with wind drag forces) dust particles into the air creating a dust storm when enough dust is lifted over extensive areas. Saltation is also the process by which dust particles are lifted from the surface by smaller weather systems such as dust devils.

Dust storms can be created by large-scale low-pressure weather systems or gust fronts, areas of cool dense air propagating ahead of thunderstorms. Intense gust fronts, capable of lifting significant amounts of dust, form when rain evaporates while falling through relatively dry air. Such intense gust fronts generate impressive dust storms that can lift large amounts of dust a few kilometers above the surface, and form well-defined dust fronts. The abrupt boundary between the dust fronts and the clear air ahead of them can reduce the visibility to nearly zero in a few seconds. This abrupt reduction in visibility is one of the major causes of accidents by dust storms.

The dense cool air that may form gust fronts is known as a density current. As a first approximation, the propagation speed of a density current is proportional to its depth and the difference in density between it and the surrounding air. Thus, the denser and deeper gust fronts produced by the evaporation of precipitation falling through extremely dry air are capable of producing the strongest and fastest propagating dust storms. These are the most hazardous dust storms that frequently cause accidents in arid regions.

Large-scale frontal weather systems capable of initiating saltation usually cause moderately strong dust storms that can last a day or more. Such large-scale dust storms are more common between autumn and spring. Gust fronts usually produce stronger and more dangerous dust storms lasting no more than a few hours. The smaller, but potentially more dangerous dust storms are more common in the summer. The abrupt reduction in visibility to nearly

Dust Storm, Figure 1 A dust storm in Niger. Courtesy of the University of Michigan

zero and the strong wind make dust storms extremely dangerous. They frequently cause serious aviation and automobile accidents.

Charge transfer occurs when sand and dust particles collide with each other and the surface during saltation. During this process, the smaller particles charge negatively whereas the surface and large particles charge positively. Near-surface electric fields in excess of 100,000 V/m have been measured during dust storms. There is evidence that such large electric fields affect saltation and can even directly lift dust particles from the surface.

Dust storms are ubiquitous on arid Mars. Every few years, global dust storms form and cover the entire planet, reducing the visibility and the flux of solar energy at the surface by more than an order of magnitude. The dust storms last a few weeks and can be hazardous to landers and rovers.

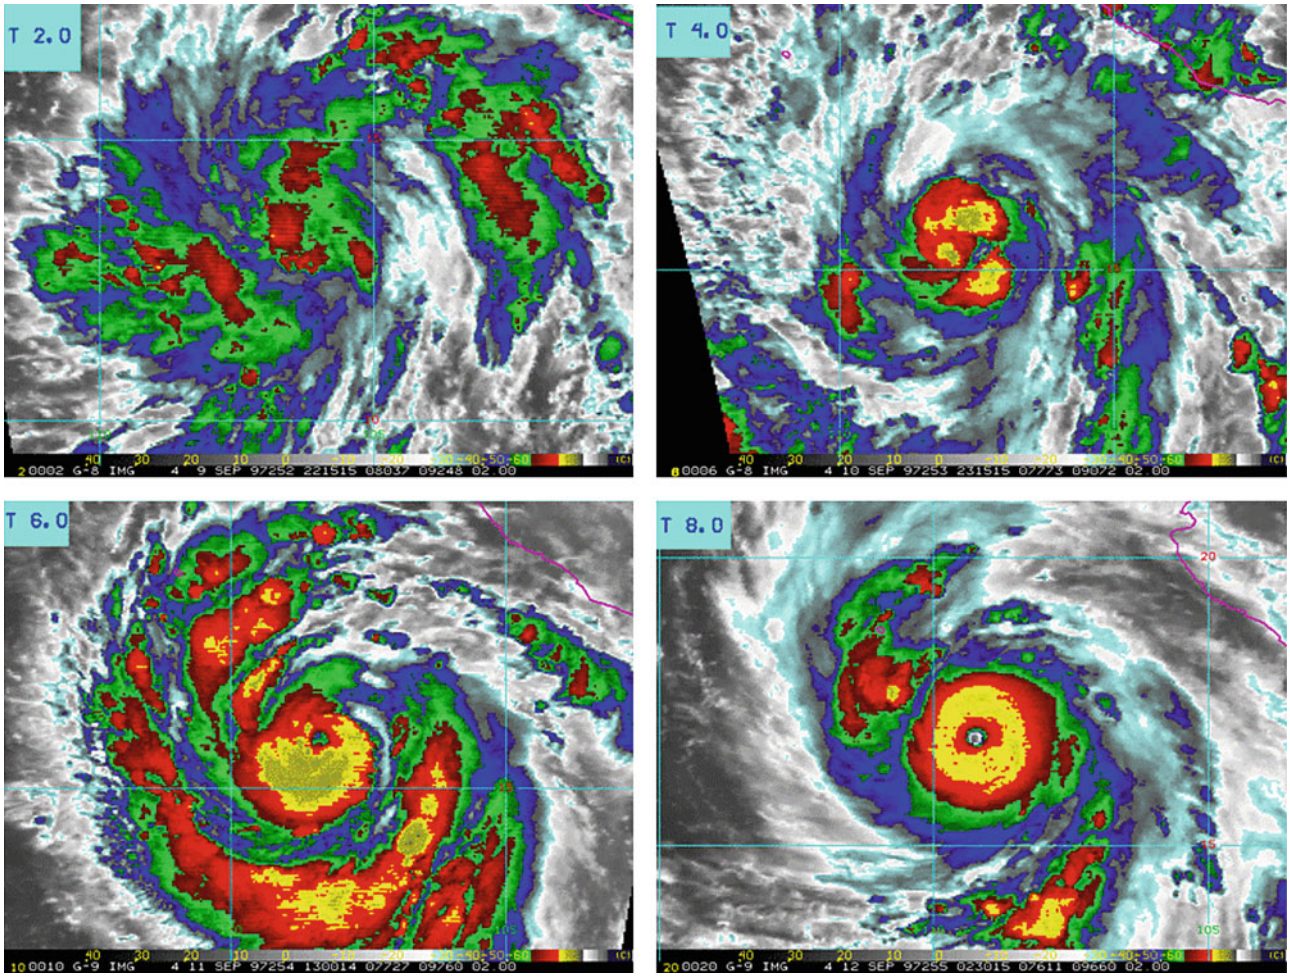
DVORAK CLASSIFICATION OF HURRICANES

Raymond Zehr
CIRA/CSU, Fort Collins, CO, USA



Definition

A method for estimating tropical cyclone intensity ranging in values from T1 to T8.

Overview

The Dvorak technique estimates tropical cyclone intensity using satellite images. Vernon Dvorak and his colleagues developed the Dvorak technique in the early 1970s. It was one of the first innovative applications of meteorological satellite imagery, and it is still widely used today at tropical cyclone forecast centers throughout the world (Velden et al., 2006).

The intensity of a tropical cyclone is generally quantified as the associated maximum surface wind speed. Near the United States, routine aircraft reconnaissance gives intensity estimates using dropsondes and flight level data. However, most of the world's tropical cyclone intensity analysis relies on satellite images and the Dvorak technique. Another indicator of tropical cyclone intensity is the minimum sea-level pressure near the tropical cyclone center. The Dvorak technique uses an intensity unit called

Dvorak Classification of Hurricanes, Figure 1 Enhanced IR images of Hurricane Linda at Dvorak intensities T2, T4, T6, and T8. Hurricane Linda was located in the eastern North Pacific, southwest of Mexico, during 9–17 September 1997.

a T-number in increments of ½ ranging from T1 to T8. The Dvorak T-number intensity scale is normalized according to typical observed daily changes in intensity. T2.5 is the minimal tropical storm intensity (35 knots = 18.0 m/s), whereas T4.0 is the minimal hurricane intensity (33.4 m/s). T6.0 has a wind maximum of 59.1 m/s, and T8.0 approximates record maximum intensity (87.4 m/s).

The Dvorak technique primarily uses satellite observed cloud patterns and infrared (IR) cloud top temperatures to estimate intensity, with independent methods for visible satellite images and IR images.

With weaker intensities, the Dvorak analysis is based on either the curved band pattern or the shear pattern. Using the curved band analysis, the extent to which a spiral-shaped band of deep convective clouds surrounds the tropical cyclone center determines the intensity. The shear pattern refers to the cloud pattern observed when broadscale vertical wind shear induces a distinctly asymmetric cloud pattern with respect to the tropical cyclone low-level circulation center. The degree of deep convective cloud displacement due to the vertical shear decreases with intensification.

With hurricane intensities, the cloud pattern typically evolves into what is called a central dense overcast, which describes the deep convective clouds that surround the center. As intensification proceeds, an eye is observed within this central dense overcast. The eye is the familiar cloud-free or cloud minimum area associated with the lowest pressure at the tropical cyclone center. The eye is surrounded by a circular area which has the strongest winds within very deep clouds and heavy rain, known as the eyewall. The Dvorak technique analyzes visible features and IR temperatures of the eye and the surrounding deep clouds to assign the intensity. In general, the Dvorak tropical cyclone intensity increases as they eye gets warmer and better defined, and the surrounding clouds get colder and more symmetric. A continuous, very

cold circular ring of cloud tops generated by the eyewall along with a warm eye temperature indicate an intense tropical cyclone. Enhanced IR images of Dvorak intensities T2, T4, T6, and T8 are shown in Figure 1 with Hurricane Linda that was located in the eastern North Pacific in September 1997.

Dvorak (1984) gives a detailed description of the methodology and procedures of the Dvorak technique. Following Dvorak's original work, research and development efforts have been focused on replicating and refining the Dvorak approach with objective and automated routines using the IR temperatures (Velden et al., 2006). Automated Dvorak techniques give reliable results that are quickly updated as the latest IR satellite image becomes available, and the tropical cyclone intensity data supplement the general use of satellite data for analysis and forecasting.

EARLY WARNING SYSTEMS

Graham S. Leonard[1], Chris E. Gregg[2],
David M. Johnston[1]
[1]GNS Science, Massey University, Lower Hutt, New Zealand
[2]East Tennessee State University, Johnson City, TN, USA

Synonyms

Alerting system; Immediate warning system; Short fuse warning; Warning systems

Definition

The term early warning system often refers to the technological monitoring, telemetry, and notification aspects of warning systems. The term is also used to distinguish cases where a warning is able to be delivered in a time frame that permits protective action, such as may occur for tsunamis, volcanic eruptions, or severe weather, but not necessarily an earthquake.

Overview

Synonyms

While all aspects of a *warning system* are sometimes referred to as an early warning system, the term early warning system overlaps most in meaning with *immediate* and *short-fuse warning systems* which are warning systems designed in regard to hazardous events with very short durations of time between the onset of the event and the occurrence of a hazardous process.

Monitoring

Methods used for monitoring natural hazards vary widely, but usually revolve around one or more environmental sensors that telemeter data to communications hardware, which is capable of disseminating a warning notification. Sensors detect a variety of geological and geophysical phenomena, including, but not limited to pressure, temperature, distance, chemistry, electromagnetic radiation, and ground-shaking. Monitoring equipment is often located in remote areas, requiring special design or housing to withstand extreme environmental conditions of cold, heat, and precipitation, in addition to its own power supply, which would include batteries and solar or fuel generators. Monitoring equipment may be positioned in permanent to semipermanent fixed locations or mounted on vehicles, balloons, aircraft, or satellites and positioned in multiple areas over short time periods. Some monitoring networks are permanent, whereas others are deployed in response to initial signs of unrest.

Telemetry

Monitoring equipment is sometimes located far from population centers. This requires development of a telemetering network that can provide communications links between the monitoring equipment and scientists or emergency managers. Data are often telemetered over a fixed communication network (e.g., a phone line) or wireless (e.g., mobile phone, VHF-UHF radio, satellite uplink) technology. Regular testing is needed for networks that are not routinely used.

Automated decision-making

Warning systems need to allow for a decision to notify (or not) based upon predetermined thresholds of monitoring data provided by the monitoring equipment. For early warning systems built around hazards with short lead times, this decision is often made automatically, or at least the system automatically processes monitoring information and provides a few simple options to a decision-maker. Warning thresholds for monitored data need to be preplanned for such a decision to be made automatically or made quickly when reviewed manually. Computer-based

P.T. Bobrowsky (ed.), *Encyclopedia of Natural Hazards*, DOI 10.1007/978-1-4020-4399-4,
© Springer Science+Business Media Dordrecht 2013

decision support models, taking into account probabilities, uncertainty, and time frames may be used.

Dissemination of notification

Warning systems need to deliver notification of an impending hazard event and there are a wide range of options available. While the term "early warning system" may be used to refer to monitoring through notification, it is vital for an effective system that people receiving the message know what it means and act appropriately in response. Early warning systems for hazards with short lead times often rely heavily on technology for notification, including warning-dedicated hardware (e.g., sirens) and hardware used for other purpose (e.g., landline telephones, mobile phones, radio, television). NOAA weather radio in the United States is an example of hardware normally used by regular radio stations that also includes a warning-specific component that will enable the device and broadcast a warning automatically.

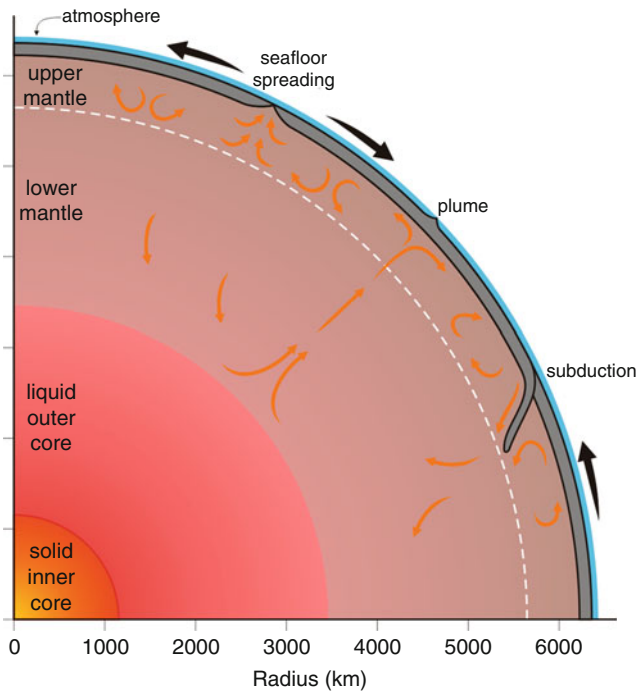
EARTHQUAKE

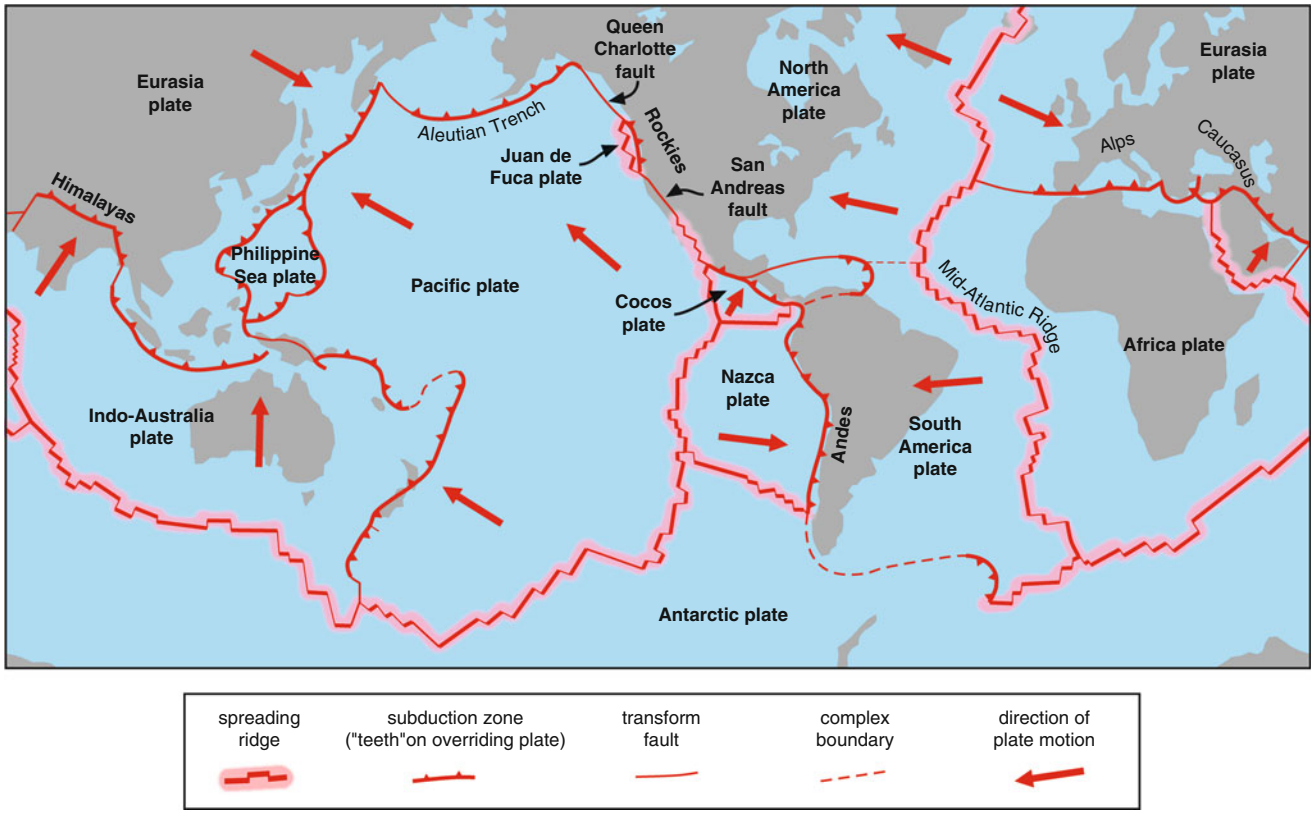
John F. Cassidy
Natural Resources Canada, Sidney, BC, Canada

Definition



Earthquake. A tectonic or volcanic phenomenon that represents the movement of rock and generates shaking or trembling of the Earth.

Introduction



Earthquakes are one of the most frightening natural phenomena that occur. They shake our very foundation – the ground beneath our feet. They almost always strike without warning. The shaking, in the form of aftershocks, can continue for days, weeks, months, or even years. The effects of earthquakes can be widespread (a tsunami caused by a large earthquake can damage regions tens of thousands of kilometers away) and wide-ranging (strong shaking, fires, landslides, liquefaction). Each year, several million earthquakes occur around the world, including about 20,000 that are large enough to be located, and, on average, more than 1,300 that are large enough (magnitude (M) greater than 5) to cause some damage. As the world's population continues to expand, losses and deaths from earthquakes are climbing rapidly, particularly in developing countries. This contribution briefly summarizes the causes of earthquakes, the history of earthquakes, the effects of earthquakes, how earthquakes are monitored and studied, and what can be done to protect ourselves from, and reduce the impact of, future earthquakes.

The causes of earthquakes

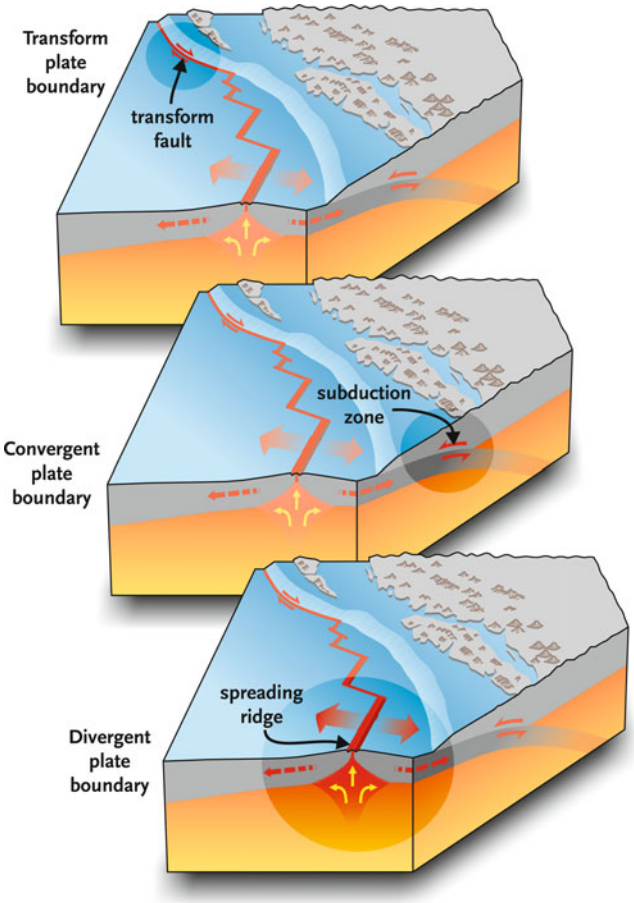
The ultimate cause of earthquakes is the interior heat of the Earth. Near the Earth's core, the temperature is estimated to be in the range of 3,500–5,700 C (De Bremaecker, 1985). This heat is trying to escape to the surface, and as it flows upward, large "circulation cells" are generated in the mantle of the Earth (Figure 1) much like convection cells in boiling water. These flow patterns help to drive the motion of the tectonic plates that make up the surface of the Earth (Figure 2). These plates, some large (like the Pacific plate),

Earthquake, Figure 1 Cartoon cross section of the Earth showing the major layers (crust mantle and core), as well as the convection cells (*orange arrows*) in the mantle that help to drive motions of the tectonic plates (*dark grey*) on the surface of the Earth (illustration by Richard Franklin).

Earthquake, Figure 2 Map of the major tectonic plates of the Earth and select faults (e.g., the San Andreas Fault). The direction of plate motions is shown by the *red arrows*, and different line types are used for different types of faults (see Figure 3). Illustration reprinted from "At Risk: Earthquakes and Tsunamis on the West Coast" (With permission from Tricouni Press).

others small (Juan de Fuca plate), are moving relative to one other at speeds of about 1–10 cm/year (this is about how fast your fingernails grow). Where plates meet (active plate boundaries), one of three things can happen (Figure 3):

1. The plates can move apart (divergent boundary).
2. The plates can slide past one another (transform boundary).
3. The plates can collide (convergent boundary).



Most of the worlds earthquakes (about 90%), and the world's largest earthquakes ($M > 8.5$) occur at these active plate boundaries. These basic plate movements (or combination of those basic motions) result in three types of earthquakes:

1. Normal faulting (usually at divergent boundaries)
2. Strike-slip earthquakes (dominated by horizontal sliding – usually at transform boundaries)
3. Subduction earthquakes (the world's largest type of earthquake that occurs at convergent boundaries)

Tectonic plates are comprised of oceanic lithosphere and continental lithosphere. Continental areas represent the oldest rocks (up to five billion years) on Earth. These are stable regions and are typically composed of a 30–50-km-thick crust of mainly granitic rock (quartz-silicone rich) underlain by a mafic mantle. Oceanic crustal rocks are much younger (the oldest oceanic plate is about 180 Ma old) and thinner and are composed of mafic material. Oceanic plates are composed of heavier and denser material, and so when oceanic lithosphere collides with a continent at a subduction zone, the oceanic plate sinks beneath the continent and is "recycled" into the Earth. This explains why no oceanic crust is older than about 180 Ma. When two continental plates collide (like India pushing north into Asia) neither plate "sinks" and the result is very high mountains (the Himalayas) and large earthquakes. When two oceanic plates collide, subduction of one plate occurs (e.g., the Marianas region of the South Pacific).

Most (about 75%) of the world's earthquakes are "shallow" (that is less than about 60 km). The remainder are "intermediate" (60–300 km) or "deep" (>300 km). At some subduction zones earthquakes extend down to about 700-km depth (Frolich, 2006).

Although the vast majority of the world's earthquakes occur at active plate boundaries, up to about 10% of the world's earthquakes (including some very large earthquakes) occur within continental plates. These are called "intraplate" earthquakes (Talwani and Rajendran, 1991). Some notable examples of intraplate events include:

Earthquake, Figure 3 Sketches of the three primary types of plate boundaries (using offshore British Columbia, Canada, as an example): transform (*top*); convergent (*middle*); and divergent (*bottom*). Illustration reprinted from "At Risk: Earthquakes and Tsunamis on the West Coast" (With permission from Tricouni Press).

1. The M 7.2-8.1 New Madrid earthquake sequence of 1811–1812 (Johnston and Schweig, 1996; Hough, 2001).
2. The M 7.8 Kutch, India earthquake of 1819 (Rajendran and Rajendran, 2001).
3. The M 5.6 Newcastle, Australia earthquake of 1989 (Rynn et al., 1992).

Several theories have been suggested to explain the occurrence of large intraplate earthquakes, including:

1. Zones of weakness – crustal stresses are transmitted from the active plate boundaries, thousands of kilometers through continental plates, to reactivate old fault zones (e.g., Johnston and Kanter, 1990).
2. Stress concentration – inhomogeneities in the crust, such as large mafic intrusions, that concentrate crustal stresses and can cause earthquakes (e.g., Chandrasekhar et al., 2007).
3. High heat flow – high temperatures weaken the rock, alter rheology, and can focus stresses and cause intraplate earthquakes (e.g., Liu and Zoback, 1997).

For more recent, and broadly applicable geodynamic models for intraplate earthquakes, see Mazzotti (2007).

Earthquakes associated with volcanic activity fall into two main categories:

1. Volcanic-tectonic (VT) earthquakes
2. Long-period earthquakes (harmonic tremor)

VT earthquakes (Roman and Cashman, 2006) are associated with either the injection, or withdrawal of magma, causing rocks to fracture. The Mount St. Helens eruption of May 1980 was preceded by more than 2 months of almost continuous volcanic-tectonic earthquake activity. For a full description of this eruption, see Lipman and Mullineaux (1981). Long-period earthquakes (Chouet, 1996) are related to pressure changes associated with the movement or venting of magma.

In addition to natural earthquakes, some earthquakes are "human made." Causes for these human-made earthquakes include filling of water reservoirs (e.g., Lamontagne et al., 2008), pumping fluids into the ground to aid with resource extraction (e.g., Horner et al., 1994), and mining (e.g., Gendzwill et al., 1982). For an overview of induced seismicity, see Guha (2000).

The history of earthquakes

Earthquakes have been a part of myth, legend, and history for as long as humans have been on the Earth. In Greek mythology, Poseidon (Neptune in the Roman pantheon), the "God of the Sea," was thought to be responsible for earthquakes. Some of the earliest references to earthquakes come from ancient China, including the following two descriptions taken from Loewe and Shaughnessy (1999):

1. In approximately the twenty-third century B.C. – "the three Miao tribes were in great disorder and for three nights it rained blood. A dragon appeared in the ancestral temple and dogs howled in the market place. Ice formed in summertime, *the earth split open until springs gushed forth*, the five grains (i.e. kinds of staple crop) grew all deformed, and the people were filled with a great terror."
2. In 1767 B.C. "the five planets deviated in their courses, and there were meteor showers in the night. *An earthquake occured*, and the Yi and Luo Rivers dried up."

The first earthquake described in some detail is the China earthquake of 1177 B.C. Historical earthquake databases for China are described in Wang (2004).

In Japan, one of the world's most seismically active countries, earthquakes have been described going back in time as far as 416 A.D. The earliest Japanese earthquakes are documented in the Journal of Disaster Research (2006).

Some of the world's largest and most devastating earthquakes have occurred in India. For documentation on nearly four centuries of significant earthquakes in this region, see Martin and Szeliga (2010) and Szeliga et al. (2010).

In Europe, historical earthquakes have been described as far back in time as about 2500 years (the first earthquake was mentioned in 580 B.C.). For details of historical European-Mediterranean earthquakes, the reader is referred to the European-Mediterranean Intensity Database at http://emidius.mi.ingv.it/EMID/. While much of the European earthquake hazard is concentrated in Italy and the Mediterranean region, large earthquakes have occurred throughout Europe, including the 1356 Basel, Switzerland earthquake that destroyed that city, and the 1755 Lisbon earthquake, which triggered a massive fire and an Atlantic-wide tsunami. The combination of strong shaking, tsunami, and fires destroyed most of the city of Lisbon and nearby areas. The geological causes and effects of this massive earthquake (likely between magnitude 8 and 9) are still being researched and debated (e.g., Mendes-Victor et al., 2009). For a description of some historical earthquakes in Europe, see Kozak and Thompson (1991). For details on some historical earthquakes of the Middle East, and an interpretation of how these earthquakes may have influenced history, see Nur and Burgess (2008) and Ambraseys (2008).

The main regions in Africa that experience earthquakes are the East African Rift zone (where the African plate is splitting apart) and North Africa (where the continent is colliding with Europe). A summary of earthquakes in North Africa beginning in the year 1045 is provided in Pelaez et al. (2007).

The earliest known earthquakes in the Americas occurred in Mexico in the late fourteenth century and in Peru in 1471, but descriptions of the effects were not well documented. For a description of historical earthquakes of Mexico, see Acosta (2004). Some historical earthquakes of South America (Chile and Peru) are documented by Lomnitz (2004). Charles Darwin was exploring the coast of Chile in February 1835 when a large earthquake (now known to be about magnitude 8.5) occurred off the coast near Concepcion. In a letter to his sister, Darwin describes this experience as follows:

"We are now on our road from Concepcion. The papers will have told you about the great Earthquake of the 20th of February. I suppose it certainly is the worst ever experienced in Chili (sic). It is no use attempting to describe the ruins – it is the most awful spectacle I ever beheld. The town of Concepcion is now nothing more than piles and lines of bricks, tiles and timbers – it is absolutely true there is not one house left habitable; some little hovels builts of sticks and reeds in the outskirts of the town have not been shaken down and these now are hired by the richest people. The force of the shock must have been immense, the ground is traversed by rents, the solid rocks are shivered, solid buttresses 6-10 feet thick are broken into fragments like so much biscuit. How fortunate it happened at the time of day when many are out of their houses and all active: if the town had been over thrown in the night, very few would have escaped to tell the tale. We were at Valdivia at the time. The shock there was considered very violent, but did no damage owing to the houses being built of wood. I am very glad we happened to call at Concepcion so shortly afterwards: it is one of the three most interesting spectacles I have beheld since leaving England – A Fuegian Savage – Tropical Vegetation – and the ruins of Concepcion. It is indeed most wonderful to witness such desolation produced in three minutes of time." (Darwin, 1845).

In the USA, the first documented earthquake occurred in 1638 (Coffman et al., 1982, and http://earthquake.usgs.gov/earthquakes/states/events/1638_06_11_hs.php). The first documented earthquake in eastern Canada occurred in 1663 in the vicinity of Charlevoix, Quebec (Smith, 1962). This earthquake triggered landslides, caused building damage, and was felt throughout New France and New England. Note that an earthquake reported in 1534–1535 in some catalogs (Smith, 1962) has been demonstrated to be a nonevent – see Gouin (1994). In 1811–1812 a series of major earthquakes (magnitude 7.2–8.1) struck the New Madrid region of the central USA. These earthquakes were felt across the eastern USA and southeastern Canada. They caused significant damage, including destroying the town of New Madrid and altering the course of the Mississippi river (Hough et al., 2000).

As Spanish expeditions were made through California, the first written records of earthquakes were obtained in 1769 and 1775 in the present-day Los Angeles area (Ellsworth, 1990). For a detailed description of historic earthquakes of the America's, see Kovach (2004).

The first reported earthquake in western Canada is described in Captain George Vancouver's journal. He wrote that on February 17, 1793, "a very severe shock of an earthquake had been felt" at the Spanish settlement at Nootka on the west coast of Vancouver Island (Rogers 1992). However, long before the Europeans explored the west coast of Canada, First Nations Peoples lived here. They have numerous oral traditions, masks, dances, and ceremonies that are earthquake related. Many of these traditions that are associated with giant subduction earthquakes (tsunamis, strong ground shaking, and aftershocks) are documented by Ludwin et al. (2005).

Around the world, more than one million earthquakes (almost all very small) occur each year. Of those, about 1,300 are large enough to cause some damage if they occur in a populated region, and about 17 are "major" (greater than magnitude 7). As the population of the Earth increases, and as development increases, particularly in developing countries, the impact of large earthquakes is becoming more significant. Table 1 is a list of the most destructive (deadliest) earthquakes in the world, and it is noteworthy that of these 22 events that have occurred during the past 1,154 years, 4 of these (or about 18% of the total) have occurred during the very short time period of 2004–2010. This trend is likely to continue in the future

Earthquake, Table 1 List of the world's most destructive earthquakes. Modified from the USGS webpage: (http://earthquake.usgs.gov/earthquakes/world/most_destructive.php)

A "?" symbol indicates that the magnitude is unknown

with increasing development and populations in earthquake-prone areas of the world.

Recording earthquakes

Originally, earthquakes were only "monitored" by humans. Intensity scales (see the following section) were developed to describe what people felt during an earthquake and the effects of that earthquake. Intensity scales are still in use today. The earliest known instrument to detect earthquakes was developed by Zhang Heng in China about 1800 years ago. That instrument, a heavy vase attached to a chassis to keep it from falling over, contained eight dragons located around the outside of the vase, and each with a brass ball. When earthquake waves approached, they would cause a ball to drop from one of the dragons into the mouth of a toad located below. This would show the direction of the earthquake waves. However, it was not until the mid-1800s that pendulum seismographs to record actual ground motions were developed. In the 1850s, Robert Mallet determined a method to measure the velocity of seismic waves. In Italy, Luigi Palmieri invented an electromagnetic seismograph. These seismographs were the first seismic instruments capable of routinely detecting earthquakes that were too small to be felt by humans. In 1881–1882, continuously recording pendulum seismographs were designed by John Milne and Thomas Gray. By 1900, the first global seismograph network was operational on every continent. For details on the early history of seismology, see Agnew (2002).

Real advancement in earthquake science required accurate recording of earthquakes, and this has only been the case for the past half-century. The modern era of seismology began in the early 1960s with the deployment of the World Wide Standard Seismograph Network (WWSSN). Since the early 1990s the digital Global Seismic Network (GSN) and Incorporated Research Institutions for Seismology (IRIS) – see http://www.iris.edu/hq/programs/gsn/maps – make high-quality digital seismic data freely available to anyone. This aspect of seismology, freely sharing data, is critical for studies of both earthquakes, and studies of the Earth. For details on international seismology, see Adams (2002). The advent of digital data since about the 1980s has changed the world of earthquake science. These high-quality data allow for details of the earthquake that could not be obtained using older analogue data (paper recordings).

The size of earthquakes

Earthquakes are described in one of two ways; by "intensity" or by "magnitude." These are very briefly described here.

Intensity scales

Intensity describes how an earthquake was felt, and its effects at a specific location (e.g., were people frightened? were items knocked from shelves? was there damage to buildings). For any given earthquake there is a range of intensity values. Intensity is controlled by a number of

factors including the magnitude and depth of the earthquake, and it varies with distance from the earthquake source, and local soil conditions.

A number of intensity scales have been developed over time, including the Rossi-Forel scale (the first intensity scale developed in the late 1800s), the Modified Mercalli Intensity (MMI) scale (Wood and Neumann, 1931), the Omori scale (used in Japan), the USGS DYFI (Wald et al., 1999b) scale currently used in the USA, and the European Macroseismic scale that is the current standard in Europe (Grünthal, 1998).

Magnitude scales

The magnitude of an earthquake is a single number that describes the "size" of an earthquake and is directly related to the energy release. Most magnitude scales are based on the recorded amplitude of seismic waves. There are many different magnitude scales, including the most famous – the Richter Scale. Other commonly used scales today (for a summary of many magnitude scales, including primary references, see Utsu, 2002) include the surface wave magnitude (Ms) which is based on the amplitude of the seismic surface waves and moment magnitude (Mw) which is directly related to the area of the rupture and the amount of movement along a fault (Hanks and Kanamori, 1979). The magnitude scale is unbounded, but in practice earthquake magnitudes range from less than 0 to the largest earthquake ever recorded at 9.5.

The effects of earthquakes

The effects of earthquakes can range from "none" (not felt or no obvious effects) to "total destruction" (or Modified Mercalli Intensity XII). The effects of an earthquake depend on a number of factors and can vary drastically across a region. Key factors include: the size of the earthquake; the depth of the earthquake; the proximity to population centers or critical infrastructure; the rupture pattern of the earthquake; local soil conditions; and local topology.

The most common effects of earthquakes are:

1. *Strong shaking*. It is strong shaking that can damage or destroy buildings and other structures. Older, or unreinforced, masonry buildings are usually at highest risk of damage. An example of adobe structures that collapsed in Constitucion, Chile, during the 2010 M 8.8 Chile earthquake is shown in Figure 4. The strength and the duration of shaking depends upon the amount of energy released (and is directly related to the earthquake magnitude). The strength and duration of shaking also depends upon a number of other factors, including: the depth of the earthquake; distance from the earthquake; rupture style of the earthquake; and

Earthquake, Figure 4 Collapse of old adobe structures in Constitucion, Chile, caused by the M 8.8 Maule earthquake of February 27, 2010 (Photo by John Cassidy).

local soil conditions. Ground motion equations, which predict how ground shaking varies with distance and magnitude, are one of the most important aspects of earthquake science and have direct applications to earthquake engineering. Additional details are provided in the following section.

2. *Tsunamis.* Tsunamis can be one of the most deadly effects of earthquakes. The impact of tsunamis can reach across an ocean. For example, the tsunami generated by the 2004 Mw 9.3 Sumatra earthquake killed more than 220,000 people from Indonesia to Thailand to Africa and India. This wave was recorded around the globe (Titov et al., 2005). Large-scale (ocean-wide) tsunamis can typically occur for earthquakes larger than about Mw 8.5, that are beneath the ocean, and have a faulting mechanism that involves vertical movement. It is this vertical motion that generates the wave. Tsunami waves travel across the ocean at speeds of about 500–1,000 km/s and their amplitude is controlled by local bathymetry and topology. For the Sumatra tsunami run-up heights varied greatly over small distances, e.g., from 5 to 25 m over distances of less than 50 km (Borrero, 2005). It is important to note that localized (smaller scale) tsunamis can be generated by smaller earthquakes (e.g., M 7) or by earthquakes beneath land that may trigger landslides or underwater slumps. These tend to be localized, but can still have devastating effects (e.g., Synolakis et al., 2002). In some cases "slow earthquakes" (or silent quakes, that cannot be "felt") can generate large, localized tsunamis. An example is the Nicaragua earthquake of 1992 (Kanamori and Kikuchi, 1993). A photo of the devastating tsunami damage in Constitucion, Chile from the 2010 M 8.8 earthquake is shown in Figure 5.
3. *Landslides*. In mountainous areas large earthquakes can trigger hundreds or thousands of landslides. Earthquake-induced landslides have been documented from as early as 373 or 372 B.C. (Seed, 1968). In a study of 40 historical earthquakes, Keefer (1984) finds a relationship between the maximum area affected by landslides as a function of magnitude (0 km for $M \sim 4$–500,000 km^2 for $M = 9.2$). The number and type of landslides depends on numerous factors including the local geological conditions, type of material, and the steepness of slopes. For details, see Keefer (1984) and Rodriguez et al. (1999).
4. *Fault displacement.* During earthquakes, displacement along a fault occurs. If that rupture reaches the surface, regions on opposite sides of a fault may move relative to one another. Displacements may be as large as 20–30 m for magnitude 8+ earthquakes. Knowing the amount of displacement that might be expected for an earthquake of a given magnitude (e.g., Wells and Coppersmith, 1994) is critically important in the design of structures crossing an active fault. For an example of the success story of the design of the Alaska Pipeline and the M 7.8 Denali earthquake, see Cluff et al. (2003).

Earthquake, Figure 6 Soil liquefaction and resulting road failure along Lake Vichuquén, Chile, resulting from the M 8.8 Maule earthquake of February 27, 2010 (Photo by John Cassidy).

5. *Liquefaction.* Strong shaking during earthquake can cause some soils to liquefy and lose their strength (Seed and Idriss, 1982; Idriss and Boulanger, 2008). Widespread liquefaction has been observed in many earthquakes including 1964 Alaska (M 9), 1964 Niigata Japan (M 7.5), 1989 Loma Prieta, CA (M 7.1), and 1995 Kobe Japan (M 6.9). For details on soil failure during the Kobe earthquake, see Aguirre and Irikura (1997). Soil failure affected numerous highways in Chile after the M 8.8 earthquake – an example is given in Figure 6.
6. *Fires*. Fires triggered by earthquakes are very common. For many years the 1906 San Francisco earthquake was referred to as the "San Francisco Fire" as the fire caused more damage than the ground shaking.
7. *Psychological effects*. People can be traumatized by earthquakes, the effects of earthquakes, and the aftershocks that may continue for weeks or months. Numerous studies have documented the psychological effects of earthquakes, and that consequences of earthquake exposure are long lasting and linked to damage/loss suffered (Bland et al., 1996; Kiliç and Ulusoy, 2003).

The science of earthquakes

People began studying earthquakes long before instruments were developed to record ground shaking. For example, Aristotle created a theory on the origin of earthquakes in 330 B.C., attributing earthquakes to heavy winds within the Earth (Missiakoulis, 2008). Aristotle also classified earthquakes into different types (Oeser, 1992), he linked some earthquakes to volcanic activity, and he made a connection between soil type and strength of shaking. Our understanding of earthquakes began to significantly change after the great Lisbon earthquake of 1755. Shortly after that event, John Mitchell in England and Elie Bertrand in Switzerland began a comprehensive study of the timing and severity of earthquakes. The study of earthquakes was also hastened by Charles Darwin and his crew of the Beagle. They experienced a large earthquake (likely close to M 9) in South America, noting the very serious effects of earthquakes, including changes in the elevation of coastlines. Recordings of earthquakes, beginning in the late 1800s and early 1900s, were basic and only the largest events ($M > \sim 7$) could be recorded. As more instruments were deployed, and as they improved in quality, a much more accurate picture of earthquake distribution began to emerge.

Seismology – the study of earthquakes and seismic waves – is a relatively young science that has developed over the past approximately 100 years. During the past two to three decades, the science of earthquakes has improved dramatically, due to a number of key factors, including:

1. The advent of widespread digital seismic recordings beginning in the 1980s (digital data were available earlier than this, but was very limited). This allowed for detailed studies of the earthquake rupture process, wave propagation, ground shaking, earthquake triggering, and more.
2. New and diverse data sets, including Global Positioning Satellite (GPS) data, Light Detection and Ranging (LIDAR), high-resolution marine imaging methods, high-resolution gravity and magnetic data, paleoseismological data, and better images of Earth structure.
3. Faster and better computers that could be used to develop more accurate models of where energy is accumulating for future earthquakes, to develop detailed models of earthquake shaking, stress transfer, and much more.

These factors are contributing to greatly improved earthquake models. Specifically, identification of where future earthquakes are more likely to occur, how large they can be (and how often they may occur), time-varying earthquake hazard, earthquake triggering, and ground shaking. The discussion below is intended to briefly highlight ten activities that have significantly contributed to our understanding of earthquakes and assessment (and mitigation) of earthquake hazard.

1. Continuous GPS monitoring. With the ability to monitor crustal movements at the fraction of an mm per year level using continuous GPS data, scientists could begin to identify regions where energy is being stored for future earthquakes, and to help identify which faults are active. A few examples of how continuous GPS data are being used to contribute to improved assessments of earthquake hazards include: (a) using crustal deformation data to map the locked portion of a subduction fault (e.g., Wang et al., 2003; Sagiya, 2004); (b) constraining fault slip rates and source zone strain rates/earthquake statistics (e.g., Field et al., 2008), and (c) examining crustal deformation rates to help obtain constraints on earthquake

recurrence rates (e.g., Hyndman et al., 2003). The next generation of GPS data is real-time, high-rate (one sample per second) data that provides information on strong ground shaking and displacements.

2. Subduction zone studies. The largest earthquakes on Earth (M 9+) occur at subduction zones. This is where an oceanic plate is pushed beneath a continental plate. Some examples of this type of earthquake include the M 9.5 1960 Chile earthquake, the M 9.1 Sumatra earthquake of 2004, the M 9 1964 Alaska earthquake, and the M 8.8 Chile earthquake of February 2010. Over the past few decades our understanding of the hazards associated with subduction earthquakes has increased dramatically. This is largely due to researchers incorporating a wide variety of data sets (e.g., heat flow, gravity, seismic reflection, magnetic, earthquakes, magnetotelluric, crustal deformation measurements, and paleoseismology – see below) to identify and model subduction zone hazards. These new datasets and improved modeling techniques allow for the identification of where past subduction earthquakes have occurred, how often, how large, when the last one occurred, where energy is being stored for future subduction earthquakes, and how the ground will shake during those future earthquakes. For additional details, see (for example) Ruff and Tichelaar (1996), Hyndman and Wang (1995), Mazzotti et al. (2003), and Hyndman (1995). Faster computers, better datasets, and more sophisticated modeling algorithms are providing for a better understanding of subduction zone hazards – both earthquakes and tsunamis (e.g., see Wada and Wang, 2009 and Wang et al., 2009).
3. Episodic Tremor and Slip. This phenomenon, involving repeated episodes of slow slip along a fault zone combined with seismic tremors, was first discovered in the Cascadia subduction zone in 2003 (Rogers and Dragert, 2003). This builds upon the discovery of "slow slip" using continuous GPS data in Cascadia as described by Dragert et al. (2001). These slip events occur in the deeper portion of the subduction fault (landward of the locked portion of the subduction fault) and release a portion (perhaps up to 50%) of the strain accumulation along this part of the fault. It also likely plays a key role in adding stress to the shallower locked portion of the fault (Rogers and Dragert, 2003). ETS has also been discovered in other subduction zones of the world (e.g., Japan, Mexico, Alaska). Recent studies of ETS using dense seismic and GPS arrays are providing critical new information on this phenomenon, including propagation and source location (e.g., Ghosh et al., 2009). ETS has also been discovered along transform faults, including the San Andreas in California (e.g., Nadeau and Dolenc, 2005).
4. Paleoseismology. Seismographs provide a relatively short recorded history of earthquakes (just over 100 years). Estimates of long-term hazard require a much longer term history of earthquake activity. In many cases, paleoseismology (geological evidence of past earthquakes) can provide information on large earthquakes going back thousands of years. Paleoseismology has been extensively applied to better understand the earthquake history of the San Andreas fault in California (e.g., see Grant and Lettis (2002) and Sieh (1978)), magnitude 9 Cascadia subduction earthquakes (e.g., see Adams, 1990; Atwater et al., 1995; Goldfinger et al., 2003) and, relatively rare cratonic earthquakes in eastern North America (e.g., Atkinson and Martens, 2007; Mazzotti and Adams 2005; Fenton et al., 2006). For additional details on paleoseismology, see McCalpin (2009).
5. Wave propagation and ground motion studies. One of the most important parameters in the development of seismic hazard maps (described in detail in the next section) is the relationship between ground shaking and distance from an earthquake. The propagation of seismic waves differs significantly around the world depending on the geological and tectonic environment. For example, the hard rock of old "continental cratons" (such as eastern North America) transmits high frequency waves very efficiently, whereas those same waves are absorbed and scattered by the complicated crustal rocks of mountainous areas (e.g., western North America). Attenuation relationships have been developed in various parts of the world (e.g., Eastern North America, California, etc.) and for different types of earthquakes (transform, subduction), and different sizes of earthquakes. Some examples of recent seismic attenuation relationships include: subduction zone earthquakes (Atkinson and Macias, 2009); shallow crustal earthquakes in active tectonic regions (Abrahamson et al., 2008); and eastern North American earthquakes (Atkinson and Boore, 2006). For a summary of numerous global relationships, see Douglas (2001).
6. LIDAR. This relatively new technique (mid-1990s) provided, for the first time, a means of "seeing through the trees" in densely vegetated regions to identify active fault scarps (Harding and Berghoff, 2000). One of the most famous examples is the identification of various strands of the Seattle Fault that extends through downtown Seattle, WA, using LIDAR data (Harding and Berghoff, 2000). Geological work on portions of the Seattle fault zone had indicated a 7-m uplift (Bucknam et al., 1992) and that earthquakes as large as magnitude 6.7 have struck this fault in the past, the most recent event being in the year 900 A.D. (Bucknam et al., 1992). LIDAR is now a standard tool for identifying active faults in regions of dense vegetation (Haugerud et al., 2003) and has been used to map numerous active faults, including strands of the Seattle Fault Zone, the Tacoma Fault, the Darrington-Devil's Mountain fault zone, the Whidbey Island Fault, and the Boulder Creek Fault. These faults have been incorporated into

earthquake hazard maps to help estimate future ground shaking during earthquakes.

7. Real-time Seismology. With readily available digital data and inexpensive communications systems, "real-time seismology" is becoming increasingly important (Kanamori et al., 1997). Applications include rapid earthquake locations and magnitudes (required for tsunami warnings and stopping trains (for example)), the development of earthquake early warning systems (see the following section), "shakemaps" (Wald et al., 1999a), "shakecast" (Wald et al., 2008a), and other real-time products such as "Pager" (Wald et al., 2008b). These near-real-time information products are providing critical new information for earthquake first responders, planners, and managers.
8. Earthquake triggering and stress changes. It has long been known that earthquakes cause aftershocks in the vicinity of the earthquake rupture. Aftershocks are typically confined to the "source region" of about 1–2 rupture lengths of the earthquake. However, until recently, the remote triggering of earthquakes was not considered possible. The M 7.3 Landers earthquake of 1992 changed all of that. This earthquake triggered a sudden and well-documented increase in earthquake activity across much of the western United States to distances of 1,350 km (Hill et al., 1993). These triggered earthquakes were concentrated in regions that experience persistent seismic activity – specifically volcanic and geothermal areas. Hill et al. (1993) argue that several processes must be taking place to explain this seismicity that occurs over a period of days and weeks. Almost all of these events were small ($M < 2$) and were likely triggered by dynamic stresses associated with the passage of the surface waves. Some events are interpreted as triggered by other processes in the days to even weeks after the Landers earthquake. This same earthquake, its aftershocks, and smaller events prior to the mainshock, all demonstrated (Stein et al., 1992) that stress changes in crustal rocks caused by earthquakes can bring neighboring fault zones closer to failure. Since that study, stress triggering of earthquakes has been shown as an important factor in time-varying earthquake hazard. An example is the migration of large earthquakes along the North Antolian fault (Stein et al., 1997). For additional details and examples, see Stein (1999) and Steacy et al. (2005).
9. Site response studies. Detailed studies of the variation in earthquake ground shaking are rapidly increasing as the number of seismographs deployed (particularly in urban settings) increases. Some factors that make significant contributions to the strength, duration, and frequency of earthquake ground shaking include: (1) surface geology (e.g., soft soils, firm soil, rock); (2) basin edge effects (as demonstrated by the Kobe Japan earthquake of 1995 – see Kawase, 1996); (3) topographic effects (shaking can be amplified at the top of hills and ridges, see Geli and Jullien, 1988; Spudich et al., 1996); and (4) the thickness and velocity contrast of surface sediments. Detailed studies of local geology, geotechnical information, and recordings of shaking are increasingly being used to produce seismic microzonation maps around the world, but great caution is still warranted in using these maps (e.g., Mucciarelli, 2008).
10. Drilling into active fault zones. Currently, a number of studies (California, Japan, Taiwan, New Zealand) are underway to drill into active fault zones to better understand the processes that control earthquakes. Two studies briefly summarized here are: (1) the San Andreas Fault Observatory at Depth (the SAFOD project); and (2) the Nankai Subduction fault drilling project in Japan. The SAFOD project involves drilling to depths of 2–3 km into the San Andreas fault near the location of the M 6 Parkfield earthquake (Zoback, 2006). Drilling began in June 2004, and reached a depth of 3.2 km in October 2007. These new data from SAFOD are providing information on the composition and mechanical properties of rocks in the fault zone, the nature of stresses that cause earthquakes, and the role of fluids in controlling faulting. For a list of some SAFOD-related publications, see the "International Continental Scientific Drilling Project" website at: http://www.icdp-online.org/front_content.php?idcat=894

The Nankai drilling project in Japan involves drilling (beneath the ocean) through the megathrust fault – the boundary region between the oceanic plate that is being pushed beneath Japan and deploying long-term instrumentation at this interface (e.g., Tobin and Kinoshita, 2006). This region has experienced repeated large (M 8+) subduction earthquakes over the past 1,300 years, with the most recent being in 1944 (M 8.1) and 1946 (M 8.3). For details on this project, including updates, see the webpage: http://www.icdp-online.org/front_content.php?idcat=1056

This study will provide an unprecedented glimpse into an active subduction fault and may also provide additional "early warning time" for future earthquakes (e.g., an additional 30 s of "warning" before the waves from an offshore earthquake hit the population centers of Japan).

The results of earthquake research are used to reduce losses from earthquakes in numerous ways, particularly through modern design codes and standards. There is also growing interest in the applications of earthquake forecasting, and earthquake early warning. These are described in the following section.

Reducing losses from future earthquakes

While there sometimes may be a public perception that the best way to reduce the impact of future earthquakes is through earthquake prediction, at this point in time the best defense against earthquakes is through modern, robust codes and standards that protect lives, buildings,

and critical infrastructure. Also, it is critical to ensure that populations living in earthquake-prone regions are aware of earthquake hazards, and that they are engaged in personal preparedness efforts. Another area of active research is in the development of "real-time early warning systems." Here, a very brief overview of these topics is presented.

Earthquake prediction

Earthquake prediction is generally defined as specifying *where*, *when*, *how big*, and *how probable* a predicted event is (and *why* the prediction was made). Predictions can be classified (Sykes et al., 1999) as short term (hours to weeks), intermediate term (1 month to 10 years), or long term (10–30 years). Attempts at earthquake prediction have existed for almost as long as earthquakes. Often these predictions are based on animal behavior, foreshock activity, "earthquake lights," electrical effects, changes in water levels, and much, much more. The most famous earthquake prediction (and the only major earthquake considered to have been successfully predicted) is that the M = 7.3 1975 Haicheng, China event. A recent reevaluation of this event (Wang et al., 2006) concluded that there was an official midterm (1–2 years) prediction. They also concluded that "the most important precursor was a foreshock sequence, but other anomalies such as geodetic deformation, changes in groundwater level, color, and chemistry, and peculiar animal behaviour also played a role." This prediction resulted in saving thousands of lives. However, a year later, an even larger earthquake occurred in China – the M 7.5 Tangshan earthquake that was not predicted and resulted in the loss of more than 250,000 lives (Table 1).

One of the most famous earthquake prediction experiments in the world was the Parkfield, California experiment – summarized in a 2006 special volume of the Bulletin of the Seismological Society of America (e.g., see Harris and Arrowsmith, 2006). The Parkfield segment of the San Andreas fault had experienced five magnitude 6 earthquakes between 1857 and 1966. Based on the regular occurrence and similarities between these earthquakes, one was expected to occur before 1993, and this segment of the fault was instrumented with numerous types of monitors in an attempt to identify precursors to the expected earthquake (Bakun and Lindh, 1985). The earthquake arrived late (very late) in September of 2004. There were no obvious precursors to this earthquake (Bakun et al., 2005) indicating that forecasting the timing of earthquakes remains a significant challenge. For a general discussion of the predictability of earthquakes, the reader is referred to Jordan (2006).

In summary, at this point in time, there is still considerable debate about the potential for earthquake prediction. Some (e.g., Geller et al., 1997) state that "reliable issuing of alarms of imminent large earthquake appears to be effectively impossible" (very-short-term prediction), while others (Sykes et al., 1999) are optimistic about the possibility of intermediate-term and long-term predictions on at least some active fault segments. Overall, the consensus appears to be that at this time earthquake prediction is still in its infancy as a scientific discipline and remains "a challenge." However, great advances are being made in the identification of regions of "higher hazard" (or long-term forecasting) based on earthquake science and the incorporation of new datasets, as described in the earthquake science section above.

Robust building codes and standards

The use of earthquake provisions in Building Codes has led to a significant reduction in earthquake-related damage. This is obvious when comparing the effects of earthquakes such as M 6.6 Bam (2003) and M 7 Haiti (2010) where codes and standards are lacking, to the M 6.7 Northridge, CA (1994) or M 6.8 Kobe (1995) earthquakes in areas with modern building codes. It is noteworthy, however, that the modern codes and standards currently in place in Japan and California are largely the result of devastating earthquakes in those countries. Earthquake provisions in building codes have generally been the result of significant earthquakes. For example, the devastating 1923 Kanto Japan earthquake (see Table 1) led to the inclusion of seismic provisions in the Japan code in 1924. Updates to these codes were made in 1950, and significant changes were made in 1981. The characteristics of building damage during the Kobe earthquake of 1995 clearly showed the improvements provided by the modern (post-1981) building code. Of the post-1981 buildings, only 3% collapsed, compared to 17% of all pre-1971 buildings. Of the post-1981 buildings, nearly 75% had no damage or little damage, compared to 26% for pre-1971 buildings.

In California, the San Francisco earthquake of 1906 led to the first inclusion of earthquake provisions in building design codes. Each of the major earthquakes in California (1925, 1933, 1971, 1989, and 1994) led to improved understanding of, and enhancements to, building codes and standards (see Cutcliffe, 2000). The 1971 San Fernando earthquake in particular led to significant improvements in the building code, and the passage of the California Hospital Seismic Safety Act.

In Canada, the first seismic provisions in the National Building Code of Canada (NBCC) were put in place in 1953. These early seismic hazard maps included four "zones," based on qualitative assessment of historic earthquake activity. Significant updates to these seismic hazard maps were made in 1970, 1985, 2005 (see Adams and Atkinson 2003), and some changes will be in the 2010 code.

The Global Seismic Hazard Assessment Program (GSHAP) was started in 1992. The purpose was to mitigate earthquake risk by providing uniform estimates of hazard on a global scale. This was a regionally coordinated effort that utilized a homogeneous approach to seismic hazard evaluation (Giardini and Basham, 1993;

Giardini, 1999). One of the key products was the GSHAP Global Seismic Hazard Map that depicts peak ground acceleration (pga) with a 10% chance of exceedance in 50 years, corresponding to a return period of 475 years. This map and all associated documentation, including regional reports, maps of seismicity, source characterization information, and GSHAP yearly reports, are available via the Internet through the GSHAP homepage, http://seismo.ethz.ch/GSHAP/.

Real-time warning systems

With advancements in instrumentation, data transmission, data processing and dissemination, there is an increased interest, and rapid advancements are being made in the area of Earthquake Early Warning (EEW). For a summary of the current state of the art, see the special volume on Earthquake Early Warning published in Seismological Research Letters (Volume 5, 2009). For earthquakes, warning times range from seconds to just over one minute, depending upon the location and depth of the earthquake and the seismic monitoring network in place in the region. A successful early warning system requires a dense seismic network. Some examples of warning systems described in this volume include the SAS system for Mexico City. Seismic stations along the west coast of Mexico (where subduction earthquakes occur) are used to provide warning to Mexico City (about 320 km inland) before the strong shaking arrives. This system, with a demonstrated ability to identify earthquakes of $M > 6$ and provide warning, is described in detail by Suarez et al. (2009). In Japan, data from thousands of seismic stations deployed across the country are used to feed into a public warning system for earthquakes (Allen et al., 2009). Warnings for strong shaking are issued when the Modified Mercalli Intensity is predicted to be greater than VII-VIII). These alerts are distributed to the public via the Japan Broadcasting Corporation, some cell-phone providers, radio stations, and some loud-speaker systems (Allen et al., 2009). These warnings are used to control traffic, stop trains, control elevators and critical factory systems, and more (Kamigaichi et al., 2009). The Japanese system was successfully employed during the M 8.9 2011 Tohoku earthquake. For example, 24 high-speed bullet trains were stopped without a single injury (Kanamori, 2012). Other examples of early warning systems using real-time seismic data are provided by Wu and Kanamori (2008) and Zechar and Jordon (2008). Allen et al. (2009) concluded that although there are still some misperceptions and challenges with EEW, significant progress has been made in developing and implementing warning systems.

Summary

Earthquakes pose a major threat to human life and economic development. We are reminded of this year after year. A recent example being the tragedy of the January 12, 2010, magnitude 7 earthquake in Port au Prince, Haiti, that resulted in the loss of more than 250,000 lives. That earthquake, like many earlier ones, clearly showed that the populations at most risk are those in developing countries with few or no guidelines for earthquake-resistant construction. This is the fastest growing population on Earth. The M 8.9 2012 Tohoku, Japan earthquake struck a country having modern building code, yet this earthquake still resulted in 15,854 deaths (most from the tsunami) and had an economic cost of more than $235B – making it the world's most expensive natural disaster.

However, we are making great progress in our ability to monitor earthquakes, study the details of the earthquake process, and estimate the ground shaking expected from future earthquakes.

Reducing losses requires better building codes, better construction, and a population that is aware of the risks and actively involved in mitigation efforts. The first step is in knowing the risks. I hope that this entry contributes, at least in a small way, to knowing the risks. I hope that this entry helps inspire you to mitigate the risks of earthquakes, whether that is by drawing up a personal preparedness plan for your home and family, volunteering for a community organization, conducting research into hazard assessments, utilizing hazard information as an engineer or community planner, or as a politician. Earthquakes cannot be stopped, but the effects of earthquakes can be minimized.

Acknowledgments

We greatly acknowledge the thoughtful and thorough review of this entry by Jane Wynne, Maurice Lamontagne and anonymous reviewers. This is ESS Contribution number 20100066.

Synonyms

Earthquake destruction; Seismic damage

Definition

Damage: Physical harm reducing the value, the operation, or the usefulness of something. (Oxford English dictionary, see "*Damage and the Built Environment*").
Earthquake: A sudden violent shaking of the ground as a result of movements within the earth's crust. (Oxford English dictionary, see "*Earthquake*").
Earthquake damage: Damage or destruction of properties and good caused by an earthquake, either as a direct result of the ground shaking, or as an induced consequence.

Introduction

In the natural hazards community, different expressions are used to differentiate the domains affected by the earthquakes. "Damage" refers to the degradation or destruction of the physical assets, such as buildings, facilities, infrastructure, or nonstructural elements (see "*Damage and the Build Environment*" and "*Structural Damage Caused by Earthquakes*"). "Loss" concerns either the casualties (e.g., human losses, see "*Casualties Following Natural Hazards*") or the economical consequences (such as lost jobs, lost properties, business interruptions, repair and reconstruction costs; see "*Costs (Economic) of Natural Hazards and Disasters*"). "Impact" focuses on the repercussions on society (socioeconomical dimensions).

The term "Earthquake damage" refers to the different kinds and levels of degradations to the physical environment resulting from seismic events. Earthquake damage is the cause of the induced consequences of earthquakes that societies have to face. In particular, there is an old say stating that: "earthquakes do not kill people, buildings do."

Causes of damage

Direct causes

Ground shaking is considered to be a major cause of damage to buildings and components due to earthquakes (Noson et al., 1988). Structures are particularly vulnerable to these horizontal, oscillatory, and dynamic loads. The ground surface, moving quickly back-and-forth and

side-to-side, creates inertial forces inside the structures. These stresses might produce irreversible damage, from cracking, permanent displacement, or entire collapses of the structures (see "*Building Failure*," "*Structural Damage Caused by Earthquakes*").

Indirect causes

However, earthquakes can trigger other secondary hazards (domino effects), which could locally inflict damage more severe than the direct effects of the ground shaking. Earthquake-induced failures of the underlying sediment or rock (see "*Fault*," "*Liquefaction*," "*Lateral Spreading*," or "*Landslide*") are likely to damage underground infrastructure, resulting in potentially widespread impacts, even in areas some distance away from the epicenter (Bird and Bommer, 2004). These ground failures could also impact on the structures' foundations, which might cause a building to lean sufficiently to cantilever and fail. Another potential cause of considerable damage is due to the disturbance of water bodies, either in open seas (see "*Tsunami*") or in enclosed bodies of water (see "*Seiche*"). The consequence of such secondary events can be catastrophic (e.g., Indian Ocean Tsunami of December 2004, generated by a Magnitude 9 earthquake).

Direct earthquake damage can also result in new causes of damage (e.g., induced technological hazards). Damaged pipelines are, for example, new threats to the integrity of the remaining infrastructures. Gas leakage might ignite fires or explosions. Water-pipe breakage might cause flooding but also prevent fire-fighters from effectively intervening. The failure of the Fukushima Nuclear Plant in 2011, triggered by a tsunami which in turn was initiated by an earthquake, is an example of such an induced technological hazard.

Factors of damage

A building will endure damages that depend on the intensity of the event (e.g., for ground shaking, these loads are function of the magnitude of the earthquake, the focal depth, the distance on the surface from the epicenter, and the side effects conditioned by the surface geology and past human intervention), but also from its own physical susceptibility to the different threats triggered by the earthquake. The susceptibility to damage is a function of several intrinsic specificities of the elements, such as existence and compliance to existing building codes (see "*Building Code*," "*Earthquake Resistant Design*"), building types, material properties, construction quality, number of storeys, building positions in the site (Şengezer et al., 2008), but also age and previous stresses applied to the structures (see "*Antecedent Conditions*"). The nonstructural elements (e.g., parapets, architectural decorations, partition walls, chimneys, doors, windows, air conditioners, and heaters) are subject to other modes of damage. They might be displaced (due to poor attachment) or distorted (due to building flexure) during ground shaking, triggering new threats for the structures and people (Fierro et al., 1994).

Measures of damage

There are several approaches to measure damage. The traditional damage assessment methods are based on surveys, resulting in an enumeration or evaluation by extrapolation of the number of damaged elements, and eventually an assessment of their value. The result will be a quantification of the property losses. However, this measure is dependent on the initial value of the stock (such as the pre-earthquake real estate value). The damage ratio (damage cost or repair cost compared to the construction cost or the replacement value) addresses this issue by evaluating the amount of degradation buildings have suffered. This method gives similar indications to the methodology which consists in estimating the proportion of damage for each component, producing classes of damage or indicators. Damage can also be assessed based on physical measures, such as Inter-Storey Drift, which provide indices correlated to the physical integrity of the buildings.

Damage scales

In order to evaluate the intensity of earthquakes based on their effects on animals, humans, and buildings, several scales have been created (Hill and Rossetto, 2008; Blong, 2003). Damage corresponding to each level is described in a qualitative way (e.g., level VII of the European Macroseismic Scale corresponds to "damaging: Most people are frightened and run outdoors. Furniture is shifted and objects fall from shelves in large numbers. Many ordinary buildings suffer moderate damage: small cracks in walls; partial collapse of chimneys" (Grünthal, 1998)). Historically, one of the first was the Rossi-Forel scale, named after the nineteenth century developers, which was divided into ten intensity levels. Damage to nonstructural objects generally relate to level IV damages, and damage to buildings, to level VIII. This scale was revised by Mercalli, and then improved successively. It is now known as the Modified Mercalli Scale (see "*Modified Mercalli (MM) Scale*"). The scale is composed of 12 levels, with 7 levels related to building damage (MM VI-XII). Other scales have been developed in order to reflect local contexts and buildings typologies. For example, the European Macroseismic Scale (EMS-98) and the Medvedev-Sponheuer-Karnik Scale (MSK-64) are used respectively in Europe and Russia, whereas HAZUS 99 or ATC-13 scales are more adapted to American buildings.

Conclusion

Earthquakes are considered to be one of the most damaging natural hazards. This is not only due to the tremendous energy released, but also due to the intrinsic uncertainties associated with this hazard. It is currently

impossible to predict when earthquakes will occur. However, significant progress has been made in the comprehension of the hazards, vulnerability (see "*Vulnerability*"), and in construction practice. Hence, where resources are available, the consequences of this threat can be, if not avoided, at least minimized, and physical susceptibility reduced. This would make human infrastructure and communities less prone to damage, and thus more resilient to earthquakes.

Synonyms

According to the Oxford Dictionary for Synonyms and Antonyms (ODSA, 2007), the words *prediction* and *forecasting* are synonyms. Meanwhile a part of the seismological community makes a difference between the terms *earthquake prediction* and *earthquake forecasting*. Namely, an *earthquake prediction* is referred to as a statement about a target earthquake of a certain range of magnitudes in a specified geographical region, which involves an *alarm*, a time window of the increased probability of the target earthquake. If a target earthquake occurs during the alarm, the prediction is true; if not, it is a false alarm; if a target earthquake occurs without an alarm it is called a failure to predict of the earthquake. An *earthquake forecast* is described as a statement about a future earthquake in a specified spatial-temporal window, which is based on the specified probabilities of target earthquakes. "*A time-independent forecast is one in which the subdomain probabilities depend only on the long-term rates of target events; the events are assumed to be randomly distributed in time, and the probabilities of future events are thus independent of earthquake history. In a time-dependent forecast, the probabilities depend on the information available at time when the forecast is made*" (Jordan et al., 2011).

The difference between *earthquake prediction* and *earthquake forecasting* presented above is related basically to methodologies rather than to definitions, and they are associated with two different (alarm-based and probability-based) approaches to earthquake prediction (or earthquake forecasting). In this entry, I do not distinguish between the terms *earthquake prediction* and *earthquake forecasting*, considering them as synonyms.

Definition

The Earth's lithosphere can be considered as a hierarchy of volumes of different size (from tectonic plates to the grains of rocks). Driven by thermal convection, the movement of the lithosphere is controlled by a wide variety of processes on and around the fractal mesh of boundary zones (fault zones) and does produce earthquakes. An earthquake is a sudden movement within the Earth's crust or the upper mantle usually triggered by the release of tectonic stress (and energy) along a fault segment. The hierarchy of movable lithospheric volumes composes a large nonlinear dynamical system (Keilis-Borok, 1990; Keilis-Borok et al., 2001). Prediction of such a complex system in the sense of extrapolating discrete future trajectories is futile. However, upon coarse-graining the integral empirical regularities emerge, premonitory seismicity

patterns (e.g., rise of seismic activity; rise of spatial-temporal earthquake clustering; changes in earthquake frequency-magnitude distribution; rise of the earthquake correlation range) signal the approach of a large earthquake, and this opens possibilities of earthquake prediction.

Earthquake prediction is a statement about future earthquake occurrence based on the information, data, and scientific methods that are available now. To predict an earthquake, one must "*specify the expected magnitude range, the geographical area within which it will occur, and the time interval within which it will happen with sufficient precision so that the ultimate success or failure of the prediction can readily be judged. Only by careful recording and analysis of failures as well as successes can the eventual success of the total effort be evaluated and future directions charted. Moreover, scientists should also assign a confidence level to each prediction*" (Allen et al., 1976).

Introduction

"An earthquake is an evil that spreads everywhere; it is inevitable and damaging for everybody. Besides the destruction of people, houses and entire towns, it can make disappear nations and even entire nations without leaving a trace of what has been once," wrote Lucius Annaeus Seneca (1 BC–65 AD), a Roman philosopher, about AD 62 Pompeii earthquake in his Quaestiones Naturales, an encyclopedia of the natural world. The extremely destructive nature of earthquakes has been known for millennia. Although the origins of observational seismology date back to the East Han Dynasty in China, when Zhang Heng (78–139 AD) invented an earthquake detection instrument, it would be misleading to pretend that state-of-the-art physics of earthquakes is a well-developed branch of science. To the contrary, most seismologists clearly understand the grand challenges for seismology (Forsyth et al., 2009). Several important questions still remain pressing: How do faults slip? What happens during an earthquake? How do we measure the size of earthquakes? Why, where, and when do earthquakes occur? The fundamental difficulty in answering these questions comes from the fact that no earthquake has been ever observed directly and only a few were subject to an in situ verification of their physical parameters.

The mature wisdom of any science is determined by its ability to forecast phenomena under study, and in the case of seismology, to predict an earthquake. The scientific research aimed at predicting earthquakes began in the second half of nineteenth century, when seismology reached the level of a recognized scientific discipline. The desire to find tools that would permit forecasting the phenomenon under study is so natural that as early as in 1880 John Milne, a British engineer-seismologist, defined earthquake prediction as one of the pivotal problems of seismology and discussed possible precursors of large earthquakes. Over the following century earthquake prediction research experienced alternating periods of high enthusiasm and critical attitude. The abruptness, along with apparent irregularity and infrequency of large earthquake occurrences, facilitates formation of a common perception that earthquakes are random unpredictable phenomena. Earthquake prediction research has been widely debated, and opinions on the possibilities of prediction vary from the statement that earthquake prediction is intrinsically impossible (Geller et al., 1997) to the statement that prediction is possible, but difficult (Knopoff, 1999).

Earthquake prediction: Success, failure, and perspectives

Two types of earthquake prediction methods can be distinguished. The first type of the prediction methods is based on finding and monitoring of an earthquake precursor (a physical, chemical, or biological signal, which indicates that a large earthquake is approaching) and issuing an alarm at the time of the abnormal behavior of the precursor. The earthquake precursors fall into several broad categories: biological (e.g., anomalous animal behavior from dogs, snakes, horses), electromagnetic (e.g., changes in an electromagnetic signal associated with a dilatancy-induced fluid flow); geochemical (e.g., changes in radon concentration in groundwater); geodetic (e.g., strain-rate changes); geoelectrical (e.g., changes in electrical conductivities of rocks); hydrological (e.g., changes in a borehole water level); physical (e.g., changes in seismic wave velocities in the crust, *Vp/Vs* changes); thermal (e.g., changes in thermal infrared radiation); and others. Although many observations reveal unusual changes of natural fields at the approach of a large earthquake, most of them report a unique case history and lack a systematic description (Wyss, 1991). Unfortunately, so far the search for a precursor of a large earthquake has been unsuccessful. Moreover, perhaps such a search for a single precursor is useless, and monitoring of a set of precursors could give more reliable answer on an anticipating earthquake.

Chinese seismologists were the first to successfully predict a devastating earthquake, the M7.0 Haicheng earthquake of 1975 (Zhang-li et al., 1984). Their prediction was based on monitoring physical fields (anomalies in land elevation, in ground water level, and in seismicity prior to the large event) and on the observations of peculiar behavior of animals. The success of this prediction stimulated further design of methods for diagnosis of an approaching large quake. Most of the prediction methods suggested at that time were not confirmed in the following years. The catastrophic M7.5 Tangshan, China earthquake of 1976, which caused hundreds of thousands of fatalities, was not predicted; this failure was like a cold shower of disillusionment, not only for Chinese seismologists. The necessity of strict formulations and stringent methods of testing the complex prediction hypotheses nominated by seismology, tests that would distinguish a lucky guess from a reliable prediction, became evident as never before.

The second type of the two methods for earthquake prediction is based on statistical analysis of seismicity. A pattern of earthquakes is an important key in understanding the dynamics of the lithosphere in an earthquake-prone region. In the 1970s the progress in formalizing the description and pattern recognition of earthquake-prone areas (e.g., Gelfand et al., 1976), which indeed deliver a term-less zero-approximation prediction of large earthquakes, resulted in better understanding of certain universal aspects of seismic processes in different tectonic environments. A distinctive similarity of criteria in zero-approximation provided an encouraging foundation for a systematic search of universal patterns, for example, a unique low-magnitude seismic sequence at the approach of a large quake. Along with 20 years of accumulated global seismic data of high quality and completeness and developments in earthquake physics, a novel understanding of seismic processes basically emerged. Several earthquake prediction methods of the second type have been developed including the CN (Keilis-Borok et al., 1988), M8 (Keilis-Borok and Kossobokov, 1990), MSc (Kossobokov et al., 1990), RTL (Sobolev, 2001), the pattern informatics (Rundle et al., 2002), STEP (Gerstenberger et al., 2005), and the RTP (Shebalin et al., 2006) methods.

According to the scientific definition of earthquake prediction (see section Definition), one can identify an earthquake prediction of certain magnitude range by duration of its time interval and/or by territorial specificity. Four major stages can be distinguished in earthquake prediction: (1) long term (a decadal time scale), (2) intermediate term (one to several years), (3) short term (weeks and months), and (4) immediate (seconds to hours) (see Table 1).

Earthquake Prediction and Forecasting, Table 1 Classification of earthquake predictions

Temporal, in years		Spatial, in source zone size L	
Long term	10–100	Long range	Up to 100
Intermediate term	1	Middle range	5–10
Short term	0.01–0.1	Narrow	2–3
Immediate	0.001	Exact	1

Long-term prediction of earthquakes (it is also called a long-term earthquake forecasting, Kanamori, 2003) is based on the elastic rebound theory, a physical theory about increasing the shear stress on the fault that forms the boundary between crustal blocks until the fault reaches its yield stress and ruptures (Reid, 1911). The Reid's model is rather simple to explain all features of earthquake dynamics, and the use of *characteristic earthquake* (Schwartz and Coppersmith, 1984) and *seismic gap* (Fedotov, 1965; Kelleher et al., 1973) hypotheses allows for developing a long-term prediction of large earthquakes on specified faults or fault segments. Based on fault slip rates, geodetic measurements, and paleoseismological studies it is possible to determine the average strain accumulation and to estimate long-term earthquake rates in terms of probabilities. However, the long-term earthquake forecast is complicated by the irregular occurrence of large earthquakes. The long-term earthquake forecasting models were developed to determine the probabilities of active fault segments to rupture for the next few decades (e.g., Working Group on California Earthquake Probabilities, 1988, 2007). The models are based on a renewal process, in which the expected time of the next event depends only on the date of the last event. The times between successive events are considered to be independent, identically distributed, random variables. When a rupture occurs on the fault segment, it resets the renewal process to its initial state (e.g., Ellsworth et al., 1999). The advanced model (UCERF2 time-dependent forecast for California, Field et al., 2009) incorporates renewal models for the major strike-slip faults of the San Andreas fault system. The long-term earthquake forecasts can guide engineering and emergency planning measures to mitigate the impact of pending large earthquakes.

An intermediate-term prediction is an update of the long-term prediction brought about by some indicators (e.g., an increase in background seismicity, clustering of events in space and time, transformation of magnitude distribution, and some others). Keilis-Borok and Kossobokov (1990) proposed an alarm-based method for intermediate-term predictions of great earthquakes (magnitude 8 and greater), so-called M8 algorithm, which is based on the analysis of seismic patterns and dynamics preceding the large event. An alarm (or time of increased probability of a large earthquake) is declared, when several functions describing seismic activity (Healy et al., 1992) become "anomalous" within a narrow time window. The earthquake prediction M8 algorithm receives a fair amount of attention, because the algorithm's testing is unprecedented in rigor and coverage. The algorithm M8 is subject to ongoing real-time experimental testing by V. Kossobokov (http://www.mitp.ru/en/default.html, section Prediction), and the relevant predictions are communicated, with due discretion, to several dozens of leading scientists and administrators in many countries including China, France, Italy, Japan, Russia, and USA. The accumulated statistics of this experiment confirms intermediate-term predictability of large earthquakes with middle- to exact-range of location (Kossobokov, 2006): For the last 25 years, 13 out of 18 great earthquakes were predicted by the M8 algorithm. The ratio of the alarms to the total space-time volume is about 33%, and a confidence level is higher than 99.9% (Ismail-Zadeh and Kossobokov, 2011). To bring the confidence level down to generally accepted value of 95%, the ongoing experimental testing has to encounter eight failures to predict in a row, which appears unlikely to happen. Independent assessments of the M8 algorithm performance show that the method is nontrivial to predict large earthquakes (Zechar and Jordan, 2008; Molchan and Romashkova, 2011),

although a drawback of the method is the limited probability gain (Jordan et al., 2011).

Stress-induced variations in the electric conductivity of rocks have been studied in lab experiments (e.g., Morat and Le Mouël, 1987). In the 1980s P. Varotsos, K. Alexopoulos, and K. Nomicos proposed a method of short-term earthquake prediction, the VAN method (named after the researchers' initials), which is based on detection of characteristic changes in the geoelectric potential (so-called seismic electric signals, SES) via a telemetric network of conductive metal rods inserted in the ground (e.g., Varotsos et al., 1986). The anomaly pattern is continually refined as to the manner of identifying SES from within the abundant electric noise the VAN sensors are picking up. The researchers have claimed to be able to predict earthquakes of magnitude larger than 5, within 100 km of epicentral location and within 0.7 units of magnitude (Lighthill, 1996; Uyeda et al., 2002). The feasibility of short-term earthquake prediction (days to weeks and months) is still controversial, and the major difficulty here is to identify short-term precursors in the background of intermediate-term alarms.

Another type of short-term prediction is based on calculating the probabilities of target events within future space-time domains. An example of this type of predictions is the Short-Term Earthquake Probability (STEP) method developed by Gerstenberger et al. (2005) and employed by the U.S. Geological Survey for operational forecasting in California. STEP uses aftershock statistics to make hourly revisions of the probabilities of strong ground motion. The probability-based forecasts are the mean for transmitting information about probabilities of earthquakes in the particular region under monitoring. While the probability gains of short-term forecasts can be high, the probabilities of potential destructive earthquakes remain much smaller than 0.1 as the forecasting intervals are much shorter than the recurrence intervals of large earthquakes. Moreover short-term forecasts to be of use for practitioners should cast an alarm, and in this case there is no principal difference between earthquake prediction and earthquake forecast in the terms as it was defined in the section Synonyms.

Immediate earthquake prediction for the next few hours is sometimes mixed with "early warning," which is usually based on the first arrival of seismic waves and transmission of an electronic alert within a lead-time of seconds. It is used (e.g., in Japan, http://www.jma.go.jp/jma/en/Activities/eew1.html, retrieved on April 10, 2012) to shut down nuclear reactors, gas and electricity grids, and to stop high-speed trains in the event of a strong earthquake.

Rethinking earthquake prediction, Sykes et al. (1999) wrote: "*The public perception in many countries and, in fact, that of many earth scientists is that earthquake prediction means short-term prediction, a warning of hours to days. They typically equate a successful prediction with one that is 100% reliable. This is in the classical tradition of the oracle. Expectations and preparations to make a short-term prediction of a great earthquake in the Tokai region of Japan have this flavor. We ask instead are there any time, spatial and physical characteristics inherent in the earthquake process that might lead to other modes of prediction and what steps might be taken in response to such predictions to reduce losses?*"

Following common perception, some investigators overlook spatial modes of predictions and concentrate their efforts on predicting the "exact" fault segment to rupture, which is by far more difficult and might be an unsolvable problem. Being related to the rupture size L of the incipient earthquake, such modes could be summarized in a classification that distinguishes the "exact" location of a source zone from wider prediction ranges (Table 1).

From a viewpoint of such a classification, the earthquake prediction problem might be approached by a hierarchical, step-by-step prediction technique, which accounts for multi-scale escalation of seismic activity to the main rupture. It starts with spatial recognition of the earthquake-prone zones (e.g., Gorshkov et al., 2003; Soloviev and Ismail-Zadeh, 2003) for earthquakes from a number of magnitude ranges, then follows with determination of temporal long- and intermediate-term areas and times of increased probability (Keilis-Borok and Soloviev, 2003), and, finally, may come out with a short-term or immediate alarm. "Predicting earthquakes is as easy as one-two-three. Step 1: Deploy your precursor detection instruments at the site of the coming earthquake. Step 2: Detect and recognize the precursors. Step 3: Get all your colleagues to agree and then publicly predict the earthquake through approved channels" (Scholz, 1997).

Accuracy and testing of earthquake predictions

Though the current accuracy of earthquake prediction is limited, any scientifically validated prediction can be useful for earthquake preparedness and disaster management, if the accuracy of the prediction is known, even though it is not high. In such a case an inexpensive low-key response to the prediction (e.g., to lower water level in reservoirs located in the area of a predicted earthquake, in order to prevent large flooding due to a possible damage of the reservoirs) would be well justified, if even a little part of the total damage due to a strong event is prevented.

K. Aki, one of the most distinguished seismologists of the twentieth century, stated at the workshop on Nonlinear Dynamics and Earthquake Prediction (Trieste, Italy, October 2003) that earthquake prediction would be greatly advanced, when we understand how the seismogenic part of the crust (featuring nonlinear dynamics) interacts with the underlying crust (featuring ductile behavior). A monitoring of the dynamics of the lower crust and physical parameters (e.g., attenuation of seismic waves) could significantly assist in accurate prediction of the large event.

Another approach to accurate prediction should be based on a multidisciplinary nature of earthquake

prediction and requires knowledge from various disciplines in geobiosciences. For example, if the time of increased probability of a large earthquake occurrence in a specific region for a specific time interval is announced based on a statistical analysis of seismicity and pattern recognition methods, then monitoring of electromagnetic field, radon emissions, animal behavior, etc. is required to determine more precisely the time and place of the large event. Despite the large scientific and financial resources needed to proceed with the tasks, the efforts would be worthwhile and less expensive compared to a disaster, which can occur due to unpredicted event.

An earthquake prediction method can be judged based on simple statistics using the number of predicted events of a certain magnitude range, versus the total number of earthquakes of the same magnitude range that have occurred in the study area; the time of alarms compared to the total time of observations; and the confidence level of predictions. In other words, each method can be assessed based on the number of successful predictions, failures to predict, and false alarms. (It is important to mention that the probability of occurrence of a large event by a random guess should be evaluated as well, if possible.)

The performance of an earthquake prediction method actually can be evaluated using only two quantities: the rate of failures to predict and the relative alarm time (Molchan, 1990). An efficient method for testing earthquake predictions is described by Zechar and Jordan (2008). This method is based on the Molchan (1990) diagram – a plot of the rates of failures to predict versus the fraction of space time occupied by alarm – and is applicable to a wide class of predictions, including probabilistic earthquake forecasts varying in space, time, and magnitude.

Conclusion

The earthquake predictions made by seismologists have a large economic impact, and as the methods of predicting improve along with seismological data, these economic effects will increase. Meanwhile, compared to the accuracy of weather forecasting, the current accuracy of earthquake forecasting might appear low. Our knowledge of earthquake physics and earthquake dynamics is limited to predicting strong earthquakes with a high accuracy. We do not know well (1) how earthquakes, especially large events, originate; (2) when an earthquake starts, when it stops, and what magnitude could it be; (3) how and why earthquakes cluster; (4) what were the initial conditions of stress state before a large event in terms of stress transfer. Moreover, there is no quantitative description of earthquake physics, namely, no mathematical equations to describe nonlinear dynamics of fault systems and earthquake "flow." The Navier-Stokes equations in meteorology describe atmospheric flow and hence allow weather forecast with a high accuracy for timescales ranging from a few hours to a few days.

The scientific community should use the full potential of mathematics, statistics, statistical physics, and computational modeling and the data derived from seismological (monitoring of physical parameters of earthquakes and tectonic stress, fluid migration, etc.), geodetic (GPS, InSAR, and other measurements of the crustal deformation), and geological (e.g., determination of the time intervals between large earthquakes using paleoseismological tools) studies to improve intermediate- and short-term earthquake predictions (Ismail-Zadeh, 2010).

Acknowledgments

The author thanks Jim McCalpin and Volodya Kossobokov for the review of the initial manuscript and constructive comments.

Definition

Earthquake resistant design consists of an evaluation of the earthquake excitation and the structure response to this excitation at a particular site in order to provide a structural system that will not collapse, that may prevent loss of life and will limit economic loss during an earthquake.

Introduction

Earthquake Engineering, the study of earthquake resistant design, is a relatively new discipline. The importance of earthquake resistant building design was first appreciated worldwide after observations of the widespread building failure, damage and life loss associated with the 1906 San Francisco earthquake (USA) (Bisch, 2009). It can be observed that the trigger to developing and updating seismic codes for regulating and guiding earthquake resistant design has often been damaging earthquake events. For example, the first seismic code in Italy was developed in 1909 following the 1908 Messina Earthquake. This code contained guidance on siting of buildings, good construction practice, and limited the heights of buildings (Fralleone and Pizza, 2000). Observation of damage to structures and infrastructure from past earthquakes has been paramount to our understanding of the seismic performance of different construction types, their problems and how to introduce measures to improve their resistance in future events.

In the early twentieth century, seismic design provisions worldwide consisted in ensuring structures could resist small lateral loads of the order of 10% of their weight applied horizontally (Bisch, 2009). Knowledge on the response of buildings to earthquake loads developed substantially since then, as earthquake ground motion recordings became available (e.g., the World Wide Standard Seismographic Network was set up in 1963) and the nature of ground motion was better understood (see also "*Seismology*"), as experiments were carried out and more sophisticated analysis methods for structures developed (e.g., Finite element methods, Clough, 1960) that allowed further understanding of the dynamic response of structures under earthquake excitation. A basic summary of current methods for the design of structures for earthquake resistance and methods for achieving this resistance is given herein.

Basic process of structure design

Structural design usually consists of several phases (1) initial concept (2) determination of structural loads to be resisted (3) analysis of the structure to determine internal forces in members, and (4) design of the structural members to resist these internal forces. A final design is often reached by starting with a rough estimated design, then moving through several cycles of analysis and redesign.

The first stage of any design process is a decision as to what structural form and materials are the most appropriate for the intended use of the building. Structural loads are then calculated. These are composed of the structure's self-weight, the weight of objects and people within it (referred to as gravity loads), and loads imposed by the surrounding environment (e.g., wind, snow, earthquakes). The internal forces within each structural member are then calculated through a structural analysis. Different forms of structural analysis can be used but most involve the mathematical modeling of the structure for the detailed evaluation of its internal forces. These internal forces are flexural moments, shear forces, compression, and tension. The stresses and strains resulting from these are resisted by the materials within the structural element. Good design of structural members ensures that the materials are of appropriate strength and appropriately distributed in the element to resist the internal forces effectively and at minimum cost. Checks on the design are carried out to ensure that the member and structure deflections under the applied loads lie within acceptable limits. In most countries structural designs are regulated by building codes, which guide the quantification of applied loads, acceptable materials, element dimensions, etc. (see also "*Building Code*"). However, key to an appropriate design is a good understanding of the loads applied to the structure and the interaction between the structure and applied loads.

The effect of earthquakes on structures

Conventional structural design provides resistance to gravity related loads that are firstly vertical. Sufficient lateral resistance is merely required to ensure lateral stability under wind loads which are comparatively moderate, (note: in design

codes lateral loads imposed by winds may be between 1% and 3% of building weight, whereas those due to typical design earthquakes in countries of medium seismicity range between 25% and 30% of the building weight). Although wind can be highly variable, the oscillating component of the force it generates on structures is usually small enough that no special provision is required to cope with it. Ground motions due to earthquakes, however, possess vertical and horizontal components, both of comparable and significant magnitude. It is the horizontal ground displacement that causes most of the damage in built structures because structures are not designed to sustain large lateral loads.

Whereas conventional design is primarily concerned with the strength and deflections of the material arrangement used, the essentially transient nature of earthquakes also brings into play the inertia of the building. This inertia (i.e., the mass) will want to remain where it is as the ground underneath starts moving sideways. As the building is nonetheless attached to the ground, the ground will eventually drag the mass into motion. Once in motion, the same inertia will make it hard for building to stop moving. The usual interplay between stiffness and mass will cause the building to oscillate, primarily at its own natural frequencies.

For most structures the materials, and therefore the inertia, are distributed throughout the building. Computing the vibration characteristics (natural frequencies and mode shapes) of the structure treated as a continuum is a fairly labor-intensive process. As the bulk of the spectral power density of earthquake motions lies below 10 Hz, only the lower vibration modes of building are actually excited (2 or 3 at most) and relevant for design purposes. In fact, a lot of useful information can be obtained from the analysis of a single degree of freedom system (SDOF). An SDOF system only requires a single coordinate to define its deformed shape. Such a system can either be viewed as an extreme simplification of the actual structure or as representing the behavior of the structure in one of its vibration modes.

During an earthquake, the external "force" felt by the building that causes it to move and deform is solely due to its inertia and the acceleration of the ground motion where it is located. This can easily be seen on a canonical mass-spring-dashpot system attached to a moving support.

The equation of motion of this single degree of freedom system is obtained by applying Newton's law to the mass. Care must be taken to measure the acceleration from a notional inertial frame that does not move with the ground. The total acceleration of the mass $\bar{u}_t$ with respect to such a frame is the sum of the ground acceleration $\bar{u}_g$ and the acceleration of the mass with respect to the ground, noted $\bar{u}$. The latter also measures the deformation of the building and is consequently the displacement governing the elastic restoring force. Eventually the equation of motion can be written as:

$$m\ddot{u}_t = m(\ddot{u}_g + \ddot{u}) = -ku$$

This equation can be rearranged to give:

$$m\ddot{u} + ku = -m\ddot{u}_g$$

showing that the equation of motion of a mass due to ground motion is the same that of a mass moving with respect to static ground and subjected to an effective force $p_{eff} = -m\bar{u}_g$.

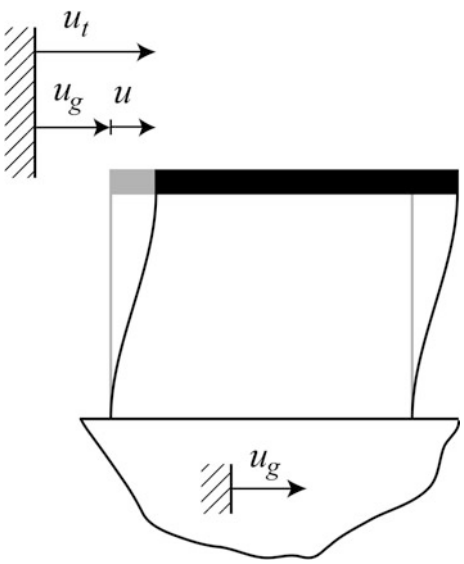
The input energy of an earthquake is transformed by a structure into three different types of energy: Kinetic energy and elastic strain energy, which are conservative, and heat, which is generated through a range of dissipative processes (Lazan, 1986). These dissipative processes include plastic work, friction at the joints, material losses, and many others of less significance. They will eventually drain all the energy out of the system and transform it into heat. If the elastic range of the structure is exceeded, it will be left with some permanent plastic deformations. Dissipation mechanisms other than plastic work are numerous and difficult to model. More for mathematical convenience than physical accuracy, they are often lumped together under a viscous damping term which represents a force proportional to the velocity. The coefficient of proportionality c is an overall measure of the amount of damping present. Adding this term to the equation of motion, results in the following formula:

$$m\ddot{u} + c\dot{u} + ku = -m\ddot{u}_g$$

This mathematical expedient has the virtue of keeping the equations linear as long as deformations are moderate. Solution of the equation of motion involves the characterization and evaluation of the earthquake excitation in terms of acceleration.

Seismic loading

Unlike many other types of dynamic actions, earthquake loads and deformations are not imposed on the structure but are generated by it (Elnashai and Di Sarno, 2008). The excitation of a structure subjected to an earthquake depends on the characteristics of the earthquake ground motion and on the inertia of the structure. The stiffness, strength, damping, and ductility of the structure interact with the ground motion to amplify or reduce the structural response to the earthquake, and hence the design forces and displacements.

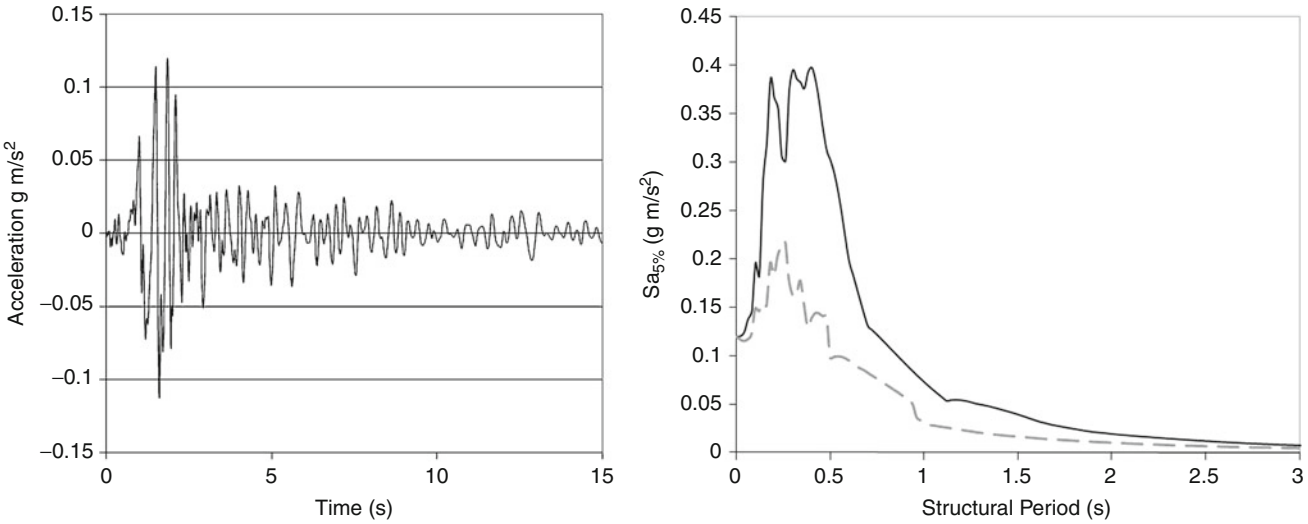


Strong-ground motion characterization for structural analysis

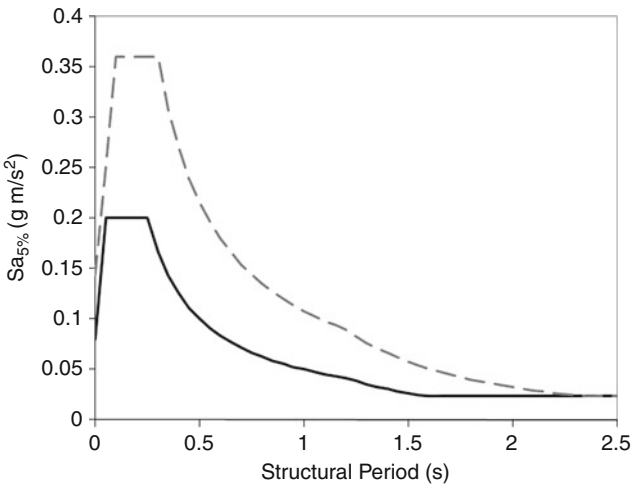
When engineers design a structure for earthquake resistance, they are designing against the strong-ground motion that an earthquake generates at the site of the structure. Strong-ground motion recording instruments (e.g., accelerographs) can accurately record the acceleration of the ground motion against time producing records called accelerograms. Velocities or displacements of the ground can also be directly recorded or derived from the accelerograms. An accelerogram gives a very complete

picture of the ground motion at a site during an earthquake. Different site soil conditions, distances from the earthquake source, and earthquake sizes will result in a change in the maximum recorded acceleration (called the peak ground acceleration), the duration of the strong-ground motion, and the frequency content of the accelerogram.

The peak ground acceleration (*pga*) is the most commonly used parameter to describe the strong-ground motion. This is because it is easy through Newton's second law to relate the *pga* to an inertial force (i.e., F = ma). However, *pga* has not been seen to correlate well with observed earthquake damage in structures. This is because it does not provide information about the duration or the frequency content of the ground motion. The damage potential of the strong-ground motion is not only dependent on the energy it imparts on the structure but also on the ability of the structure to dissipate that energy. The response of the building is dependent upon the relationship between its modal frequencies of vibration and the predominant frequencies in the ground motion. If these are similar then a greater dynamic response of the structure will be observed (concept of resonance) and hence more structural damage will occur. This consideration has given rise to the use of Response Spectra for the characterization of ground motion (Figure 1).



The response spectrum describes the variation in the maximum response of any single degree of freedom system (SDOF) to an earthquake accelerogram. It is derived by calculating the response of a series of SDOF systems with either elastic or elastic perfectly plastic behavior (inelastic), a given damping (*c*), and a varying natural period of vibration (T), when they are subjected to a particular acceleration time history at their base. For each SDOF, the maximum response value is determined and plotted against T. The curve joining all the points is the response spectrum (see Figure 2). Spectra can be derived that show the maximum relative displacement response (*Sd*), the maximum relative velocity response (*Sv*), and the absolute acceleration response (*Sa*) of the mass of the SDOF.



Earthquake Resistant Design, Figure 1 Excitation by a ground motion u_g of a single degree of freedom system of mass *m* and overall stiffness *k*.

The most commonly used spectrum is that derived for maximum acceleration response (*Sa*), as acceleration relates to forces and hence to building loads. A period of T = 0 s represents an infinitely stiff structure for which the maximum acceleration response is equal to the peak ground acceleration. Usually the peak acceleration responses (spectral accelerations) are distributed irregularly across the period range, but decrease significantly in the long period range. In the low to medium structural period range (up to around 0.5 s), response shows significant amplification above the *pga* value. The period at which peak elastic response occurs depends on the earthquake characteristics and the ground conditions at the site of the earthquake recording. A response spectrum as it is derived from an accelerogram also reflects the characteristics of the motion, particularly in terms of the frequency content. In building codes equations that represent an idealized response spectral shape are provided, which represent the ensemble average response of an SDOF under a range of accelerograms (see Figure 3). These idealized response spectral shapes define the average amplification across the structure period range and are anchored to a *pga* value obtained from a seismic hazard map (see below).

For regular structures static analyses can be carried out to determine the structural design forces that use acceleration spectra to characterize the earthquake strong motion. Such methods include the Spectral Modal Analysis Method and the Equivalent Lateral Load Method. The latter is the simplest method of all and is used most commonly in structural design codes. It is a special case (involving only the fundamental vibration mode of the structure) of the spectral modal analysis method. It represents the earthquake excitation as an equivalent static lateral load (or base shear) that is distributed over the height of the structure according to its first mode shape. The base shear is calculated as a combination of the structure weight and the spectral acceleration at the structure's fundamental period of vibration ($S_a(T_1)$). This lateral load is also modified to account for the importance of the structure (Importance factor), the soil type at the site and its effect on the response (soil factor), and the structure inelasticity. The latter parameter is based on the structure ductility and takes on several names in different building codes, e.g., the "behavior factor" in Eurocode 8 (CEN, 2003) and the "Response Modification Factor" in the Uniform Building Code, (1997). It reduces the value of spectral acceleration response (see section "*Force-Based Earthquake Resistant Design*" later).

Earthquake Resistant Design, Figure 2 (**a**) The accelerogram from the November 28, 1974, Hollister (USA) earthquake, recorded at the City Hall recording station. The *pga* of this record is 0.12 g m/s^2 (**b**) the elastic ($\mu = 1$, *solid line*) and inelastic (for $\mu = 2$, *dashed line*) acceleration spectrum derived for 5% damping for the accelerogram in (**a**). Note: the maximum spectral acceleration is much greater than the *pga* of the record.

Earthquake Resistant Design, Figure 3 Comparison of elastic spectra for rock (*solid line*) and soft soil (*dashed line*) site conditions as given by Eurocode 8 (CEN, 2003). Assumptions made in drawing the graph are: "Type 2" spectral shape (for high seismicity areas), a regular importance structure, a behavior factor of 1.5 and pga of 0.12 g m/s^2, soil class A for representing rock and soil class D for representing soft soil.

Static methods are acceptable for the analysis of structures which have a dominant first mode response. If higher modes of vibration contribute in a significant manner to the overall structure response or where the structure is highly irregular, nonlinear time-history analyses are required to determine the design forces. This method of analysis usually requires the finite element modeling of the structure and uses accelerograms directly as a forcing function. The analysis involves applying the acceleration time history to the structure in time increments and resolving the equations of motion at each time step to assess the structure response. Due to the uncertainty in determining the ground motion at any particular site, the analysis is often repeated multiple times using different accelerograms (see also "*Uncertainty*"). This method of analysis is therefore only used for high importance or highly irregular structures as it is computationally and time expensive.

Effects of founding soil conditions on structure response to earthquake

Different idealized response spectra shapes are usually presented in codes for different site soil conditions (see Figure 3). This is because the accelerogram, and consequently the response spectrum, are heavily influenced by local site geology.

When seismic waves pass from the bedrock to the surface, they pass through soil layers where their velocity of propagation is less and hence they slow down. In a similar way to what happens with sea waves entering shallow waters, in order to conserve energy, the amplitudes of the seismic waves increase as they slow down. The amount of increase in amplitude depends on the relative velocities in the bedrock and overlying soil. This phenomenon is known as "impedance" and is the main way in which soil layers amplify the ground motion. Waves can also be reflected by the surface of the Earth and then as they propagate downward they are again reflected back upward at the rock face and in this way they become "trapped" in the soil layer. This has the effect of increasing the duration of the strong-ground motion.

If the dominant period of the ground motion coincides with the natural period of vibration of the underlying soil column, then resonant response can result in very high amplitudes on the spectrum in that range of vibration periods. In general, structures founded on rock will be subjected to short period ground motion, whereas soft sites result in longer period excitation. Hence all standard spectral shapes given in codes show greater spectral amplitudes at long periods on soft soils than on rock sites (see Figure 3).

A further phenomenon associated with soil at a site, which might directly cause damage to buildings is Liquefaction (see "*Liquefaction*"). In earthquake resistant design liquefiable sites can be improved by removing and replacing unsatisfactory material, densifying the loose deposits, improving material by mixing additives, through grouting or chemical stabilization or by implementing drainage solutions (e.g., Brennan and Madabhushi, 2006). Generally however, the easiest thing is not to build on a site that might potentially liquefy.

Seismic hazard maps

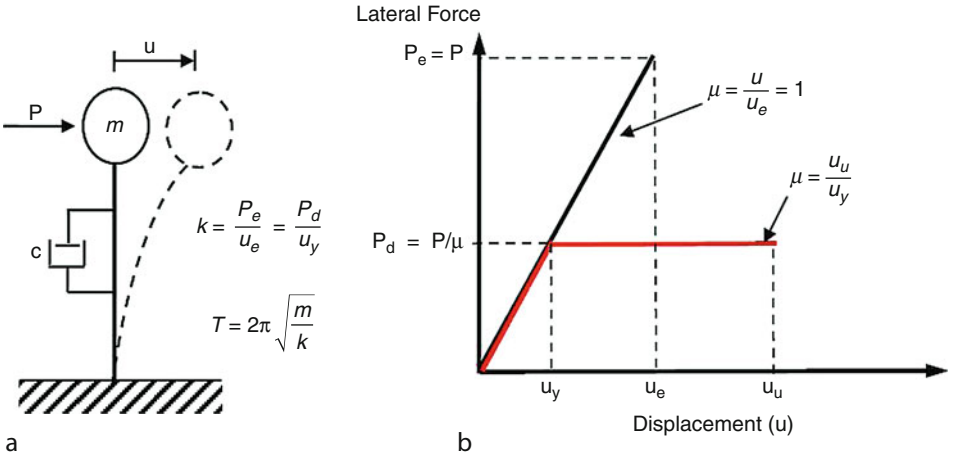
Seismologists have developed methods to provide probabilistic estimates of the seismic hazard at a site based on studies of regional tectonics, active faults in the area and their associated seismic activity, and local geology. The seismic hazard presents estimates of strong ground motion parameter values at a site and their associated recurrence interval (see "*Recurrence Interval*"). If seismic hazard analyses are carried out at several points on a grid covering a region, then a map can be drawn of the strong-ground motion parameter values occurring at each grid point for a given recurrence interval. By joining these points we can draw contours of the parameter values. Such hazard maps present the engineer with a graphical representation of the distribution of seismic hazard in a country or region. Many seismic hazard maps exist for countries around the world that present values of peak ground acceleration (*pga*) for set recurrence intervals. This is due to the fact that *pga* is used together with idealized spectral shapes in building codes to define the earthquake load on a structure in force-based methods of design (see above).

The recurrence interval on hazard maps present in building codes is often represented in terms of the probability that the *pga* value will be equaled or exceeded during the lifetime of the assessed structure (assumed to be 50 years). In most seismic codes of practice the design seismic ground motions (design earthquake) for residential buildings is determined from hazard maps showing *pga* values associated with a 10% probability of exceedance in 50 years. This implies a recurrence interval of 475 years (if a Poisson process is assumed for earthquake occurrence). For more important structures hazard maps for larger recurrence intervals are used, which correspond to the occurrence of larger *pga* values.

Design strategies

Force-based earthquake resistant design

Force-based design of structures for earthquake resistance is at the basis of building codes worldwide (see "*Building Code*"), and is regarded as the conventional mode of such design. The method consists in determining the applied loads to the structure from a combination of the structure's self-weight, the design earthquake (see section "*Seismic Loading*" above), and other live loads (nonpermanent actions) applied with appropriate safety factors to account for uncertainties. The resulting internal forces (flexural) moments, shear forces and tension/compression felt by each element of the structure are calculated. Then the elements are dimensioned and detailed (provided with reinforcement) to resist these internal forces. In this way building failure (see "*Building Failure*") is avoided in the case of occurrence of the design earthquake event.



Model earthquake codes such as the Uniform Building Code 1997 and later International Building Code 2009 have two main purposes:

- Provide minimum provisions for the design and construction of structures to resist earthquake effects
- ". . .to safeguard against major structural failures and loss of life, not to limit damage or maintain function" (UBC, 1997)

The aim of the design is therefore to provide life safety (or no collapse) under the design earthquake. Life safety practically means that heavy irreparable damage may occur in the structure but collapse and loss of life are avoided. This desired performance is assumed to coincide with achievement of the ultimate limit state in critical structural members. The ultimate limit state in a structural member is reached when it is unable to stably carry any further load or deformation, and is often characterized by a loss of 20% of its maximum strength. This state is characterized by a state of stress and strain in the element critical sections, which values are used to design the elements.

If life safety is to be achieved with no damage occurring in the structure, then the structure should be designed to remain within its elastic range of deformation during the earthquake and dissipate the input earthquake energy solely through the notional viscous damping. This is the case for structures where the consequences of damage are unacceptable (e.g., nuclear power plants). Elastic design implies high design forces with correspondingly large structural elements to resist the forces elastically, and consequently high construction costs.

However, an earthquake usually constitutes the most severe loading to which most civil engineering structures might possibly be subjected. Yet in most parts of the world, even those that are highly seismic, it is possible that an earthquake may not occur during the life of the structure. Therefore, it is generally uneconomic, and often unnecessary to design structures to respond to design-level earthquakes in the elastic range, unless it is

Earthquake Resistant Design, Figure 4 (**a**) Diagram of a single degree of freedom (SDOF) system with mass *m*, stiffness *k*, damping *c*, and fundamental period of vibration *T*. (**b**) The force versus top displacement diagram for the SDOF showing elastic response (*black line*) and inelastic response (*red line*). In the elastic system the SDOF resists the applied load by being designed to have a strength $P_e = P$ and shows no residual deformation after loading. In the inelastic system, the structure is designed to have a resistance $P_d = P/\mu$ but yields at a displacement of u_y and undergoes large inelastic deformations until it reaches its ultimate deflection, u_u.

absolutely critical that the structure remains functional during and immediately after the event.

In the majority of structures a degree of damage under an earthquake event is allowed, so that part of the input earthquake energy is dissipated through plastic deformation. Figure 4 shows the difference in the force – displacement response of a single degree of freedom (SDOF) system, (with short natural period of vibration) subjected to a lateral load (P). In both the elastic and inelastic cases the same amount of energy is dissipated by the structure (i.e., area under the black and red response curves is the same) but in the case of the inelastic structure, its ductility is used to reduce the design loads. The ductility of a structure is defined as its ability to withstand large deformations beyond its yield point without fracture (Williams, 2009). Ductility (μ) can be expressed as the ratio of maximum displacement (or deformation) response to the yield displacement, and is illustrated for the single degree of freedom (SDOF) system in Figure 4. In civil engineering design, high ductility is mainly achieved through the provision of good materials, connections, and detailing rather than through large member sizes. This can result in more economic designs but physically, allowing a structure to deform inelastically means that it will sustain a degree of damage, e.g., through yielding of steel and possibly concrete or masonry crushing. Provided that the strength does not degrade as a result of the inelastic deformation, acceptable resistance can be achieved.

As previously stated, where damage is acceptable, the inelasticity of the structure can be taken into account to reduce the design-level forces. Figure 2b shows the difference in the acceleration response spectrum obtained analyzing an SDOF with elastic and inelastic behavior for the same ground motion. In codes of practice a reduction factor is applied to the elastic acceleration spectrum to account for this effect and reduce the calculated applied loads (see earlier). Most buildings are generally designed for only about 10–30% of the elastic earthquake lateral loads, but the lateral resisting system, structure connections and member detailing are chosen and designed to allow the structure to undergo inelastic deformations without losing strength. In this manner the energy imparted by the earthquake is dissipated through the inelastic deformation and controlled damage (see "Capacity Design" below).

Most codes of practice lead to designs that satisfy a single limit state (ultimate) to ensure safety under the maximum expected loads but they also carry out checks under smaller loads to satisfy other limit states (e.g., serviceability, where the function of the structure is not compromised). In earthquake resistant codes, the typical design procedure is similar to that for gravity load design, where the main structural design is carried out to satisfy the ultimate limit under the design earthquake. The design earthquake is characterized by a peak ground acceleration (see later) that is associated with a given frequency of occurrence, which in most codes of practice is 10% exceedance probability in 50 years, (the typical life of a building). Following the primary design, a check is carried out to ensure the structure performance satisfies the serviceability limit state under a scaled down value of the seismic action (representative of a more frequent earthquake event occurrence). These limit states may have different names in different codes of practice.

New concepts in earthquake resistant design

Conventional earthquake resistant design allows the designer to control the structural performance (i.e., life-safety) at one limit state (ultimate) under excitation by a design earthquake event. Until recently, the general

belief was that designing structures explicitly for life safety provides adequate damage protection. However, several recent earthquakes have shown that this perception is false. Although the vast majority of the structures designed to new codes met the life safety requirement, the financial cost, due to direct damage of structural or nonstructural members and business interruption, was much higher than expected. A noticeable example is the January 17, 1994, earthquake in Northridge, California. Although the death toll was not high (57 deaths) the direct financial cost amounted at US $20–40 billion. The economic consequences of the January 17, 1995, Hyogo-ken-Nanbu earthquake, Japan, were even more dramatic, affecting the economy not only in Japan but worldwide. The estimates of the repair costs only have been reported in the range of US $95–147 billion. After these two earthquakes the importance of performance goals that go beyond simple life safety, such as damage control, have been widely acknowledged. A consensus among most researchers and professional institutions has been reached that new design methodologies need to focus more on performance criteria.

Over the last 20 years there is a movement toward developing frameworks for the design of structures under multiple limit states (performance limits) for earthquake events associated with different frequencies of occurrence. The performance-based design approach was first introduced by Vision 2000 (SEOAC, 1995) which outlined a relationship between performance objectives, the type and importance of the designed facility and the probability of earthquakes of different sizes (see also "*Frequency and Magnitude of Events*"). For a normal importance structure it suggests the following limit states for design:

- No damage under a frequent earthquake event (with an exceedance probability of 68% in 50 years)
- Serviceability should be ensured under an occasional event (with an exceedance probability of 50% in 50 years)
- Damage control should be ensured under a rare earthquake event (with an exceedance probability of 10% in 50 years)
- Life safety should be ensured under a very rare earthquake event (with an exceedance probability of 5% in 50 years)

It states that the performance objective must increase (i.e., less damage is acceptable) for a high probability earthquake (one that can occur several times during the life of the structure) or for an important structure or one whose damage will have severe consequences (e.g., a hospital or nuclear power station). Conversely more damage is acceptable for a rare, severe earthquake event and for less critical or temporary facilities. The framework has been further refined by several researchers and code documents (e.g., see Ghobarah, 2001).

Performance-based design assumes engineers are able to check or carry out designs for specific damage levels other than ultimate limit state, that is collapse (see also "*Structural Damage Caused by Earthquakes*"). This is not possible using conventional force-based techniques of damage, as it has long been recognized by the earthquake engineering community that forces are poor indicators of structural damage. Once a structure passes its yield limit, the strength of a structure can remain largely unchanged throughout the inelastic range (see Figure 1b, red curve), thus changes in strength are not indicative of the achievement of different damage states between the yield limit and collapse. Moehle (1992) first proposed the concept of designing a structure directly for displacements. This differs from conventional force-based design where the primary input to the process is a set of forces, with a check on deformation only being carried out in a second stage. In displacement-based design this process is reversed and the main design quantity is a target displacement, which corresponds to a deformation value with associated damage state. Several improvements to the displacement-based design approach proposed by Moehle (1992) have been made by other authors (e.g., Kowalsky et al., 1994; Priestley et al., 2008). Displacement-based design frameworks are currently a theme of active research and have spurred the development of displacement-based parameters for earthquake load characterization (e.g., Displacement spectra, see below) and of relationships between a structural element's mechanical properties and its deformation capacity (e.g., Panagiotakos and Fardis, 2001; Rossetto, 2002). No consensus has yet been reached regarding performance-based (and displacement-based) design methods and tools.

Methods for providing earthquake resistance in structures

Seismic codes of practice

A seismic code is a building code (see "*Building Code*") that regulates the design of earthquake resistant structures in a country. They provide guidance and tools for the evaluation of the seismic loads and to provide safe and economic structural design to resist these loads. They incorporate seismic hazard maps specific to the area covered by the code. Examples of existing national codes include "IS1893 (Part1): Earthquake Resistant Design of Structures: General Provisions for Buildings" for India and the "NZS 4203:1992 Code of Practice for General Structural Design Loadings for Buildings" for New Zealand. In the USA several seismic codes exist that have been developed for each State based on the "NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures." The latter is a multi-edition guidance (latest edition in 2009) that aims to aid seismic code development. Recently, the European seismic code Eurocode 8 (CEN, 2003) has been developed that regulates seismic design of structures in the European member states. Each member state is also equipped with a National Annex to the code that accounts for variations in building practice in different countries and contains a country specific hazard map.

At the basis of all these seismic codes are similar concepts of earthquake load calculation (see above), a minimum standard for building materials and basic design principles to provide life-safe structures. The latter can be summarized as:

1. Regularity of form, mass, and stiffness distribution
2. Pounding with adjacent buildings should be avoided
3. Appropriate lateral load resisting system
4. Detailing for ductility and structural integrity
5. Capacity design for a controlled failure mechanism

Structures should have a simple and regular form in plan and elevation to avoid nonuniform stress and ductility demand distributions. Where complex geometries exist in plan, the structure can be subdivided into more regular layouts using seismic joints. Height restrictions or restrictions on other structure characteristics may be imposed by codes depending on local seismicity and structure importance. Considerations for the location in plan of structural components are included in codes to ensure that the center of stiffness and mass are coincident. The center of mass is essentially where the resultant earthquake force is applied. The center of stiffness of the lateral load resisting elements instead defines the center of structural resistance. If the two are not coincident, then a couple is applied and torsion occurs in the structure, which may not have been considered in the design. Code procedures for seismic design assume a regular distribution of seismic loads over the building height. Hence, if there are severe mass or stiffness irregularities in elevation (e.g., a concentrated load or large change in lateral stiffness between stories), high demand concentrations will ensue that are not taken into account in the design.

Buildings must be protected from earthquake induced collisions with adjacent structures (pounding), by allowing adequate spacing between structures.

A clear system for resisting the vertical and lateral loads imposed by the structure's self-weight and by earthquakes should exist, where there is a good transfer of lateral loads between resisting structural elements and to the foundations. Continuity and regular transitions are essential requirements to achieving an adequate load path (Elnashai and Di Sarno, 2008). Equally, it is important that horizontal elements in the structure (e.g., beams and floor diaphragms) are sufficiently rigid to be able to transfer the seismic loads to the vertical resisting elements (that provide the main seismic resistance). Excessive deformation of the structure under the applied loads should be avoided. This can be achieved through the addition of shear walls or braces in tall buildings.

The structure should be designed so as to allow its full ductility to be reached. This is done in two ways. Firstly, since the seismic performance of the structure depends on the behavior of its critical regions, the detailing of these regions (or structural elements) must be such as to maintain under cyclic loading the ability to transmit the necessary forces and to dissipate energy. The detailing of members should ensure that they do not fail in a brittle manner (such as shear dominated failure). The structure should act as a single unit and appropriate connections between structural elements should be ensured. Failure of a building is often seen when poor connections exist that do not allow the transfer of loads between elements and for the structure to work together as a system for resisting the lateral loads. Secondly, to avoid brittle failures or unstable mechanisms of failure and to make sure that damage occurs only at the desired locations, the concept of "capacity design" is used. Once an engineer has chosen a desirable failure mechanism for the structure being designed (i.e., one that ensures life safety) they can identify those structural elements that should enter their inelastic range and act as dissipators (noncritical members) and those that instead should remain elastic in order to avoid complete collapse (critical elements). The latter are often the vertical elements in a structure as they "hold up" the building. Capacity design is the principle that critical members should be protected and designed to withstand, not the applied forces, but those commensurate with the achievement of plasticity in adjacent noncritical elements. In practical design, this means that the noncritical elements are designed first so that they are able to resist the applied earthquake loads. The critical elements are then designed to be stronger than the designed noncritical elements, taking into account any possible source of overstrength. This allows the designer to control the sequence of occurrence of plasticity and damage in the structure and avoid unstable failure mechanisms. However, it also means that a tight control must be maintained on sources of overstrength during construction, such as the use of a higher grade steel, as this can compromise the occurrence of the desired building failure mechanism. Further discussion of all the above issues can be found in Booth and Key (2006), Elnashai and Di Sarno (2008) and Elghazouli (2009).

Resisting earthquakes using devices

The design techniques discussed thus far essentially consist of carefully sizing and locating members and structural elements in buildings. A range of technological devices can be used in conjunction with code-based designs in order to relax requirements and constraints imposed on the structural elements. A comprehensive review of these types of solutions can be found in Soong and Dargush (1997). These devices essentially fall into two main categories: solely dissipative devices or base-isolation devices.

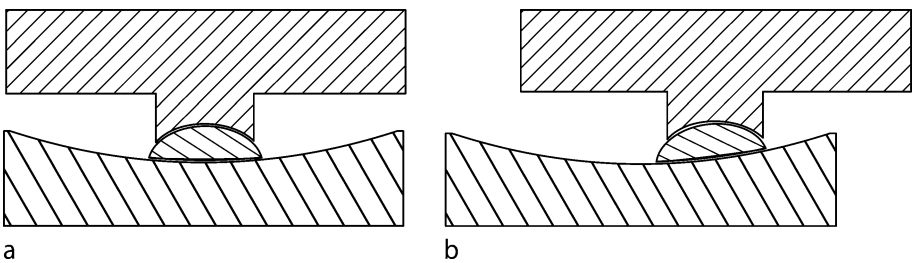
Base-isolation devices

If one could imagine a building floating in thin air like a hovercraft, then obviously it would be unaffected and remain intact through any earthquake ground motion. The inertia of the building would keep it steady while the ground underneath could slide back and forth. Such isolation could actually be achieved by basing the building on some kind of rollers. When the building is well

isolated, most of the deformation induced by the ground motion occurs at the interface between the ground and the building, i.e., the isolating device suffers most of the deformation whereas the structure above remains relatively undeformed. However, this presents a number of difficulties. Although a building can be effectively isolated from the ground structurally (at least in any horizontal direction), service supplies (gas, water supply, and waste) still need to be connected to it in such a way that they survive earthquake events. To achieve this, special flexible connections must fit to pipes or cables connecting the building to utilities networks. Access to the building must also be carefully considered in order to allow large relative displacements between the building and surrounding pavements and access routes. In practice, this means that isolated buildings must be surrounded by a clear gap all around. If the building is completely free to move sideways then any moderate lateral load could push it and offset its position. Hence, mechanisms need to be introduced that restore the building to its initial position after an earthquake.

Two main types of devices can be used to isolate a structure from the ground: (1) laminated rubber bearings and (2) friction-pendulum bearings. Laminated rubber bearings are weak in shear (laterally) but strong enough vertically to resist the weight of the building above. The natural elasticity of the rubber solves any issue of re-centring and will also resist wind loading. However they constitute a lateral connection to the ground – albeit a weak one – so they will transmit some ground motion to the structure. The rubber is usually treated so as to provide large energy dissipation through deformation thereby releasing some the input energy as heat rather than transmitting it to the building. Friction-pendulum bearings, in their simplest form, rely on a top part and a bottom part sliding along a curved interface as shown diagrammatically in Figure 5.

The bottom part is attached to the ground (foundation) whereas columns supporting the building rest above the top part. The middle crescent shaped element allows the top and bottom part to move sideways without actually rotating. The friction between the two parts dissipates some of the input energy. Re-centering and resistance to winds is ensured by the shape of the surface, which allows gravity to bring the system back to its lower point. These devices can be effective for earthquakes of moderate amplitude but can lead to large sudden accelerations being transmitted to the structure if the ground motion is so large that the relative displacement exceeds the range of the device. Double friction pendulums are improvements on the simplest version and are designed especially to increase this range. Both single and double friction pendulums present intrinsic nonlinear behavior as they rely on friction. This makes the behavior of structures fitted with them difficult to model and analyze (Zayas et al., 1990).



Dissipative devices

The next class of devices are dissipative devices. Most of these are composed of some type of ram or piston that dissipates energy using fluid viscosity. They often consist of long members that are bolted diagonally between floors so as to be worked to their maximum when the building is oscillating in an earthquake and its stories undergo relative displacements. Unlike base isolation, they rely on the building deforming to work effectively but the energy they dissipate also reduces the extent of this deformation to acceptable limits. They effectively play the role of ductility in conventional design by focusing the dissipation of energy to specific areas of the structure. These devices are also used to dampen wind-induced oscillation in tall buildings.

Tune-mass dampers (TMD) are another category of dissipative device. They consist of a mass-spring system whose natural frequency is tuned to that of a particular problematic resonant frequency of the structure. As both systems are tuned, the device is set in resonance at the same time as the building. This causes the mass of the TMD to undergo large displacements when the building resonates. By immersing the damper's mass in oil, its displacement is converted into heat due to the fluid viscosity. This effectively drains a significant amount of energy out of the system. A single TMD must be fine-tuned to work well and it can only be effective at a specific frequency.

Summary

Earthquake resistant design is carried out to ensure a desired structural behavior in the case of a seismic event with given recurrence interval. The seismic excitation of a structure depends on the characteristics of the earthquake ground

Earthquake Resistant Design, Figure 5 Schematic representation of a friction pendulum in neutral (**a**) and shifted position (**b**). Supporting columns of the building rest on top while the lower part of the device rests on the foundation. The curved shape allows the structure to slide back in neutral position under gravity.

motion and on the inertia of the structure. The stiffness, strength, damping, and ductility of the structure interact with the ground motion to amplify or reduce the structural response to the earthquake, and hence the design forces and displacements. Earthquake resistant design can be achieved through the direct design of structural elements to resist the applied earthquake loads coupled with requirements for regularity of structural form, good interconnection of elements, and capacity design principles for the control of the building failure mechanism. Alternatively, devices can be used to reduce seismic actions on the structure by isolating it from the ground or to enhance its energy dissipation capacity.

ECONOMIC VALUATION OF LIFE

Indirect Methods of Placing a Monetary Value on the Whole Life of an Individual

Definition

Methods employed to assign a monetary value on an individual's life which may be useful for insurance purposes, or for assessing compensation or damages due to loss of life, as a result of accidents or as a result of natural disasters.

Economic valuation

There are at least four methods that can be used to determine the economic value of human life. These are the: (1) human capital approach (HK), (2) willingness-to-pay approach (or WTP), (3) actuarial basis, and (4) the value of a statistical life (VSL). The human capital approach considers the value of a human life as the present value of an individual's net earnings discounted over his/her lifetime; net earnings are defined as an individual's income over his/her useful lifetime less the portion which he/she spends on consumption. This approach requires an individual to have a lifetime income stream or requires some measure of potential earnings. Problems may arise in evaluating the earnings of the elderly, children, the unemployed, and the handicapped since they may have

no income stream. This method of valuing a human life omits the value placed by individuals on leisure time activities as well as periods of ill health which can affect lifetime earnings. Due to HK's heavy reliance on income in its evaluation, low-income earners are technically of "lower value" than high-income earners as they have less potential future income, which is ethically debatable. Also, the discount rate chosen in the HK calculation is arbitrary, and difficult to justify, which raises another ethical problem. The monetary valuation of human life depends heavily on the rate of discount chosen.

The willingness-to-pay method places a value on life according to how much an individual is willing to pay to reduce the probability of death or is willing to pay for an improvement in health. The WTP approach can be calculated in two ways: (1) the contingent valuation method and (2) the revealed preference method. In the contingent valuation method, individuals are asked to supply information, usually via a survey or questionnaire, on how much they are willing to pay in monetary terms to receive a decrease in the probability of death or ill health. This would involve the construction of hypothetical or contingent scenarios where respondents will in effect estimate their willingness to pay. The disadvantages of this method are all of those which are associated with surveys: respondents may over- or understate their willingness to pay; an individual's willingness to pay in the hypothetical scenario may differ from his/her real reaction to when a particular contingency is in fact a reality; and individuals may interpret and answer abstract hypothetical questions in a manner very different from the way it was intended by the designers of the survey. However, once properly designed, the contingent approach can provide estimates on the valuation of life or at the least a decrease in a unit probability of death from respondents. On the other hand, the revealed preference method is based on individuals revealing their preferences implicitly or explicitly during actual market behavior. For instance, in wage-risk studies, a wage premium acts as an indicator for the trade-off between willingness to pay for an increase in a unit of risk which causes harm (e.g., workplace injury or even death). This can explain why high-risk occupations correlate well with high wage premia. In consumer-market studies, a similar trade-off is found between willingness to pay and consumption goods which reduce the probability of injury or death. For instance, the value of a human life can be calculated from the reduction in the probability of death arising from the purchase of vehicle safety features or fire alarms (Dionne & Lanoie, 2002). Both the contingent valuation method as well as the revealed preference method are *ex ante* (before the fact) and reflect an individual's valuation given current conditions. Individuals may change their preferences *ex post* (or after the fact), for example, an injury sustained from a vehicular accident leaves an individual out of work for the remainder of his/her life; as a result income levels, level of risk aversion, and consumption preferences would also change.

The third method to the value of life is based on actuarial estimation. Actuaries use elements of the HK and WTP approach in their valuation of human life. Economic and demographic assumptions are the two key elements in the valuation of human life under the actuarial basis. For the economic aspect, the present value of future liabilities and potential earnings are calculated. For the demographic assumptions, factors such as employment status, gender, occupation, disability, and health status (whether the person is a smoker, is a diabetic, or has cancer), are used by the actuary to determine the net effect on mortality rate for an individual. Many insurance companies use an actuarial (also called mortality or life) table to compute the probability of mortality given the economic status and demographic factors associated with a particular individual. This information is then used to compute the value of a life insurance policy which is in effect the economic valuation of the individual's life.

Finally, the value of a statistical life (VSL) is often associated with the economic value of human life. If individuals were asked to attach a numerical monetary value on their lives, many would respond by saying that life is "priceless" or "of infinite value." However, under this method of valuation, the cost–benefit analysis of projects that reduce the risk of death by a very small amount would be deemed worthwhile regardless of its cost (Erickson and Moskalev, 2009). To avoid this, a quantifiable and justifiable method of evaluating a human life within practical monetary boundaries is required; hence a statistical approach to valuing life. The term statistical emphasizes the nature in which human life is evaluated: via a methodology including calculations. The value arrived at represents a monetary trade-off between accepting an extra unit of risk associated with death and an increase in wealth. VSL represents the summation of such trade-offs for an entire population; hence the VSL for an individual or for a population would on average be the amount the entire population would pay to reduce the risk of death by a certain increment. In order to estimate VSL, Viscusi and Aldy (2003) analyzed data on risk premia from ten countries and 60 studies as well as current estimates of injury risk premiums from 40 studies. Their study indicates a contribution of around $0.50–$0.60 to the value of a statistical life for every dollar increase in income. They found that the value of statistical life for an individual in the UK ranges from US $4.2 to $21.7 millions in constant 2,000 dollars whereas for India this value lies between US $1.2 and $4.1 m. In Canada, some studies have reported the VSL to be as low as US $2.2 m and as high as US $21.7 m whereas for Japan, Korea, Austria, and Australia, the estimated VSL can be as high as US $9.7 m, $0.89 m, $6.5 m, and $19.1 m, respectively. The VSL for the US varies quite considerably, mainly due to the number of studies conducted in the country. However, VSL can range from a low of $0.5 m to a high of $20.8 m constant 2,000 dollars. Other studies such as Murphy and Topel (2006) found that due to improvements in health care in the US, a 1% decline in cancer mortality can

contribute up to a $500bn gain to society. In fact increased life expectancy contributed $3.2 m per year to national wealth since 1970 (Murphy and Topel, 2006).

ECONOMICS OF DISASTERS

Pierre-Alain Schieb
OECD SGE/AU IFP, Paris, France

Definition

The economics of disasters. An emerging branch of economics which studies the economic dimensions of disasters. Its primary domain encompasses the economic consequences of disasters, be they direct or indirect, short-term or long-term, and negative or positive, and on how to deal with them. Its whole domain entails all the economic dimensions associated with the different stages of the risk management cycle: identification, assessment, prevention, mitigation, emergency, rescue and recovery activities, post-impact issues, and reconstruction.

Disasters: definition and scope

A disaster can be defined as an event that adversely affects a significant number of people, devastates a significant geographical area, and taxes the assets and resources of local communities and governments (adapted from Gad-el-Hak, 2008).

- A disaster is not an event/accident impacting an isolated victim: a single family house fire, a car accident, a boat or someone drowning in the sea, a tree falling on a house, a lightning strike impacting a farm, are all isolated events and do not fit with the concept of a disaster. Of course, in the eyes of the victims, it can be a disaster.
- According to the definition, human, but also social or environmental consequences are discussed with monetary or financial indicators (losses, liabilities, costs, budgets, . . .) even if the primary data are in physical terms: number of casualties, job losses, and area of polluted sea.
- The definition starts by identifying the trigger, an "event." In the case of natural disasters, examples include earthquakes, floods, hurricanes, tsunamis, forest fires, etc. Disasters can also be provoked by man-made events such as wars, financial crises due to economic cycles or bubble bursts, industrial accidents (Bhopal, Seveso, Chernobyl, oil spills from tankers, etc.), and even terrorist acts.
- The definition could be extended to also cover "silent phenomena." A silent risk can go unnoticed for a long period before the negative consequences take a significant toll: for example, asbestos with its health, social, and economic impacts in the twentieth century is often described as leading to one of the biggest economic disasters of the twenty-first century. The potential impacts of the rising obesity rates among humans could be another example of a silent upcoming risk in the twenty-first century.
- Although the common understanding is that "disasters" have mostly negative economic consequences, it should be noted that some economic consequences can be "positive" even though it does not look morally correct to highlight the "benefits" from disasters. For example, a destroyed manufacturing plant can be rebuilt with the latest technological equipment and then an unprecedented level of productivity achieved: new and more appropriate legislation can be passed; regenerative medicine could progress; and disaster resilience could be improved.
- A disaster is the result of the occurrence of a damaging event. In insurance terms, a risk is quantified as the probability of occurrence of a damaging event multiplied by the estimated potential damages. A risk becomes a disaster only when the event has occurred with a significant economic impact after which the actual damages can be recorded.
- A disaster also has to be distinguished from a catastrophe. "Catastrophe" is professionally used in two different ways: (a) to refer to casualties, human losses; and often to the case of extreme events characterized by low probability, high loss, and less empirical data and (b) as a subset of large-scale disasters, relative to the resources of the impacted community, whereby both the public authorities, the first responders and the victims, are overwhelmed by the damages and are not in a position to cope with the situation in an orderly fashion.

- Intrinsic to the definition of disasters lays the question of scale and proportions. An earthquake of magnitude 7.2 for a country such as Turkey, or Chinese Taipei in 1999 for example, may seem to be a disaster; however, a similar event can be a devastating catastrophe for a more fragile country, such as Haiti in 2010, without the resources to cope.

What can be learned from the economics of disasters?

To what extent do disasters affect the national GDP?

The economic context of disasters in industrialized OECD countries and developing countries is not the same. OECD countries are often equipped with a set of prevention and insurance tools that make the situation much easier to cope with; for instance, the economic losses are much larger in OECD countries than in developing countries in absolute numbers but quite less in relative percentage of the GDP.

To what extent do disasters affect longer-term growth?

The negative impact on GDP is usually a very short one for OECD countries, a matter of months quite often, as opposed to other countries for which the impacts can be very long lasting. The Chernobyl nuclear accident in Ukraine is supposed to have had a negative impact on their GDP for 20 years (OECD, 2004).

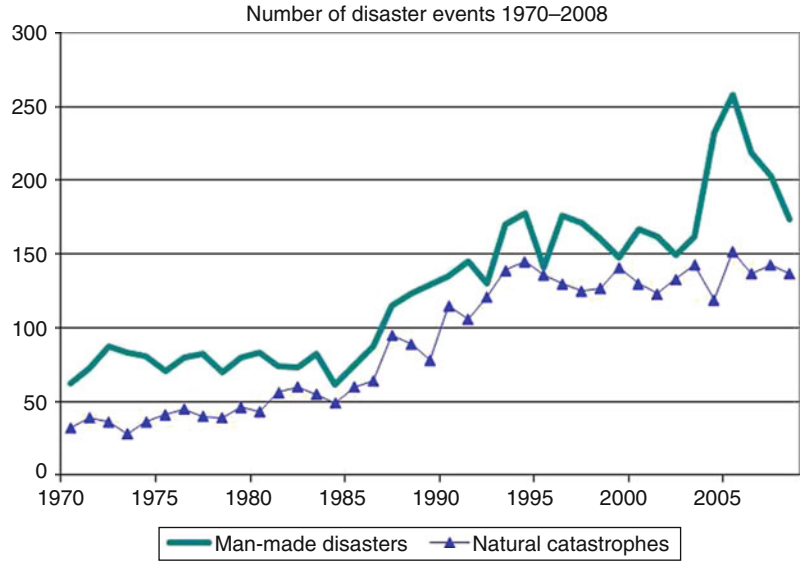
However, Chicago recovered from the Great Fire of 1871 in approximately one and one-half years (Macaulay, 2005). San Francisco was almost completely rebuilt within 3 years after the 1906 earthquake. Economic activity in Kobe, Japan, returned to normal 19 months after the massive earthquake in 1995 (Macaulay, Philips, OECD 2008).

Unexpectedly, in OECD countries, after a disaster, the trend is for the GDP to rise, due to the massive injection of recovery funds by government and insurance. For example, it is estimated that 40% of the losses were covered by insurance in the September 11, 2001 terrorist attack in New York. Of course, this process can create a transfer of public debt to the next generation since the budget of the government could then suffer a deficit. It also affects the balance sheet of insurance companies, which could then be forced to sell assets to be able to pay the indemnities. Overall, because of potential public deficit and increase of insurance premiums, this process can lead to rising interest rates in the country (Table 1).

To what extent does the number of damaging events grow over time and why?

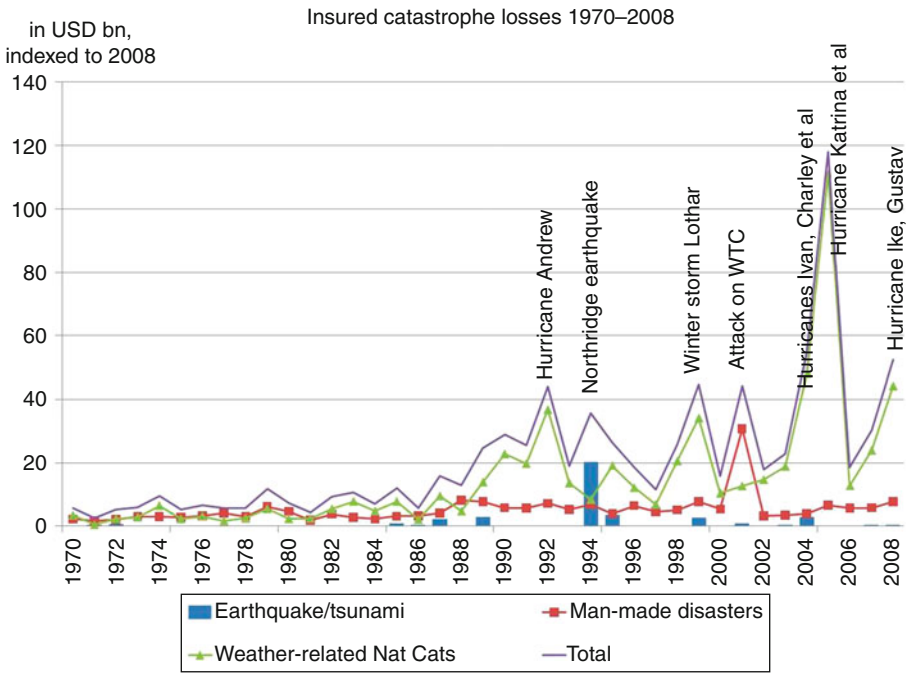
The number of damaging events is globally increasing over time. This trend can be attributed to two sources: (a) with modern communication tools, natural and man-made disasters are much more recorded than in the past, creating a possible bias in the trend; and (b) man-made footprints can create conditions which are more favorable to the repetition of disasters (e.g., anthropic emissions and climate change) (Figure 1).

To what extent are damages from disasters growing over time?



It is now understood that as urbanization increases (51% of global population, at a fast rate in non-OECD countries, and at a slower rate in OECD countries) the assets of society (human, real estate, industrial, and financial, . . .) are increasingly concentrated in cities or even megacities. Therefore, even at a constant probability of an earthquake over time, any occurrence will create more damages in economic terms. Increased human development along the coastal margin has lead to an increase in hurricane and typhoon losses (Figure 2).

What are the questions/issues that economists of disasters have to answer?



Typical questions/issues: In what ways do disasters impact the economy (impacts on GDP, production, consumption, scarcity of resources, savings, investment, productivity, interest rates, public or private debt, . . .)? To what extent are these impacts a function of the stock of capital (more or less recent, in compliance with building codes and other safety regulations), of the level of technology involved, or the level and quality of maintenance? What kinds of incentives for individual or community protection,

Economics of Disasters, Table 1 Impact of large-scale disasters on GDP (Source: Adapted from OECD, 2004)

Year	Disaster	Economic cost (estimates)	% of GDP (estimates)
1995	Kobe earthquake, Japan	USD 130 billion	Over 2%
2001	September 11	USD 120 billion	1.2%
Since 1986	Bovine spongiform encephalopathy (BSE) in Europe	EUR 92 billion	1% (EU15)
2003	Severe acute respiratory syndrome (SARS) in E/SE Asia	USD 60 billion	2%
1992	Hurricane Andrew	USD 25 billion	About 0.5%
2002	Central European flooding (Germany, Austria, Czech Republic)	EUR 15 billion	About 0.75%
1999	Marmara earthquake, Turkey	USD 9–13 billion (SPO) USD 6–10 billion (World Bank)	About 6% About 4%
2000	"I love you" computer virus	USD 8 billion	–
2000	Foot and mouth disease, UK	£6 billion	0.6%

Economics of Disasters, Figure 1 Number of disaster events 1970–2008 (Source: Swiss, 2009).

mitigation, and insurance are provided within existing institutions? In short, how can or will the markets react? What can governments do in terms of economic and other policies (public expenditures, incentives, regulations, monetary policies, . . .)?

Other issues that the economists have to contribute to are as follows: Trade-offs between investments in prevention versus recovery; Actors' level of risk tolerance or preference; Channels for transfer of risks; Role of State as last resort guarantor of asymmetry of information; and Opportunities for predatory behavior and/or free-riding impacts on labor markets, and price mechanisms such as impacts on interest rates or insurance premiums, and intergenerational debts.

Status as a branch of economics

Economics of disasters can be defined as an emerging branch since:

- In the past, it was not a case for scientific investigation. In the western world at least, disasters were often perceived by monotheist religions as revenge by god or "acts of god," more than a scientific phenomena that could be investigated.
- The economic dimension of disasters has only recently been studied. Of course, numerous records have been written on such large disasters, such as the Black Plague (1347–1350) or more recently the Spanish Flu (1918–1919), but they were not trying to identify "economic laws." Early work on economics can be traced to the 1950s with work by Jack Hirshleifer of the RAND Corporation (Hirshleifer, 1987) and in the 1960s when Douglas C. Dacy and Howard Kunreuther published *The Economics of Natural Disasters* (1969). The relevant facts and databases are slow to emerge in a consistent way and are still not at the desired level of accuracy, comprehensiveness, or comparability. There is still no reliable database aimed at collecting the data and the common definitions of the parameters accounting for economic disasters, besides the few and confidential databases of insurers. Few inroads have since been made by other players, such as International Governmental Organizations, the research community, or NGOs.

Example of "laws" or working hypothesis in the field of economics of disasters

- The more resources allocated for the recovery and construction after a disaster, the faster is the speed of recovery (Okuyama and Chang, 2004).
- Due to the replacement of older equipment with new equipment based on newer technologies after a disaster, it is assumed that the rate of technological progress in the stressed area will increase but on temporary basis only (Okuyama and Chang, 2004).

However, still in its infancy, it can be claimed that the economics of disasters already has the attributes of a branch of economics: a separate/specific scope and domain; produced laws and principles, if not yet a general body of knowledge; and the adaption to its own domain of some specific concepts and methodological tools. Not unrelated is the fact that interest in disaster management during the beginning of twenty-first century is increasing among all stakeholders: governments; the private sector; and taxpayers and citizens as well, for the following reasons: (a) Disasters are not acceptable by populations in "welfare states." (b) They should not "happen again." (c) The repetition of shocks within the process of globalization is a threat (the last frontier) to the human well-being.

Related branches

Economics of disasters as a branch ought to be distinguished from the economics of insurance, although insurance economics is older and there are overlaps between the two. For instance, mandatory insurance can lead to a disincentive for the risk-bearer to act prudently (a case of moral hazards): this issue could be discussed under the two branches. However, the question of economic impact of a disaster on GDP, on interest rates, or even on the insurance industry, following a disbursement of funds, is more a question of economics of disaster than insurance.

Economics of disasters has a strong link to economic and other policy areas which is specific to its scope. A disaster quite often has a direct effect on policy shaping and decision making processes, such as special programs for restoring the capacity of public services, or changing the policies related to building codes in case of floods, or changing the regulations of safety features of industrial plants.

Related sciences

As is the case for most branches of this discipline, economics of disasters can use a number of tools or principles that are generic to the other branches of economics; this is the case of probabilistic or mathematical approaches to risks, the concept of extreme events and all tools linked to cost/benefit approaches in decision making, for instance.

Social sciences such as philosophy, history, psychology or sociology, organizational theory, and political science can be useful to economists when dealing with disasters (Slovic, 1993; 2001) (e.g., the issues of risk perception, willingness to be insured, moral hazards, and long-term social psychological consequences of disasters all have economic consequences).

Hard sciences are extremely useful for the economics of disasters as they provide the basis for the assessment of potential risks: estimates of probabilities of occurrence and of magnitude of possible damaging events in the case of natural disasters or man-made events are indispensable for economists as a foundation for their own estimate of economic consequences as well as their analysis of options for prevention, mitigation, emergency or recovery processes, and as a prerequisite for cost/benefit analysis.

Toolbox and methodological tools specific to the economics of disasters

Approaches from the perspective of conventional economic methodologies are used in economics of disasters. This is particularly true when one tries to measure and understand the impacts of disasters. Input/output tables, social accounting, and general equilibrium models are generally found in the literature (Cochrane, 2004; Okuyama and Chang, 2004).

More adaptations of the methodologies to the specific nature of disasters can be found. A recent example is CATSIM, which is a model originally started by the Inter-American Development Bank for Latin American countries and enhanced by the IIASA on estimates of

impacts of disasters on public finance. The concept of financial resilience of public finance is a major factor which can encompass the degree of preparation of the public sector as well as the potential access to funds both ex ante and ex post disaster.

A number of methodologies at the interface of macro- and microeconomics as well as probabilistic and stochastic decision processes can also be found under loss estimation models, risk mitigation decisions under uncertainty, and modeling mitigation strategies with cost/benefit analyses.

At the forefront of the improvement of economic tools lies the convergence of interest from multiple stakeholders in implementing GIS databases, fed by satellites and other remote sensing measurement, census information, and databases from the private sector. These databases will increasingly provide data that disaster economists need to help decision and policy makers, as well as investors, to make informed decisions.

Conclusions

Although, economics of disasters is an emerging branch of economics, international governmental organizations (such as the OECD, the World Bank, specialized UN agencies), the European Union, regional development banks, and national governments, as well as universities, research centers, consultants have started in the early twenty-first century to increase activities in the domain of risk management policies, risk indicators, and databases, as well as in economics of disasters.

Another branch of economics is trying to link knowledge of economics and physics, under the name of "econophysics." It mainly tries to use inductive or experimental methods from physics, as well as concepts from thermodynamics, to learn more on the economics particularly of financial processes including bubbles. Some of the potential benefits are to avoid being constrained by the previous assumptions of economists, such as general equilibrium conditions, and also to improve the "detrending" capacity in database analysis to overcome the weaknesses of older multiple linear regression tools and therefore, better identify the risks of disruption, cycles and crises, etc. These developments could be also helpful in the economics of disasters.

A parallel and convergent effort is underway with the emerging body of knowledge on complex systems, which also uses interdisciplinary concepts and tools from ecology, biology, mathematics, and physics in trying to identify universal features of complex systems and particularly their endogenous dynamics. An example is the concept criticality in economics of disasters which has been defined as the impact of a disaster which drives the economy at a critical state at macroeconomic level, together with strong localized interactions between individual elements at the microeconomic level. An illustration would be the fall of the Iron Curtain in 1989 (a disaster for some, a shock in more neutral terms) with macroeconomic impact on the East German economy and local impacts on the labor markets of Western Germany (Reggiani and Nijkamp, 2004).

Summary

A few centuries ago, disasters were "acts of gods." During the twentieth century, disasters progressively became an important theme for hard sciences (e.g., seismology for earthquakes, hydrology for floods) as well as, slowly, a theme for economics. It is now recognized that potential negative damages from natural and man-made hazards are large enough to justify efforts to better understand the laws and principles that govern the economic dimensions of disasters: primarily assessing their costs and impacts. Even more importantly, economic questions are linked to the decisions that governments, firms, and citizens have to make about potential disasters: invest in research or not, and if yes, to what extent? In prevention or not? In early warning or not? In insurance or not? And, if yes, up to what extent? As efforts to understand these laws are growing, economics of disasters is becoming a branch of economics.

EDUCATION AND TRAINING FOR EMERGENCY PREPAREDNESS

Kevin R. Ronan
CQUniversity Australia, North Rockhampton, QLD, Australia

Synonyms

Emergency readiness

Definition

Emergency Preparedness: Actions taken in anticipation of an emergency to facilitate rapid, effective, and appropriate response to the situation (Inter-Agency Contingency Planning Guidelines for Humanitarian Assistance, 2001).

This entry is based on Ronan and Johnston (2005). Portions are reprinted from that book, also published by Springer.

Education and training for emergency preparedness

The effects of natural hazards are many. One classification system considers effects at three levels: primary effects, secondary effects, and higher order effects (Petak and Atkisson, 1982; see also Ronan and Johnston, 2005). Primary effects include direct effects (e.g., death and injury; physical damage; changes to river flows, flood plains, and landscapes; and trauma); secondary effects include the need for evacuation, lifeline disruptions, industry, business and school closure; financial expenditure for response and recovery; insurance; and secondary stressors). Higher order effects include flow on effects such as alteration of population trends, unemployment, loss of income, capital, savings, land values, changes to socioeconomic trends, and increased cost and tax burden.

Given the many and potentially large-scale effects of natural hazards, societies must undertake certain activities if they are to coexist with hazardous events. Emergency preparedness is one of those activities. The other tasks include risk reduction (or mitigation), response, and recovery. These tasks are linked together across the phases of a hazardous event and include those activities that can be done prior to an event (preparedness, risk reduction), during the event itself (response), and following the event (recovery). Emergency managers emphasize prevention in the form of risk reduction and preparedness activities as the key to effective response and recovery (Tierney et al., 2001).

Research has supported the idea that the effects of a hazardous event can be reduced through sound decision making and planning (e.g., Peek and Mileti, 2002). On the other hand, some forms of planning can be intended to assist emergency preparedness but inadvertently create other problems. For instance, costly solutions such as construction of levees or flood banks and raising sea walls may divert attention from more effective social solutions. Extending this example, putting in flood banks aimed at 100-year floods may then also lead to population growth that is then at risk in the event of a flood that exceeds 100-year return periods.

In light of this backdrop, education and training for emergency preparedness needs to consider both physical and social solutions to assist a community mitigate risk as well as be prepared to respond more effectively. Strategies available for emergency preparedness include (Burby et al., 2000): (1) building standards and codes, (2) development regulations, (3) policies for public and critical facilities, (4) good fiscal policy including taxation, (5) property management and *Land-Use Planning*, and (6) dissemination of information through various channels. The dissemination of information includes through training and educating government, organizations, and the public about the value of emergency preparedness, including specific risk reduction and readiness activities that can be undertaken.

Thus, the goal in education and training for emergency preparedness is to assist all sectors of the community to understand risk in relation to natural (and other) hazards, how to reduce risk and how to prepare to respond more effectively (Johnston and Ronan, 2000). Activities related include creating response plans, undertaking training, including simulation exercises and drills, and engaging in necessary physical and social activities that will reduce risk and increase preparedness to respond. Of course, all of these activities can, and do, occur at various levels within a community, including at community level, organization level, and household level. Communities in many parts of the world have a statutory obligation to have an *Emergency Management* preparedness and response plan. However, many organizations also engage in some forms of education and training in emergency preparedness, including having written emergency plans. At the household level, research has demonstrated that in general, most communities have low rates of household planning and preparedness, even in high hazard zones (Mileti and Darlington, 1997; Ronan and Johnston, 2005).

In addition, even where emergency plans are available, they will not be effective if they are not disseminated or applied by stakeholders. Thus, a written plan is a necessary but by no means sufficient component of an adequate emergency preparedness education and training program. In fact, prior to a written plan, the more input and buy-in from several sectors of a community that there is, the more likely that it will then be adopted and applied

when necessary. This implicates a need for developing relationships across several sectors of a community, initiated by those with the most vested interests in emergency preparedness. Those with the most vested interests of course will include local emergency planners and other government agencies but may also come from several other community sectors, including schools, non-governmental organizations, scientists, business and industry, neighborhood, community, service and volunteer groups, and the media. Research has demonstrated that it does not merely have to be officials that initiate and raise the level of community concern about education and training, but it can include "emergent groups" of concerned citizens (Quarantelli, 1985).

The written plan itself should serve two major functions (Tierney et al., 2001): (1) an agreement that is signed off by various organizations and documents specific roles and related functions for promoting training and education, preparedness activities and activation thresholds for specific response, and recovery related activities and (2) a template for continuing training and education. The importance of this second function is to buffer against the chances that the plan itself is not "filed, shelved, and forgotten" (see also Ronan and Johnston, 2005).

With a template for ongoing training and education, practice, simulations, and important community linkages, an integrated approach to community-based emergency preparedness can then be a continuing process of keeping community members up-to-date with risk-related information. Ensuring community members have up-to-date knowledge will have members informed on what to do to be prepared for, and respond to hazardous events. This includes not only raising awareness but providing specific guidance across multiple media, all endorsed by multiple, linked, and trusted organizations (Mileti, 1999). This up-to-date knowledge should come from different trusted information sources (e.g., from school education programs, emergency management, businesses, scientists, and government officials); emphasize important content (e.g., specific guidance on protective and response actions by households and organizations, physical effects and features of an expected hazard, and anticipating and responding effectively to warnings); and use a range of education delivery modes (education through schools, public media, brochures, demonstrations, community, organizational, and household-response exercises) aimed at different target audiences (youth, adults, and those in higher risk groups including those in low socioeconomic groups; see also Lindell and Perry, 2007; Ronan and Johnston, 2005).

A final point on the motivation to engage in emergency preparedness and training: owing to community emergency preparedness levels typically being low, motivation to prepare is quite obviously an issue that is worth keeping in mind when planning emergency preparedness training and education programs. Developing multiple relationships and linkages through community partnerships is one key to raising community motivation to engage in a variety of activities aimed at strengthening communities, including emergency preparedness (Ronan and Johnston, 2005). Another is to locate "motivational reservoirs" within communities, including schools and schoolchildren and concerned citizens' groups, and include them in training and education efforts.

Summary and outlook for emergency preparedness

Research indicates that continuing research and efforts on the parts of localities to encourage emergency preparedness has merit. For example, documented preparedness for earthquakes and other natural hazards in California has seen quite a significant improvement in the last 3 decades of research done in that US state (Lindell and Perry, 2000). However, there also appears to be a certain "half-life" to community-focused education and training efforts, where effectiveness can diminish over time. Thus, a "spaced" effort across time rather than a one-off "massed" effort appears to be the more fruitful pathway for helping a community prepare more effectively for a range of hazardous events (Ronan and Johnston, 2005).

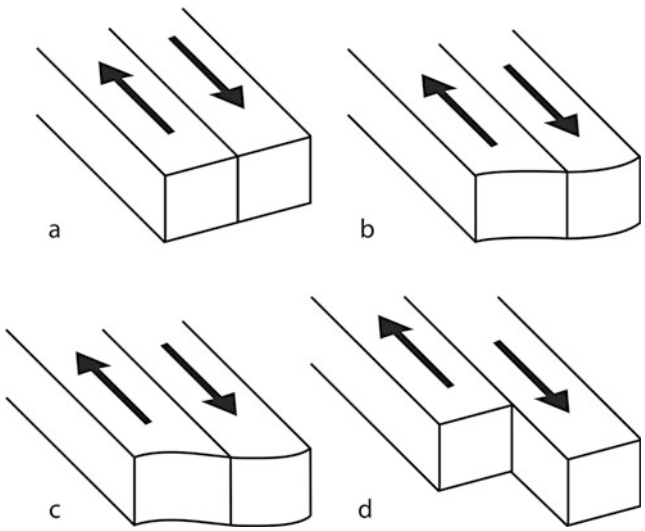
ELASTIC REBOUND THEORY

John Ristau
GNS Science, Avalon, Lower Hutt, New Zealand

Synonyms



Earthquake cycle; Strain accumulation

Definition

The gradual accumulation of elastic strain on either side of a locked fault.

Overview

Elastic rebound theory is one of the central ideas to the mechanics of earthquakes and was originally proposed by Reid (1910) following the 1906 San Francisco earthquake on the San Andreas Fault. The theory involves the slow build up of elastic strain due to large-scale stresses in the crust on either side of a locked fault (i.e., a fault on which steady movement is not occurring). Once the strain accumulation exceeds the strength of the locked fault, the stored energy is abruptly released by rapid displacement along the fault in the form of an earthquake, whereby the rocks return to their original state, and the cycle repeats. Elastic rebound theory fits in well with the theory of plate tectonics and helps explains the cyclical nature of many earthquakes including why earthquakes repeatedly occur in the same regions. It is now known that the actual accumulation of strain does not follow a simple, steady-strain accumulation, and that the concept of a single breaking point is overly simplistic; however, as a general concept, elastic rebound theory works well (Figure 1).

Elastic Rebound Theory, Figure 1 Due to large-scale stress in the crust strain is built up along a fault from the unstrained state (**a**), through (**b**) to the fully strained state (**c**) at which point sudden displacement occurs along the fault to release strain and return to the original state (**d**).

ELECTROMAGNETIC RADIATION (EMR)

Norman Kerle
Faculty of Geo-Information Science and Earth Observation (ITC), University of Twente, Enschede, The Netherlands

Synonyms

Electromagnetic waves; Radiant energy

Definition

Energy propagating through space at the speed of light in the form of sine-shaped electromagnetic waves, composed of perpendicularly arranged electric and magnetic fields. EMR ranges from gamma rays with very short wavelength to long radio waves. The shortest wavelengths can also be modeled as particles (photons). The interaction of EMR with matter forms the basis for remote sensing.

Overview

Electromagnetic radiation (EMR) is composed of sine-shaped waves that propagate through space at the speed of light (approximately 300,000 km s^{-2}), characterized by electrical and magnetic fields that are arranged perpendicular to each other (Lillesand et al., 2004). The central property of EMR is wavelength, inversely proportional to frequency. It ranges from high-frequency gamma rays (with picometer [10^{-16} m] wavelength and that are better thought of as particles or photons) to radio waves many kilometers long and with low frequencies, collectively known as the electromagnetic spectrum (EMS). Wave energy is also proportional to frequency.

EMR forms the basis for remote sensing (RS), which has gained great relevance in studying and monitoring of hazards (Tralli et al., 2005). RS is divided into passive and active methods: reflected or emitted radiation is recorded (passive), or the response of an artificial signal is received (active, for example radar). To detect or monitor phenomena related to hazards, a careful selection of the appropriate part of the EMS is critical. Most Earth observation instruments, such as regular cameras, passively record EMR in the visible part of the spectrum (approximately 0.4–0.7 μm [10^{-6} m]), and in the adjacent near-infrared (NIR, 0.7–1.4 μm). This is ideal to detect the state of vegetation, as the cell structure of healthy green leaves strongly reflects NIR energy, which declines in stressed leaves. Vegetation stress possibly leading to crop failure can thus be detected early.

Less common are detectors that record thermal infrared (TIR) radiation (8–14 μm), for example, to measure surface temperatures. The main forms of active RS are lidar (laser scanning), radar, and sonar (*li*ght/*ra*dio/*so*und *d*etection *a*nd *r*anging, respectively). Lidar uses very short waves between about 400 nm and 1 μm, whereas radar waves range between approximately 0.1–1 m. Sonar uses acoustic waves several meters long. An advantage of all active sensors is that they are largely weather-independent and may also be applied at night.

EMR is also the basis for other tools important in hazard work, for example, GPS, which uses radio waves of about 20 cm, marginally more than other important communication systems, such as wireless networks.

EMR itself can constitute a hazard to living organisms. Well-known examples of radiation to which exposure should be minimized or avoided are X-rays (wavelength of a few nm), ultraviolet rays than cause sunburn (about 0.3–0.4 μm), but also microwaves (wavelength of about 12 cm).

Synonyms

El Niño; Southern oscillation; Tropical pacific warming

Definitions

Easterlies. Low-latitude trade winds that blow from east to west and extend from the Galapagos Islands to Indonesia.
Kelvin wave. A nondispersive subsurface oceanic wave, several centimeters high and hundreds of kilometers wide, that balances the Earth's Coriolis force against the equator.
El Niño. A recurrent increase of the ocean surface temperature across much of the tropical eastern and central Pacific; the term was introduced by Peruvian fishermen.
La Niña. The opposite to El Niño – cooling of the ocean surface temperature across much of the tropical eastern and central Pacific.
Rossby wave. A planetary-scale wave caused by the variation in the Coriolis force with latitude, discovered by Carl-Gustaf Rossby in 1939.
Southern oscillation. Coupled changes in surface air pressure between the eastern and western Pacific associated with El Niño and La Niña events; the term was introduced by Sir Gilbert Walker in 1924.
Southern Oscillation Index (*SOI*). A scalar measure of the strength of Southern Oscillation, calculated as the difference in surface air pressure between Tahiti and Darwin, Australia. El Niño episodes correspond to negative SOI values, La Niñas to positive ones.
Thermocline. A thin layer of ocean water that divides a layer of relatively warm water just below the surface from colder, deeper, nutrient-rich waters. The thermocline is usually a few tens of meters deep in the eastern Tropical Pacific, and can reach depths of hundreds of meters in the western Tropical Pacific. The thermocline depth is heavily affected by El Niño dynamics.
Thermohaline circulation. Large-scale circulation throughout the world's oceans that transforms low-density upper-ocean waters to higher-density intermediate and deep waters, and returns the latter back to the upper ocean.
Walker circulation. Zonal flow in a roughly longitude-altitude plane near the Equator, caused by differences in heat distribution between ocean and land, and described by Sir Gilbert Walker during the 1920s.

El Niño/Southern Oscillation, Figure 1 Schematic diagram of the atmospheric and oceanic circulation in the Tropical Pacific. *Upper panel*: climatological mean ("normal"), *lower panel*: El Niño (warm) phase. The three-dimensional diagrams show the deepening of the thermocline near the coast of Peru during the warm phase, accompanied by anomalous surface winds (*heavy white arrows*), modified Walker circulation (*lighter black arrows*), and a displacement and broadening of the warmest SSTs from the "warm pool" in the western Tropical Pacific, near Indonesia, toward the east (After McPhaden et al., 1998, with permission of the American Geophysical Union AGU.).

Introduction

The El-Niño/Southern Oscillation(ENSO) phenomenon is the most prominent signal of global seasonal-to-interannual climate variability. It was known for centuries to fishermen and sailors along the west coast of South America, who witnessed a seemingly sporadic and abrupt warming of the cold, nutrient-rich waters that support the food chains in those regions; these warmings caused havoc to the fish harvests (Diaz and Markgraf, 1993; Philander, 1990). The common occurrence of such warmings shortly after Christmas inspired Peruvians to name it El Niño, after the "Christ child" (*el niño* is Spanish for *little boy*). The phenomenon was discussed at the Geographical Society of Lima meeting in 1892, and El Niño became the official name of this phenomenon.

The ENSO phenomenon manifests itself in both atmospheric and oceanic processes (Figure 1). The terms El Niño and La Niña refer to the temperature state of the oceanic surface. An *El Niño* (or warm ENSO phase) represents the warming of waters across much of the tropical eastern and central Pacific. A *La Niña* is the opposite, cooling phase (*la niña* is Spanish for *little girl*). The warm phase occurs typically, to some extent at least, every boreal winter. More significant warm episodes, as well as not so warm ones, occur roughly every 2 years: this is the so-called quasi-biennial oscillation (QBO). In the climate literature, differences between the instantaneous, or short-term average map, and the climatological or *normal* values associated with the mean seasonal cycle are called *anomalies*; in the context of interannual variability, El Niño and La Niña represent, respectively, warm and cold anomalies of sea surface temperature (SST).

These changes in the ocean temperature are directly related to the atmospheric pressure; the changes in pressure between the eastern and western Pacific associated with El Niño and La Niña events are referred to as the *Southern Oscillation*; the term was coined by Sir Gilbert Walker in 1924. El Niño favors higher pressure in the western Pacific; La Niña favors higher pressure in the eastern Pacific.

ENSO dynamics is commonly monitored by averaging SST anomalies over some portion of the Tropical Pacific. The *normal* SST field is defined here in terms of a long-term average (often taken to be 30 years) of mean-monthly maps. There are four regions commonly used for ENSO monitoring:

- Niño 1 + 2 (0°–10°S, 80°–90°W) – the region that typically warms first when an El Niño event develops
- Niño 3 (5°S–5°N; 150°–90°W) – the region with the largest variability in SST on El Niño time scales
- Niño 3.4 (5°S–5°N; 170°–120°W) – the region that is most important for monitoring global climate variability, because the SST variability in this region has the strongest effect on shifting rainfall in the western Pacific and elsewhere
- Niño 4 (5°S–5°N; 160°E–150°W) – the region with average SST close to 27.5°C, which is thought to be an important threshold in producing rainfall

As is typical for threshold-crossing episodes in a continuous field, there is no objective, quantitative definition of ENSO events. Trenberth (1997) addressed the problem of formally defining El Niño and La Niña by suggesting that "an El Niño can be said to occur if 5-month running means of sea surface temperature (SST) anomalies in the Niño 3.4 region exceed 0.4°C for 6 months or more." Table 1 lists all the ENSO events since 1950 according to this definition.

El Niño/Southern Oscillation, Table 1 El Niño and La Niña years, after IRI (2010)

El Niño	Year	La Niña	Year
1	1951	1	1950–1951
2	1953	2	1954–1956
3	1957–1958	3	1964–1965
4	1963–1964	4	1967–1968
5	1965–1966	5	1970–1972
6	1968–1970	6	1973–1976
7	1972–1973	7	1984–1985
8	1976–1977	8	1988–1989
9	1977–1978	9	1995–1996
10	1982–1983	10	1998–2000
11	1986–1988	11	2000–2001
12	1990–1992		
13	1993		
14	1994–1995		
15	1997–1998		

Global climatic and socioeconomic impacts

Starting in the 1970s, El Niño's climatic, and hence socioeconomic, effects were found to be far broader than its manifestations off the shores of Peru (Glantz et al., 1991; Diaz and Markgraf, 1993). This realization was triggered in particular by the strong El Niño episode of 1976–1977 that coincided with a so-called global "climate shift" (Miller et al., 1994) in the Pacific Ocean, and it led to a global awareness of ENSO's significance and to an increased interest in modeling (Cane and Zebiak, 1985; Philander, 1990; Neelin et al., 1992, 1994, 1998), as well as in monitoring and forecasting (Barnston et al., 1994; Latif et al., 1994; Ghil and Jiang, 1998) exceptionally strong El Niño and La Niña events.

Affected by numerous competing mechanisms, the remote effects of ENSO, also called *teleconnections*, do vary from one El Niño or La Niña event to another. Nevertheless, it has been observed that significant ENSO events are consistently related to particular weather anomalies around the globe. In many regions, these anomalies present the second largest contribution to climate variability after the seasonal cycle (IRI, 2010). Seasonal climate changes, in turn, affect the flood and landslide frequencies, air quality, forest fire likelihood, agricultural production, disease outbreaks, fisheries catches, energy demand and supply, as well as food and water availability. Accordingly, both damages and benefits of ENSO's impact present an important component of the socioeconomical and political life of the affected regions. This impact is generally more severe in developing countries, where people's lives are heavily dependent on agricultural production and natural water sources. ENSO effects, as well as any other climate impacts, can be amplified or reduced by such factors as government policies; infrastructure resilience; crop and human diseases; current military, economic, or political conflicts; disruption of storage and shipping facilities; mitigation policies for natural hazards; and many others (IRI, 2010).

In the physical climate system, ENSO affects SSTs, wind, pressure, and rainfall patterns: it does so directly in the Tropical Pacific and via teleconnections in many other parts of the globe. The key observation in understanding ENSO climatic patterns is that the SST field plays a key role in determining rainfall intensity: the higher the SSTs, the higher are the rainfalls. Under *normal conditions* (absence of El Niño), the largest SSTs and greatest rainfall intensity is found over the "warm pool" in the western Tropical Pacific, whereas the eastern Tropical Pacific and the west coast of South America enjoy cold, nutrient-rich waters; the prevailing winds are the *easterly* trade winds. *El Niño conditions* shift the highest SSTs and rainfall eastward and weaken the easterlies; *La Niña conditions* shift high SSTs and rainfall farther west, extend the cold waters to the central Pacific, and strengthen the easterlies. ENSO teleconnections manifest the close relationship between the tropical rainfall and prevailing winds on the one hand and the global atmospheric wind patterns on the other.

A large El Niño event affects, within the next year, the temperature and precipitation patterns along both coasts of South America, the Caribbean, the Equatorial Pacific, Southeast Asia, India, Southeast and West Africa, Australia, and both coasts of North America (Ropelewski and Halpert, 1987; New and Jones, 2000). Hurricanes, typhoons, and tropical cyclones are also affected by ENSO, either directly (in the Pacific) or via teleconnections (in the Indian and Atlantic Oceans): the changes may be seen in the frequency of events or in the initial location of these storms (Landsea, 2000).

The most important impact of El Niño events on local hydroclimatic conditions and thus on regional ecology and economics can be seen in floods and landslides caused by high rainfalls in Southern California and Peru, forest fires and air pollution in Indonesia, crop failures and famine due to droughts in southern Africa, as well as in the collapse of Peruvian anchovy fisheries due to the warming of coastal waters. At the same time, ENSO affects in one way or another all continents and diverse sectors of socio-economic systems around the globe. Table 2 illustrates the global ENSO impacts according to the data from the International Research Institute for Climate and Society (IRI, http://portal.iri.columbia.edu).

What causes ENSO?

The following conceptual elements play a determining role in ENSO dynamics.

The Bjerknes hypothesis. Jacob Bjerknes (1897–1975) laid the foundation of modern ENSO research. Bjerknes (1969) suggested a *positive feedback* as a mechanism for the growth of an internal instability that could produce large positive anomalies of SSTs in the eastern Tropical Pacific. Using observations from the International Geophysical Year (1957–1958), he realized that this mechanism must involve air-sea interaction in the tropics. The "chain reaction" starts with an initial warming of SSTs in the "cold tongue" that occupies the eastern part of the equatorial Pacific. This warming causes a weakening of the thermally direct Walker cell circulation; this circulation involves air rising over the warmer SSTs near Indonesia and sinking over the colder SSTs near Peru. As the trade winds blowing from the east weaken and give way to westerly wind anomalies, the ensuing local changes in the ocean circulation encourage further SST increase. Thus the feedback loop is closed and further amplification of the instability is triggered.

El Niño/Southern Oscillation, Table 2 Global impacts of ENSO (according to the IRI data base http://iri.columbia.edu/climate/ENSO/)

Region	Impact
Africa	Changes in land use
Asia	Changes in available water resources; droughts and floods; changes in river discharge; outbreaks of wheat stripe rust disease, cholera, hemorrhagic fever, dengue; interannual variability of ozone; influence on rice production
Australia and the Pacific	Changes in alpine-lake inflow; changes in river discharge; amount of rainfall; outbreaks of encephalitis; availability of banana prawns
Central America and the Caribbean	Floods; changes of a coastal fish assemblage; variations of annual maize yields; coral bleaching; mortality rates
Europe	Agricultural yields; wine production and quality
North America	Variations in the occurrence of wildfires; annual runoff; insect population
South America	Invertebrate behavior; maize, grain production; precipitation and streamflow; river discharge

Delayed oceanic wave adjustments. Compensating for Bjerknes positive feedback is a *negative feedback* in the system that allows a return to colder conditions in the basin's eastern part. During the peak of the cold-tongue warming, called the *warm* or El Niño phase of ENSO, westerly wind anomalies prevail in the central part of the basin. As part of the ocean's adjustment to this atmospheric forcing, a Kelvin wave is set up in the tropical wave guide and carries a warming signal eastward. This signal deepens the eastern-basin thermocline, which separates the warmer, well-mixed surface waters from the colder waters below, and thus contributes to the positive feedback described above. Concurrently, slower Rossby waves propagate westward, and are reflected at the basin's western boundary, giving rise therewith to an eastward-propagating Kelvin wave that has a cooling, thermocline-shoaling effect. Over time, the arrival of this signal erodes the warm event, ultimately causing a switch to a *cold* or La Niña phase.

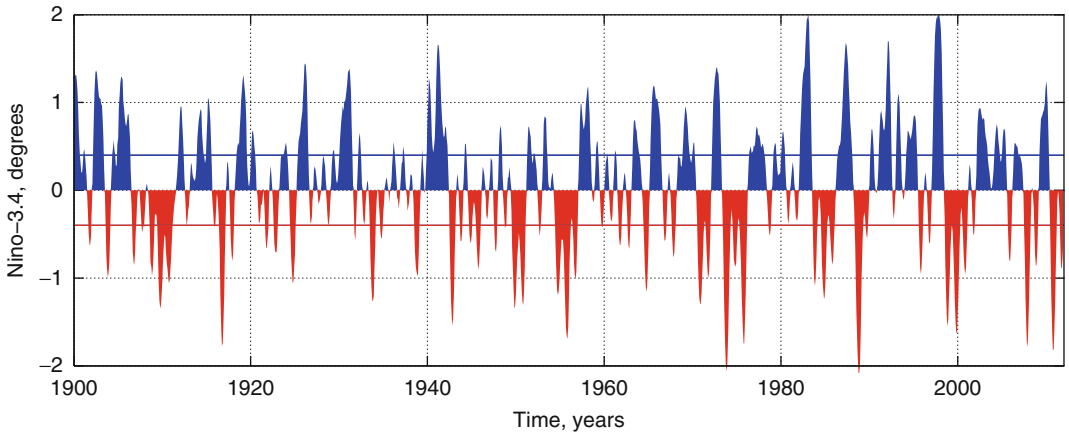
Seasonal forcing. A growing body of work (Chang et al., 1994; Jin et al., 1994; Tziperman et al., 1994; Ghil and Robertson, 2000) points to resonances between the Pacific basin's intrinsic air-sea oscillator and the annual cycle as a possible cause for the tendency of warm events to peak in boreal winter, as well as for ENSO's intriguing mix of temporal regularities and irregularities. The mechanisms by which this interaction takes place are numerous and intricate and their relative importance is not yet fully understood (Battisti, 1988; Tziperman et al., 1994; Dijkstra, 2005).

Time series that depict ENSO dynamics

An international 10-year (1985–1994) Tropical-Ocean–Global-Atmosphere (TOGA) Program greatly improved the observation (McPhaden et al., 1998), theoretical modeling (Neelin et al., 1994, 1998), and prediction (Latif et al., 1994) of exceptionally strong El Niño events. It has confirmed, in particular, that ENSO's significance extends far beyond the Tropical Pacific, where its causes lie.

An important conclusion of this program was that – in spite of the great complexity of the phenomenon and the

differences between the spatiotemporal characteristics of any particular ENSO cycle and other cycles – the state of the Tropical Pacific's ocean-atmosphere system could be characterized, mainly, by either one of two highly anticorrelated scalar indices. These two indices are an SST index and the Southern Oscillation Index (SOI): they capture the East-West seesaw in SSTs and sea level pressures, respectively.



A typical version of the SST index is the so-called Niño-3.4 index, which summarizes the mean anomalies of the spatially averaged SSTs over the Niño-3.4 region (Trenberth, 1997). The evolution of this index since 1900 is shown in Figure 2: it clearly exhibits some degree of regularity on the one hand as well as numerous features characteristic of a deterministically chaotic system on the other. The regularity manifests itself as the rough superposition of two dominant oscillations, the quasi-biennial (QBO) and quasi-quadrennial (Jiang et al., 1995c; Ghil et al., 2002) mode, by the phase locking of warm events to boreal winter that gives El Niño its name and by a near-symmetry of the local maxima and minima (i.e., of the positive and negative peaks). The lack of regularity has been associated with the presence of a "Devil's staircase," which is discussed in further detail below (Chang et al., 1994; Jin et al., 1994; Tziperman et al., 1994), and may be due to stochastic effects as well (Ghil et al., 2008a).

A hierarchy of climate models

Climate dynamics has emerged as a modern scientific discipline about a half-century ago (Pfeffer, 1960), and it is within this broader framework that ENSO variability should be considered. The climate system is highly complex, its main subsystems have very different characteristic times, and the specific phenomena involved in various climate problems are quite diverse. It is inconceivable, therefore, that a single model could successfully be used to incorporate all the subsystems, capture all the phenomena, and solve all the problems.

Hence the concept of a *hierarchy of models*, from the simple to the complex, had been developed almost four decades ago (Schneider and Dickinson, 1974). Climate models can be divided into *atmospheric*, *oceanic*, and *coupled*. Each group is characterized, in addition, by the model dimension, where the number of dimensions, from zero to three, refers to the number of independent space variables used to describe the model domain, i.e., to physical-space dimensions. Coupled atmosphere-ocean models – from the simplest zero-dimensional (0-D) ones to three-dimensional (3-D), general circulation models (GCMs) – might be better able to model ENSO dynamics than other climatic phenomena, because ENSO is generally thought to operate through atmosphere-ocean coupling.

A fairly well-developed hierarchy of coupled ocean-atmosphere models has been applied to the problem of seasonal-to-interannual variability in the Tropical Pacific ocean, directly related to ENSO dynamics (Neelin et al., 1994). Its most important rungs are, in ascending order: essentially 0-D simple models, like the delay-oscillator model of Suarez and Schopf (1988); essentially 1-D intermediate coupled models (ICMs: Cane and Zebiak, 1985; Jin et al., 1994); essentially 3-D hybrid coupled models, in which an ocean GCM is coupled to a much simpler, diagnostic atmospheric model (Neelin, 1990; Barnett et al., 1993); and fully coupled GCMs (Neelin et al., 1992; Robertson et al., 1995). Hybrid models of this type have also been applied to climate variability for the mid-latitude (Weng and Neelin, 1998) and global (Chen and Ghil, 1996; Wang et al., 1999) coupled system.

El Niño/Southern Oscillation, Figure 2 Time evolution of the Niño-3.4 index during 1900–2012. The index depicts the sea surface temperature (SST) anomalies (deviations from the climatological mean) in the Niño-3.4 region, between 170°W–120°W and 5°S–5°N. Horizontal lines are drawn at ±0.4°; according to Trenberth (1997), El Niño (warm) and La Niña (cold) events can be defined as a 6-month exceedance of these thresholds.

Modeling ENSO: Goals and approaches

ENSO modeling is focused on a broad twofold goal: (1) to depict the essential mechanisms behind the observed ENSO variability and (2) to forecast future ENSO dynamics, in particular large El Niño and La Niña events that have potential to impact on human activity. The modeling efforts are fostered by understanding the basic physical principles behind the examined phenomenon (see the section above) as well as confronting the existing models with observations.

There are two main paradigms in modeling ENSO variability (Neelin et al., 1994, 1998; Ghil and Robertson, 2000). A *deterministically chaotic, nonlinear* paradigm explains the complexities of ENSO dynamics by the nonlinear interplay of various internal driving mechanisms. For instance, the complex evolution of the SST and thermocline depth can be simulated by the interplay of the two basic ENSO oscillators: an internal, highly nonlinear one, produced by a delayed feedback of the oceanic wave propagation, and a forced, seasonal one (Tziperman et al., 1994; Zaliapin and Ghil, 2010). A *stochastic, linear paradigm*, on the other hand, attempts to explain characteristic features of ENSO dynamics by the action of fast *weather noise* on a linear or weakly nonlinear slow system, composed mainly on the upper ocean near the equator. Boulanger et al. (2004) and Lengaigne et al. (2004), among others, provide a comprehensive discussion of how weather noise could be responsible for the complex dynamics of ENSO, and, in particular, whether westerly wind bursts trigger El Niño events. It seems that any successful modeling effort should combine these two paradigms to obtain richer and more complete insights into climate dynamics in general (e.g., Ghil et al., 2008a).

Much of our theoretical understanding of ENSO comes from relatively simple, essentially 0-D and 1-D coupled models, consisting of a shallow-water or two-layer ocean model coupled to steady-state, shallow-water-like atmospheric models with heavily parameterized physics; the more complete ones among these models are the previously mentioned ICMs (Neelin et al., 1994). In these models, ENSO-like variability results from an oscillatory instability of the coupled ocean-atmosphere's annual-mean climatological state. Its nature has been investigated in terms of the dependence on fundamental parameters, such as the coupling strength, oceanic adjustment time scale, and the strength of surface currents (Jin and Neelin, 1993).

The growth mechanism of ENSO is fairly well established, arising from positive atmospheric feedbacks on equatorial SST anomalies via the surface wind stress, as first hypothesized by Bjerknes (1969). The cyclic nature of the unstable mode is subtler and depends on the time scales of response within the ocean. The next section reviews the deterministic, nonlinear paradigm in understanding ENSO's quasi-periodic behavior; the section emphasizes a toy-modeling approach, which is sufficient to capture the main ENSO-driving mechanisms and, unlike GCMs, can be reviewed here in sufficient detail.

ENSO as a coupled oscillator

The 1980s and 1990s saw the development of a dynamical theory that explains ENSO variability via the interaction of two oscillators: *internal*, driven by the negative feedback associated with oceanic wave propagation, and *external*, due to the seasonal cycle.

Schopf and Suarez (1988), Battisti (1988), Suarez and Schopf (1988), and Battisti and Hirst (1989) demonstrated that ENSO's complex dynamics can be studied using the formalism of *delayed differential equations* (DDE). The first attempts dealt with autonomous DDEs, without seasonal forcing, and with a linear delayed part:

$$\frac{dT}{dt} = -\alpha T(t-\tau) + T \tag{1}$$

Here, T represents the SSTs averaged over the eastern equatorial Pacific. The first term on the right-hand side of Equation 1 mimics the negative feedback due to the Kelvin and Rossby waves, while the second term reflects Bjerknes's positive feedback.

The delay equation idea happens to be very successful in explaining the recurrent nature of ENSO events in easily intelligible mathematical settings. Indeed, the delayed negative feedback does not let a solution of Eq. 1 converge to zero or go to infinity as it would go in the ordinary differential equation case with $\tau = 0$: the delay effect thus creates an internal oscillator whose period depends on the delay and the particular form of the equation's right-hand side. Thus, a simple DDE like Eq. 1 has reproduced some of the main features of a fully nonlinear, coupled atmosphere-ocean model of ENSO dynamics in the tropics (Zebiak and Cane, 1987; Battisti, 1988; Battisti and Hirst, 1989). DDE modeling has also emphasized the importance of nonlinear interactions in shaping the complex dynamics of the ENSO cycle.

At the same time, many important details of ENSO variability still had to be explained. First, a delayed oscillator similar to Eq. 1 typically has periodic solutions with a well-defined period of about 4τ. However, the occurrence of ENSO events is irregular. Second, the period suggested by delay equations deviates significantly from the actual recurrence time of warm events, which is about 2–7 years. The delay τ, which is the sum of the basin-transit times of the westward Rossby and eastward Kelvin waves, can be roughly estimated to lie in the range of 6–8 months. Accordingly, model (1) suggests a period of 24–32 months, at most, for the repeating warm events; this period lies at the lower end of the range of recurrence times. Finally, El Niño and La Niña events always peak during the Northern Hemisphere (boreal) winter, hence their name; such phase locking does not exist in a purely internal delayed oscillator.

The next important step in developing ENSO modeling in the DDE framework was made by Tziperman et al. (1994), who demonstrated that the above discrepancies can be removed by considering nonlinear interactions between the internal oscillator and the external periodic forcing by the seasonal cycle. These authors also introduced a more realistic nonlinear coupling between atmosphere and ocean to reflect the fact that the delayed negative feedback saturates as the absolute value of the key dependent variable T increases.

Munnich et al. (1991) made a detailed comparison between cubic and sigmoid nonlinearities in an iterated map model of ENSO. As a result, the sigmoid type of nonlinearity was chosen in Tziperman et al. (1994), resulting in the periodically forced, nonlinear DDE:

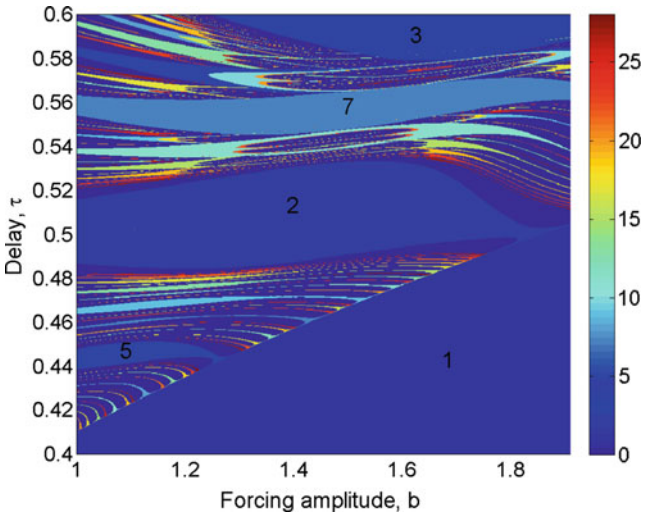
$$\frac{dT}{dt} = -\alpha \tanh[\kappa T(t-\tau_1)] + \beta \tanh[\kappa T(t-\tau_2)] + \gamma \cos(\omega t) \quad (2)$$

Here, the first term on the right represents the westward-traveling Rossby wave, the second term represents the eastward Kelvin wave, and the last one is a seasonal forcing. The parameters α, β, and γ represent the relative strengths of these three driving forces; τ_1 and τ_2 are Rossby and Kelvin wave delays, respectively; ω determines the period of the seasonal forcing; and κ represents the strength of the atmosphere-ocean coupling.

Depending on the parameter values, this model has solutions that possess an integer period, are quasi-periodic, or exhibit chaotic behavior. The increase of solution complexity – from period one, to integer but higher period, and on to quasi-periodicity and chaos – is caused by the increase of the atmosphere-ocean coupling parameter κ. Tziperman et al. (1994) also demonstrated that this forced DDE system exhibits period locking, when the external "explicit" oscillator wins the competition with the internal delayed one, causing the system to stick to an integer period; dependence of the system's period on model parameters is realized in the form of a *Devil's staircase* (see below).

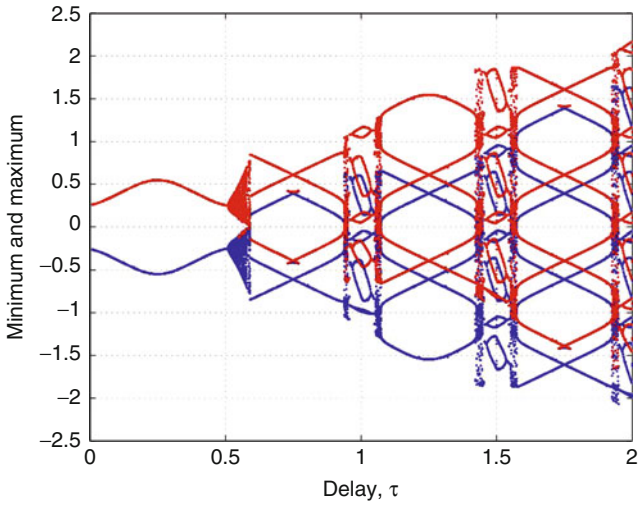
These and other ENSO studies with DDE models have been limited to (1) the linear stability analysis of steady-state solutions, which are not typical in forced systems; (2) case studies of particular trajectories; or (3) one-dimensional scenarios of transition to chaos, where one varies a single parameter, while the others are kept fixed. A major obstacle for the complete bifurcation and sensitivity analysis of such DDE models lies in the complex nature of DDEs, whose numerical and analytical treatment is harder than that of models with no delays.

Zaliapin and Ghil (2010) took several steps toward a comprehensive analysis, numerical as well as theoretical, of DDE models relevant for ENSO phenomenology. These authors considered a simplified version of Eq. 2:



$$\frac{dT}{dt} = -\tanh[\kappa T(t-\tau)] + b\cos(2\pi t) \quad (3)$$

and, for the first time, performed its analysis in the complete 3-D space of the physically relevant parameters: strength of seasonal forcing b, ocean-atmosphere coupling κ, and transit time τ of oceanic waves across the Tropical Pacific. This model reproduces many scenarios relevant to ENSO phenomenology, including prototypes of El Niño and La Niña events; intraseasonal activity reminiscent of Madden-Julian oscillations (Madden and Julian, 1994) or westerly wind bursts; and spontaneous interdecadal oscillations.



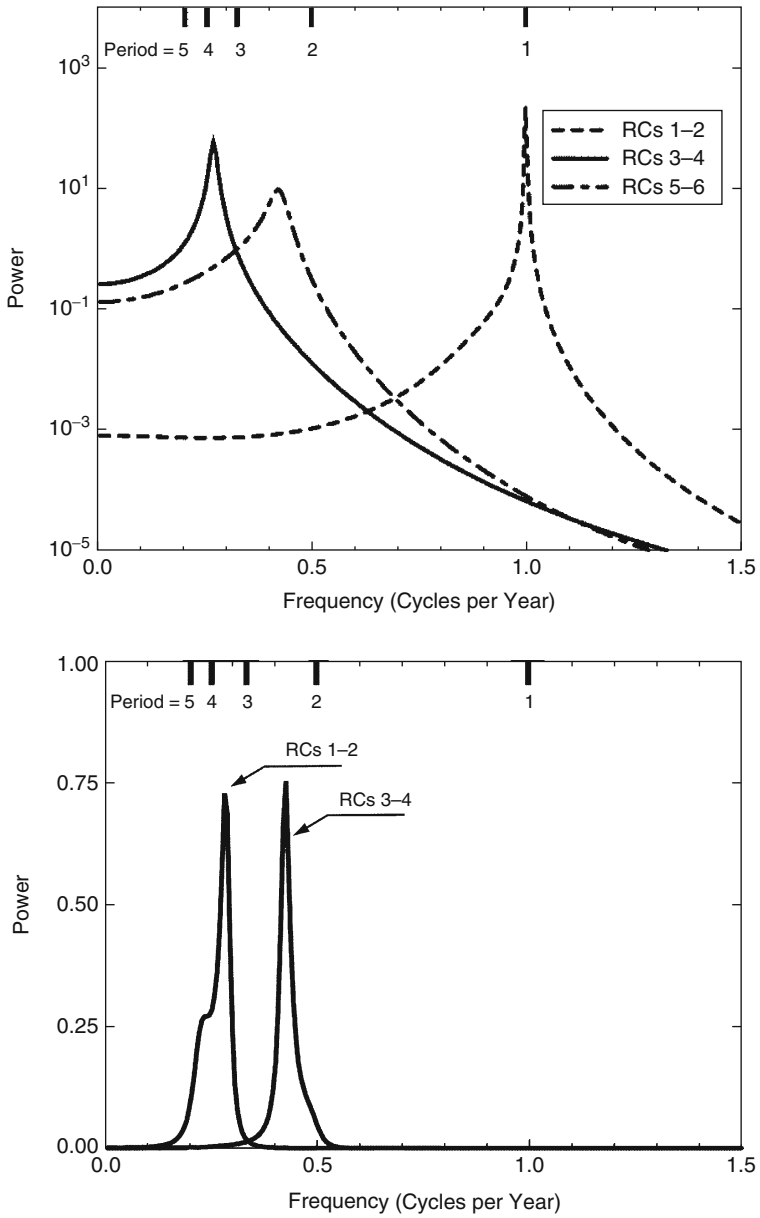
The model also provided a good justification for the observed QBO in Tropical Pacific SSTs and trade winds (Philander, 1990; Diaz and Markgraf, 1993; Jiang et al., 1995b; Ghil et al., 2002), with the 2–3-year period arising naturally as the correct multiple (four times) of the sum of the basin transit times of Kelvin and Rossby waves. Zaliapin and Ghil (2010) found regions of stable and unstable solution behavior in the model's parameter space; these regions have a complex and possibly fractal distribution of solution properties. The local continuous dependence theorem (Zaliapin and Ghil, 2010) suggests that the complex discontinuity patterns indicate the presence of a rich family of unstable solutions that point, in turn, to a complicated attractor.

The simple DDE model (3), with a single delay, does reproduce the Devil's staircase scenario documented in other ENSO models, including ICMs and GCMs, as well as in observations (Jin et al., 1994; Tziperman et al., 1994; Ghil and Robertson, 2000). The latter result suggests that interdecadal variability in the extratropical, thermohaline circulation (Dijkstra, 2005; Dijkstra and Ghil, 2005) might interfere constructively with ENSO's intrinsic variability on this time scale. Zaliapin and Ghil (2010) found that model (3) is characterized by *phase locking* of the solutions' local extrema to the seasonal cycle; in particular, solution maxima – i.e., model El Niños – tend to occur in boreal winter. These authors also found multiple solutions coexisting for physically relevant values of the model parameters.

Figure 3 illustrates the model's sensitive dependence on parameters in a region that corresponds roughly to actual ENSO dynamics. The figure shows the behavior of the period P of model solutions as a function of two parameters: the propagation period τ of oceanic waves across the Tropical Pacific and the amplitude b of the seasonal forcing; for aperiodic solutions one takes $P = 0$. Although the model is sensitive to each of its three parameters (b,κ,τ), sharp variations in P are mainly associated with changing the delay τ, which is plotted on the ordinate. This sensitivity is an important qualitative conclusion since in reality the propagation times of Rossby and Kelvin waves are affected by numerous phenomena that are not related directly to ENSO dynamics. The sensitive dependence of the period on the model's parameters is consistent with the irregularity of occurrence of strong El Niños, and can help explain the difficulty in predicting them (Latif et al., 1994; Ghil and Jiang, 1998).

El Niño/Southern Oscillation, Figure 3 Period map for the delayed coupled oscillator of Eq. 3. The figure shows the period P as a function of two model parameters: amplitude b of seasonal forcing and delay τ of the oceanic waves; the ocean-atmosphere coupling strength is fixed at $\kappa = 10$. Aperiodic solutions correspond to $P = 0$. *Numbers* indicate the period values within the largest constant-period regions.

El Niño/Southern Oscillation, Figure 4 Local maxima (*red*) and minima (*blue*) of solutions of Eq. 3 as a function of delay τ; the other parameter values are fixed at $\kappa = 11$ and $b = 2$. Note the aperiodic regimes between periodic windows of gradually increasing period. This figure corresponds to the rightmost vertical section of the region shown in Figure 3 (From Zaliapin and Ghil, 2010).



The model's instabilities disappear and the dynamics of the system becomes purely periodic, with a period of 1 year (not shown), as soon as the atmosphere-ocean coupling κ τ vanishes or the delay τ decreases below a critical value. Figure 4 illustrates this effect in greater detail: the period P of model solutions increases with τ in discrete jumps, $P = 2k + 1$, $k = 0, 1, 2, \ldots$, separated by narrow, apparently chaotic "windows" in τ. This increase in P is associated with the increase of the number of distinct local extrema, all of which tend to occur at the same position within the seasonal cycle. This resembles in fact the behavior of chaotic dynamical systems in discrete time (Kadanoff, 1983) and suggests that the model's aperiodic dynamics is in fact chaotic. This chaotic behavior implies, in particular, that small perturbations in the model parameters or in initial states may lead to significant changes of the model dynamics. Due to this sensitive dependence, forecasting the model's behavior, as well as that of the related natural phenomenon, is a hard problem.

The boundary between the domains of stable and unstable model behavior is clearly visible at the lower right of Figure 3. The period-1 region below and to the right of this boundary contains simple solutions that change smoothly with the values of model parameters. The region above and to the left is characterized by sensitive dependence on parameters. The range of parameters that corresponds to present-day ENSO dynamics lies on the border between the model's stable and unstable regions. Hence, if the dynamical phenomena found in the model have any relation to reality, Tropical Pacific SSTs and other fields that are highly correlated with them, inside and outside the Tropics, can be expected to behave in an intrinsically unstable manner; they could, in particular, change quite drastically with global warming.

Quasi-periodic behavior

The ENSO phenomenon dominates interannual climate variability over the Tropical Pacific. Figure 5, top panel, shows the power spectrum of the monthly SSTs averaged over the eastern equatorial Pacific's Niño-3 area, for the time interval 1960–1997 (Ghil and Robertson, 2000). The observed SST time series contains a sharp annual cycle, together with two broader interannual peaks centered at periods of 44 months (the so-called quasi-quadrennial or low-frequency ENSO cycle) and 28 months (the QBO cycle).

This power spectrum provides a fine example of the distinction between the sharp lines produced by purely periodic forcing and the broader peaks resulting from internal climate variability or from the interaction of the latter with the former. The sharp annual peak reflects the seasonal cycle of heat influx into the tropical Pacific and the phase locking of warm events to boreal winter that gives El Niño its name. The two interannual peaks correspond to the quasi-quadrennial and QBO components of ENSO, as identified by a number of authors (Rasmusson et al., 1990; Allen and Robertson, 1996). These components play a determining role in the ENSO dynamics: Jiang et al. (1995b) have demonstrated that these two

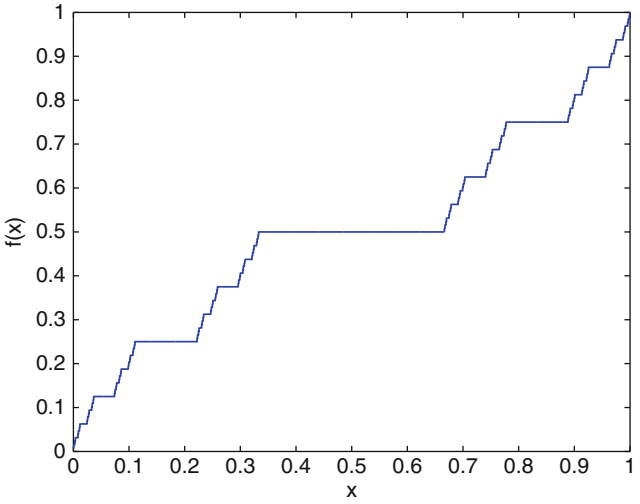
El Niño/Southern Oscillation, Figure 5 *Top*: Power spectrum of the leading reconstructed components (RCs) of the Niño-3 SSTs for the time interval 1960–1997, using monthly data from the Climate Prediction Center of the National Centers for Environmental Prediction (NCEP). An SSA analysis with a window width of 72 months was used to derive the RCs, whose power spectra were then computed using the maximum entropy method, with 20 poles. RCs (1,2) capture the annual cycle, RCs (3,4) the quasi-quadrennial oscillation, and RCs (5,6) the QBO. *Bottom*: Power spectrum of Niño-3 SST anomalies from a 60-year integration of NCEP's coupled GCM, with the seasonal cycle removed (Ji et al., 1998).

components account for about 30% of the variance in the time series analyzed in Figure 5; accordingly, the major El Niño (warm) and La Niña (cold) events during the time interval 1950–1990 can be well reconstructed from ENSO's quasi-quadrennial and QBO components.

The existence of both these oscillatory components has been established in coupled GCMs. The University of California Los Angeles (UCLA) atmospheric GCM, coupled to a tropical-Pacific basin version of the Geophysical Fluid Dynamics Laboratory (GFDL) ocean GCM (Mechoso et al., 2000), is characterized by ENSO-like quasi-quadrennial and QBO modes, but with weaker variability than that of the observed modes (Robertson et al., 1995). A 100-year-long simulation with NASA Goddard's Aries-Poseidon coupled GCM exhibits both quasi-quadrennial and QBO spectral peaks of a strength

very similar to that in observations (not shown). These results are further confirmed by a 60-year run of National Center for Environmental Prediction's (NCEP) coupled GCM (Ji et al., 1998).

Devil's staircase



Various toy and intermediate models (Chang et al., 1994; Jin et al., 1994; Tziperman et al., 1994; Ghil et al., 2008b) have demonstrated that annual forcing causes the internal ENSO cycle to lock to rational multiples of the annual frequency in a Devil's staircase. The period map for the DDE ENSO model of Eq. 3, as shown in Figure 3, is a representative example of this behavior. The Devil's staircase is a function that exhibits peculiar properties, which challenge our intuition about the concept of continuity: it is continuous on the interval [0, 1]; its values span the entire range between 0 and 1; and at the same time it is constant almost everywhere. In other words, the total length of the point sets over which the function increases equals zero!

A classical example of a Devil's staircase, related to the celebrated Cantor set, is shown in Figure 6. Despite its seemingly unnatural features, this type of behavior is commonly seen in coupled, oscillatory mechanical systems, as well as in phase-locked electronic loops (Rasband, 1990). In these systems, the Devil's staircase depicts the relations between the phase of a driven nonlinear oscillatory system and the phase of the external driving force. This staircase represents a generic scenario of transition to deterministic chaos via a subharmonic resonance (e.g., period doubling). Such a scenario involves two parameters: the phase of the external force and the degree of coupling to the driving force.

The period staircase of ENSO also involves two parameters: one governs the period of the intrinsic ENSO instability (i.e., the propagation time of oceanic Kelvin and Rossby waves), whereas the other is the coupling strength between the model's ocean and atmosphere. As the intrinsic period increases, a subharmonic resonance causes frequency locking to successively longer rational multiples of the annual cycle. As the coupling strength increases, the steps on the staircase broaden and begin to overlap, and the model's ENSO cycle becomes irregular, due to jumps between the steps.

The complete Devil's staircase scenario, in fact, calls for successively smaller peaks associated with the harmonics of the 4-year (quasi-quadrennial) mode, at 4/1 = 4, 4/2 = 2, and 4/3 years. Both the QBO and the 4/3-year = 16-month peak are present in observed SST data (Jiang et al., 1995b; Allen and Robertson, 1996). There is a smaller and broader 18–20 month peak present in the UCLA coupled GCM, which can be interpreted as a merged version of these two peaks (Robertson et al., 1995).

Thus, the results of GCM simulations, along with existing observational data, provide reasonable support to the following conjecture: the interaction of the seasonal cycle and the fundamental ENSO mode nonlinearly entrain this mode to a rational multiple of the annual frequency, and produce additional peaks, according to a Devil's staircase. Still, it is possible that different frequency peaks, in particular the quasi-quadrennial and the QBO peaks, could represent separate oscillations, generated by different mechanisms, each with an independent frequency (see Neelin et al., 1998, and references therein).

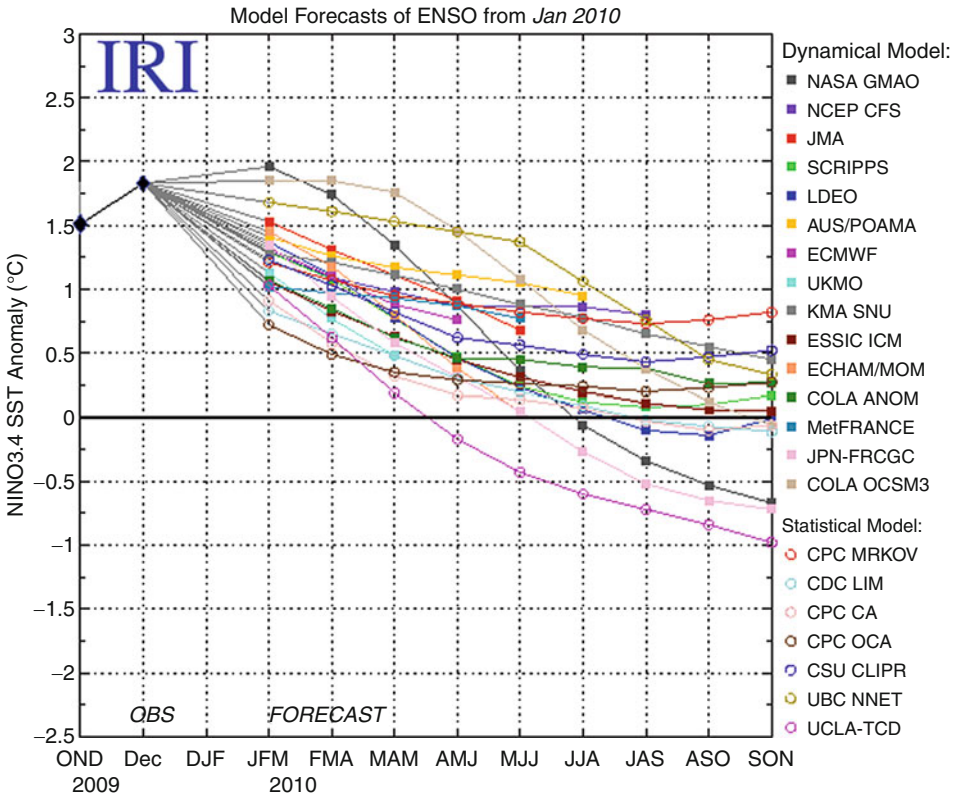
El Niño/Southern Oscillation, Figure 6 Devil's staircase *f(x)*: a continuous function that takes all the values between 0 and 1 and at the same time is constant almost everywhere. There is solid evidence that period locking phenomena in the ENSO system are organized according to a Devil's staircase.

Forecasts

Forecasts of ENSO dynamics are commonly based on modeling and monitoring the evolution of the equatorial Pacific SST. There are two main types of such models: *dynamical* and *statistical*. Roughly speaking, a dynamical model extrapolates the current oceanic and atmospheric conditions into the future by using deterministic principles of atmosphere-ocean interaction. A statistical model uses the past observations to identify conditions that statistically favor occurrence of an El Niño or a La Niña event. The dynamical and statistical models can span the entire modeling hierarchy: from toy to intermediate to fully coupled.

ENSO forecasts are facilitated by (1) the dominant ENSO regularities, mainly the quasi-quadrennial and QBO modes described above, and (2) the persistent nature of ENSO warm and cold episodes, each of which lasts for a few months up to a year. Hence, episode initiation in April–May does facilitate forecasting an event's peak in December–January; likewise, the absence of an episode by June is a very reliable signal for normal conditions in the next year.

In spite of these marked regularities, forecasting El Niño and La Niña events has met with mixed success, even for



short, subannual lead times (Latif et al., 1994). The authors of over a dozen models – all of which routinely produce ENSO forecasts on a monthly or quarterly basis – have noticed year-to-year variations in forecast skill at a lead time of 6–12 months. In addition, forecasts from individual models may significantly vary from one to another.

We illustrate the latter statement with an example of SST forecasts by 15 coupled GCMs (dynamical) and 7 statistical models for the time interval from December 2009 to November 2010, summarized by the International Research Institute for Climate and Society (IRI, 2010); they are shown in Figure 7. All the models start from the observed Niño-3.4 SST anomaly of about 1.8° in December 2009 and try to extrapolate it into the future. Strikingly, this "forecast plume" is characterized by overall regression to the mean of most forecasts: many of the models, dynamical as well as statistical, regress to the no-anomaly mean in about a year. This regression is due to the well-known statistical principle that the best long-term prediction of an ergodic process is its mean. Even so, one observes a persistent 2-degree spread in individual forecasts at all lead times, a spread that characterizes the existing "state-of-the-art" uncertainty in the ENSO prediction problem.

Barnston et al. (1994) and Ghil and Jiang (1998) formally assessed the 6-month lead forecast skills of six ENSO models, three dynamical and three statistical. They used the following two measures of the forecast skill: (1) the Pearson correlation r between the monthly forecast and actual SST anomaly values and (2) the root-mean-squared error (RMSE) of the forecast versus actual SST normalized by the variation of the actual values. This assessment, illustrated in Table 3, suggests that different models have comparable forecast skills with $r \approx 0.65$; these skills are of intermediate quality (RMSE ≈ 0.9), and most probably different models will show different local performance under different circumstances.

Summary and outlook

El Niño/Southern Oscillation (ENSO) is a prominent climatic phenomenon that affects Earth's atmosphere and oceans, as well as their interactions, on time scales up to several years and influences the global climate. ENSO creates anomalies in the sea-surface temperature (SST), thermocline depth, and atmospheric pressure across the Tropical Pacific and affects most immediately the waters off Peru, where this phenomenon was noticed centuries ago. ENSO's oceanic manifestations are called El Niño (warmer waters in the eastern Pacific) and La Niña (colder

El Niño/Southern Oscillation, Figure 7 "Forecast plume": juxtaposition of SST forecasts for the year 2010, made in December 2009 by 15 dynamical and 7 statistical models (IRI, 2010). Most forecasts regress to the no-anomaly mean within a year, while still giving a persistent 2-degree spread of the individual values at all lead times larger than 3 months.

waters there), whereas its atmospheric part is referred to as the Southern Oscillation. The most prominent natural hazards caused by ENSO are felt in all parts of the World (see Table 2); they include local hydroclimatic extremes and affect the regional ecology and economy.

The physical growth mechanism of ENSO is due to the positive atmospheric feedbacks on equatorial SST anomalies via the surface wind stress, cf. Bjerknes (1969). Still, its unstable quasi-periodic behavior prevents robust ENSO predictions, even at subannual lead times. Numerical modeling plays a prominent role in understanding ENSO variability and developing forecasts. There are two main paradigms in ENSO modeling. A *deterministically chaotic, nonlinear* paradigm tries to explain the complexities of ENSO dynamics by the nonlinear interplay of various internal mechanisms. A *stochastic*, *linear paradigm* approaches this problem via the action of fast *weather noise* on an essentially linear, slow system, composed mainly of the upper ocean near the Equator. Despite the existence and importance of comprehensive numerical models, much of our theoretical understanding of ENSO comes from relatively simple models. Initiated in the 1980s, the study of such conceptual models has significantly contributed to shedding new light on many aspects of ENSO, including its quasi-periodic behavior, onset of instabilities, phase locking, power spectrum, and interdecadal variability; some of the most interesting simple models involve delay effects and are summarized herein.

The easiest to forecast are the large-scale SST and sea level patterns in the Tropical Pacific; even here, forecast skill rarely extends beyond 6–12 months. Beyond this ocean basin, atmospheric teleconnections provide some skill in certain parts of the world where ENSO effects are statistically significant, especially during major warm or cold events. Enhanced probabilities for local and regional hazards can be inferred from the larger-scale atmospheric anomalies via downscaling, but such probabilistic forecasts are clearly less reliable than the large-scale patterns on which they are based. Due to the importance of the associated natural hazards, considerable effort is invested in improving these forecasts.

EMERGENCY MANAGEMENT

Michael K. Lindell
Texas A&M University, College Station, TX, USA

Definition

Emergency management. The process by which communities identify the hazards to which they are exposed and the physical (casualties and damage) and social (psychological, demographic, economic, and political) impacts these hazards might inflict, as well as assess and develop their capabilities to mitigate, prepare for, respond to, and recover from these impacts.
Hazard mitigation. Preimpact activities that provide passive protection during disaster impact by eliminating the causes of a disaster, reducing the likelihood of its occurrence, or limiting the magnitude of its impacts if it does occur.
Disaster preparedness. Preimpact activities that provide the trained personnel plans and procedures, facilities, and equipment needed to support active response at the time of disaster impact.
Emergency response. Activities conducted between the detection of hazardous conditions and the stabilization of the situation following impact whose goal is to minimize physical and social impacts.
Disaster recovery. Activities that restore a community's buildings (residential, commercial, and industrial), physical infrastructure (water, waste disposal, electric power, fuel, telecommunication, and transportation), and social, economic, and political activities to at least the same level as they were before disaster impact.

Introduction

Losses from disasters, in the United States and the rest of the world, have been growing over the years and are likely to continue to grow (Berke, 1995; Bourque et al, 2006; Mileti, 1999; Noji, 1997). Losses can be measured in a variety of ways – with physical impacts (casualties and property damage) being the most common indexes. The 2004 Indian Ocean earthquake and tsunami is estimated to have killed more than 258,000 people, and the 2010 Haiti earthquake is estimated to have killed more than 230,000. Recent economic losses have also been staggering; Hurricane Katrina cost over US$100 billion, and disaster costs are rising exponentially (Mileti, 1999).

Communities can cope with the potential for disasters through emergency management, which is the process by which communities identify the hazards to which they are exposed and the physical (casualties and damage) and social (psychological, demographic, economic, and political) impacts these hazards might inflict, as well as assess and develop their capabilities to mitigate, prepare for, respond to, and recover from these impacts. Although emergency management is often conceived as the responsibility of government, households, neighborhoods, and private business organizations are taking an increasing interest in reducing their hazard vulnerability. As a consequence, community emergency management should comprise a network of organizations at all levels of government and throughout the broader social and economic sectors – including for-profit and nonprofit organizations.

Emergency management is necessary because people occupy physical environments that consist of natural (geophysical, meteorological, and hydrological) and technological (energy producing and materials handling) systems that pose a variety of risks to the people, property, and the natural environment. The term *hazard* refers to the potential for variations in natural and technological processes to produce extreme events having very negative consequences (Burton et al., 1993). Communities can adjust to hazards by modifying human behavior (including land use and building construction practices) or modifying environmental systems to enable people to live in greater safety (Lindell and Perry, 2004). Thus, an event that is extremely hazardous to one community might not be so hazardous to another. For example, the 2010 Chile earthquake (M_W 8.8) released substantially more energy than the 2010 Haiti earthquake (M_W 7.0), but the death toll in Chile (approximately 500 persons) was less than one percent of that in Haiti.

The term *emergency* is commonly used in two slightly different but closely related ways. One usage of the term refers to an event involving a minor consequences for part of a community – perhaps a few casualties and a limited amount of property damage. Thus, emergencies are events that are "routine" in the sense that they are frequently experienced, relatively well understood, and can be managed successfully with local resources – sometimes with a single local government agency using standardized response protocols and specialized equipment (Quarantelli, 1987). Nonetheless, it is important to understand that each emergency can present unusual elements. For example, there is no such thing as a "routine" house fire; the belief that each new fire will be like all the previous ones has a high probability of producing firefighter deaths and injuries (Brunacini, 2002).

Another usage of the term emergency refers to the imminence of an event rather than the severity of its consequences. In this context, an emergency is a situation in which there is a higher than normal probability of an extreme event occurring, a meaning that is more appropriately designated by the term *crisis*. For example, a hurricane approaching a coastal community creates an

emergency because the probability of casualties and damage is much greater than it was when the hurricane was far offshore. The urgency of the situation requires increased attention and, at some point, action to minimize the impacts if the hurricane should strike. Unlike the previous usage of the term emergency, the event has not occurred, the consequences are not likely to be minor, and routine methods of response by a single agency are unlikely to be effective if the event does occur.

The term *disaster* is reserved for the actual occurrence of events that produce substantial casualties, damage, and social disruption. Unlike the uncertain time of impact associated with a hazard (whether or not the impact would exceed community resources), a disaster reflects the actuality of an event whose consequences exceed a community's resources. Unlike crises, the consequences have occurred; unlike routine emergencies, disasters involve severe consequences for the community. By extension, a *catastrophe* is an event that exceeds the resources of many local jurisdictions – in some cases crippling those jurisdictions' emergency response capacity and disrupting the continuity of other local government operations.

Characterizing emergency management activities

Emergency management is a local responsibility because few counties are small enough for national authorities to initiate an immediate disaster response. Indeed, local volunteers and emergent groups are often the first responders in a disaster (Fischer, 2008). Moreover, in some countries such as the United States, local jurisdictions establish land use planning and building construction policies that determine the extent of their hazard vulnerability. As will be discussed in more detail below, communities can manage their hazard vulnerability through one of four major types of emergency management strategies – hazard mitigation, disaster preparedness, emergency response, and disaster recovery. Hazard mitigation comprises preimpact actions that protect passively against casualties and damage at the time of hazard impact (as opposed to an active emergency response to reduce those casualties and damage). Disaster preparedness consists of preimpact actions that provide the human and material resources needed to support active responses at the time of hazard impact, whereas emergency response comprises the planned and improvised actions implemented at the time of disaster impact to limit physical (casualties and damage) and social (psychological, demographic, economic, and political) impacts. Disaster recovery is the emergency management function that seeks to reestablish normal social, economic, and political routines once an incident has been stabilized – that is, after the immediate threats to human safety and property resulting from the physical impacts of the primary and secondary (e.g., fires following earthquakes) hazard agents have been resolved.

Community hazard management strategies can be individually implemented by households and businesses or collectively implemented by government agencies acting on behalf of the entire community. The individual strategies, which only reduce the vulnerability of a single household or business, generally involve simple measures such as elevating structures above expected flood heights, developing emergency response plans, and purchasing emergency supplies and hazard insurance. The collective strategies are generally complex – and expensive – technological systems that protect entire communities. Thus, they mitigate hazards through community protection works such as dams and levees and prepare for hazard impacts through measures such as installing warning systems and expanding highways to facilitate rapid evacuation.

Collective hazard adjustments are relatively popular because they permit continued development of hazard-prone areas and yet do not impose any constraints on individual households or businesses. In addition, their cost is spread over the entire community and often buried in the overall budget. Indeed, the cost is often unknowingly subsidized by taxpayers in other communities. For this reason, these collective hazard adjustments are often called "technological fixes." By contrast, individual hazard adjustment strategies require changes in households' and businesses' land use practices and building construction practices. Such changes require one of three types of motivational tactics – incentives, sanctions, or risk communication. Incentives provide *extrinsic rewards* for compliance with community policies. That is, they offer positive inducements that add to the inherent positive consequences of a hazard adjustment or offset the inherent negative consequences of that hazard adjustment. Incentives are used to provide immediate extrinsic rewards when the inherent rewards are delayed or when people must incur a short-term cost to obtain a long-term benefit. For example, incentives are used to encourage people to buy flood insurance by subsidizing the premiums.

Sanctions provide *extrinsic punishments* for noncompliance with community policies. That is, they offer negative inducements that add to the inherent negative consequences of a hazard adjustment or offset the inherent positive consequences of that hazard adjustment. Sanctions are used to provide immediate extrinsic punishments when the inherent punishments are delayed or when people incur a short-term benefit that results in a long-term cost. For example, sanctions are used to prevent developers from building in hazard-prone areas or using unsafe construction materials and methods. The establishment of incentives and sanctions involves using the political process to adopt a policy, and the enforcement of incentives and sanctions requires an effective implementation program (Lindell et al., 2006). By contrast, risk communication seeks to change households' and businesses' practices for land use, building construction, and contents protection by pointing out the *intrinsic* consequences of their behavior. That is, risk communication explains specifically what are the personal risks associated with risk area occupancy and also the hazard adjustments that can be taken to reduce hazard vulnerability.

Principles of community emergency planning

Over the years, researchers have identified eight fundamental principles of community emergency planning that can be used to increase the level of community preparedness regardless of the amount of available funding (Lindell and Perry, 2007):

1. Anticipate both active and passive resistance to the planning process and develop strategies to manage these obstacles.
2. Identify and address all hazards to which the community is exposed.
3. Include all response organizations, seeking their participation, commitment, and clearly defined agreement.
4. Base preimpact planning on accurate assumptions about the threat, about typical human behavior in disasters, and about likely support from external sources such as state and federal agencies.
5. Identify the types of emergency response actions that are most likely to be appropriate, but encourage improvisation based on continuing emergency assessment.
6. Address the linkage of emergency response to disaster recovery and hazard mitigation.
7. Provide for training and evaluating the emergency response organization at all levels – individual, team, department, and community.
8. Recognize that disaster planning is a continuing process.

Emergency management functions

Emergency management involves six functions – community preparedness analysis, hazard mitigation, disaster preparedness, emergency response, disaster recovery, and evaluation of the emergency management system.

Community preparedness analysis

Community preparedness analysis involves hazard/vulnerability analysis, hazard operations analysis, population protection analysis, and incident management analysis. Hazard/vulnerability analysis identifies the natural and technological hazards to which the community is exposed, the locations that would be affected, and the amount of damage that could be expected from events of various intensities. It also assesses the community's structures (residential, commercial, and industrial buildings) and infrastructure systems (water, waste disposal, electric power, fuel, telecommunication, and transportation) in terms of their ability to withstand the events identified in the hazard analyses. Finally, it assesses the community's susceptibility to psychological, demographic, economic, and political impacts. Both the physical and social impacts are examined to determine the degree to which demographic segments and economic sectors differ in their susceptibility to physical and social impacts. This social vulnerability analysis (Wisner et al., 2004) represents an important extension of previous theories of hazard vulnerability (Burton et al., 1993). Whereas people's physical vulnerability refers to their susceptibility to biological changes (i.e., impacts on anatomical structures and physiological functioning), their social vulnerability refers to limitations in their physical assets (buildings, furnishings, vehicles) and psychological (knowledge, skills, and abilities), social (community integration), economic (financial savings), and political (public policy influence) resources. The central point of the social vulnerability perspective is that just as people's occupancy of hazard-prone areas and the physical vulnerability of the structures in which they live and work are not randomly distributed, neither is social vulnerability randomly distributed – either geographically or demographically. Thus, just as variations in structural vulnerability can increase or decrease the effect of hazard exposure on physical impacts (property damage and casualties), so too can variations in social vulnerability (Bolin, 2006; Enarson et al., 2006).

Hazard operations analysis and population protection analysis identify alternative responses to disaster demands and evaluate them in terms of their effectiveness in protecting persons and property and their resource requirements – the amount of time, effort, money, and organizational cooperation needed to adopt and implement them (Lindell et al., 2006). For some hazard agents, especially technological hazards, it is possible to intervene into the hazard generating process to prevent a disaster from occurring. Thus, hazard operations analysis seeks to identify the hazard source control, community protection works augmentation, building construction augmentation, and building contents protection actions that can protect property from destruction. In the case of hazardous materials releases, source control involves actions such as patching holes or replacing leaking valves in tank cars. Community protection works augmentation can be accomplished by adding sandbags to increase the height of levees or cutting fire breaks to isolate wildfires. Building construction augmentation can be achieved by strengthening building soft spots, as when storm shutters are installed to protect against high wind. Finally, building contents protection can be accomplished by moving furniture and appliances to higher floors when flooding is forecast.

Population protection analyses identify the actions that can reduce casualties, as well as the facilities, equipment, and training that is needed to implement these actions. Thus, population protection analyses address systems for hazard detection and notification, warning, evacuation traffic management and transportation support, search and rescue, and emergency medical transportation and treatment. Finally, incident management assessment determines whether households, businesses, government agencies, and nongovernmental organizations have the capacity (i.e., resources) and commitment (i.e., motivation) needed to implement the hazard operations and population protection actions.

Hazard mitigation

FEMA defines mitigation as "any action of a long-term, permanent nature that reduces the actual or potential risk of loss of life or property from a hazardous event" (Federal Emergency Management Agency, 1998, p. 9). This definition is rather ambiguous because it encompasses the development of forecast and warning systems, evacuation route systems, and other preimpact actions that are designed to develop a capability for active response to an imminent threat. Thus, Lindell and Perry (2000) contended that the defining characteristic of hazard mitigation was that it provides passive protection at the time of disaster impact, whereas emergency preparedness measures develop the capability to conduct an active response at the time of disaster impact. Thus, hazard mitigation should be defined as activities that provide passive protection during disaster impact by eliminating the causes of a disaster, reducing the likelihood of its occurrence, or limiting the magnitude of its impacts if it does occur.

Since 1995, FEMA has emphasized mitigation as the most effective and cost-efficient strategy for dealing with hazards. Indeed, a recent study by the Multihazard Mitigation Council (2005) concluded that investments in hazard mitigation return four dollars in losses averted for every dollar invested. The ways in which mitigation activities can reduce hazard losses can best be understood by recognizing that natural hazards arise from the interaction of natural event systems and human use systems (Burton et al., 1993). Thus, the potential human impact of an extreme natural event such as a flood, hurricane, or earthquake can be altered by modifying either the natural event system or the human use system or both. In the case of floods, for example, the natural event system can be modified by dams or levees that confine floodwater. The human use system can be modified by land use practices that limit development of the flood plain or building construction practices that flood-proof structures.

Attempts to mitigate natural hazards, or events over which there is little human control, involve controlling human activities in ways that minimize hazard exposure. Thus, land use practices restricting residential construction in floodplains are important mitigation measures against riverine floods. The Hazard Mitigation and Relocation and Assistance Act of 1993, for example, allows FEMA to purchase homes and businesses in floodplains and remove these structures from harm's way. Although moving entire communities involves considerable stress for all concerned, an intense and systematic management process – characterized especially by close coordination among federal, state, and local agencies – can produce successful protection of large numbers of citizens and break the repetitive cycle of "flood-rebuild-flood-rebuild" that is so costly to the nation's taxpayers (Perry and Lindell, 1997). Likewise, building code requirements are used to restrict construction to those designs that can better withstand the stresses of hurricane force winds or earthquake shocks. However, the adoption of land use and building construction policies is an intensely political process (Prater and Lindell, 2000; Stallings, 1995).

Although the amount of control that human societies can exercise over natural event systems is often limited, technological hazards are inherently susceptible to such controls. Chemical, biological, radiological/nuclear, and explosive/flammable materials can all be produced, stored, and transported in ways that minimize adverse effects to plant workers, local residents, and the public at large. However, this control can be lost, resulting in releases to the air or to surface or groundwater. It is possible to control the hazard agent by locating the system away from populated areas, designing it with diverse and redundant components, or by operating it with smaller quantities of hazardous materials, lower temperatures and pressures, safer operations and maintenance procedures, and more effective worker selection, training, and supervision. Alternatively, one can control the human use system by preventing residential and commercial development – especially schools and hospitals – near hazardous facilities and major hazardous materials transportation routes. As is the case with natural hazards, the choice of whether to mitigate technological hazards by controlling the hazard agent or the human use system depends upon political and economic decisions about the relative costs and benefits of these two types of control.

Disaster preparedness

Disaster preparedness activities are undertaken to protect human lives and property in response to threats that cannot be controlled by means of mitigation measures or from which only partial protection is achieved. Thus, preparedness activities are based upon the premise that disaster impact will occur and that plans, procedures, and response resources must be established in advance. These are designed not only to support a timely and effective emergency response to the threat of imminent impact but also to guide the process of disaster recovery. A jurisdiction's disaster preparedness program needs to be defined in terms of:

- Which agencies will participate in disaster preparedness and the process by which they will plan
- What emergency response and disaster recovery actions are feasible for that community
- How the emergency response and disaster recovery organizations will function and what resources they require
- How disaster preparedness will be established and maintained

Emergency managers can address the first of these issues – which agencies will participate and what will be the process for developing disaster preparedness – by promoting the development of a local emergency management committee. As will be discussed later, this requires identifying the emergency management stakeholders in the community and developing a collaborative structure

within which they can work effectively. It also requires ensuring an adequate statutory basis for disaster preparedness and administrative support from senior elected and appointed officials. Moreover, they can address the second issue – what are the feasible response and recovery actions – by means of analyses conducted to guide the development of major plan functions. These include, for example, evacuation analyses to assess the population of the risk areas, the number of vehicles that will be taken in evacuation, when people will leave, and what is the capacity of the evacuation route system.

Emergency managers can address the third issue – how the response and recovery organizations will function – in the emergency operations plan (EOP) and the recovery operations plan (ROP), which might be combined in an emergency management plan (EMP). These documents define which agencies are responsible for each of the functions that must be performed in the emergency response and disaster recovery phases. Some of the generic emergency response functions include emergency assessment, hazard operations, population protection, and incident management (Lindell and Perry, 1992; Perry and Lindell, 2007). While developing the plans and procedures, emergency managers also need to identify the resources required to implement them. Such resources include facilities (e.g., mobile command posts and emergency operations centers – EOCs), trained personnel (e.g., police, fire, and EMS), equipment (e.g., detection systems such as river gages and chemical sensors, siren systems, pagers, emergency vehicles, and radios), materials and supplies (e.g., traffic barricades, chemical detection kits, and self-contained breathing apparatus), and information (e.g., chemical inventories in hazmat facilities, congregate care facility locations and capacities, and local equipment inventories).

Emergency managers can also address the fourth issue – how disaster preparedness will be established and maintained – in the EOP and ROP. Sections of these plans should define the methods and schedule for plan maintenance, training, drills, and exercises. Training should always be conducted for emergency responders in fire, police, and EMS. In addition, training is needed for personnel in special facilities such as hospitals, nursing homes, and schools.

Emergency response

Emergency response activities are conducted during the time period that begins with the detection of hazardous conditions and ends with the stabilization of the situation following impact. For some hazards, monitoring systems ensure authorities are promptly alerted to disaster onset either by means of systematic forecasts (e.g., hurricanes) or prompt detection (e.g., flash floods detected by stream gages), so there is adequate forewarning and sufficient time to activate the emergency response organization. For other hazards such as earthquakes, preimpact prediction is not available, but prompt assessment of the impact area is feasible within a matter of minutes to hours and can quickly direct emergency response resources to the most severely affected areas.

The actual performance of individuals and organizations in disasters can be characterized by four basic emergency response functions – emergency assessment, hazard operations, population protection, and incident management (Lindell and Perry, 1992). *Emergency assessment* comprises diagnoses of past and present conditions and prognoses of future conditions that guide the emergency response. *Hazard operations* refers to expedient hazard mitigation actions that emergency personnel take to limit the magnitude or duration of disaster impact (e.g., sandbagging a flooding river or patching a leaking railroad tank car). *Population protection* refers to actions – such as sheltering in-place, evacuation, and risk area access control – that protect people from hazard agents. *Incident management* consists of the activities by which the human and physical resources used to respond to an emergency are prioritized, mobilized, and directed to accomplish the goals of the emergency response organization. These emergency response functions provide a useful framework for summarizing and evaluating existing research on disaster preparedness and response. These functions are similar, but not identical, to the Incident Command System structure of *command, operations, planning, logistics* and *finance and administration*. Emergency assessment is performed within the planning section, hazard operations and population protection are performed within the operations section, and incident support is performed within the command, planning, logistics, and finance and administration sections.

Emergency response activities are usually accomplished through the efforts of diverse groups – some formally constituted, others volunteer – coordinated through an EOC. Usually, local emergency responders dominate the response period. These almost always include police, firefighters, and EMS personnel, and often include public works and transportation employees. Uncertainty and urgency – less prevalent in mitigation, preparedness, and recovery – are important features of the response period. In the world of disaster response, minutes of delay can cost lives and property, so speed is typically essential. However, speed of response must be balanced with good planning and intelligent assessment to avoid actions that are impulsive and possibly counterproductive. Finally, emergency response actions need to be coordinated with disaster recovery. That is, life and property are priorities, but response actions foreshadow recovery actions. For example, damage assessments are later used to support requests for presidential disaster declarations and debris removal might be concentrated on roadways that are essential for restoring infrastructure.

Disaster recovery

Disaster recovery activities begin after disaster impact has been stabilized and extends until the community's citizens

have returned to their normal activities. The immediate objective of recovery activities is to reconstruct damages or destroyed buildings and restore the physical infrastructure – water, waste disposal, electric power, fuel (e.g., natural gas), telecommunication, and transportation – but the ultimate objective is to return the community's quality of life to at least the same level as it was before the disaster. Recovery has been defined in terms of short-range (relief and rehabilitation) measures versus long-range (reconstruction) measures. Relief and rehabilitation activities usually include clearance of debris and restoration of access to the impact area, reestablishment of economic (commercial and industrial) activities, restoration of essential government or community services, and provision of an interim system for caring for victims – especially housing, clothing, and food. Reconstruction activities tend to be dominated by the rebuilding of major structures – buildings, roads, bridges, dams, and such – and by efforts to revitalize the area's economic system. In some communities, leaders view the reconstruction phase as an opportunity to institute plans for change that existed before the disaster or to introduce mitigation measures into reconstruction that would reduce the community's preimpact hazard vulnerability.

One important finding from disaster research is that the speed, efficiency, and equity of community recovery depend significantly upon local government's ability to improvise effective recovery strategies (Rubin et al., 1985). That is, communities recover more quickly and effectively if they can identify and respond to the specific problems that arise from its unique circumstances. More recently, practitioners and researchers have begun to agree that community disaster recovery is even faster and more effective if it is based on a recovery plan that has been developed prior to disaster impact (Schwab et al., 1998; Wu and Lindell, 2004). The recovery plan needs to establish clear goals and an implementation strategy (Smith and Wenger, 2006), preferably one that does not reproduce the community's preimpact hazard vulnerability. Of course, disaster recovery requires a substantial amount of resources, most of which (particularly in reconstruction) are derived from extracommunity sources. In the United States, these sources include insurance proceeds as well as grants and loans from private organizations and state governments. However, most of the resources for recovery from major disasters come from the federal government.

Evaluation of the emergency management system

In the past, jurisdictions focused most of their preimpact disaster planning on their preparedness programs and evaluated their emergency management systems by having the staff of the local emergency management agency compare the emergency operations plan and emergency response resources (equipment, facilities, and personnel) to the requirements identified in the community preparedness analyses, although the audit was sometimes conducted by outside consultants from private industry or from state or federal agencies. In addition, they conducted performance evaluations by conducting drills, exercises, and critiques. More recently, the National Fire Protection Association developed Standard 1600 which, in turn, led to the development of the Emergency Management Accreditation Program (EMAP). In addition to providing more systematic methods for auditing the local emergency preparedness program, NFPA 1600 and EMAP serve as a basis for evaluating the entire emergency management program – including hazard mitigation and disaster recovery preparedness.

Performance evaluations

Drills are techniques by which an individual emergency responder is given an emergency response task and his or her performance is evaluated by a qualified observer. Exercises are similar in concept but are broader in scope – generally involving entire teams or multiple organizations. In either case, the observers assess responders' ability to perform the necessary tasks effectively. Oral and written performance critiques are integral components of drills and exercises because they help the participants to identify deficiencies in plans, procedures, training, equipment, and facilities. In turn, the deficiencies can serve as the basis for specific, measurable, and achievable objectives for revising these emergency response resources.

National fire protection association standard 1600

The National Fire Protection Association (NFPA) Standards Council established a disaster management committee in 1991 that developed standards for preparedness, response, and recovery from the entire range of disasters. The current version of NFPA 1600 (National Fire Protection Association, 2007) defines a set of criteria for all emergency management programs, including business continuity programs. The standard requires a public or private sector organization to have a documented emergency management program with an adequate administrative structure, an identified coordinator, an advisory committee, and procedures for evaluation. NFPA 1600 can be used in self-assessment and also by external evaluators. The program must address the elements identified in Table 1.

The emergency management accreditation program

The Emergency Management Accreditation Program (EMAP) is based on NFPA 1600 (Emergency Management Accreditation Program, 2004), but has language that is specifically appropriate for state and local emergency management agencies (EMAs). An EMA that submits an application for EMAP accreditation must conduct a self-assessment that includes a proof of compliance record for each EMAP standard. Following a review of the self-assessment, the EMAP Commission dispatches an assessor team to conduct an onsite assessment that examines the jurisdiction's written documents, interviews local personnel, and inspects facilities, equipment, materials, and supplies to verify their adequacy. If accredited, the

Emergency Management, Table 1 Emergency management program elements

Element	Title
1	General
2	Laws and authorities
3	Risk assessment
4	Incident prevention
5	Mitigation
6	Resource management and logistics
7	Mutual aid/assistance
8	Planning
9	Incident management
10	Communications and warning
11	Operational procedures
12	Facilities
13	Training
14	Exercises, evaluations, and corrective actions
15	Crisis communications and public information
16	Finance and administration

applicant is issued a certificate that is valid for five years, subject to continuing compliance with the EMAP Standard, continuing documentation of compliance, and filing an annual report with the EMAP Commission.

Emergency management policy development

All public policy is determined by stakeholders, which are people who have, *or think they have*, a personal interest in the outcome of a policy. This interest motivates them to attempt to influence the development of that policy. Community stakeholder groups can be divided into three different categories – social groups, economic groups, and political groups. In turn, each of these types of groups can be characterized by its horizontal and vertical linkages (Berke et al., 1993). Horizontal linkages are defined by the frequency and importance of contacts with other groups of the same type; vertical linkages consist of ties with larger groups at regional, national, or international levels.

Social groups comprise households and other groups such as neighborhoods, religious organizations, service organizations, environmental organizations, and other nongovernmental organizations (NGOs), nonprofit organizations (NPOs), and community-based organizations (CBOs). All of these groups vary widely in size, level of organizational complexity, and amount of resources available to them. They also vary based on the functions they perform in society and, thus, varying levels of interest in community emergency management activities. Nonetheless, all are potential partners in formulating emergency management policies as well as participating in hazard mitigation, disaster preparedness, emergency response, and disaster recovery activities.

The principal type of economic group, the business, is an important stakeholder because these organizations are responsible for most of the flow of goods and services in society. One especially important type of business that is a stakeholder in emergency management is the public utility provider, whether privately or publicly owned. This includes the providers of electricity, fuel, water, sewer services, solid waste management, and communications such as telephone, television, and Internet access. Another set of businesses – the news media – is especially important to the success of emergency management programs because their coverage of all phases of emergency management can be an important way to educate the public about hazards that might strike the community, not just to inform them of an imminent disaster.

Finally, there are various types of governmental stakeholders. The lowest levels of organization, the municipality (i.e., town or city) and the county, have varying levels of power because states differ in the powers that they grant to their political subdivisions. Much emergency management policy is set at the state level, and the federal government has historically been seen as a supporter to local and state efforts.

Social, economic, and political stakeholders are all involved in developing emergency management policy, which can be explained by the *policy process model.* This model, which is adapted from Anderson (1994), lists five stages through which policies move – agenda setting, policy formulation, policy adoption, policy implementation, and policy evaluation (see Table 2). Those who are concerned about reducing their communities' hazard vulnerability need to understand the policy process thoroughly so they can be effective advocates. In particular, they need to use the occurrence of a natural or technological disaster in their own or another jurisdiction as a *focusing event* to draw public attention to the need for local disaster planning and hazard mitigation (Birkland, 1997). The focus of public and official attention on a particular hazard for some period of time provides a *window of opportunity* for policy change (Kingdon, 1984).

Institutionalizing emergency management networks

The achievement of valued organizational outcomes such as high-quality plans, procedures, training, equipment, and facilities is substantially determined by two factors – the quality of the emergency planning process and the individual outcomes experienced by each LEMA or LEMC member (Lindell and Perry, 2007). Important outcomes for individual LEMA and LEMC members include job satisfaction, organizational commitment, organizational attachment behaviors, and organizational citizenship behaviors. Positive individual outcomes are important because the time people must contribute to the activities of LEMCs is often unpaid. Consequently, people are more likely to commit their time and energy when they perceive social and environmental problems within their community, they are committed to the success of these communities, and they expect the LEMC to be successful in solving these problems.

Emergency Management, Table 2 The policy process model

Policy terminology	Stage 1: Agenda setting	Stage 2: Policy formulation	Stage 3: Policy adoption	Stage 4: Policy implementation	Stage 5: Policy evaluation
Definition of policy stage	Establishing which problems will be considered by public officials	Developing pertinent and acceptable proposed courses of action for dealing with a public problem	Developing support for a specific proposal so that a policy can be legitimized or authorized	Applying the policy by using government's administrative machinery	Determining whether the policy was effective and what adjustments are needed to achieve desired outcomes
Typical objective	Getting the government to consider action on a problem	Generating alternative solutions to the problem	Getting the government to accept a particular solution to the problem	Applying the government's policy to the problem	Evaluating effectiveness and identifying improvements

Source: Lindell et al. (2006)

An effective planning process is characterized by the involvement of key personnel from diverse agencies in a participative and consensus-oriented process that acquires critical resources such as emergency personnel, facilities, and equipment. In addition, these organizations create positive organizational climates that have five major facets (Lindell et al., 2006, Chap. 3). The *leadership* facet involves being clear about what tasks are to be performed, as well as recognizing individual members' strengths and weaknesses and being supportive of their needs. The *team* facet is characterized by task (rather than purely social) orientation, coordination among members, a high level of inclusiveness that produces team cohesion, and a belief in excellence of their organization (team pride). An organization with a high quality *role* facet avoids member role ambiguity (uncertainty about what to do), role conflict (disagreement about what to do), and role overload (too much work to do). When the *job* facet has high quality, members have independence (personal autonomy) in the way they exercise a variety of significant skills (skill variety) to perform a "whole" piece of work that provides a meaningful contribution to the group product (task identity). Finally, a positive *reward* facet is characterized by members having opportunities to perform new and challenging tasks (member challenge), opportunities to work with other people (social contacts), and being told that other people appreciate their work (social recognition).

LEMAs and LEMCs also must make strategic choices. These strategies include a *resource building strategy*, which emphasizes acquisition of human, technical, and capital resources needed for effective agency performance, and an *emergency resource strategy*, defined by securing the participation of emergency-relevant organizations in emergency planning and response. An *elite representation strategy* involves placing members of a focal organization (in this case, the LEMA) in positions where they can interact with influential members of other emergency-relevant organizations; the *constituency strategy* consists of establishing a symbiotic relationship between two organizations, whereby both benefit from cooperation. The *co-optation strategy* consists of absorbing key personnel, especially those from other organizations, into the focal organization's formal structure as directors or advisors, whereas the *audience strategy* focuses on educating community organizations and the public at large about the importance of community emergency preparedness. Finally, there is the *organizational development strategy*, when local emergency managers actively try to increase the resource base of all local agencies, not just their own, in order to foster predisaster relationships among organizations that must respond to a disaster. Emergency managers can pursue this strategy by relying on committees and joint ventures to involve other community organizations and by having frequent contacts and formalized interagency agreements (e.g., memoranda of understanding), especially with other emergency-relevant agencies.

Finally, LEMAs and LEMCs can obtain the resources they need to support an effective planning process by increasing community support through an effective risk communication program and acquiring extracommunity resources by developing horizontal ties with neighboring jurisdictions and vertical ties with state and federal agencies. LEMAs and LEMCs can also enhance their staffing and organization by establishing defined roles for elected officials, clear internal hierarchy, good interpersonal relationships, commitment to planning as a continuing activity, member and citizen motivation for involvement, coordination among participating agencies, and public/private cooperation. Ultimately, though LEMAs and LEMCs do need money to accomplish objectives, there are many things they can do to increase their effectiveness that can be achieved at little or no cost (Lindell and Perry, 2007).

Summary

Emergency management is the process by which communities identify the hazards to which they are exposed and the potential impacts these hazards might inflict, as well as assess and develop their capabilities to respond to these impacts. In particular, communities implement hazard

mitigation, disaster preparedness, emergency response, and disaster recovery actions to manage their hazard vulnerability. Communities can evaluate their emergency management systems by conducting performance evaluations as well as standardized audits using the National Fire Protection Association's Standard 1600. Finally, communities can maintain their emergency management agencies through an effective planning process that involves the development of an effective organizational climate, the implementation of strategic choices, and acquisition of resources from inside and outside the jurisdiction.

Crisis mapping

Definition

The term "Emergency mapping" refers to the creation and use of maps – paper or digital – before, during or after emergencies and disasters. While "hazard and risk mapping" is primarily used to visualize the hazards and risks during the pre-event phase, "emergency mapping" focuses on supporting response and relief efforts. Nevertheless, both types of maps are closely related to one another since hazard and risk maps can be included into emergency maps as important components. Currently "Geographic (al) Information Systems" (GIS) play a critical role in the development and use of these maps. GIS-based emergency maps are often an integral part of web-enabled crisis information management systems.

Introduction

Successful emergency management would not be possible without maps. Emergency maps visualize vital spatial information for planning and response through an easily understandable mean. One of the well-known early examples of emergency maps is the mapping of the cholera outbreak in London around 1850. During the cholera outbreak, Dr. John Snow plotted the observed cholera deaths on a hand-drawn map. He realized that many deaths occurred in the immediate vicinity of a specific water pump. By examining this pump it became obvious that it drew polluted water from the sewage system. Dr. Snow simply recommended to remove the handle. The Cholera outbreak stopped soon afterward (Snow, 1855). In the course of time, emergency maps became more sophisticated and with the advent of Geographical Information Systems in the 1980s the creation of these maps and the analysis of emergency management-related information became easier and more efficient. Today emergency managers rely heavily on map products created before and after a disaster. Recent experiences during the response to the World Trade Center attacks (2001), the Indian Ocean tsunami (2004), Hurricane Katrina (2005), and the recent Haiti earthquake (2010) show that emergency maps were used very successfully (Committee on Planning for Catastrophe, 2007).

Categories of emergency maps

Up to now, no overall accepted classification of emergency maps exists. One commonly used classification is based on the usage of the maps related to an incident. Whereas some emergency maps are used prior to an incident (pre-emergency maps) others are used during the response to and recovery from an event (post-emergency maps). Both categories are discussed below in more detail.

Pre-event emergency maps

Pre-event emergency maps are typically used for emergency planning. They are integral part of emergency plans and are either publicly available or attached to planning documents of response agencies or high-risk industrial facilities. The goal of pre-event maps is to improve speed and efficiency in case of an actual event as they provide guidelines on intended behavior or desired response activities. Pre-event emergency maps may exist for any type of possible incident, including evacuation of buildings and areas, large events, or possible emergencies due to natural and technological hazards. They should be updated frequently and should reflect the most current information about the potential hazards and risks.

Evacuation maps are often included in public information materials related to possible threats, like building fire or industrial accidents. In many countries, evacuation maps have to be highly visible in public use buildings, including hotels, shopping malls, or stadiums. The goal of these maps is to provide guidance to the best possible evacuation routes under the assumption that people are unfamiliar with the area and may be under stress.

Pre-emergency maps for large areas, like maps for accidents of nuclear power plants or snow emergency maps are mainly addressed to local residents. These maps have slightly different design requirements because people usually have a longer time available to familiarize themselves with the map. Different zones for different alert levels are frequently used in these large-scale maps (e.g., evacuation zones for storm surges).

Pre-event maps addressed to responders serve a different purpose and are dependent on the domain. These maps may include information about locations of possible response resources, detailed hazard and risk maps, and detailed estimates for possible event scenarios.

Post-event emergency maps

Although post-event emergency maps are sometimes created to guide and support the affected population, emergency managers are the key users of this type of maps. Post-event maps are used to support any kind of emergency management function. Among others, some of the most critical functions using emergency maps include:

- Damage and needs assessment
- Emergency logistics and resource tracking
- Mass care and shelter
- Search and rescue
- Fire fighting
- Health and medical care
- Evacuation
- Hazardous material response

- Forecasts (e.g., storm and plume modeling)
- Public safety and security support, including crowd control
- Critical infrastructure repair and recovery

While each function has its own relevant map data and design requirements, the common denominator is that the maps are used in time-critical decision environments. Therefore, these maps are created to answer one or more operational questions through visual representation of key information.

Symbology

As with any other map, symbols are essential components of emergency maps. Symbols are abstract graphical objects used for the representation of natural or artificial features. Although the use of self-developed sets of emergency symbols is still very common among response organizations, several standardization approaches try to create a set of standard cartographic symbols. The main goal of these initiatives is to facilitate information sharing between involved response agencies. One of these standards is the US Homeland Security Mapping Standard (ANSI/INCITS, 2006). It includes a set of common symbols for different types of incidents and natural events, infrastructures, and operational data. In Germany, the responding organizations use a standardized set of tactical symbols (SKK, 2003). In Netherlands, a set of symbols was designed for emergency response sector (Heide and Hullenaar, 2007). Some of these symbols, especially for resources, can be rather complex since they include information about organizational affiliation, resource type, unit size, direction, and time.

Geospatial data needs

The information needed for emergency response can be grouped into two large clusters, dynamic information (situational and operational) and static (existing) information. Data collected during a disaster are denoted as dynamic data, whereas the information existing prior the disaster is named static information. Static information provides also the basis for pre-event emergency maps. For both categories, the collected information can either apply to all hazards or it is specific to a single hazard or type of event. Typical information needs are, for example, published in (Board on Natural Disasters, 1999) or (US DHS et al., 2008).

Some examples of dynamic information are:

- Incident: location, nature, scale
- Effects/consequences: affected and threatened area, predictive modeling results
- Damages: damaged objects, damaged infrastructure
- Casualties: dead, injured, missing, and trapped people and animals
- Accessibility: building entrances, in- and out-routes, traffic direction, blocked roads
- Temporary centers: places for accommodating people (and animals), relief centers, morgues
- Meteorological information: wind direction, humidity, temperature
- Remote sensing imagery of the affected area
- Up-to-date data about involved response personnel and resources
- Hazard-specific information: for example, in case of flood – velocity and water depth, flood pattern

The most commonly used static (existing) information used for emergency maps includes

- Reference data: topographic maps, aerial photographs (orthophoto images), satellite images, cadastral maps and data
- Managerial and administrative data: census data, administrative borders, risk objects (gas stations, storage places of dangerous goods, etc.), vulnerable objects (schools, nursing homes, etc.)
- Infrastructure: road network, utility networks (gas, water, electricity), parking lots, dykes, etc.
- Building catalogs: high/low-rise, material, number of floors, usage (residential, industrial), presence of hazardous materials, owners, cables and pipes, etc.
- Accessibility maps: for buildings, industrial terrains, etc.
- Locations of preplanned resources
- Planned evacuation routes and shelters
- Water sources: fire hydrants, uncovered water, drilled water well, capacity, etc.
- Hazard-specific information: Hazard and risk maps, calculated event scenarios

Existing data is usually available from a variety of sources, including local authorities, national mapping agencies, cadastre, and private companies.

Emergency mapping and remote sensing

In emergency mapping, the use of sensors is very important for collecting dynamic data before and shortly after a disaster. The information derived from sensor products is critical for monitoring the natural hazard and ensuring a better situational and operational awareness.

Remote sensing refers to the entire suite of sensors that allow the collection of data from various platforms. Relevant sensors (optical, thermal, range, radar, acoustic, temperature, water level, humidity, etc.) can be deployed on the ground, in the air, or in space. Some sensors (water level gauges, seismic, air quality sensors, etc.) can be mounted on stationary platforms (near rivers, volcanoes, chemical and nuclear plants) while others (optical, thermal, acoustic, range, etc.) are often mounted on moving platforms (satellites, aircrafts, helicopters, unmanned aerial vehicles, cars, etc.). To be able to estimate which technology is appropriate for a specific disaster a number of technical, cost, and usability aspects have to be considered. Some of the most important technical aspects related to emergency maps are spatial resolution, spatial

coverage, and deployment time (Kerle et al., 2008). Examples of usability factors include:

- *Availability of software for data processing*: For example, software packages for raster image processing are widely available for all major GIS systems whereas software for laser scanner data processing is still subject to extensive research.
- *Required expertise*: Some products such as images (satellite or airborne) and videos do not require a specific expertise and can easily be used. However, many products are either not human-readable or require processing to derive the needed information. Expert knowledge may be required for the interpretation of this data.
- *Required post-processing time*: Some products like image classifications, feature extraction, creating digital terrain models, and creation of damage assessment maps can require days or even weeks.
- *Sensor suitability for different emergencies*: Different sensors have strengths for different emergencies: radar sensors are appropriate for mapping flooded areas, damage detection, land subsidence; laser scanners are useful for mapping emergencies with height differences before and after an event; thermal and infrared images are appropriate for fire monitoring.

Sensors and their products can also be used simultaneously. The integration requires geo-referencing to one predefined coordinate reference system. For example, using frequent snapshots from several sensors contributed greatly to the emergency response following the World Trade Center collapse (Rodarmel et al., 2003). For comparative analyses before and after a disaster, sensor products are regularly overlaid with existing maps and imagery. Examples for large-scale disasters like the Indian Ocean tsunami and Hurricane Katrina are published, for example, by Brecht (2008) and Kevany (2008).

Interaction with emergency maps and visual analytics

Many classifications for interactions with digital maps exist, but most commonly they can be grouped in:

- Animation/video
- Interaction (navigate, zoom, manipulate)
- Query (explore)
- Feedback
- Change (edit)

Amongst all the interactions, emergency mapping benefits greatly from animation, query, and change/edit.

Animation is a dynamic visualization of a series of images. The images can be snapshots of an area (or a specific object of the area) with different time stamps or a walk-through/flyover of a given area. Whereas the first technique is used mostly for the simulation of hazardous events, the second is used for orientation, path finding, and navigation. Although visually "dynamic," the user can only observe, but not change the sequence of visualized materials. Video recording falls in the same group due to the same characteristics. Animations are widely used to represent expected flooded areas, plume spread, forest fires, or tsunamis. For example, Jern et al. (2010) describe how animations can be applied as final visualization technique in different stages of flood management.

Querying objects allows the user to obtain additional information about an object on the map or information about new maps. The additional information can be simple text, explaining a characteristic, or the query may execute an animation or voice recording. All major Geographic Information Systems allow for rather complex querying including selection by location or by attribute (e.g., buffer analysis) or spatial joins and relates.

Change (edit) is the highest level of interaction. It allows users to invoke changes in the shape of an object or its attributes. This is usually the most critical functionality for a successful collaboration during emergencies. The editing could either be temporal (to explore different options) or permanent (persistently recording the changes in the map). Many of the emergency response systems developed in the last years largely rely on such change/edit functionalities (e.g., Eagle, IBridge in the Netherlands).

Visual Analytics is yet another emerging technology, which is defined as the science of analytical reasoning facilitated by interactive visual interfaces (Andrienko and Andrienko, 2005; Thomas and Cook, 2005). Visual Analytics introduces a new level of indigence in the visualization, by finding specific patterns in a data set or after integration with other portions of information. Visual Analytics can be seen as fusion of visualization techniques with other areas such as data mining, databases, and spatial analysis. Advanced emergency response systems apply Visual Analytics to support the decision making process. Examples are published by Todin et al. (2004) and Jern et al. (2010).

Innovative systems for emergency mapping

In the past, many systems for emergency mapping of different disasters have been developed as specialized centralized systems (e.g., desktop systems) in which the data are available in a single repository (Amdabl, 2001; Greene, 2002). In centralized systems, data are constantly accessible; however, they might be easily outdated and due to proprietary data formats the integration of new data sets might be problematic. Related to centralized systems is the notion of scenario-based systems, in which complex models can be used to create realistic predictions and simulations.

In contrast, distributed systems rely on access and integration of data from different repositories. Since emergency mapping is highly dependent on the dynamics of the disaster, it is difficult to predict which information is actually needed in a specific situation. Generally, emergency mapping has to fulfill two premises: (1) ensure supply of sufficient data from the field and (2) discover,

access, and fetch the most appropriate data from existing information sources. Consequently, emergency mapping can be also seen as an on-demand system. One of the main challenges of on-demand systems is the design and implementation of well-defined standardized services for discovery and exchange of existing information. Such services are closely related to the development of a Spatial Information Infrastructure (SII) for local, regional, national, and international levels. As of 2010 a number of SII-initiatives are in progress worldwide, including INSPIRE in Europe (www.ec-gis.org/inspire). Those initiatives are further enriched with specific services for the emergency management sector. Large international projects like ORCHESTRA (www.eu-orchestra.org), OASIS (www.oasis-fp6.org), and WIN (www.win-eu.org) have reported valuable results.

Most of the technology that is required for access and exchange of 2D spatial information is available as implementation standards (e.g., WFS, WMS, WCS, WPS, WCPS, OpenLS, SFS, SOS, and GML), or as concepts (e.g., OGC Abstract specifications for open distributed management of geographical imagery, GeoRSS). Many extensions of existing standards are proposed for further discussions and new ones have also been developed now for 3D (CityGML, Web3D Service). The third dimension is also considered with respect to indoor modeling and integration with Building Information Models (BIM) for evacuation and navigation (Lapierre and Cote, 2008; Lee, 2007).

Systems for emergency mapping have been traditionally developed by and for specialists involved in relief operations. However, experiences from recent disasters have clearly shown that information provided by local citizens and volunteers could be of great help especially in the first critical hours. For example, Ushahidi, Google Map, Open Street map, MS Bing Maps have been successfully used in Afghanistan, Pakistan, and Haiti to share logistical and recue information. Although there are many open issues (reliability, security, accuracy, etc.), such technologies should be further investigated and developed.

Conclusions

Emergency maps are an essential component of effective emergency management during planning, response, and recovery. Obtaining the best possible information about potential or ongoing emergencies is vital for emergency managers and the involved public. Since access to a disaster area is frequently limited the use of remote sensing technologies is often the primary way to receive initial information about the affected area, but the applicability of different sensor technologies and platforms often depends on the actual type event. Collected data can be integrated, manipulated, and analyzed via GIS and other related systems. Because of the complexity resulting from data diversity, sophisticated analysis tools, and due to the involvement of multiple stakeholders, new approaches for collaboration using emergency maps are currently being developed. Although the research in this field is still very young, recent disasters proof the value of the integration of emergency maps with distributed, collaborative systems.

EMERGENCY PLANNING

Scira Menoni
DIAP-Politecnico di Milano, Milan, Italy

Definition

Emergency or contingency planning is the activity aimed at preparing all concerned organizations to face a given crisis when an accident or a natural extreme occurs in a given area, provoking victims, damage, and various degrees of disruption of everyday life. According to Perry and Lindell (2003), emergency planning, training, and exercising are key aspects of emergency preparedness. The latter is to be intended as "the readiness" of social systems and governmental organizations to respond to environmental stress, minimizing negative consequence in terms of health and safety for people and avoiding the breakdown of fundamental community functions. The most important point raised by the two authors refers to the fact that emergency planning must be looked at more like a process rather than a product. Emergency plans, in fact, have to be updated often, according to changes in the environment to be protected, to the kind and severity of threats, to the amount and quality of available personnel, resources, and means. Contingency plans are closely related to those who developed it, they constitute a sort of predefined agreement on how certain problems and situations will be tackled by concerned actors rather than a consultation document. In this respect, updating does not only mean that data and information may/have to change but also that the same stakeholders who are in charge of emergency management should continuously check the efficacy of the plan or get acquainted to it if they have not participated to its development. In other words, whenever a new officer or a new disaster manager enters the teams in charge of contingency planning and management, he/she must learn not only the details of the plan but also the reasoning behind it.

In general terms, it can be said that contingency plans provide reference guidance to those who will be caught in an emergency and should work as a platform allowing for adjustments while making decisions in a turbulent environment. In this respect, emergency planning must start with a careful and deep analysis of crises, of weaknesses that past crises have manifested, so as to develop a tool that will be actually tailored to the specific context rather than being an act of formal compliance with some law. Therefore, understanding what crises exist, what their main features are and what specific character they may assume in a given area is crucial before any emergency planning is initiated (see *Civil Protection and Crisis Management*). The latter in fact should respond to problems and challenges posed by crises rather than constitute a predetermined list of functions or actions to be delivered but detached from the real potential development of a disaster.

While this is true in general, in the following some aspects of emergency planning specific to natural hazards will be treated.

Types of plans

As emergency planning is a process aimed at tackling crises in the best way possible, plans can be also grouped into categories depending on which types of crises they should be prepared for.

As for spatial and geographical aspects, the first aspect to be considered is whether in the area of concern one or more natural hazards exist. When the second option is confirmed, a further analysis must be carried out to understand whether existing hazards may or may not be linked in one single complex event (this would be the case of landslides triggered by earthquakes or lahars triggered by volcanic explosions, etc.). While independent events can be treated separately, even though the unfortunate co-occurrence of the latter can be a concern, it is certainly much more appropriate to be prepared for linked events, one triggered by the other. In this respect, in highly urbanized areas, na-techs (technological disasters initiated by a natural hazard, see Showalter and Fran Myers, 1992) must be always taken into consideration and prepared for in order to disentangle the dramatic sequence of a fire induced by damages to plants or lifelines or contamination of water as a consequence of flooding in areas where hazardous material are stored.

In general terms, multi-hazard plans provide a complete reference for rescuers and concerned authorities as well as permit economies of scale in identifying stakeholders, personnel, and means and resources to be deployed in case of need.

As far as the spatial dimension is concerned, the scale factor is crucial in contingency planning. In most countries in fact, there is some subsidiarity principle according to which emergencies must be dealt with by the governmental level closest to the extreme event. The intervention of higher levels, going as far as regional, national, or even international levels must be sought for when the extent of damage, disruption, and magnitude of the disaster goes far beyond local, provincial, regional, or national coping capacities. This implies that all levels, at least up to the national, must prepare contingency plans responding to the requirements and responsibilities that are applicable to the scale of concern. The concept of scale then becomes extremely important, as at each scale different problems, means, and opportunities must be considered, as well as different responsibilities. Nevertheless, because temporary multiple organizations will work in the crisis management, plans must be conceived in a way and shaped in a format best fit to provide guidance to all involved organizations and to constitute a common, shared, and agreed platform for cooperation.

It must also be remembered that many of the involved organizations, for example, the firemen or medical doctors organisations, are also split among various levels of government and are often organized in territorial districts and units. This means that there may even be a situation in which a good level of cooperation among agencies exists at the regional but not at the provincial level, at the local but not at the national scale, with all the consequent problems that such a situation may entail.

As for the time dimension, clearly the characteristic of the threat and the vulnerability of places imply varieties of options for detailed planning. An alert phase must be planned for those hazards that allow for prediction and forecasting, whereas it is useless when forecasting is not possible and for fast onset crises. In the meantime, it should be reminded that an emergency plan should cover the entire extent of a crisis, be it short or long, including the monitoring of crucial variables in the aftermath. Such monitoring may regard health issues (e.g., after a volcanic eruption with toxic gases), the quality of water in cases of contamination, and even psychological distress due to the event itself and to the traumatic consequences it may imply.

The likely duration of crises determines the type of decisions and resource deployment that must be set, which clearly varies in case of short or long crises, in case a large or small number of people are potentially affected.

Mode of development and structure of emergency plans

Following what has been said about emergency planning being a process rather than a product and the variety of organizations that are inevitably involved in its development and updating, the mode of development is a fundamental aspect to be carefully designed. As Lagadec (1993) correctly noted, coordination cannot be obtained by decree, it has to be constructed with the people who are in charge of crisis management. A minimum number of organizations, particularly those with a key role during emergencies must be involved in all stages of the plan development. Although this seems rather obvious and trivial, often it is not the case. Plans are prepared by a limited number of stakeholders and then disseminated, with the inevitable result that those who did not participate to its development will not use it and sometimes will even forget about its existence. In the meantime, it is also true that there are time constraints in the number of plans which each stakeholder can contribute to, particularly when the same people are mandated to represent an authority in different arenas. Countries have identified different ways to cope with such difficulty, some more efficient than others. What can be certainly said is that the problem of how to harmonize and integrate the various levels of emergency plans has still to be solved in a satisfactory way. In many instances and in many organizations, this is not even recognized as a relevant problem. The criticalities clearly increase when larger scales are concerned, reaching the maximal complexity in disasters in poor or developing countries where international assistance is required (see *Natural Hazards in Developing Countries*). Abstracting from individual occasions and controversies, there are growing concerns about the failure and partial failure of international aid and assistance during crises and in supporting reconstruction in poor countries. The lack of common plans and common understanding, protocols about what is really needed and how operations should be carried out results in conflicts between the military and nonmilitary bodies, between governmental agencies and NGOs, and between those who are willing to assist the population in the immediate

aftermath of a disaster leaving reconstruction to local forces and those who are mandated of development and rehabilitation missions. The main problem of such international intervention has to be indicated in the complete lack of useful information about the vulnerability of places and the specific factors that make a community in a given context vulnerable (see *Vulnerability*). Needs are often guessed but not really identified, whereas tools for rapid assessment are also lacking and in any case not agreed upon before missions start.

The knowledge of the vulnerability of places, as well as their strengths and opportunities for coping and rebuilding are seldom accounted for in emergency plans, even in developed countries (see *Resilience*; *Coping Capacity*). Instead, it is essential, as plans should be tailored not only to respond to specific threats and their spatial and time features but also to the specific weaknesses and resilience factors of both the built environment and the population.

Structure and main ingredients of emergency plans

As for the structure of an emergency plan, there are several forms that it can take, some more efficient than others. Plans that rely too much on scientific reports about risk areas are in general poorly operational; plans that do not contain logistics information and maps (see *Emergency Mapping*) provide little guidance to those who will come from outside to provide help. In general terms, it can be suggested that emergency plans must be synthetic documents, organized in working sheets and forms, containing the crucial information mostly needed to handle a crisis:

- Who are the people in charge of what and what are the basic actions they are expected to take, particularly at the beginning, when confusion is sovereign?
- What are the means and resources that are available to face the problems created by the crisis, where can these be found and how can they be obtained?
- What are the main features of the involved areas, in terms of maps, logistics, any information that can be relevant for managing the crisis in a specific context?

It is a challenging task to identify the key components of an emergency plan in abstraction from a given hazard and a specific area. There are nevertheless some crucial parts that should be never neglected.

The first relates to the event scenarios to which the plan is aimed to respond. Event scenarios are images of what may happen when a given natural extreme hits a specific context. The latter is made of a spatial setting, a given built environment including the strategic facilities and infrastructures that will be used to tackle the crisis, of a community, comprised by individuals, families, and social groups of different age, culture, origin, etc. Scenarios should depict how a given stress (provided by the occurrence of a natural hazard) is likely to affect constructions, roads, networks, people, etc. Further, the scenarios should consider how damage and losses may trigger secondary and induced consequences, given a certain level of systemic vulnerability, to be understood as level of interdependence and structure making a facility and/or a service able to keep functioning even in case some physical damage has occurred. Scenarios are essential in that they show how a natural phenomenon may transform itself into a severe challenge to a given environment, as a consequence of the specific and particular features of the latter. This means that in contrast to what is often done, emergency plans are unique to the area of interest, they respond to that particular community only, they cannot be transferred from one place to another without carefully evaluating the local conditions from a variety of points of view (geographical, natural, social, economic).

The development of scenarios is a critical stage in emergency plans development as they are an expression of the knowledge existing in a place regarding the combination of hazards, vulnerabilities, resilience of the natural, the built environment and of the settled population.

A second fundamental component of any emergency plan relates to the resources, both human and material, that can be deployed in case of need. The "needs" that may arise are partially indicated by scenarios, which are there also to provide hints about the necessities that would probably arise under given circumstances in a given place. A structured survey of available resources, including indication of proprietary usage conditions, is the part of the plan to which concerned agencies will contribute more enthusiastically. In fact, the development of an emergency plan may prove to be a unique occasion for identifying crucial requirements in terms, for example, of protection means for search and rescue personnel, tools designed to look for people under debris, and for monitoring given environmental conditions. This is also a part of the plan that must be constantly updated, not only because new means can be obtained by various organizations but also because new devices may be introduced in the market. The prior development of scenarios, with the complete description of the features of the area of interest is relevant also for selecting means that can be effectively used under specific environmental conditions. For example, heavy material like cranes are difficult to transport on an island; large trucks are not likely to make it in narrow mountain lanes, etc., in other words, resources must fit the environmental conditions of places for which the emergency plan is developed.

A third part, often the most problematic, refers to the stakeholders who must agree on actions and responsibilities in the emergency plan. The complete and exact description of tasks that will be accomplished, even though always cited as one of the crucial thing to do, proves to be unrealistic and unfeasible, particularly as multiple organizations, each with a definite hierarchy, structure, and mode of operation will have to meet and cooperate in the emergency situation. In part, the exact forces, agencies, and organizations that will be asked to intervene depend on the scenario itself as they cannot be

completely imagined before the event strikes. Furthermore, political external concerns may override the plan and call for stronger interference of forces that were not necessarily involved at the beginning. Given as a general rule that the largest number possible of organizations likely to be involved should be involved in the plan development, what can be suggested is that the latter constitute a reference, a guidance for making coordinated decisions responding to the problems raised by the crisis and for renegotiating the use of resources in case of need. Actually this is not too far from what happens in the field when collaborative organizations work together during a contingency: they often share resources and expertise improvising new forms of mutual cooperation. As those are the situations generating the best outcomes, it can be suggested that the plan contains elements, information, and tools to facilitate such process of mutual exchange and aid that often takes place in real emergencies. Predefining on paper what each organization will do will probably work only for the most obvious operations (first aid, search and rescue, etc.) but will not help in ambiguous or unexpected situations.

Finally, the emergency plan, being a process, should contain indications for its own upgrading, like sections where lessons learned from real events, simulations, and exercises can be archived.

Summarizing, it can be held that emergency plans are a tool to keep collective memory alive (Middleton and Edwards, 1990), to store it and make it available to the largest number of stakeholders in charge of a crisis. Such a tool maintains its validity as long as concerned actors see it as a reference and a guidance of their activity, recognizing it as a repository of information and criteria to make decisions.

The importancce of communication in emergency planning

The Canadian Roundtable on Crisis Management (2003), in a rather interesting booklet of guidance for emergency managers indicates that contingency plans are made of two main parts: the operational and the communicational. The latter must be granted the same attention as the previous, as information, knowledge, and perceptions exchange is crucial for a successful exit from crises.

Within the emergency planning process, communication not only holds a central role but must be carefully designed according to the involved actors and stakeholders (see *Communicating Emergency Information*).

As for the latter, there are at least three main areas for which communication processes must be carefully designed and maintained: among the temporary multiorganizations that will take part in the contingency management operations, between the decision makers, the various organizations, and the public. In the case of a disaster, further distinctions should be drawn between the population directly affected and the more general public, as well as between scientists and decision makers, when the intervention of the latter is deemed essential.

As for the time dimension, communication during the event is clearly different from the information that must be guaranteed in "normal" time, so as to prepare people to react correctly and to apply the parts of the plan that are relevant to them in case of an extreme event.

The communication plan is therefore a significant chapter of the emergency plan itself, be it separated or nested into it. In any case, if people in different governmental positions, pertaining to various organizations and the same public are not fully aware about the content and the implications of the contingency plan, the latter is likely to fail, no matter how well conceived and developed it is.

Lagadec (1993) stresses the importance to have the media as part of the contingency management framework, because media are better equipped to transfer information to people, because in any case they will be there whenever and wherever a disaster occurs. As a suggestion, instead of trying to avoid contacts with the media, that will be inevitably there, one should allocate time, resources, and tools to accommodate the media within the entire process of emergency management, so as to be as transparent as possible in conveying news in a turbulent situation and perhaps even be able to exploit media's capability to dispatch information for the victims (like facilitating contacts among relatives and friends, disseminating information about health care, shelters, etc.).

Major challenges of emergency planning

Emergency planning is successful if involved parties and stakeholders take actually part in the process and if documents that are produced are known and used by the largest number possible of agencies and organizations. Clearly, in all those cases where plans are forgotten in the drawers or are not used as a reference guidance to prepare for and during emergencies, it means the process has failed in one or more steps and components. It can be held that the major challenge for emergency planning is therefore to generate a process of mutual respect, trust, and cooperation among the multiorganizations in charge of civil protection and produce documents that constitute a reference for operations (see *Civil Protection and Crisis Management*).

Future challenges imply the starting of processes of preparation and production of plans for the crises of the future. In this respect, increased probability of na-tech in urban and metropolitan environments are to be considered as more likely than in the past and therefore requiring specific intervention. The effects of climate change as a potential trigger of changes in other hydrometeorological hazards might be also accounted for (see *Global Change and Its Implications for Natural Disasters*). Multi-hazard emergency plans and stronger cooperation among different levels of government and among countries to deal with likely transboundary threats are part of the actions that can be suggested for the future. Certainly one major aspect is rethinking the linkages among different scales, including the global one, when global threats are at stake and whenever international

intervention as part of humanitarian aid is sought in the aftermath of a calamity. Arrangements found until now proved often of limited efficacy: while intervention on the concrete action is always local, the implications, when regional, multisite events are implied, must be carefully envisaged, as well as when local events become international, because of political, economic, or even humanitarian reasons.

Summary

Emergency or contingency planning is the activity aimed at preparing all concerned organizations to face a given crisis when an accident or a natural extreme occurs in a given area, provoking victims, damage, and various degrees of disruption of everyday life.

Emergency planning is fundamentally a multidisciplinary activity, requiring the active participation and contribution of several experts and particularly of those stakeholders who will have the responsibility to implement the plan.

Emergency plans should constitute a valid reference for action and intervention in case of a natural disaster for all agencies and forces implied in emergency management and in search and rescue activities. It must respond to apparently two contradictory requirements: be the basis of standardization on the one hand (for all those tasks and procedures that have to be carried out more frequently and repeated in almost all contingencies) and create the condition for good improvisation and collaboration on the other. Such a balance is needed as emergency plans have to be used not only to tackle "usual" contingencies but also "exceptional" threats and conditions, typically associated with crisis management.

Therefore emergency planning should not focus only on the expected product (the contingency plan) but rather be viewed as a process aimed at finding solutions and creating the conditions for negotiating and renegotiating tasks and use of available resources in case of need, whenever surprises challenge the most standardized procedures.

EMERGENCY SHELTER

Camillo Boano, William Hunter
University College London, London, UK

Synonyms

Emergency relief; Immediate relief phase

Definition

Emergency shelter: The initial, immediate phase of crisis recovery development; a type of physical structure used to accommodate people in the immediate aftermath of a crisis or disaster situation; accommodation for actual or potential disaster victims seeking quarters outside of their own permanent homes for short periods: hours in many cases, overnight at most (Quarantelli, 1995:45).
Transitional shelter/settlements: Accommodation resulting from conflict and natural disasters, ranging from emergency response to durable solutions (Corsellis and Vitale, 2005).

Introduction

In the wake of a disaster or crisis, whether man-made or the result of natural occurrence, or as often the case, a combination of these and other factors, shelter remains a sometimes elusive and consistently controversial and challenging element of sustainable recovery efforts. Compounding the challenge is the delineation of terminology (Quarantelli, 1995; Zetter, 1995; Zetter and Boano, 2008) and physical attributes assigned to autonomous and overlapping phase shifts within disaster relief planning and implementation.

If temporary accommodation fills the gap between immediate relief and later reconstructive stage, the initial emergency shelter phase of the recovery process is fundamental and requires strategic interdisciplinary collaboration and decision-making between diverse actors and expertise. Emergency shelter involves different scales regarding time, space, and resources.

Each disaster situation is unique, and thus, it begs for a unique set of appropriate actions rather than prescriptive standardized solutions. Determining a "best-fit" solution for eventual shelter means that emergency relief, rehabilitation, and development mechanisms, including preparedness planning and immediate disaster assessment, must be produced in a coordinated manner. Thus, emergency

sheltering should be conceived as an act of providing suitable habitat that fosters security and protection rather than mere logistics and object distribution or at the scale, encampment (Zetter, 1995; Zetter and Boano, 2008; Babister and Kelman, 2002; Boano, 2009). Hence, the ever-changing nature of emergencies and the complex multi-faced shelter process render emergency shelter an intricate, debatable topic of discussion among professionals and institutions.

Emergency shelter and rights to shelter: toward adequate housing

The provision of adequate shelter designed to satisfactory and appropriate physical and cultural standards during a disaster triggered by natural hazards is obligatory for governments, agencies, and institutions in order to offer protection and relief and could be conceived as a basic human right concept. Although it is not directly grounded in international human rights law, humanitarian law, or in codes of conduct (see Zetter and Boano, 2008), it can be recalled indirectly in a rich body of laws specifically referring to an adequate standard of living and right to housing (UN, 1948).

The UN ECOSOC (1992) provides the most authoritative legal interpretation of the right to adequate housing, suggesting that shelter is not seen exclusively as a commodity. Rather it views that it is the right "to live somewhere in security, peace, and dignity" stressing different integral components of the right (para 8.) as "legal security of tenure; availability of services, materials, facilities, and infrastructure; affordability; habitability; accessibility; location; and cultural adequacy." Although emergency shelter by definition normally does not meet the criteria of "adequate housing," a number of minimum human requirements are still applicable in such context (UN, 1948, 1966).

Protection related to shelter, housing, and adequate living conditions is acknowledged through *The Guiding Principles on Internal Displacement* as the right to be protected if displaced from "home or place of habitual residence" (UN, 1998). Principle 7(1) expresses the need to explore alternative solutions to displacement in order to minimize its adverse effect, whereas 7(2) affirms the need for proper accommodation in satisfactory conditions of safety.

In order to protect an individual from the elements, shelter must be constructed in a fashion appropriate to the effects of its environment. Described as protection from human elements, preservation of dignity is a less-tangible issue. Dignity demands an understanding of how shelter can temper relationships between displaced individuals or between the migrant and host communities. The restoration of an individual's dignity in an emergency situation involves the construction and provision of a place where the person can enjoy privacy and safety. This often has as much to do with the layout and location of shelter units as the type of shelter unit itself.

For this reason a house can be a keystone for recovery, providing a physical support mechanism, where other resources cannot. Though different shelter types breed different cultural associations (Rapoport, 1969), if provided, *temporary shelter* is often considered best to reduce the risk of future disasters. However, this is difficult to implement. Unsuitable sites can lead to lost livelihoods, lost sense of community and social capital, cultural alienation, poverty, and people abandoning new sites and returning to their original community (Cernea, 1997).

Emergency shelter in discourse and practice

In the aftermath of disasters, international agencies, governments, and NGOs often emphasize the quick delivery of emergency shelters to show progress results and to alleviate the suffering and psychological stress caused by devastation and homelessness and faster transition to a "normal" situation (Davis, 1978; UN, 2008). Even though this objective seems correct initially, vast literature confirms continuous failures in addressing such transition (Zetter, 1995; Lizarralde et al., 2010). Building affordable housing is a complex process that, even in regular circumstances, consumes great amounts of time and resources, requiring complex logistics, administrative innovation, and careful management (an argument studied by Keivani and Werna, 2001). Thus, providing emergency shelter raises a variety of corollary issues such as availability, affordability, location and use of land, scale, technology, and participation – all themes that converge on the issue of displacement.

The processes that people go through after a disaster to stabilize their housing situation can be quite lengthy and convoluted. People affected by the same disaster are affected differently and respond differently. Some will begin repairs of their damaged houses in the first days after the disaster, whereas others will be displaced for a period of time, even finding their situation changing weekly, monthly, or yearly. Because of such diversity, it is important to understand the range of options people face without imposing artificial "phases."

Shelter literature is based on the assumption that three levels of solutions are normally employed (Quarantelli, 1995) – emergency sheltering, temporary housing, and permanent housing. In this logic, emergency sheltering corresponds to the immediate protection against natural elements for the first few days after the disaster. This type of sheltering often includes handing out tents, plastics, corrugated iron sheets, among other materials to affected families. Emergency sheltering is essentially provisional and the agencies that provide it do not usually build houses. Therefore, their intervention is limited in time. Once the emergency assistance phase has been completed, the problem of housing is still present but permanent solutions often seem far away.

Adding to confusion among the sector is considerable variation in the terms used to describe shelter in humanitarian crises and these vary from location to location:

transitional shelter "provides a habitable, covered living space. . .over the period between a disaster and achieving a durable shelter solution" as Corsellis and Vitale (2005) suggests; emergency shelter typically involves the supply of temporary shelter materials such as tents and plastic sheeting, as UNHCR (2006:7) argues; temporary shelter/mass shelter/collective building may include the use of public buildings such as mosques, churches, and schools, empty binding (Holzman and Nezam, 2004), and specially built temporary living centers (Lambert and Pougin de la Maisonneuve 2007:12).

Following disasters, it is imperative to minimize the distance and duration of displacement, while keeping safety in mind. This allows people to better maintain their livelihoods and allows households to protect their land, property, and possessions. Displacement can continue long after risks have receded, due to (1) the inability of households to document their property rights, which may be a prerequisite to reconstruction; (2) inappropriate reconstruction strategies, such as one that ignores the variety of needs within the affected population; or (3) the lack of resources and capacities of government and agencies to assist the displaced population.

People displaced from their original location have different sheltering options as recognized internationally by UN (2008):

- *Host families*: The displaced are sheltered within the households of local families, or on land or in properties owned by them.
- *Urban self-settlement*: The displaced settle in an urban area, occupying available public or private property or land.
- *Rural self-settlement*: The displaced settle in a rural area, occupying available public or private property or land.
- *Collective centers*: The displaced shelter in collective centers, or mass shelters, often-transitory facilities housed in pre-existing structures.
- *Self-settled camps*: The displaced settle independently in camps, often without services and infrastructure.
- *Planned camps*: The displaced settle in purposely built sites, where services and infrastructure are offered by government or the humanitarian community.

During the 1970s and 1980s, temporary housing was often delivered by special contractors with high-tech industrialized methods (UNDRO, 1982). These solutions usually implied industrialization and standardization and resulted in repetition of a universal solution that rarely responded to the specifics of climate, topography, local customs, and local forms of living. Most recent practices include the construction of shack-type temporary units made of timber and/or corrugated iron sheets. Usually located in public or vacant land and built with perishable materials, this form of housing usually has primitive infrastructure and is made by organizations that are rather transitional solution providers and not permanent (regular) housing builders (Boano, 2009) but (Corsellis and Vitale, 2005).

Camps, just as they are manifested spatially between the open and the closed, exist somewhere between the complex and difficult categorization of what is temporary and what is permanent. Essentially a time-based concept, "camps are understood as having a limited, although sometimes indeterminate, duration" (Hailey, 2009: 4). Perhaps the most obvious camp in terms of emergency is the *refugee camp* – designated zones for displaced persons and more specifically as a mandated space of protection. The UNHCR objective is to administer camps that work between safety and assistance, though it is not always able, or required to assist refugees (Hailey, 2009). Stemming from debates in the 1990s regarding refugee camp management, *Transitional Settlement* declared that "camps are not intended to be sustainable settlements, but every effort should be made to create and support livelihood opportunities for displaced populations, to empower them by increasing their self-sufficiency, and to reduce demands upon the aid community" (Hailey, 2009: 325).

This seemingly contradictory assumption of definitive limitation versus expectant-sustained independency led to the concept of "neighborhood planning" (Hester, 1984; Jones, 1990) that should be adopted in the design and layout of camps and settlements to promote a sense of community and reinforcement of community-based protection (IASC, 2005:54; Goethert and Hamdi, 1989) while also preserving the privacy of the family unit (Corsellis and Vitale, 2005) in order to avoid the camp becoming a "zone of indistinction" (Hailey, 2009: 325). Specifically, the *Camp Management Toolkit* suggested to "start planning from the family unit" (NRC, 2008: 201) and then expand to whom they normally relate to and live near. While this may seem like the description of a more long-term permanent situation, the fact remains that in many emergency situations, the established camps existed and developed for much longer than expected (Zetter, 1995; Boano and Floris, 2005).

Fred Cuny, a pioneer in the development of holistic approaches to planning and organization of refugee camps, in *Refugee camps and Camp Planning: The State of The Art* (1977) proposed a system of organization and management based on the full participation of the refugees themselves (UN IASC, 2006:18). The first edition of the UNHCR emergency manual came out in 1982 and is mainly based on Cuny's work. Further steps to define standards, founded on a rights-based perspective were further developed and introduced by the Sphere Charter for Humanitarian Intervention (Sphere Project, 2004) where basic dimensional standards were suggested. More recently, The IASC Emergency Shelter Cluster has outlined a set of general principles that it claimed had assisted in widening the community of practitioners, strengthened coordination systems in the global and national level, and more importantly encouraged concerned agencies to target alternative and more appropriate methods for ensuring "integrated and robust humanitarian programming" (ISAC, 2008).

Currently Humanitarian community and practitioners are more inclined to work around the notion of transitional shelters as used to house affected households with habitable, covered living space and a secure, healthy living environment with privacy and dignity during the period between a natural disaster and the availability of a permanent shelter solution (Corsellis and Vitale, 2005; UN, 2008). This approach to sheltering provides incremental support from the moment recovery begins, and gives households mobility and autonomy.

Conclusion

Emergency shelter and settlement should provide protection and privacy, for "human dignity and to sustain family and community life as far as possible in difficult circumstances" (Sphere Project, 2004:208). Far from being merely a design exercise, or logistic distribution, the practice of such spatialities and the notion of *camp* render evident that the design of shelters and settlements, which are responsive to the wide range of needs and values which housing serves, is a complex task. Complexity exacerbated by the political economy contours in which "makeshift architecture and emergency urbanism" (Lewis, 2008) take place.

The central concern is that the conceptualization of shelter, notably around the principles of space and place, is a critical factor in addressing the widely documented shortcomings of shelter and settlement responses. As advocated elsewhere (Zetter and Boano, 2008; Boano, 2009) post-disaster shelter inventions should be constructed around (1) a coherent understanding of the space and place nexus which embodies a pluralistic perception – as physical commodity, as the expression of social processes, cultural relations, and as an economic resource; (2) a clearer articulation of the processes linking relief, rehabilitation, and development in the production of space and place; (3) addressing national- and international-level institutional constraints to achieving better integrated responses; and (4) recognition of rights-based approaches.

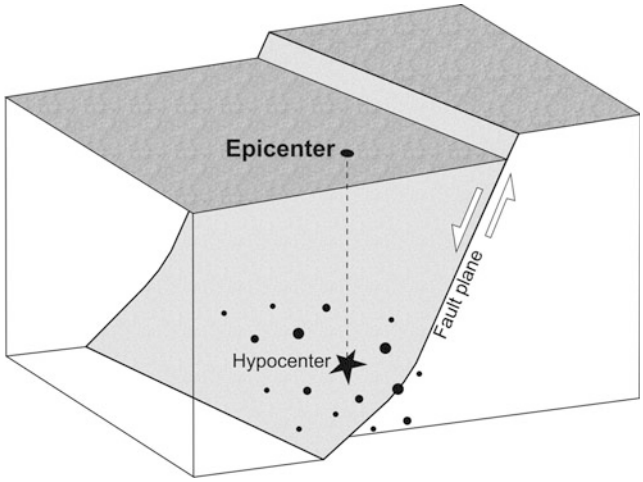
EPICENTER



Valerio Comerci
ISPRA - Institute for Environmental Protection and Research, Roma, Italy

Definition

The epicenter is the point on the earth's surface which lies vertically above the *hypocenter*.

Overview

The epicenter was originally defined before the development of *seismographs*: it was commonly taken to be near the center of the meizoseismal area (the area within the *isoseismals* of higher intensity). Subsequently, instrumental records proved that in most cases the epicenter was at one side of the meizoseismal area (Richter, 1958, 17–18, 144). Therefore, macroseismic and instrumental epicenters seldom coincide.

Epicenter, Figure 1 The epicenter is the point on the surface vertically above the *hypocenter*. The star represents the point where the rupture along the *fault* starts, while the dots represent smaller earthquakes generally occurring before and after the main shock (foreshocks and aftershocks).

Today, epicenters (Figure 1) are generally determined based on the travel time of seismic waves, such as *primary waves* (and sometimes *secondary waves*), from the *hypocenter* to the *seismographs*.

EPIDEMIOLOGY OF DISEASE IN NATURAL DISASTERS

Gilbert M. Burnham
The Johns Hopkins Bloomberg School of Public Health, Center for Refugee and Disaster Response, Baltimore, MD, USA

Definition

The epidemiology of disease in natural disasters encompasses both *epidemic diseases*, defined as a group of illnesses of similar nature, clearly in excess of normal expectancy and derived from a common or propagated sources, and *endemic diseases* which are those usually or commonly present in a population (Gordis, 2004). Whereas epidemic diseases are commonly thought of as communicable diseases, epidemics of non-communicable diseases can occur with a disaster. Examples include increases in injuries or mental health conditions arising from a disaster, the common source in the Gordis definition. Endemic conditions can become epidemic following a disaster, directly related to the event, or indirectly, arising from the collapse of health services and other support services. Examples include communicable diseases such as respiratory infections, scabies, hepatitis, or sexually transmitted diseases.

Introduction

Epidemics of communicable diseases are less a feature of natural disasters than they are of Complex Humanitarian Emergencies (CHE), where populations are displaced, food insecure, and with limited access to health services (Watson et al., 2007). Outbreaks of communicable disease and natural disasters are often thought to go hand in hand. The news media continues to believe that epidemics of cholera and natural disasters are inextricably linked, even where cholera is not normally present. Although rare, conditions such as cholera, meningitis, or dysentery when they do occur after natural disasters can overwhelm health services and create widespread fear. More common infections are outbreaks of conjunctivitis among people temporarily housed in schools and public buildings or head lice among children temporarily displaced. There are many factors which contribute to the increased transmission of disease after natural disasters. Each of these needs to be considered in estimating potential risk to a disaster-affected population so that limited resources can focus on potential response to those events which are most probable. Although the nature of the disaster does affect the type and nature of disease transmission, the extent and duration of population displacement from the disaster is often a more powerful determinant of risk. Communicable disease outbreaks are more a feature of countries in epidemiological transitions where the major causes of illness and death are infectious agents commonly present before disaster.

In more developed countries, where populations live longer, complications of chronic and degenerative diseases may increase with disasters, as patients are cut off from diabetes and cardiovascular medications or cannot access dialysis for kidney failure. The importance of understanding the epidemiology of these conditions and how persons with these conditions are affected by lack of access to services is only recently being appreciated (Chan, 2009; Howe et al., 2008).

Factors contributing to disease after disasters

Nature and extent of the disaster

Not all disasters generate the same type or level of risk. Whereas earthquakes may create a great demand for injury care, and sometimes for complex orthopedic procedures, in themselves they cause little direct increase in disease transmission. The preoccupation with dead bodies as a potential source of epidemic disease continues in spite of multiple publications to the contrary (PAHO, 2005). Hasty mass burials carried out because of the fear of disease outbreaks can have negative psychological effect on those surviving (Morgan et al., 2006).

Flooding or other disasters affecting water and sanitation are disasters most likely to be associated with increased transmission of disease (Ahern et al., 2005). Wells or water sources can be directly contaminated since contamination can occur through disruption to water reticulation systems, as Gomez et al. (1987) noted in the 1985 Mexico City earthquake. Contamination with human fecal material is generally, but not always of more risk than animal fecal contamination, *Cryptosporidium* being an exception (MacKenzie et al., 1994).

More indirectly, flooding may increase the breeding sites for vectors of disease or bring populations and vectors into closer proximity. Outbreaks of malaria and dengue fever have occurred after flooding. Rodents dislocated by flooding may introduce leptospirosis into a human population. Those in suboptimal conditions post disaster may have increased exposure to disease vectors.

At the other extreme, drastic reductions in water available for personal hygiene can increase prevalence of skin conditions as well as transmission of fecal-oral infections.

Existing endemic disease patterns

The disease pattern post disaster is likely to represent alterations or variations from the patterns observed before disaster. In locations where cholera or meningococcal meningitis are endemic, such conditions might appear with the population displacement and collapse of health service. When new epidemic conditions are introduced into a community with a disaster, it is usually associated with population displacement (Jawaid, 2008). The pattern

of care-seeking for chronic diseases in a community can be expected to change following a natural disaster (Guha-Sapir et al., 2008) and this may be a function of the priorities of both the community and those selected by emergency health services.

Health of the population

Where widespread acute malnutrition exists, illness and death from common conditions are likely to increase if the equilibrium between the status of the population and their environment is worsened. This is a common pattern seen where there is prolonged food insecurity, particularly among children. Populations debilitated by physical exhaustion may be more susceptible to disease. In countries with low immunization coverage, events associated with a disaster may increase the risk of a measles outbreak among young children. More than 18,000 cases of measles were diagnosed among the population displaced by the Mt Pinatubo eruption in 1991 (Surmieda et al., 1992). Such events can have a devastating impact, especially if there is preexisting malnutrition and vitamin A deficiency. Following a disaster, injuries may be extensive in the cleanup process. Poor immunization coverage led to an outbreak of tetanus following the tsunami in Indonesia (Jeremijenko et al., 2007).

Some fragile states have experienced a series of interspersed conflicts and natural disasters. This series of events can leave a population physically and psychologically debilitated and with increased susceptibility to disease even before the next event occurs.

Population characteristics

Populations with a high dependency ratio have increased disease risks. In some high income countries, this would be mostly elderly, and in high fertility countries, this would be mostly young children. Vulnerability is increased if the household head is physically or psychologically impaired or the household is headed by a single parent or a child. Populations with a high density may be at an increased risk of injury and disability both from the direct effects from the natural disaster as well as from communicable diseases. A population which is forced from their location of usual residence is likely to be at increased risk of illness and death (Wilder-Smith, 2005). For example, during the 1992 Somalia famine, households that were not displaced had a lower mortality than those who were forced to move (Moore et al., 1993). Households which sought shelter in camps had the highest mortality. The extent of crowding in temporary housing also contributes to the risk of communicable diseases such as measles, meningitis, and tuberculosis. The physical location where a population lives will also influence the epidemiology of injury and the illness patterns resulting from the disaster.

Response capacity

The epidemiology of diseases and conditions which follow a natural disaster is heavily influenced by the capacity of health services. At the same time that disasters increase health needs, they often dramatically decrease in the capacity of the health services to provide services. Both structural and nonstructural components of health services are at risk. In the 2003 Algeria earthquake, half of health facilities could not function (Lancet, 2008). Similarly, Indonesia lost 122 hospitals and health centers during the 2004 tsunami. Even when facilities are adequately protected or left intact by a disaster, the health workforce may be decimated or incapacitated because of their internal personal losses. Conditions which could be otherwise managed or contained by a functioning health system may worsen and potentially spread. Although most countries have national disaster plans, the presence of district, provincial, or facility disaster response plans is variable. Following the 2007 Ica earthquake in Perú, Chapin found those facilities which had developed emergency response plans were able to more effectively provide services than those without plans.

Where present, voluntary and auxiliary groups can provide community assistance which will help to contain outbreaks of disease and help to meet the needs of those with disabilities or chronic conditions (Kilby, 2008).

Prevention and control

Managing disease in disaster is based on the basic prevention concepts of public health which start with efforts to prevent disease and limit the spread or deterioration of disease once it has occurred.

Primary prevention is the prevention of disease through preventing exposure of a population to potential pathogens. Examples are ensuring water is safe, and sanitation maintained, and that immunization coverage is adequate to prevent infection. Prompt information to those at risk about preventing exposure or infection is another example. Primary prevention is also an approach to prevent exposure to hazardous substance released during disasters, and to prevent complications in persons requiring regular treatment of chronic diseases such as insulin-dependent diabetes. Many primary prevention actions are part of preparedness planning, but others can be done to avoid specific threats as a disaster occurs.

Secondary prevention is the prompt treatment or prompt action to prevent a disease having serious consequences. In the first instance, this is the control of outbreaks so that the spread of infection is limited. Once a disease or condition is established in a population, it also means good case management. This can include rescue and transport for persons with surgical injuries, as well as proper treatment of diseases such as malaria, meningitis, or tetanus. Establishing standard procedures or protocols is an early step in disease outbreak control as well as clinical management of disease. During disaster preparedness, creation of short just-in-time training courses materials can make implementation more rapid.

Although outbreaks of communicable diseases may occupy health services immediately post disaster, the demands for care of chronic and routine conditions soon

become predominant. Understanding the epidemiology of chronic disease in communities, and prevention of deterioration in existing conditions is important to ensure health needs of all are being met. This is especially true for populations with large numbers of elderly populations, or where many people are receiving treatment for TB or HIV.

Tertiary prevention is the long-term treatment of the complications which arise from disasters. This is especially applicable after earthquakes where physical rehabilitation of those injured may extend for years.

Surveillance systems

An effective surveillance system is central to understanding the evolving epidemiology of disease in a community affected by a disaster. Surveillance provides the ongoing systematic collection of data which are then analyzed and interpreted to provide the basis for public health interventions and also used for evaluating the success of efforts (Connolly, 2005; WHO, 2005). Establishing a surveillance system is one of the immediate public health tasks in emergencies. Surveillance systems may develop as an outgrowth of initial rapid assessment surveys or may start with organizing reporting from functioning health facilities. This initial information helps identify the common conditions or potential epidemic diseases for a population. Establishing case definitions for potentially epidemic conditions is an early activity, if they do not exist already. Although information is important from all health units for a comprehensive understanding of disease epidemiology, using sentinel sites may be an interim step before full coverage of health services can be achieved. Initially the conditions tracked by a surveillance system may be limited to those of major public health importance, because of limited resources. Surveillance systems for cases of cholera, measles, or meningitis are examples of such priority conditions where these are likely threats. It is critical that information gathered through surveillance be quickly transferred into public health action. This part may break down if there is weak implementation capacity or a lack of coordination among agencies or groups assisting a population.

As services are restored, surveillance systems must mature to better monitor the health status of the affected population. This means including data from community sources, not just facility data, as much morbidity and mortality occurs outside the health system in many developing countries. In addition to tracking incidence of routine conditions, a well-functioning surveillance system can identify new or unexpected conditions. Identification of "tsunami lung" in Aceh is one example (Allworth, 2005). Surveillance systems can include verbal autopsy methods to establish cause-specific mortality, which is particularly important where many deaths occur outside the health system. As assistance programming has become increasingly rights based, the utilization of health services by age and sex is now carefully tracked almost everywhere, as measures of equal access and utilization.

Establishing accurate population denominators, stratified by age and sex, is critical to the estimation of the rates and ratios needed to measure effectiveness of programs for populations affected. This is often very difficult in the rapidly changing environment post disaster where substantial population shifts are common. Without these population estimates, programs may use resources inefficiently, leaving some vulnerable groups unassisted.

Summary

Natural disasters are not commonly associated with large outbreaks of epidemic diseases, with the possible exception of flooding. Once a population is displaced by a disaster, the risks of epidemic disease rise. Natural disasters may affect the epidemiology of endemic diseases or chronic diseases present in a community through reducing or changing the access a population has to health services. Preventing or limiting the public health impact of a disaster requires an effective disease surveillance system that is a critical early measure to establish in any emergency. Acting on surveillance data can not only prevent or limit epidemics from developing, but is also a means of evaluating the public health response to disasters.

EROSION

Matija Zorn, Blaž Komac
Anton Melik Geographical Institute, Ljubljana, Slovenia

Definition

Erosion is a geomorphic process that detaches and removes material (soil, rock debris, and associated organic matter) from its primary location by some natural erosive agents or through human or animal activity.

Overview

The term is derived from the Latin *erodere*, to gnaw away, and is often used for overall exogenic processes in contrast to endogenic processes that build up. In this wide meaning, it includes also transportation and deposition processes. In the most broad and common meaning, erosion includes all exogenic processes, in the absence of weathering (which causes the breakdown of rock material) and mass movements.

Natural agents of erosion include water, wind, glaciers, snow, sea/lake waves, and gravity (as a constant force on unstable slopes). Besides these, human activity can also be the cause for erosion processes. Erosion can be either mechanical or chemical (e.g., corrosion). Erosive agents transport material either by traction (rolling, sliding, pushing, jumping), suspension (moving material in turbulent flows either in running water or wind) or solution ("chemical" transportation in running water).

Erosion is a function of the erosivity of erosion agents and erodibility of the ground. Connected to these are various erosion factors (e.g., relief, bedrock geology, climate, vegetation, humans). For example, bedrock geology controls erosion as erodibility depends on it. Erodibility also depends on tectonic deformation of bedrock; the higher the deformation, the greater the erodibility.

Climate influences weathering and influences several erosive agents (e.g., rainfall, wind). It also influences vegetation that controls the erosivity of some erosive agents.

The principal types of erosion related to single erosion agents are water erosion, wind erosion, glacial erosion, snow erosion, sea/lake erosion, and anthropogenic/animal erosion. The most important erosion connected to several erosive agents is soil erosion.

Water erosion is connected to running water, ranging from raindrops that cause splash erosion, to sheet, rill, and gully erosion that occur because of surface runoff. The former prior to and the latter after surface runoff merges into trickles and begins to erode vertically to form erosion rills and eventually erosion gullies. In river channels, water erosion is referred to as river or stream erosion. When a river/stream erodes a riverbank, this is referred to as lateral or bank erosion, which is often accelerated by flooding.

Sea and lake erosion can also be considered as water erosion. It is a consequence of wave action affecting coasts.

Wind erosion is the consequence of wind action usually connected to climatic aridity and the absence of vegetation cover.

Snow erosion is usually connected to erosive effects of avalanches, whereas glacial erosion is connected to the erosion effects of glaciers, and it is considered the most powerful type of mechanical erosion.

Soil erosion is any removal of soil particles and regolith by natural agents that is often accelerated by the activity of humans (clear-cutting, overgrazing, road construction) and animals, and which is more intensive than soil formation.

Today, the most visible and economically serious is anthropogenic erosion. It is commonly expressed as accelerated soil erosion and connected to the destruction of natural vegetation thus exposing the bare soil or bedrock.

In common conditions, erosion is usually a low-magnitude, high-frequency process, e.g., water erosion may be reflected in a gradual change of hydrological

response and hence a change in flood frequency. On the other hand, erosion may occur over the short term through catastrophic loss in specific situations.

Erosion hazard in a landscape is usually significant only in the long-term perspective and can be determined by social and economic losses.

EROSIVITY

Matija Zorn, Blaž Komac
Anton Melik Geographical Institute, Ljubljana, Slovenia

Definition

Erosivity is a measure of the potential ability of soil, regolith, or other weathered material to be eroded by rain, wind, or surface runoff.

Overview

Historically, the term erosivity was first associated with an *R*-factor (rainfall-runoff erosivity factor) in the Universal Soil Loss Equation (USLE). *R*-factor as used in the USLE and the revised USLE (RUSLE) relates to the mean annual sum of EI_{30} values. EI_{30} is the most commonly used rainfall erosivity index, where E is the total kinetic energy per unit area during a precipitation event (MJ·ha^{-1}) and I_{30} is its peak 30-min intensity (mm·ha^{-1}). Thus, erosivity of precipitation events is a function of their intensity and duration, and of the mass, diameter, and velocity of the raindrops. In principle, each detachment-transport system can be represented by an equation that has an erosivity term.

Wind erosivity has often been determined using indices based on wind velocities and durations above certain threshold velocities, precipitation and potential evaporation.

Erosivity is one of the influential factors of erosion hazard which is influenced by both, physical and social factors. Physical factors are represented by changing climate-influenced erosivity factors, such as intensive precipitation or strong winds in storm events. Highly erosive precipitation is a key climate variable that determines the type and magnitude of water erosion and some mass movements.

The effects of vegetation on erosivity depend on type and density of vegetation. It reduces the intensity of precipitation (or kinetic energy of raindrops) and its erosivity. Vegetation also influences runoff erosivity by restraining the action of running water and wind erosivity with obstruction of winds. Drought, dry soil surface, and sparse vegetation cover are necessary for strong winds to become highly erosive.

Erosivity is also influenced by climate patterns and land use changes that are controlled also by human activity, leading to increased hazard especially in agricultural areas.

A term connected to erosivity is erodibility as both are functions of erosion.

Magmatic eruptions; Volcanic explosions

Definition

Volcanic Eruptions. The expulsion of liquid rock (*magma*) – explosively or effusively – onto the earth's surface, either above or below water, through a vent. During a volcanic eruption, lava, tephra (ash, lapilli, rocks, pumice), and various gases are expelled. The following are the main eruption types:
Hawaiian low viscosity lava, high effusion rates, passive venting to fire-fountaining; low level to no plume
Strombolian moderate viscosity lava, high effusion rates, vigorous fire-fountaining; low level plume
Vulcanian moderate viscosity lava, moderate effusion rates, fire-fountaining to explosive ejection; low-mod level plume; early phases sometime phreatomagmatic
Peléan moderate viscosity lava, low-moderate effusion rates, explosive ejection; low-mod level plume
Plinian high viscosity lava, moderate effusion rates, explosive ejection; moderate-high level plume
Ultra-Plinian high viscosity lava, high effusion rates, explosive ejection; very high level plume
Surtseyan low viscosity lava, moderate-high effusion rates, explosive ejection with water interaction; moderate plume
Phreatoplinean low-high viscosity lava, moderate-high effusion rates, explosive ejection with water interaction; very high level plume

In addition, another eruption type, called *phreatic* (or *steam-blast*), involves explosive activity that only ejects nonmagmatic materials (preexisting volcanic or country rock) but no new magma. A variant involves magma-water interaction, *phreatomagmatic*, or *hydrovolcanic*, with its most violent variant being Phreatoplinean.

Volcanic eruptions range from passive to explosive, benign to catastrophic, and can have local to global impacts. The "style" of eruption is a fundamental characteristic that influences the eruption and its impact. The morphological form as well as the severity and impact of the hazards posed by a volcano are all related to the characteristics of the eruption and have been classified into eight main categories: *Hawaiian, Strombolian, Vulcanian, Peléan, Plinian, Ultra-Plinian, Surtseyan*, and *Phreatoplinian.* Some rarely used variants of categories include *Bandaian*, *Icelandic*, and *Katmaian*.

These names were for the most part derived from the respective volcanoes where characteristic eruptions had been observed. Early workers realized that there was consistency between certain types of eruptions, so they began to describe eruptions at other places in terms of those seen at the "type" locality. For example, Mount Pelée has lent its name to "Peléan" eruptions because eruptions there early in the twentieth century were well documented (c.f. Fisher and Heiken, 1982). Similar eruptions at other volcanoes could be described within the context of what was understood at Mount Pelée.

The Volcanic Explosivity index (VEI; Newhall and Self, 1982) provides a numerical and graphical, semiquantitative, logarithmic measure of *volcanic eruption's* magnitude or size, determined by the force of the eruption and volume of erupted (ejected) material (Figure 1). It is a methodology to better quantify eruptions rather than referring back to the "type locality." It seeks to understand the commonality of eruptions of similar size, style, etc. Accordingly, a rough correlation exists between eruptive style, type of eruptive vent, erupted volume, and the estimated VEI values (Figure 1). VEI 1–2 eruptions generally form only small cinder cones (*Hawaiian* to *Strombolian*), whereas with increasing eruptive energy the amount of erupted material increases. VEI 3 eruptions are typically *Strombolian* to *Vulcanian* through *Peléan*. VEI 4–5 are typical of major eruptions at stratovolcanoes (*Peléan* to *Plinian*), and VEIs $>$ 5 (*Plinian* to *Ultra-Plinian*) often results in caldera forming eruptions (c.f. Miller and Wark, 2008; Sparks et al., 2005). Nonexplosive eruptions, regardless of size, are assigned VEI = 0. If sufficient data exist, VEI rankings can be estimated for eruptions during the Holocene (Simkin and Siebert, 1994).

Passive *volcanic eruptions* (*Hawaiian;* VEI 0–1) are dominated by the effusion of lava of a viscosity sufficiently low such that the fluid behaves as a liquid and flows under the influence of gravity. Flowage will stop when the lava crosses the liquid-solid boundary (crystallizes), or when gravity is insufficient to overcome obstacles along the flow surface or channels; effusive flows pond in topographic lows. Depending on viscosity, lavas may form thin flows less than a meter in thickness, or thick tabular bodies, sometimes referred to as flow domes. For more detail about the wide variety of effusive volcanic activity, see, for example, Tilling (2009) and papers in Sigurdsson et al., 2000: Part III.

In explosive *volcanic eruptions* (*Peléan, Plinian, Ultra-Plinian;* VEI $>$ 3) magma has sufficient viscosity such that it moves only with great difficulty. Nonetheless, density contrasts with surrounding wall rock allow viscous magma to continue to ascend. At the same time, as pressure decreases progressively during ascent, fluids begin to exsolve from the rising magma, forming bubbles. With continued pressure decline the bubbles expand until they rupture, breaking their surrounding lava carapace.

VEI	Ejecta Volume	Eruption Type	Description	Plume	Frequency	Dispersal area (km^2)	Fragmentation
0	< 10,000 m^3	Hawaiian	non-explosive	< 100 m	constant	< 0.05 km; nil to very small	None to low
1	> 10,000 m^3	Hawaiian/Strombolian	gentle	100-1000 m	daily	0.05 – 5; small	Low
2	> 1,000,000 m^3	Strombolian/Vulcanian	explosive	1-5 km	weekly	0.05 – 5; small to moderate	Moderately low
3	> 10,000,000 m^3	Vulcanian/Peléan	severe	3-15 km	yearly	0.05 – 5; moderate	Moderate
4	> 0.1 km^3	Peléan/Plinian/Surtseyan	cataclysmic	10-25 km	≥ 10 yrs	5 – 500; moderate to large	High
5	> 1 km^3	Plinian/Surtseyan	paroxysmal	> 25 km	≥ 50 yrs	500 – 5000; large	Very high
6	> 10 km^3	Plinian/Ultra-Plinian/Phreatoplinian	colossal	> 25 km	≥ 100 yrs	5000; very large	Extreme
7	> 100 km^3	Plinian/Ultra-Plinian/Phreatoplinian	super-colossal	> 25 km	≥ 1000 yrs	>5000; extensive (continental scale)	Extreme
8	> 1,000 km^3	Ultra-Plinian/Phreatoplinian	mega-colossal	> 25 km	≥ 10,000 yrs	>5000; continental to global scale	Extreme

Eruption Types (Volcanic Eruptions), Figure 1 Adapted from Cas and Wright (1987); Newhall and Self (1982) and Walker (1973).

The expanding fluid, whose volume increases by orders of magnitude during the phase change from water to steam, is initially confined by the volcano's conduit and overburden pressure but then ultimately is released suddenly to produce an explosive discharge of fragmented lava (Cashman et al., 2000). Such discharges can be extremely vigorous and will propel eruption plumes of particles and gases many kilometers into the air. The variation in explosiveness and fragmentation is shown in Figure 1 (Cas and Wright, 1987; Newhall and Self, 1982; Walker, 1973).

The most explosive *eruption types* are those involving mixing of magma and water. If there is mixing of magma with subsurface water, the resulting phreatomagmatic (hydromagmatic) explosion can create an extremely destructive to catastrophic eruptions (*Surtseyan, Phreatoplinian; VEI 4>*; Figure 1). These types of eruptions create erosive pyroclastic surges (Moore et al., 1966a, b; Valentine and Fisher, 2000). The surges can sculpt the landscape by being highly erosive near source, stripping and scouring underlying soils and vegetation and infrastructure, yet leave relatively thin (or no) stratigraphic marker horizons in the geologic record. This lack of preserved "marker" horizons makes their frequency and intensity sometimes difficult to determine, impacting the validity of hazard assessments at volcanoes prone to these types of eruptions. More distally, pyroclastic surges are less destructive, depositing material, but they still have environmental consequences that takes years to decades before recovering.

Eruptions involving intermediate to higher silica composition magmas (e.g., andesitic dacitic, and rhyolitic) typically are moderately to highly explosive. However, basaltic eruptions, normally benign (*Hawaiian; VEI 0 – 1*), can on occasion become explosive and highly destructive (Fiske et al., 2009). Well-documented phreatomagmatic basaltic eruptions in Hawaii devastated an area of 420 km^2 with a highly explosive eruption between 2,800 and 2,100 ^{14}C years ago (Dzurizin et al., 1995). The violent basaltic subsea eruptions of Surtsey, Iceland, during 1963–1967, which formed a new volcanic island, lent their name to the

Surtseyan eruption type. Even stratovolcanoes subject to *plinian* eruptions can erupt more violently when water mixes with magma as in the May 18th, 1980, eruption of Mount St. Helens. This eruption proved to be far more explosive than anticipated. A growing lava dome inside the volcano ("cryptodome") failed with spectacular and devastating results. The hydrothermal system developed within the volcano over past eons, combined with water melted from the overlying glaciers by the cryptodome, created a phreatomagmatic eruption upon the virtually instantaneous depressurization due to gravitational failure of the volcanoes north flank (flank collapse). The blast from the mixing of the depressurizing cryptodome with ice and expanding steam from the hydrothermal system (Lipman and Mullineaux, 1981) destroyed more than 650 km^2 leaving a thin, characteristic pyroclastic surge deposit (Hickson et al., 1982; Moore and Albee, 1981). The thickness of the deposit is not indicative of the force of the eruption and is something that must be carefully analyzed when carrying out hazard assessments (MAP:GAC, 2007).

The rate and volume of expelled magma dictate the size of the *volcanic eruption*. If explosive, high discharge rates will create soaring eruption plumes (*Plinian*), the effects of which can impact areas of 100 s of square kilometers (Figure 1). High plumes (>30 km; *Ultra-Plinian*) from large explosive eruptions can affect global weather by injecting acidic aerosols into the atmosphere along with particles of ash (Mills, 2000). The airborne particles typically cause global cooling for several years following a very large eruption. Drifting eruption clouds containing abrasive ash particles also present a significant hazard to aviation (Casadevall, 1994; Miller and Casadevall, 2000). The biggest eruptions create subsurface void space that often collapses, forming a large crater or depression referred to as a caldera (Lipman, 2000).

If the magma is sufficiently fluid, high volumes of erupted lava – effusively or explosively erupted – can overwhelm rivers and snow fields, substantially altering the existing landforms by infilling topography and also by creating lahars or floods. The interaction of lava and rivers has been the focus of recent investigations (e.g., Grant and Cashman, 2007). Unstable dams of lava or other volcanic debris can fail catastrophically, leading to significant downstream hazards and morphological changes in the river channel (Hickson et al., 1999).

In addition to eruption rate and duration, conduit diameters and the rheology of the erupting material from a volcano also results in *volcanic eruptions* of widely differing scales.

Summary

Volcanic eruptions range from benign to highly destructive events with devastating consequence for people, flora, fauna, and infrastructure. The style of eruption is dependent on the viscosity, chemical composition, morphology, magma discharge rate, and a number of other factors.

Definition

Evacuation: The temporary or permanent relocation of people from hazardous environments to minimize injuries and deaths from disasters.

Evacuation context

In 1999, approximately 25,000 people were evacuated from communities around the Tungurahua volcano in Ecuador. Fears of a major eruption had spurred authorities to declare an emergency and enforce a mandatory evacuation. People relocated to homes of families and friends and to apartments in nearby towns, or they were sent to temporary shelters in old schools. While some residents returned to their homes after 2 months, others remained in the shelters for up to a year waiting for the volcano to stop erupting (Whiteford and Tobin, 2004). In 2005, as Hurricane Katrina approached land along the Gulf coast of the USA, warnings were issued for residents to move inland away from storm surge areas (see *Hurricane Katrina*). Thousands of people left, with some moving to homes of family and friends, and others to hotels. Still others evacuated to *Emergency Shelter* such as the New Orleans sports' arena. However, many individuals stayed in their homes, whereas others were unable to evacuate. Some of those who evacuated are scattered in cities across the USA and will never return (Brinkley, 2006). Another example, the 2009 bushfires in Victoria, Australia tested the national policy of "prepare, stay and defend, or leave early". More than 170 people died in the fires illustrating the importance of the timing of evacuations, which in turn, is dependent on sufficient warnings.

These experiences are emblematic of the complexities of evacuation, no matter what the scale or location of the disaster, and illustrate some of the successes and failures of evacuation strategies. Certainly, the evacuation of people from hazardous areas in the face of impending disaster appears to be a sensible policy to follow if lives are to be saved. Indeed, getting out of harm's way and relocating to a safe place is logical. However, evacuation is not simple; it is embedded with many conflicting pressures that affect both efficiency and effectiveness of evacuation strategies. Not all individuals will evacuate, for instance, and even those who do, may suffer untoward difficulties. The concept of evacuation, therefore, requires an understanding of those factors that influence calls for evacuation and response, including characteristics of the impending event and the socio-economic context of the location at risk.

Evacuation can occur without formal notification, but more typically, comes as a result of warnings about an imminent event from official sources such as emergency managers (see *Early Warning Systems*). Thus, evacuation is part of an emergency management (see entry *Emergency Management*) plan that addresses critical issues including the timing of evacuations, modes of transport and routes, alternative safe sheltering sites, and return. Evacuation, of course, is just one of many possible responses to warnings, but it is one that requires active participation on the part of those at risk. However, getting out of harm's way may not be perceived as necessary, desirable, or even viable. Understanding this decision-making process, then, is important and requires consideration of the human dimensions associated with forecasting, warning, and response (Sorenson, 2000).

Evacuation is the result of a complex of decisions by many parties (from public officials to those at various levels of risk) regarding the location and nature of an event's potential impacts as well as the balance of costs and benefits, in both real dollars and unquantifiable factors, including loss of social networks. The effectiveness

and efficiency of evacuation practices are introduced here through an integrated human–environment framework, by addressing complexities regarding notification and through consideration of factors affecting responses to evacuation notices.

Evacuation decision-making: the notification side

The movement of populations in large-scale evacuations requires careful planning, preparation, and sufficient resources. If a community, state, or nation has poor organizational arrangements and limited wealth, evacuations may be problematic. It might be expected that centralized economies will exert control over their populations and enforce mandatory evacuation policies. This is reflected in the low number of deaths from hurricanes in Cuba and in China's demonstrated capacity for evacuating large numbers of people. In contrast, evacuation may be less frequently enforced in decentralized economies. This is typical of the USA, where mandatory evacuation notices may be issued, but in reality those at risk are free to choose whether to evacuate or not. Evacuation also creates conflicts over appropriate levels of responsibility and whether local, regional, or national authorities should play a role. This balancing of different legislation associated with evacuation policy has been examined by Bea (2005) in the USA, addressing the suspension of local laws, enacting curfews, and implementing quarantine procedures.

In general, mandatory evacuation may be more effective in reducing deaths than voluntary programs, but it can engender ill feelings and create social turmoil especially if evacuees feel powerless and unprotected. In Ecuador, for example, some residents broke down military barricades and marched into their communities because the military had failed to protect their homes (Whiteford and Tobin, 2004). Nevertheless, Rashid et al. (2007) showed that mandatory evacuation was the preferred policy when the likelihood of a flood disaster was severe. Trust in authorities can also influence evacuation response. People may be wary to leave their homes on the promise of assistance when in the past this may not have been provided. There is evidence to support the notion that people will not evacuate if they fear looting of property left behind. While the degree of looting is often exaggerated, it is the perception that carries weight and affects decision-making. To counter this, Perry (1979) recommended incentive programs, providing meaningful information and guaranteeing protection to enhance voluntary evacuation rates.

Temporal concerns

Evacuation success is dependent upon timing, because sufficient time is required for action following a warning, although it should be noted that some people may evacuate before any official warnings are released (Dixit et al., 2008; Fu et al., 2007; Lindell et al., 2005). Some extreme events lend themselves to long lead times, such as the relatively accurate notices issued of impending landfall of tropical cyclones. Alerts made several days in advance suggest ample time to evacuate populations from coastal locations. Yet, lengthy warnings were available for Hurricane Katrina, but many did not leave. Other events do not allow for evacuation because the time to onset is far too short. Flash floods and tornadoes usually permit only a few minutes warning for action that is inadequate to mount large-scale evacuations. There is also considerable discussion about how much time is needed to evacuate. While long warning periods may be conducive to effective evacuation, too much time between warning messages and probable impacts may promulgate blasé attitudes about impending events (Simmons and Sutter, 2008).

The timing of evacuations involves more than early warning. Some recent evacuations in the USA have led to noteworthy traffic jams, such as during Hurricane Rita. Subsequent research has recommended increasing capacity for evacuation routes, using reverse flows, and employing intelligent transportation systems (Urbina and Wolshon, 2003). Yet, it may be the perception of traffic problems more than actual difficulties that deter people from evacuating (Dash and Morrow, 2000).

The length of evacuation is another temporal concern. In some circumstances, short-term evacuation is highly effective, such as evacuating for a day or less during a flood. In other cases, evacuation can be substantially longer such as in the volcanic eruption in Ecuador, where some individuals were out of their homes for up to a year. Other evacuations can become permanent as resettlements and relocation take place, as for instance with some evacuees from Hurricane Katrina.

Spatial concerns

Evacuation also entails an appreciation of the geography of the event (see *Hazard and Risk Mapping*). Specifically, where the event occurs can influence whether or not evacuation is a reasonable option. Small island nations may have little choice but to shelter in place because alternative safe land is not available. The Commonwealth of the Bahamas, for example, is situated in a hurricane zone and has adopted mitigation strategies that involve limited evacuation procedures (Hughey, 2008). On the other hand, evacuation is easier in places like the USA where it is relatively easy to provide a safe temporary location. In addition, others may opt to evacuate vertically, seeking refuge above perceived flood levels (Ruch et al., 1991).

In some events, entire populations have been evacuated over great distances. When the volcano erupted on Tristan da Cunha in 1961, the entire population of the island was evacuated thousands of kilometers to the UK for 2 years. Similarly, when Darwin, Australia was destroyed by Typhoon Tracy in 1974, people were evacuated to cities far to the south (Tobin and Montz, 1997). Such evacuations save lives, but create stress and anxiety and destroy social networks; indeed social difficulties arose in both

populations. Other evacuations may entail relatively short distances, which may be conducive to higher rates of evacuation since people can leave and return relatively easily. However, with Hurricane Charley in 2004, some Florida residents evacuated inland only for the storm to take a slight directional change and pass directly over those areas.

Evacuation decision-making: behavioral factors

The reasons why some people evacuate and others do not are varied (see Dash and Gladwin, 2007). The literature suggests that decisions to evacuate are contingent upon several determinants, each of which can work to either promote or deter evacuation.

Perception of risk

It is the perception of risk (see *Risk Perception and Communication*), rather than the scientifically estimated risk (see *Risk*, and *Risk Assessment*), that influences evacuation decision-making (Tobin and Montz, 1997). If an impending disaster is perceived as a significant threat, then action, such as evacuation, is more likely to take place, than when the risk is seen as minimal. Understanding risk perception and behavior, therefore, is essential to effective emergency management and there is now substantial literature on risk (Slovic, 2000). The failure of some residents to evacuate the Gulf coast prior to landfall of Hurricane Katrina illustrates how risk can be underestimated with severe consequences. In contrast, there are instances of evacuation taking place when not entirely necessary, a process termed shadow evacuation (Gladwin and Peacock, 1997; Zeigler et al., 1981), which complicates evacuation procedures and progress.

Numerous factors influence risk perception. One relates to the warnings themselves and the messages they convey which have profound effects on evacuation practices (Bell, 2007). The challenge is to construct messages that are believable, reach the maximum number of people, and generate positive responses. Even the message source influences decision-making. For example, Lindell et al. (2005) found that the most extensively accessed source of information for Hurricane Lili was local news media, especially television, although people do not generally rely on one source, but rather seek confirmation information as they decide whether or not to evacuate (Dow and Cutter, 2002).

Another factor influencing perception is experience. For example, if hazard experience has been frightening or worrisome, then future evacuation rates may be enhanced. In contrast, experience of small-scale events that are less disturbing may foster a false sense of security and limit evacuations. Hazard experience, then, works in different ways providing knowledge and insights that can both promote and inhibit suitable actions in disasters. Evacuation experiences also affect decision-making. Unnecessary evacuation or repetitive false alarms, for instance, may create a reluctance to evacuate the next time, often termed the "cry wolf" syndrome (Atwood and Major, 1998), although others have suggested that evacuation rates will not be diminished by unwarranted evacuation (Lindell et al., 2007). Fortunately, several factors ameliorate this problem, including reliance on several information sources. On the other hand, if prior evacuation was unpleasant, a reluctance to evacuate may be engendered. For instance, disease potential can be a major (or perceived) problem at evacuation sites, especially where large numbers of people are living in close proximity. In the Superdome in New Orleans, conditions included overcrowding and inadequate food and water supplies, and poor sanitation facilities (Brinkley, 2006). Similarly in the Ecuador shelters, whole families were living in small partitioned spaces in run-down facilities providing little more than a roof and a communal kitchen. Many stated that they would not evacuate again, preferring to die on the mountain than live under such conditions (Whiteford and Tobin, 2004).

Resources and social factors

Even when evacuation is regarded as the most appropriate action, other factors may intervene. If adequate resources are not available, then options for evacuation are severely curtailed. This is a particular concern for less wealthy individuals who may not have money or transportation necessary to evacuate. Resource access is pertinent at any scale, from the individual to the community and nation. For example, the ability of Haiti to evacuate and shelter its inhabitants after the earthquake in 2010 was limited by extreme poverty. Similarly, many residents in New Orleans in 2005 could not evacuate easily because they had no access to transportation (Brinkley, 2006).

Even with adequate resources, decisions to evacuate are affected by family demographics (Dash and Gladwin, 2007). Whenever family members are separated, difficulties ensue. A strategy to enhance evacuation-response rates, therefore, is to enable families to remain together. Furthermore, families with young children are more likely to evacuate than those composed primarily of adults. Parents and caregivers will seek to protect children whereas older adults are more likely to attempt to protect property. Age and gender may also affect evacuation. Women and elderly are more likely to evacuate than men and middle-age groups. While these evacuation patterns have been found in many different studies, the combination of such different traits can confound expectations.

Linked to family structure are social networks that provide support and socio-economic interaction in daily lives. Evacuation inevitably places considerable pressure on networks in several ways. Relocation of families, even for a short period, can mean separation from traditional connections and isolation from contacts, which provide invaluable assistance and may be vital in circumstances such as disasters (Hurlbert et al., 2001). Researchers are now examining how social networks operate and what factors may motivate successful evacuations. In Mexico,

for example, it was found that characteristics of social networks affect the levels of support (Murphy et al., in press). The ramifications for evacuation, especially if long-term, could be devastating.

External networks can be affected, too. Evacuees may move en masse to homes of families and friends in other areas, thus putting stress on recipient communities especially when this entails long stays (Whiteford and Tobin, 2004). In addition, a large influx of evacuees can change the dynamics of receiving communities creating new challenges. Long-term evacuation, relocation projects, and permanent resettlements can all have such impacts. For example, a resettlement project in Ecuador has more than doubled the size of a village near Tungurahua, changing social interactions within the community. Thus, it is important to look at the effects of evacuation on the receiving area and on the people and networks of evacuees.

Summary and conclusion

Evacuation is a wise choice to avoid loss of life and injuries when faced with severe geophysical events. However, this wisdom is constrained by numerous factors that relate to the nature of the impending event, the political context, and various social and individual variables that influence response. Perception and social and family networks affect decision-making whereas temporal and spatial elements define evacuation opportunities and constraints. An over-riding theme is one of complexity that embeds evacuation planning and management with individual decision-making in different social and economic situations, leading to differential *Vulnerability* and, thus, unequal access to the benefits of evacuation.

Definition

Expansive soils and clays: Soils (or clay minerals) that exhibit considerable volume change with change in moisture content. Expansive soils contain appreciable amounts of swelling clay minerals.

Introduction

Expansive soils, known by various nomenclatures worldwide, are a unique group of soils that expand when wetted and shrink when dried. These include predominantly Vertisols and vertic intergrades in US soil taxonomy (Soil Survey Staff, 2006). The extent of Vertisols alone is estimated at 350 million ha worldwide. The pressure these soils exert can be strong enough to crack driveways, floors, walls and foundations. The American Society of Civil engineers estimates that 25% of all homes in the United States have some damage caused by expansive soils. Expansive soils cause substantial damage and yet few people are aware of this hazard. It is estimated that shrinking and swelling soils cause about $2.3 billion damage annually in the United States alone (Holtz and Kovacs, 1981) which is more than twice the annual cost of damage from floods, hurricanes, tornadoes, and earthquakes combined!

Swell-shrink process

A soil may be described as a three phase system: solid, liquid, and gaseous. Under ideal conditions, about half of the volume is occupied by the solid phase and the other half is shared in equal proportion by liquid and gaseous phases. In non-expansive soils, the bulk volume would not change whether hydrated or dehydrated. The liquid and gaseous phases would interchange without significantly affecting the volume and other soil properties. However, in expansive soils considerable volume changes occur upon hydration and dehydration due to changes in porosity and water content (Figure 1). When the soil is rewetted, part of the volume occupied by air is replaced by water, but the pore volume of the soil also increases and, consequently, its water content (Coulombe et al., 1996a).

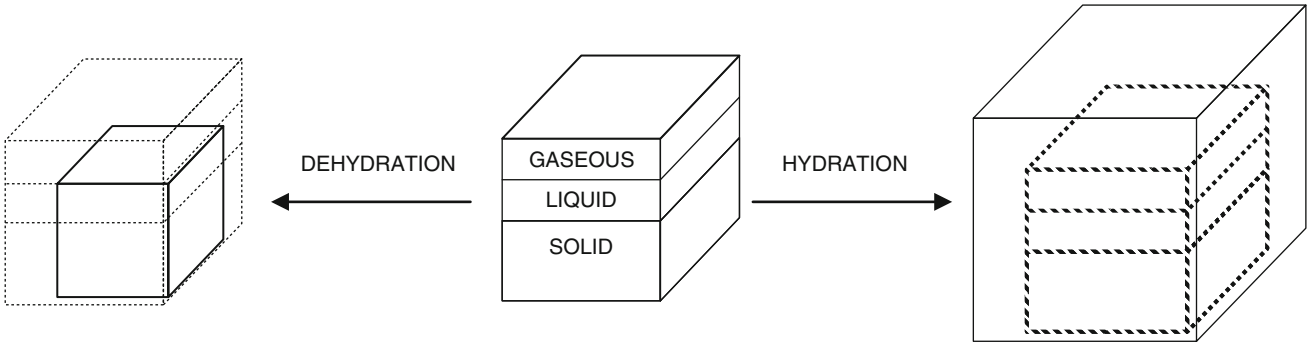
When the soil dehydration process starts, three stages are usually observed in the shrinking phenomenon. The first one termed "structural shrinkage" corresponds to a slight volume change when water is removed from larger pores (Figure 2). The second stage represents a volume reduction which is proportional to water loss in the system. This stage is termed "linear shrinkage" and occurs around 0.03–1 MPa, and even down to 1.5 MPa of suction in the case of smectitic soils (Coulombe et al., 1996a). With further drying, the decrease in volume is much less than the water lost and is termed "residual shrinkage." Further collapse is prevented by electrostatic repulsion, strongly bound water, and particle rigidity.

Interparticle and intraparticle porosity of the microstructures is largely responsible for the shrink-swell phenomena in soils. The other theories of expansion/collapse of the interlayer space of clay minerals and diffuse double layer, reportedly, have a slight influence on swelling under very specific conditions (Coulombe et al., 1996b).

The three groups of factors that influence the shrink-swell potential of the soil are soil properties, environmental factors, and the state of stress. The soil properties include clay mineralogy, fabric, and dry density. The initial moisture content, moisture fluctuations induced by climate, ground water, drainage, and vegetation are factors related to environment (Nelson and Miller, 1992). Everything else being equal, smectites swell more than illites, which swell more than kaolinites. Soils with random fabrics tend to swell more than soils with oriented fabrics and monovalent cation clays swell more than divalent clays. Cementation and organic substances tend to reduce swelling (Holtz and Kovacs, 1981).

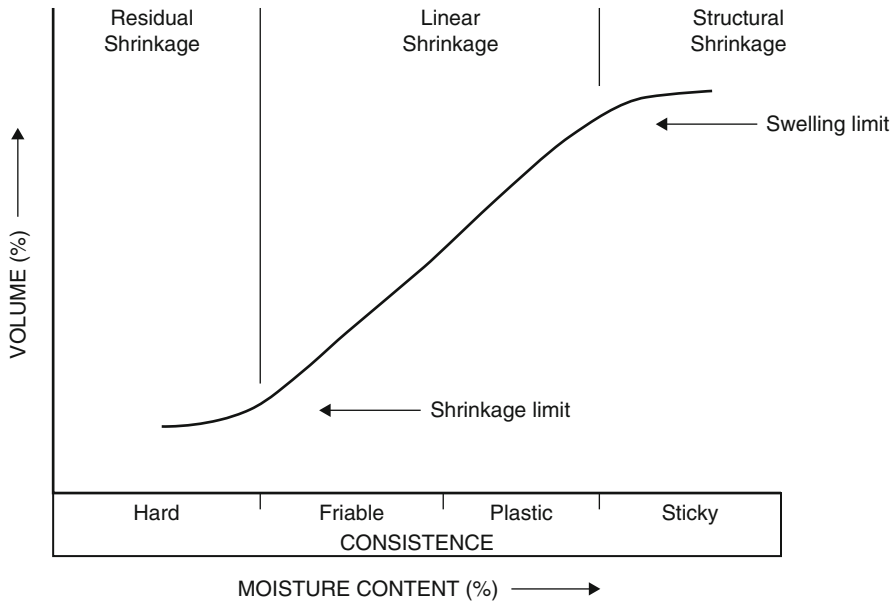
Characterization of expansive soils

Expansive soils are characterized by a number of test parameters and the popular ones are liquid limit (LL), plastic limit (PL), and plasticity index (LL-PL). Skempton (1953) defined activity(A) as the ratio of plasticity index to clay fraction (percent of soil particles finer than 2 μm) and is given as:



$$\text{Activity, A} = \frac{\textit{plasticity index}}{(\% < 2\mu m) - 5}$$

Soils are considered *inactive* if A is less than 0.75, normal for activities between 0.75 and 1.25 and active with values greater than 1.25.



Free swell test is one of the simple swelling tests performed by slowly pouring 10 cm^3 of dry soil, which had passed the No. 40 sieve, into a 100 cm^3 graduated cylinder filled with water, and observing the equilibrium swelled volume. Free swell is defined as:

$$\text{Free swell} = \frac{(\textit{final volume}) - (\textit{initial volume})}{\textit{initial volume}} \times 100(\%)$$

Highly swelling bentonites (Na-montmorillonite) are known to have free swell values of greater than 1,200%.

Expansive Soils and Clays, Figure 1 Schematic representation of soil volume change in an expansive soil (Modified from Coulombe et al., 1996a).

Expansive Soils and Clays, Figure 2 Schematic representation of shrinkage curve and consistence as a function of moisture content (From Coulombe et al., 1996a).

Even soils with free swells of 100% may cause damage to light structures when they become wet and soils with free swells less than 50% have been found to exhibit only small volume changes. The degree of expansion in relation to various soil test parameters is suggested in Table 1.

COLE (Coefficient of Linear Extensibility) is a measure of the change in sample dimension from the moist to dry state and is estimated from the bulk densities of the soil clod at a suction of 33 kPa (BDm) and oven dry moisture conditions (BDd).

$$\text{The value of COLE} = (\text{BDd}/\text{BDm})^{-1/3} - 1$$

COLE, widely used in soil classification, is influenced by clay content and clay mineralogy.

Clay content, nature of clay minerals, CEC, and surface area which are all determined in the laboratory also help to identify expansion in soils. Thomas et al. (2000) developed Expansive Soil Index (ESI) by summing the absolute values of swelling 2:1 minerals, swell index, liquid limit, and CEC.

Potential volume change (PVC), Expansion index (EI), and California bearing ratio (CBR) are other tests performed in soil mechanics laboratories to measure one-dimensional swell, under a surcharge pressure, of compacted remolded soils under varying moisture conditions.

Active zone

Expansion in soils occurs as a result of an increase in water content in the upper few meters from ground surface

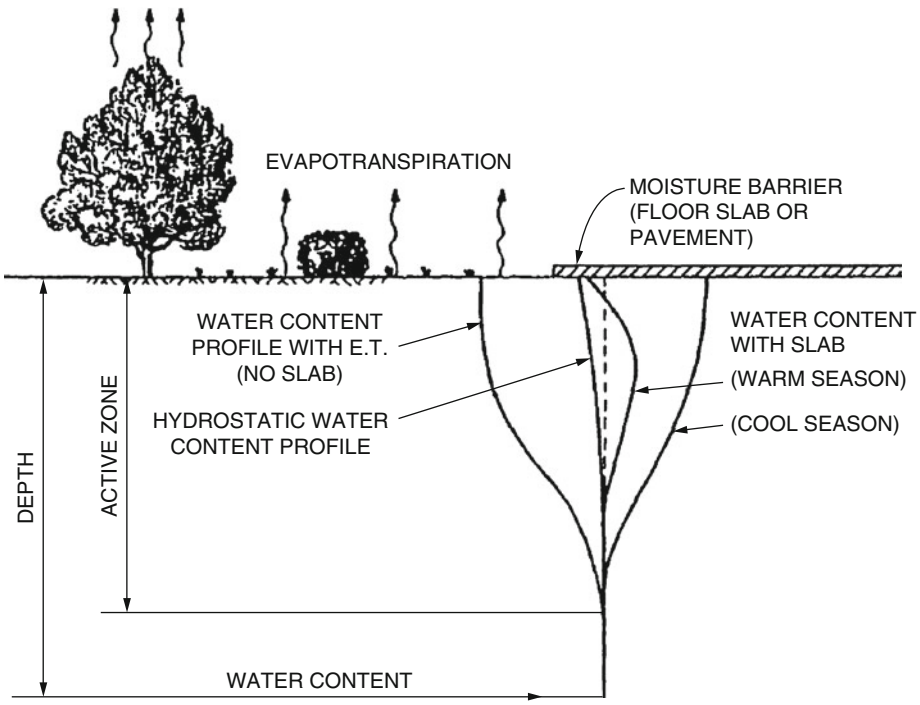
influenced by climatic conditions and environmental factors. The zone affected by seasonal fluctuation of moisture is termed active zone as illustrated in Figure 3.

If the moisture content and/or soil type differs at various locations under the foundation of a structure, localized or nonuniform settlement may occur in the structure. This differential settlement of sections of the structure can cause damage to the foundation and framing, evidenced by cracking of the slab or foundation, cracking in the exterior and/or interior wall covering (indicating movement of the framing) uneven floors and/or misaligned doors and windows (Nelson and Miller, 1992).

A second effect of expansive soils is additional horizontal pressure applied to foundation walls found in basements and crawlspaces. Increased moisture in the soils adjacent to the foundation wall will cause the soils to expand and increase the lateral pressure applied to the foundation wall. If the foundation wall does not have sufficient strength, minor cracking, bowing or movement up to serious structural damage to, or even failure of, the wall may occur. If the soil is located on a slope, the top layer of soil can creep (slow movement) downhill or even cause a landslide.

The depth of surface cracks in expansive soils determine the depth of the active zone in many cases (Picornell and Lytton, 1989). Rainfall and surface runoff can fill these cracks, and the water in the cracks can travel, wherever the crack goes. If the water travels beneath a pavement, it will remain there, soaking into the soil on each side of the crack, and cause swelling. Thus, the depth of the surface cracks determines the depth to which a vertical moisture barrier should be placed in order to control moisture beneath a pavement.

Expansive Soils and Clays, Table 1 Probable expansion as estimated from classification test data



Degree of expansion	Probable expansion as a % of the total volume change	Colloidal content (% < 1 μm)	Plasticity index PI	Shrinkage limit SL
Very high	>30	>28	>35	<11
High	20–30	20–31	25–41	7–12
Medium	10–20	13–23	15–28	10–16
Low	<10	<15	<18	>15

From Holtz and Kovacs (1981)

Solutions

Prior to building a structure, a soil test will assist in determining if the soils are capable of properly supporting the structure. In addition, information on the soil properties can ensure that the foundation is designed to withstand the effects of the existing soil conditions.

For structures already in existence, common preventative solutions include proper soil maintenance such as maintaining a uniform and constant moisture level in the soil. This may involve introducing moisture into the soils continually and uniformly to prevent shrinking; and/or

Expansive Soils and Clays, Figure 3 Figure showing the moisture content in active zone with and without moisture barrier (From Nelson and Miller, 1992).

preventing excessive or isolated saturation of the soil through proper drainage and grading techniques that prevent swelling. For structures affected by expansive soils, further movement can be prevented by providing additional strength and support to the foundation. This may include preventing vertical movement and/or sliding and/or reinforcing of the foundation walls to withstand lateral pressure. Addition of lime, gypsum, sand, and cohesive non-swelling (CNS) material are known to decrease the swelling pressure and are prescribed to mitigate swelling.

Significance of shrinkage and swelling

The effects of shrinkage of expansive soils can be of considerable significance from an engineering point of view. Shrinkage cracks can occur locally when the capillary pressures exceed the cohesion or the tensile strength of the soil. These cracks reduce the overall strength of a soil mass and affect the stability of clay slopes and the bearing capacity of' foundations. The desiccated and cracked dry crust usually found over deposits of soft clay affects the stability of, for example, highway embankments constructed on these deposits. The volume changes resulting from both shrinkage and swelling of fine-grained soils are often large enough to seriously damage small buildings, highway pavements, and canal linings. An ordinary building is believed to weigh about 10 kPa per story. An embankment of 5 or 6 m would be required to prevent all swelling of subgrade with swelling pressures of 100 or 200 kPa (Holtz and Kovacs, 1981).

Summary

Expansive soils are known to cause damage to driveways, floors, and foundations and in monetary terms this damage annually amounts to billions of dollars. Structural, linear, and residual shrinkage are the three distinct stages in soil shrinkage of which linear shrinkage is predominant over a wide moisture range and is directly related to moisture loss. Interparticle and intraparticle porosity is largely considered responsible for the shrink-swell phenomenon in these soils.

Soil characteristics like clay mineralogy and dry density and environmental factors such as moisture content, moisture fluctuation range induced by climate, ground water, and vegetation, and the state of stress are known to influence the shrink-swell potential of the soil. These soils are characterized mainly by liquid limit and plastic limit, clay content, or COLE (Coefficient of Linear Extensibility), a term used in soil classification by USDA. The swell-shrink is limited to what is termed as an active zone in the upper few meters affected by seasonal moisture fluctuations and is related to the depth of surface cracks in these soils. To overcome the hazardous effects due to expansion, a soil test is recommended prior to construction of a structure. Treatment of soil with lime, gypsum, sand, and other non-swelling materials is known to mitigate swelling.

Definition

Natural disaster: Serious disruption triggered by natural hazards (earthquakes, floods, droughts, landslides, volcanoes, tsunamis, wildfires, avalanches, storms, cyclones, and tornadoes) causing human, material, economic, or environmental losses which exceed the ability of those affected to cope (ISDR, 2004).

Disaster management: Systematic management of administrative decisions, organization, operational skills, and abilities to implement policies, strategies, and coping capacities of the society or individuals to lessen the impacts of natural and related environmental and technological hazards (ISDR, 2004).
Expert system: An intelligent computer program that uses knowledge and inferences procedures to solve problems that are difficult enough to require significant human expertise for their solution. The knowledge of an expert system consists of facts and heuristics. The "facts" constitute a body of information that is widely shared, publicly available, and generally agreed upon by experts in the field (Harmon and King, 1985).

Introduction

Throughout the year, the world is subjected to natural hazards of a variety of types, sizes, and impacts. They may be geological hazards such as avalanches, earthquakes or volcanic eruptions, hydrological hazards such as floods or tsunamis, or climatic and atmospheric hazards such as cyclonic storms or tornadoes. Occasionally, they are particularly devastating: the tsunami in Indonesia in December 2004 claimed some 230 000 victims and the earthquake in Haiti in January 2010 may have had a comparable death total with virtual complete destruction of local infrastructures. Disaster management consists in coping with such major crises by planning, arranging, and controlling activities and resources in order to minimize the impact of these inherently uncertain and catastrophic phenomena.

As with any decision situation, disaster management requires one to obtain and use information for decision making. Not only expert systems but also Information systems are therefore essential tools to provide real-time information and help decision at the different crisis and disaster management phases.

Crisis and disaster management phases

Several spatial and temporal steps can be identified in a disaster management (cf. Figure 1):

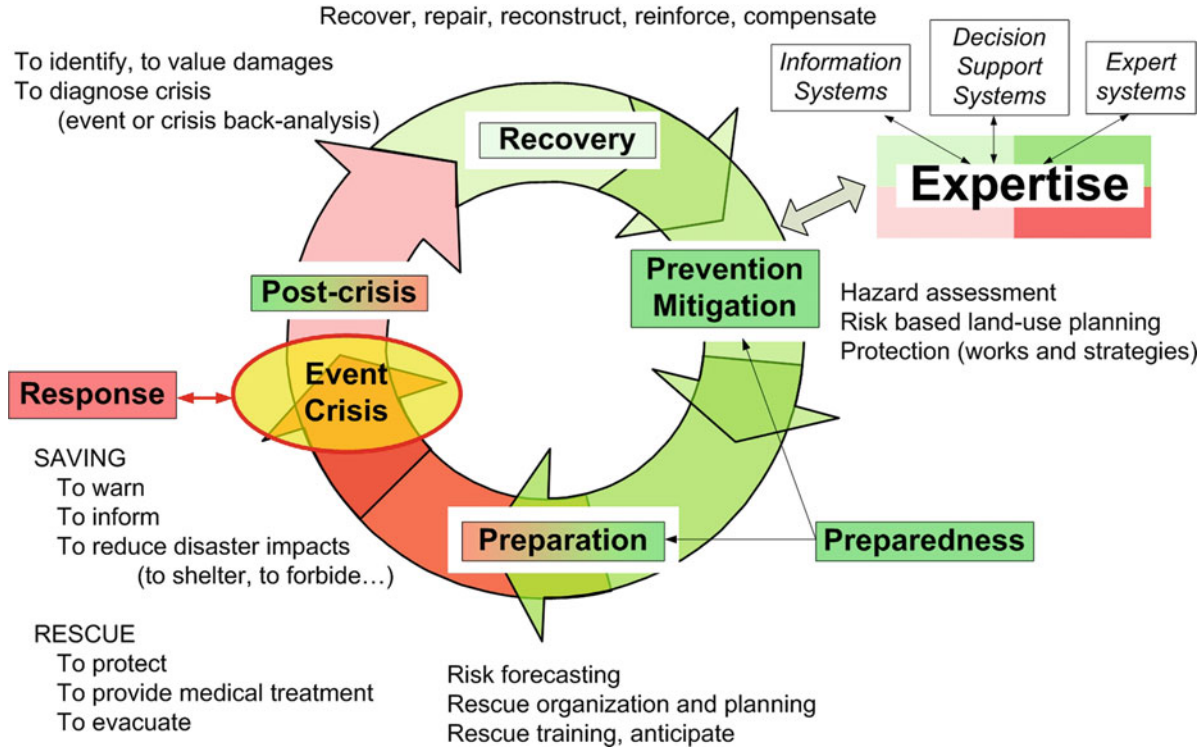
- Crisis management and response consist in taking emergency measures to save and rescue people and infrastructure at risk.
- Recovery is the postcrisis step.
- Prevention and mitigation aim at avoiding damage through structural (protection works) or nonstructural measures (land-use planning).
- Preparation aims at anticipating the crisis through forecasting, rescue training, and resources positioning and inventory.

The management of these different steps involves many different activities and tools (cf. Figure 1). Decision Support Systems (DSS) are developed to help governments and public bodies to manage the impact of natural catastrophes and mitigate (ideally prevent) their disastrous consequences (Wallace and De Balogh, 1985). Some of them are expertise or knowledge based.

Expertise and expert systems for disaster management

Expert knowledge encompasses what qualified individuals know with respect to their technical practices, training, and experience. It is related to an individual and is acquired by studies or practical experience. Expert knowledge can be categorized into "expertise" and "expert judgment." Expertise refers to the tacit thinking processes used in everyday decision making and problem solving. The definition and structure of the problem, its representation and scope, determining relevant information, information organization, and flow through the problem are aspects of the expertise. In contrast, expert judgment, expert estimates, or expert opinion refer to the contents of the problem (Booker and McNamara, 2004).

Expertise is not always clearly described and explained. Knowledge or formal description is an important step for traceability and quality improvement (cf. Figure 2). Expert (or knowledge-based) systems constitute a method to formalize the available knowledge retained by experts. This supposes that knowledge is available.



An expert system or knowledge-based system is able to propose a conclusion through an automated reasoning process. Rule-based systems, which are the oldest systems, consist in a knowledge base, a rule-based inference engine, and a user interface. The knowledge base is set of rules and facts: rules are chained together and executed according to logic statements to provide a solution. In case-based systems, experiences are used instead of rules. New problems are solved through adaptation of old solutions (Bossé et al., 2007). Expert systems are not the only techniques of artificial intelligence techniques, which also include pattern matching algorithms and self-learning systems such as neural networks (Woo, 1999).

Expert systems are very interesting tools but present some limits. In addition to those involved in any software systems, expert system failures result (Bell, 1985) both from:

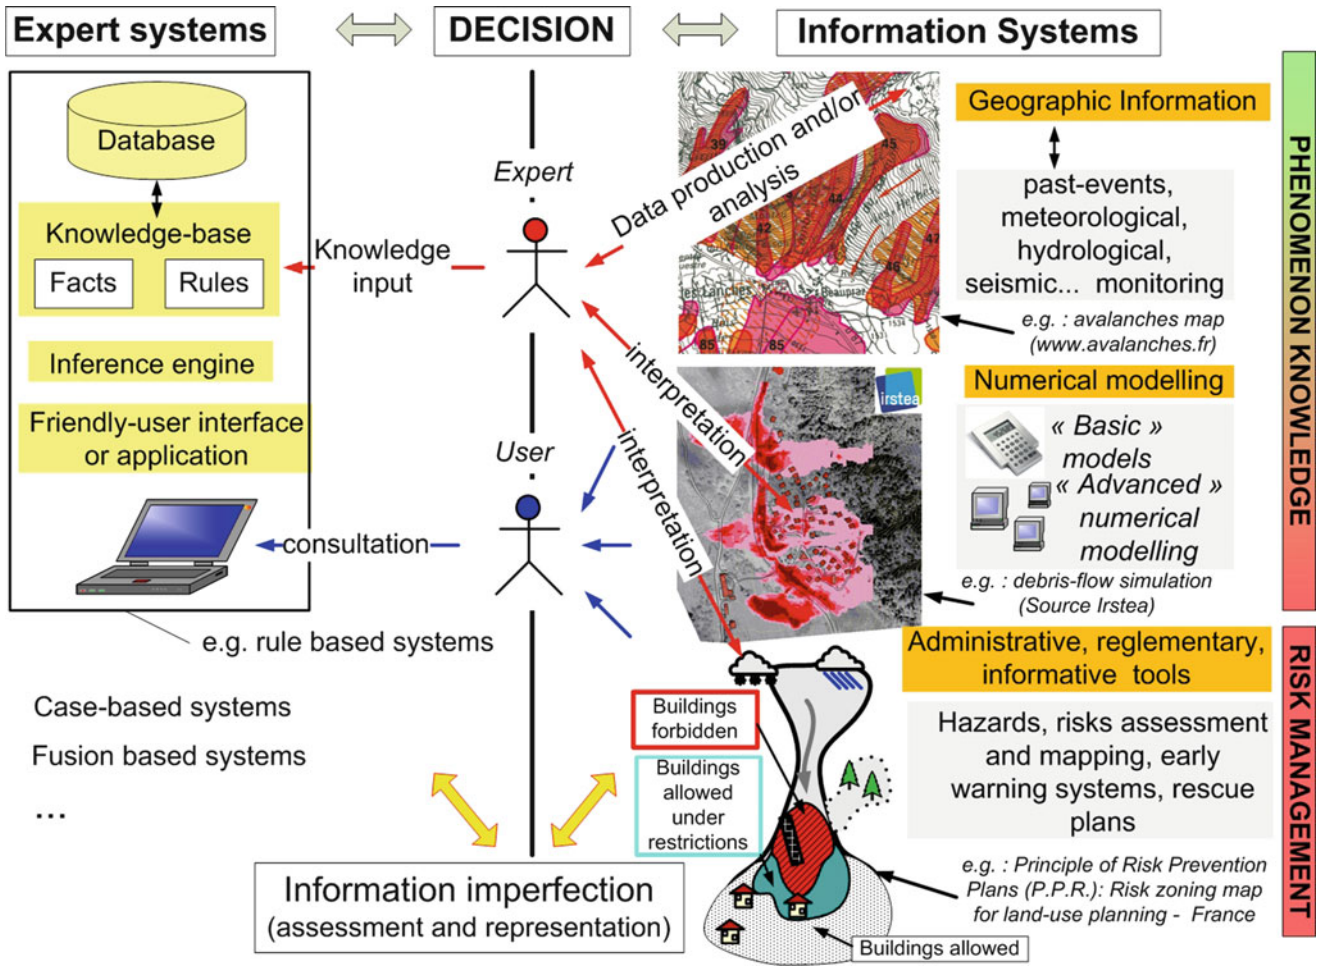
- Lack of knowledge about the problem to solve.
- Lack of awareness from the designers, users about this missing, incomplete, or imperfect knowledge.
- Difficulties or impossibilities to test the systems.
- Lack of confidence from the users due to partial understanding of used rules and reduced traceability of reasoning processes involved in those systems.

From the point of view of disaster management, expert (knowledge-based) systems can concern:

- Prevention:
  - Phenomenon analysis, hazard and risk assessment such as the forecasting of avalanches (Buisson and Charlier (1989); Buisson and Giraud, 1995; McClung, 1995; Naresh and Pant, 1999; Zischg et al., 2005; Singh and Ganju, 2008) or the

Expert (Knowledge-Based) Systems for Disaster Management, Figure 1 Description of main steps of natural hazards and risks management.

landslide-hazard mapping (Muthu and Petrou, 2007; Chmelina and Eichhorn, 2008);
- Land-use planning;
- Protection works (description, design, security, and reliability assessment) such as in the case of floods (Ahmad and Simonovic, 2001) or the design of hazard resistant infrastructures such in the case of earthquake (Syrmakezis and Mikroudis, 1997; Berrais, 2005).



- Crisis: development of an expert system combined with an information system supporting the onsite search and rescue (Schweier and Markus, 2009), early warning and decision (Woo, 1999).
- Recovery: development of an expert system combined with an information system for the evaluation of buildings' states after earthquake (Schweier and Markus, 2009).

Particularities of knowledge-based systems for disaster management

In the context of natural hazards, knowledge and information are often imperfect meaning either incomplete, imprecise, uncertain, inconsistent, or conflicting. Expertise is therefore required to produce phenomenon maps, to interpret numerical modeling results and/or to produce hazards or risk maps (cf. Figure 2). At each step, expertise using and interpreting available information is required to take decisions. Finally, to apply their expertise, experts use different systems including (cf. Figure 2):

- Databases and GIS (Geographical Information Systems)-based information systems. Databases are essential to trace the geography of risk and factors producing hazard and vulnerability (UNDP, 2004). Some expert (or knowledge-based) systems can be coupled with a GIS when spatial representation or decision are needed to produce estimates of hazard-related damage before, or after, a disaster occurs: HAZUS-MH is an example of a methodology for analyzing potential losses from floods, hurricane winds, and earthquakes (FEMA, 2010). Others are linked to information systems.
- Numerical modeling.
- Decision support systems based either on Artificial Intelligence or Multicriteria decision frameworks.
- Expert systems (automatic reasoning applications).

Conversely, Information Systems collect information resulting both from measures, including sensors but also from expert analysis. Therefore, information is not only a simple collection of data but also includes some expert interpretation. For that reason, information systems can often be considered in risk management and for a better disaster management, the classical vision of expert systems should be extended to the information systems used to make decisions (Tacnet et al., 2009).

Expert (Knowledge-Based) Systems for Disaster Management, Figure 2 Expert systems and information produced by experts for risk management.

A typology can be proposed according to the added value:

- Systems corresponding to data collection and provision: information is stored and available when needed. This can be basic information (phenomenon maps, exposed buildings, or infrastructures), preprocessed information (modeling results);
- Systems designed to help and propose solutions through an automated and preprocessed way.

Data are frequently incomplete, outdated, or unusable for a variety of reasons (Guha-Sapir and Below, 2002). Thus, experts are needed to cope with all of these information imperfections and to help with decisions. As a consequence, decision, expertise and imperfect information are closely linked together in the natural hazards context whereas decisions have to be provided quickly. Methods that prevent information overload but also take into account imprecise, uncertain, contradicting expert analysis have to be used in combination with expert systems. Information fusion techniques based on quantitative theories such as fuzzy sets, possibility or evidence theory are particularly interesting to represent imperfect knowledge and take decisions in the case of natural hazards. The older theory developed to deal with uncertainty is the probability theory. Indeed, it cannot always be used because the probability laws are not always known. Moreover, information is often vague, imprecise, or incomplete (Bouchon-Meunier, 1999; Ben Armor and Martel, 2004). This lack of knowledge may stem from a partial lack of data, either because collecting this data is too difficult or costly, or because only experts can provide certain items of imprecise information. In this case, the evidence theory (Dempster, 1967; Shafer, 1976; Smarandache and Dezert, 2004–2009) or the possibility theory (Zadeh, 1965; Zadeh, 1978; Mauris et al., 2000; Baudrit et al., 2004; Dubois, 2006) provide tools that are better adapted to represent imperfections. In the natural hazards context, expertise can be considered as a combination of decisions based on multiple criteria imprecisely evaluated by more or less

conflicting and reliable sources: multicriteria decision analysis and information fusion are combined to help decisions (Tacnet et al., 2009).

Summary and conclusions

In the context of natural hazards, expert systems must be considered in a broader sense than in classical industrial applications due to the role of expert in information production. Information systems and expert systems have an essential contribution to improve the organizations and society resilience (ability to withstand and minimize human and financial losses to natural disasters).

Due to imperfections of knowledge and information, disaster management cannot be operated through the exclusive use of experts systems. Operational Research (OR) and Management Science (MS) can also provide valuable tools to make decisions for disaster management (Altay and Green, 2006).

EXPOSURE TO NATURAL HAZARDS

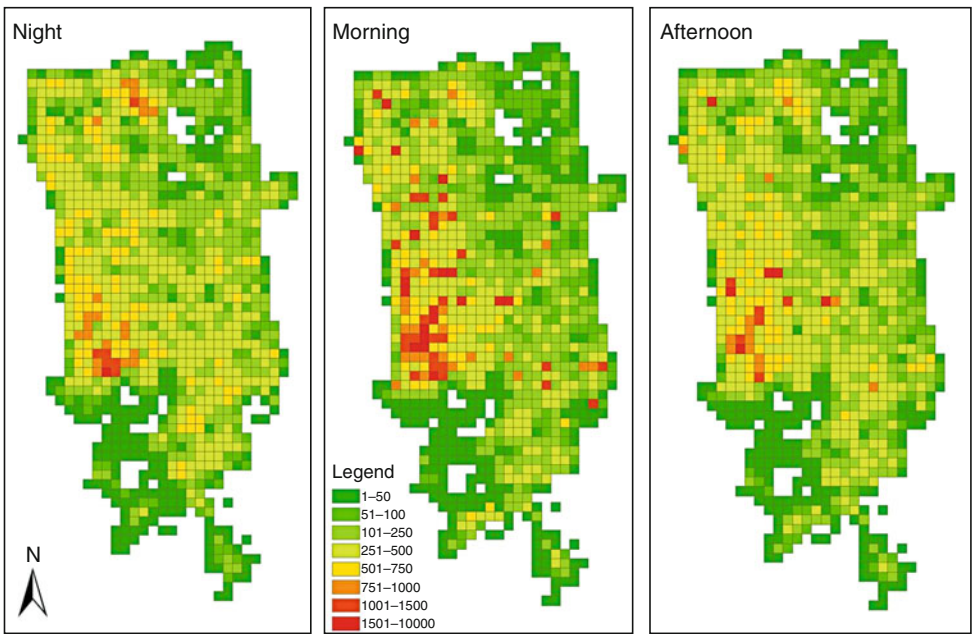
Jörn Birkmann
United Nations University, Bonn, Germany

Synonyms

Elements at risk; Risk inventory

Definition

Exposure encompasses all elements, processes, and subjects that might be affected by a hazardous event. Consequently, exposure is the presence of social, economic, environmental or cultural assets in areas that may be impacted by a hazard.



Overview

Exposure is most commonly understood, in risk and natural hazard research, as the social and material context represented by persons, resources, infrastructure, production, goods, services, and ecosystems that may be affected by a hazardous event. Hence, the term is often used to characterize, in a more general sense, the components of *society* and *environment* and respective processes that are exposed to a specific hazard or a variety of potential hazardous phenomena. That means exposure can further be qualified by focusing on the spatial and temporal patterns of exposure of the element at risk.

Temporal aspects of exposure deal with the questions of when and how long an element at risk might be exposed to a hazard or stressor.

For example, in Indonesia, in coastal communities potentially exposed to tsunami hazards, it is noteworthy that the male population in contrast to female population, children, and elderly (more than 65 years) have a different spatial exposure at different times of the day, related to their respective activities and mobility patterns. Setiadi et al. (2010) analyzed temporal exposure patterns in the coastal city of Padang and found that the more vulnerable population groups (female, children, and elderly) to tsunamis have a different spatiotemporal exposure to potential tsunami risks in the high-risk zone as compared to the male population (see Setiadi et al., 2010; see also Figure 1).

The *spatial dimension of exposure* deals with the question of how much territory is exposed to a certain hazard phenomena as compared to the total territory of the entity exposed such as a community, city, or country. This spatial exposure provides a rough overview of how strongly an exposed entity would be affected. If a coastal storm hits a larger country, recovery processes and losses often remain relatively small, since the level of exposure is low compared to the overall population and values of the country. In contrast, small islands, where nearly 100% of

Exposure to Natural Hazards, Figure 1 Female, elderly, and children concentration by daytime (see Setiadi et al., 2010; Setiadi, 2011).

Exposure to Natural Hazards, Figure 2 Male population concentration by daytime (see Setiadi et al. 2010; Setiadi 2011).

the territory and population is exposed and could be impacted by a storm surge, would, consequently, already be more at risk. Exposure is in some concepts seen as a component of vulnerability and respectively risk, since it contributes in the degree of impacts brought by a hazard event (see Birkmann, 2006).

Risk reduction, in terms of exposure, may encompass different strategies and measures. Spatial and urban planning, for example, can potentially restrict growth of exposure of people and settlements in high-risk zones. In addition, the consideration of temporal and spatial exposure calls for measures, such as the construction of safe places in areas where many people are or will be exposed. Furthermore, awareness and understanding is needed that people might be exposed differently to certain hazards and stressors during different phases of the day. Based on the improved understanding of dynamic exposure patterns, differences between women and men, in terms of spatial exposure could also be used to develop specific awareness, early warning, and preparedness strategies (Figures 1 and 2).

EXTENSOMETERS

Erik Eberhardt
University of British Columbia, Vancouver, BC, Canada

Synonyms

Convergence gauges; Crack gauges; Crackmeters; Distometers; Jointmeters; Sliding micrometers; Strainmeters

Definition

Extensometers are devices used to measure the changing distance between two points. They are commonly used in the monitoring of landslides.

Overview

Measurement points may be located on the surface of a landslide to measure ground movements, for example, spanning a tension crack to monitor its rate of opening, or in a borehole to measure differential displacements at depth, for instance to identify active landslide shear surfaces. Extensometers vary in type between those that involve manual measurements and those that are automated using vibrating wire electronics, differential transducers, or more recently fiber optics. Another variant involves the use of mechanical or electrical probes (i.e., probe extensometers) to monitor changing distances between fixed points with depth along a borehole as determined by the probe position. Measurement accuracy and repeatability depend on the type of sensing device and the distance between the monitoring points. Typical accuracies range from submillimeter to millimeter over distances of less than a meter when using probe extensometers or stiff sliding rods fixed between the monitoring points, to millimeter to centimeter over distances of meters or several tens of meters when extending a flexible tape or wire between the monitoring points.

Extensometers are frequently employed in landslide investigations to determine the active boundaries of the landslide (on the surface and at depth), correlate landslide movements to external environmental factors (e.g., precipitation events), and for early warning of accelerating landslide behavior. Recent examples of their use for landslide hazard investigations include those reported by Corominas et al. (2000), Coe et al. (2003), Willenberg et al. (2008), and Wang et al. (2008).

Species loss

Definition

Complete loss of a species, which occurs when all individuals comprising the species' populations disappear without issue. Loss of one or more (but not all) constituent populations (subspecies) of a species constitutes *extirpation*, since in fact the species still exists and may possibly recover.

Introduction

The *IUCN Red List* (published under various extended titles, now available online at www.iucnredlist.org) has provided a biennial snapshot of the state of the world's biota for more than five decades, with particular attention given to identifying endangered species. The list's purpose is to provide (optimally) the conservation status of every species within a given taxonomic group, rated according to a series of criteria. From its inception, the *Red List* has published compendia of extinct species (and often subspecies), initially relying on expert opinion alone but in recent years moving toward a more transparent and quantitative system of analysis through its network of Species Survival Commission (SSC) Specialist Groups. The current *Red List* (2008) provides status assessments for nearly 45,000 species, some 800 of which are classified as extinct.

Extinction: an overview

More than 99% of all species that have ever lived since organized life first appeared more than 2 billion years ago are now extinct (Eldredge, 1999). One implication of this figure is that extinction is and always has been a ubiquitous feature of life on Earth, which means that extinction is an entirely natural process. Indeed, it is inconceivable that life as we know it could have evolved to its present tremendous complexity were it not for the

fact that species have always come and gone, with the disappeared being succeeded by others having different adaptations, different lifestyles, and different capacities to handle the effects of natural change over time. However, the concern at present is whether humans, with their unprecedented capacity to alter habitats and degrade ecosystems, are now influencing this pattern in a way no other species ever has.

From the standpoint of extinction biology, this pattern has two primary features. Over geologically long periods of time, the vast majority of species losses have tended to occur in clumps (*mass extinctions*), prompted by unusual forcing functions such as the bolide impact 65 million years ago that wiped out non-avian dinosaurs and perhaps as much as 70% of other life. It is also clear from the fossil record that a continuous but relatively low turnover of species, not related to massive episodic losses, is another long-standing feature. This turnover, measured in a variety of ways, can be used to formulate a *background extinction rate* (see below), against which, for example, the much larger rates of loss characteristic of mass extinctions can be compared.

The relevant question from a natural hazards standpoint, of course, is whether the current rate of species loss qualifies as a mass extinction. Many scientists believe that, within the next few centuries, the number of losses will place modern extinctions among the six greatest episodes of extinction of all time (Eldredge, 1999; Vié et al., 2009). This makes an understanding of the biology of extinction one of the critical issues of our time. This entry is devoted to three fundamental questions: what is biological extinction, how is it measured, and how is it caused?

Biological extinction and related concepts

For the sake of simplicity, discussion in this text is framed around the formal categories "extinct" and "possibly extinct" as developed or endorsed by member units of the International Union for the Conservation of Nature (IUCN) (www.iucnredlist.org).

At first glance, determining whether the complete loss of a given species has occurred would appear to be a strictly empirical issue – a species either is, or is not, in existence. However, making realistic, verifiable determinations can be complicated (Diamond, 1989; Butchart et al., 2006). Actual census taking to establish whether any viable populations or individuals persist is often not practicable, for a host of reasons. In the case of well-characterized taxa that are highly visible or "charismatic" (at least to humans), making a plausible inference of complete extinction may be straightforward, as in the case of species formerly numerous in a particular area that are now no longer seen (passenger pigeon scenario). However, a finding of "not seen," even over an appreciable interval such as 50 years may nevertheless be insufficient to conclude that final extinction has actually occurred (MacPhee and Flemming, 1999; MacPhee, 2008). For example, surviving populations may have withdrawn to a new range outside of the census area. Or overlooked individuals may survive in unexpected pockets, so that extreme rarity is misinterpreted as final disappearance (e.g., *Campephilus principali*, ivory-bill woodpecker, possibly surviving in Cuba and Arkansas; Fitzpatrick et al., 2005).

Erroneous claims of extinction are, however, comparatively rare, and little is gained scientifically or by requiring potentially unattainable levels of certainty before declaring a species to be extinct. A typical problem is the difficulty of detecting *cryptic survivorship*, as in the situation in which a few individuals from a severely endangered species, perhaps rarely or never seen, manage to survive in a small part of their original range or at greatly reduced densities. If this possibility seems real in a given case, some other designation such as Birdlife International's (www.birdlife.org) category of *possibly extinct* – species likely to be extinct, but for which there is a small chance that of survival – is much to be preferred over any other.

Some other extinction-related concepts and definitions merit brief mention. A species that is possibly extinct is probably already *functionally extinct*: The taxon is probably no longer a viable entity and may well completely disappear in short order. The concept of *ecologically extinct* is essentially identical: A species whose populations have collapsed down to a few individuals is unlikely to be an effective participant in normal ecological processes in any significant way, and from that standpoint might as well be regarded as nonexistent (Purvis et al., 2000). More problematic is *Extinct in the Wild*, an IUCN status that is assigned to species (or subspecies) which have been so reduced that they survive only in captivity or outside their historic range in very small numbers. This category, however, is semantically confusing because it applies to taxa that are acknowledged not to be completely extinct in any formal sense. While it is doubtless true that very few species currently considered extinct in the wild will ever return to non-managed, natural conditions, there are examples of recovery to normal levels in original habitats even after stupendous losses – once, of course, the agent of loss is removed (e.g., northern elephant seal, *Mirounga angustirostris*; (Hedrick, 1995), reduced to a few tens of individuals by overhunting in the nineteenth century, now returning to pre-seal-hunting levels).

Despite difficulties in application, the concepts just described are useful in conservation education, as they emphasize the close connection between species welfare and population size, structure, and geographic range.

Rates of extinction

Measurement of extinction is conventionally presented in the form of an *extinction rate*. Several rate-estimation methods are currently in use (for an extensive treatment, see papers collected by Lawton and May, 1995).

Paleontological studies reveal that rates have varied widely across space, time, and taxa, even when losses due to mass extinctions are excluded. According to prevailing interpretations of the fossil record, on a per-taxon basis, extinction outside of periods of mass extinction is comparatively rare. However, paleontological evidence is of very uneven quality for many groups, and doubtless many instances of extinction have been missed even for comparatively well-researched groups with extensive fossil records, such as many marine groups and land vertebrates.

Nevertheless, estimates of "normal" or background rates developed using paleontological data have assumed particular prominence in contemporary conservation biology because of the need to provide a baseline for evaluating the severity of the current biodiversity crisis (e.g., Gaston and Spicer, 2004; Pimm et al., 2006). In light of growing human impacts on biodiversity, it is crucial that we find ways to accurately forecast species extinctions in order to minimize biodiversity loss and maintain critical ecosystem functions. From the basic science standpoint, it is important to note that, because forecasted losses have not actually occurred (yet), rate estimates cannot be based on direct counts of the disappeared but depend instead on reasonable proxies for species viability (e.g., likelihood that very small populations will disappear in a specific envelope of years; Caughley and Gunn, 1996). Thus although IUCN currently records only ~80 instances of recent extinction among mammals (1% of total number of assessed species, about 5,500), the model projection is that 1 in 4 species (25%) are threatened to some degree. How many of these threatened species will actually go extinct within the next century or so cannot be known in advance, but the real point is that having some idea of which species are more likely to disappear provides a needed focus for directing mitigation efforts. Much work is now being directed toward establishing better methodologies for using IUCN categories of information (Butchart et al., 2005).

Losses on islands in the last several centuries have been investigated with particular intensity, in part because such contexts often feature (at least for land vertebrates) relatively low population numbers and restricted habitats, two constraints that are widely regarded as factors predisposing species to extinction (MacPhee, 2008). Harrison and Stiassny (1999) have pointed out that freshwater habitats, which for a given species might consist of a single watershed, stream, or lake, function in an island-like manner from a probability-of-extinction standpoint. And indeed, "aquatic islands" account for a large proportion of recent extinctions among all freshwater fishes. In the case of birds and mammals, the correlation between the first arrival of humans, as determined archeologically, and evidence of catastrophic species losses tends to follow a particularly strong pattern of "dreadful syncopation" (MacPhee and Flemming, 1999; MacPhee, 2008): When the humans come, the animals disappear shortly thereafter. On some Pacific islands extinctions of large endemic birds appear to have occurred within a few decades of human colonization (Worthy and Holdaway, 2002), leading in the end to losses that have been conservatively estimated at several hundred species. The endemic mammals of the West Indies were also hit hard, and in similar fashion. Because more than 80% of the land mammals (excluding bats) that lived on these islands during the Holocene (last 10,000 years) are now extinct, the West Indies is not normally thought of as having once had a significant fauna. On most continents with the exception of Australia, mammal and bird losses have not been nearly as severe as island losses during the past 500 years. However, because of forest clear-cutting, rampant urbanization, and ever-higher levels of resource exploitation, many parts of the world – including those with the highest concentrations of biodiversity at the species level – exhibit extensive areas of forest that are beginning to be cut to pieces by exploitation, becoming in the process "virtual islands." There is an immense danger in this; there is probably no single factor more important than contiguous, untransformed habitat in providing for species welfare (Gaston and Spicer, 2004).

Causation of extinctions

Although extinctions may theoretically have many (including multiple) causes, most attention at present is directed toward defining so-called anthropogenic causes. These are too numerous to document here and are individually the subject of much current research: Climate change, invasive species, forest loss, emerging diseases, pollution, and by-catch as causative agents of species declines and extinction are among the topics being most actively investigated at present (www.redlist.org).

A particularly interesting and useful approach is to compare extinctions in particular groups (when possible) across a much longer timeline than is usually the case, for example, the entire Holocene (i.e., the past 10,000 years). The perspective that is gained by these means is to place the last several hundred years in proper perspective (see Turvey, 2009), by revealing periods and places in which extinction rates notably climbed and attempting to account for them with the kinds of sophisticated methods now available. However, this can only be meaningfully done for taxa that leave behind hard tissues (bones, shells) as documents of their former existence. For the vast majority of living things, especially invertebrates, the unseen departed will likely remain among the least documented.

Summary

Biological extinction is a natural process; indeed, the natural loss of species over time needs to be thought of as the complement to, not the antithesis of, the production of new species by natural selection. The objective pattern of life on Earth is that species are continually going extinct, but not in large numbers (at a so-called

background rate). However, mass extinctions, or short periods of greatly enhanced loss, are also part of this pattern. A question for our time is whether species loss rates have surged to such a great degree in the last several hundred years that it is meaningful to identify the modern era as another of these mass extinction events. For more than 50 years, the International Union for the Conservation of Nature (IUCN) has tracked endangerment and loss with increasing sophistication. Although no one can predict the exact form the future will take, there is no doubt that public education efforts are key to conservation efforts, and that the IUCN is in the forefront of organizations performing this essential task.

Università del Salento, Lecce, Italy

Synonyms

Theory of outliers

Definition

The Extreme Value Theory deals with the study of the limiting behavior of nondegenerate probability distributions of vectors of componentwise maxima (or minima) of random variables.

Overview

Extreme Value Theory can be further examined as follows. Since $\min\{X_1, \ldots, X_n\} = -\max\{-X_1, \ldots, -X_n\}$, usually only the laws of maxima are investigated.

Two complementary methods are used to study extremes: the "Blocks" and the "Peaks-Over-Threshold" approach. The former involves a partition of the sample into arbitrary subsets (or *blocks*), and maxima are extracted from the population in each block. The latter requires one to fix an arbitrary high threshold, and only the *excesses* above it are therefore analyzed.

In the univariate case (Coles, 2001), the *Generalized Extreme Value* distribution provides the probability law of the "blocks" maxima, whereas the *Generalized Pareto* distribution models the statistics of the excesses. In the multivariate case, universal laws do not exist. A general representation of a Multivariate Extreme Value distribution F can be given (Salvadori et al., 2007) in terms of its univariate marginals F_i's (which must be Generalized

Extreme Value laws), and a suitable multivariate *copula* (or *dependence function*) C satisfying the Max-Stable property, i.e., $C(u_1^t, \ldots, u_d^t) = C^t(u_1, \ldots, u_d)$ for all $t > 0$ and $u_i \in [0, 1]$. In fact, for all $x_i \in \Re$, it holds $F(x_1, \ldots, x_d) = C(F_1(x_1), \ldots, F_d(x_d))$.

The Extreme Value Theory is a fundamental tool in applications, since it provides the theoretical framework for performing risk assessment and rational decision-making in all areas of geophysics.

CASE STUDY

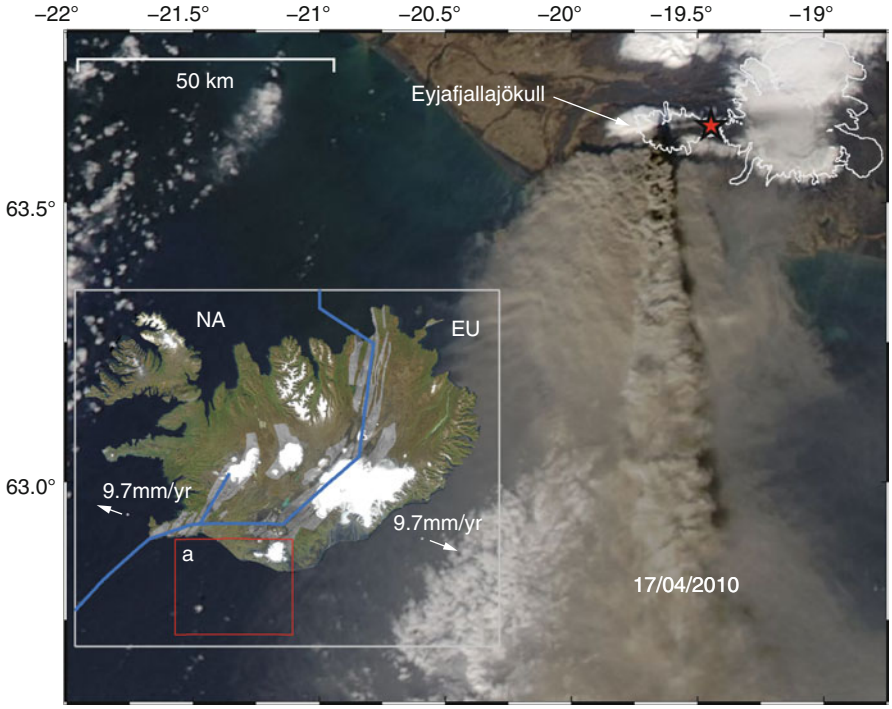
EYJAFJALLAJÖKULL ERUPTIONS 2010

Freysteinn Sigmundsson
Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland

Definition

Eyjafjallajökull. An ice-capped volcano in South Iceland that erupted in 2010 and disrupted air traffic. The ice cap covering the volcano has the same name as the volcano itself.

Eyjafjallajökull eruptions 2010. Two eruptions at Eyjafjallajökull in 2010. An explosive summit eruption beginning 14 April, with sustained activity until 22 May. Ash transported toward mainland Europe led to closure of large part of European airspace for many days, with global disruption of air traffic and economic influence at an unprecedented scale. A preceding effusive eruption occurred 20 March–12 April at the eastern flank of the volcano, in the Fimmvörðuháls area just east of the Eyjafjallajökull ice cap. The effusive eruption is also referred to as the Fimmvörðuháls eruption and the explosive summit eruption as the Eyjafjallajökull eruption of 2010. The two eruptions are also sometimes referred to as a single eruption with different phases of activity.



Introduction

Iceland is a subaerial part of the divergent plate boundary between the North American and Eurasian plates, with over 30 active volcanic systems and eruptions occurring an average every 3–4 years (Thordarson and Larsen, 2007; Sigmundsson, 2006). Basaltic eruptions are common, but explosive eruptions of more evolved magma do also occur. Some of the most active volcanoes are subglacial, leading to generation of eruption plumes due to explosive phreatomagmatic fragmentation of magma even in basaltic eruptions that would, without ice cover in the source area, have generated lava flows. Although the effects of many eruptions in Iceland remain local, there is the potential for widespread influence from long-range transport of ash and gas from Icelandic eruptions. This was the case for the explosive eruption of Eyjafjallajökull volcano that began on 14 April 2010 and directly influenced more people on Earth than any preceding eruption. Advice of the Volcanic Ash Advisory Centre in London (London VAAC) formed the basis for closure of large part of European airspace 15–21 April, leading to cancellation of over 100,000 European flights (Oxford Economics, 2010). Additional airspace closure occurred in early May in a limited area.

Tectonic setting and volcanic unrest

Mt. Eyjafjallajökull (~1,660 m.a.s.l.) is a moderately active ice-capped volcano with eruptive periods producing both tephra (airborne eruptive material) and lava, separated by hundreds of years of dormancy. The volcano is located south of the spreading part of the Eastern Volcanic Zone of Iceland and has a tectonic setting comparable to an intraplate volcano within the Eurasian Plate (Figure 1). The volcano is aligned in an east–west direction, with a shape intermediate between that of a stratovolcano and an elongated shield, with a small summit caldera. Its edifice links to the edifice of the neighboring Katla volcano, one of the most active volcanoes in Iceland that has had ten explosive eruptions breaking through the ice cover of the overlying Mýrdalsjökull since 1500 A.D. (Larsen, 2000; Eliasson et al., 2006). Volcanic hazards due to eruptions at Eyjafjallajökull include tephra fallout and short lava flows, but the main local threats of eruptions of Eyjafjallajökull are jökulhlaups, sudden glacial outburst floods that come swiftly down the slopes of the volcano when eruptions melt their way through overlying ice (Gudmundsson et al., 2008).

Eyjafjallajökull had a prolonged summit eruption 1821–1823, when a short phreatomagmatic phase in December 1821 was followed by a yearlong period of intermittent magmatic/phreatomagmatic activity and flooding (Larsen, 1999). After that, no activity is known at Eyjafjallajökull until unrest began in 1992 with increased seismicity. Intrusive episodes occurred in 1994 and 1999–2000, witnessed as ground deformation and seismicity interpreted in terms of ~$(10–30) \times 10^6$ m^3 sill intrusions at 4.5–6.5 km depth (Sigmundsson et al., 2010;

Eyjafjallajökull Eruptions 2010, Figure 1 Satellite image (MODIS) of the eruption plume emanating from Eyjafjallajökull main crater on 17 April 2010. Outline of ice caps shown with *gray line*. *Red star*, location of the preceding flank eruption. *Inset*, satellite image of Iceland overlain by fissure swarms in rift zones (*shaded grey*) and showing schematically in *blue* the main axes of the plate boundary between the North American (*NA*) and Eurasian (*EU*) plates. Half-spreading rate is 9.7 mm/year. (Modified from Sigmundsson et al., 2010). The MODIS image is courtesy of NASA/GSFC, MODIS Rapid Response (http://rapidfire.sci.gsfc.nasa.gov/).

Hjaltadóttir et al., 2009; Pedersen and Sigmundsson, 2004, 2006; Sturkell et al., 2003, 2010; Hooper et al., 2009). A peak in seismicity occurred also in 1996, without observed deformation. After 2000, no deformation was detected until mid-2009, when a period of elevated seismic activity was associated with 10–12-mm displacement at a continuously recording GPS geodetic station at the base of the volcano, related to minor intrusive activity.

Activity in 2010

In January 2010, deformation and elevated seismicity indicated the beginning of a new intrusive episode in the roots of Eyjafjallajökull that escalated until 20 March when an eruptive fissure opened at the eastern slopes of the volcano. The unrest signals were stronger than in the earlier intrusion periods, in particular in the last 3 weeks preceding the flank eruption, with more than 100 earthquakes recorded on some days and observed deformation rates of more than 5 mm/day. The deformation was well mapped with both GPS geodesy and InSAR (interferometric analysis of satellite synthetic aperture radar images). Interpretation of these data suggests evolution of a complicated intrusion in the volcano roots, with magma flow rates into the intrusion of 30–40 m^3/s after 4 March (Sigmundsson et al., 2010). Detailed seismic studies also reveal the evolution of the intrusive complex (Hjaltadottir and Vogfjord, 2010; Tarasewicz et al., 2012). The eruptive activity that began on 20 March ended 18 years of intermittent precursory activity of the volcano, associated with main intrusions formed in 1994 and 1999 in addition to the 2010 intrusion that evolved in the volcano roots for 3 months prior to delivering magma toward the surface.

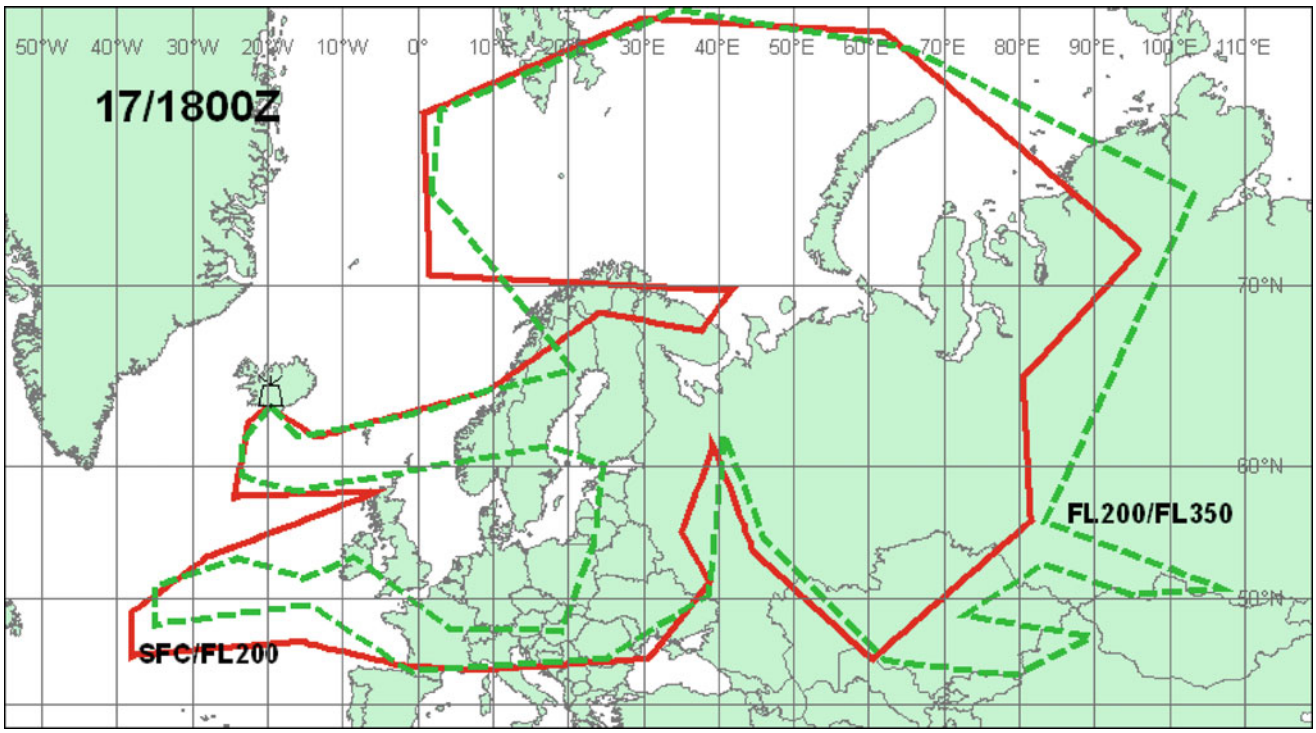
From 20 March to 12 April, an effusive basaltic eruption at a short fissure complex at the eastern flank of the Eyjafjallajökull, just east of the ice cap, produced ~0.02-km^3 lava field (Edwards et al., 2012; Eyjólfur Magnússon, personal communication, 2012) (Figure 2). Activity on a short eruptive fissure focused quickly onto several craters; in early May, another short fissure opened up directly northwest of the initial one. During this eruption, lava flowed toward north into steep canyons producing lava falls and steam plumes originating at the lava fronts, as the advancing lava melted snow. Plume originating at the eruptive craters, and tephra produced, was miniscule. The volcano practically stopped deforming during this eruption, signifying magma drainage from a large depth through the intrusive complex formed in the preceding months, rather than draining and collapse of the intrusive complex (Sigmundsson et al., 2010). When the eruptive fissure opened in late evening of 20 March, the earthquake activity had been declining and the onset of eruption tremor was very gradual. Seismic signals of the immediate precursors in the preceding few hours and the

Eyjafjallajökull Eruptions 2010, Figure 2 The Eyjafjallajökull flank eruption during its later stages in early April 2010 (Photo: Freysteinn Sigmundsson.).

eruption beginning were so minor that the exact timing of the eruption was not forecast; the eruption was visually confirmed before it was recognized on instrument recordings. The eruption attracted a large crowd of tourists who enjoyed spectacular lava fountaining at close distance, as well as the lava falls into canyons. Lava expelled during the eruption is olivine- and plagioclase-bearing mildly alkali basalt with SiO_2 content about 46 wt% (Sigmarsson et al., 2011; Moune et al., 2012).

In late evening of 13 April, seismic activity renewed, this time under the ice-capped summit, signified new propagation of magma toward the surface (Tarasewicz et al., 2012). At about 1:30 h on 14 April, a new eruption broke out at the ice-capped summit of Eyjafjallajökull, with initial phase of the eruption (few hours) being fully subglacial. Ice cauldrons melted by heat of eruptive products, creating floods of meltwater rushing down the slopes of the volcano in jökulhlaups. The catastrophic explosive phase of the eruption began when the eruption had melted its way through the overlying ice cap. A complete cloud cover hindered initially visual observations in the summit region, but airborne SAR instrument on board an airplane of the Icelandic Coast Guard allowed mapping of the development of the ice cauldrons.

The height of the eruption plume was monitored throughout the eruption with weather radar at the Keflavik airport, at a distance of 155 km (Arason et al., 2011), as well as web cameras, and visual evaluations from ground and overview flights. The eruption was highly explosive on 14–18 April and again after 4 May, with



Eyjafjallajökull Eruptions 2010, Figure 3 The Eyjafjallajökull explosive eruption on 17 April 2010 (Photo: Eyjólfur Magnússon.).

a 5–10-km-high eruption plume (Figure 3). In the intervening interval, the plume was mostly below 5 km height. During that interval, a narrow lava stream flowed northward from the crater area, at the Gígjökull outlet glacier. It produced a massive white steam plume due to ice melt, in addition to the ash-loaded eruption plume. Westerly and northerly winds prevailed during most of the eruption (Petersen et al., 2012), carrying ash quickly toward mainland Europe (Prata and Prata, 2012). The latter explosive phase followed renewed flow of basaltic magma from depth into the volcano as witnessed by seismicity and deformation. Intense ash fallout occurred in some inhabited areas in south Iceland both in the initial as well as the latter explosive phase of the eruption, associated with total darkness during the periods of most intense tephra fall.

This eruption was the first in Iceland to be monitored with web cameras. They provided valuable timely information on pulsating activity of the plume and allowed the general population easy access to monitor the progress of the eruption. A number of other techniques were also used for the first time to monitor Icelandic eruptive activity, including acoustic observations of infrasound and lidar measurements of the arrival of the ash cloud in Europe.

Magma erupted during the summit eruption was benmoreitic to trachytic in composition with SiO_2 content in the range of 55–61 wt% (Sigmarsson et al., 2011). This silicic magma was mingled with basalt, revealed by a variety of basaltic, intermediate, and silicic glass in the eruption fallout. The geochemical studies thus show that the summit eruption was triggered by injection of basalt into silicic magma. This was also suggested by Sigmundsson et al. (2010) based on the pattern of deformation associated with the eruptions and intrusions. The deflation source associated with the explosive eruption under the summit of the volcano had not inflated during the preceding unrest. Rather, the recharging of the volcano was associated with inflow of basaltic magma under its eastern flank into an intrusive complex that later started to "leak" magma toward the surface in the flank eruption. The meeting of the two different magmas, silicic magma residing under the summit area and newly arrived basaltic magma, was a key feature triggering the summit eruption.

Ash generated in the explosive eruption was unusually fine grained, fragmented by two processes. Purely brittle magmatic fragmentation due to gas exsolution in the eruption conduit occurred throughout the eruption. This fragmentation process was augmented by fragmentation due to magma-water interaction at least in the initial phase of the eruption; the eruption plume was rich in water vapor during the initial explosive phase but dry during the later one (Dellino et al., 2012). A study using nanotechniques demonstrated that ash particles from the initial explosive phase were especially sharp and abrasive over their entire size range from submillimeter to tens of nanometers

Eyjafjallajökull Eruptions 2010, Figure 4 Graphical display of volcanic ash advisory on 17 April 2010 at 18:00 GMT from the London VAAC. *Red and green outlines* delimit airspace with predicted contamination of ash. *Red outline* from the Earth's surface to flight levels (FL) 200, corresponding to about 20,000 ft. *Dashed line* for FL200-350, or from about 20,000 to 35,000 ft.

(Gislason et al., 2011). Long-range ash transport was facilitated by the fine-grained ash, but aggregation of ash particles was an important process contributing to the fallout (Taddeucci et al., 2011). The amount of erupted material during the summit eruption is estimated to corresponding to dense rock equivalent of 0.18 ± 0.05 km^3 (Gudmundsson et al., submitted manuscript).

Eruption response and impact

Monitoring of eruptive activity was led by the Icelandic Meteorological Office and the Institute of Earth Sciences at University of Iceland (Gudmundsson et al., 2010) that provided advice to civil protection authorities. A National Crisis Coordination Centre operated by Icelandic civil protection authorities, hosted by the National Commissioner of the Icelandic Police, coordinated communication with the public, local, national, and international authorities; scientists; and the media and was the hub for emergency operations. Good response plans were in place at a local level because of prior evaluation of the volcanic hazards and training of population in the area. During the 2010 eruptions, the area surrounding the volcano was temporarily evacuated for short periods during times of uncertain development of eruptive activity and jökulhlaups.

The catastrophic effect of the explosive eruption was the closure of large part of European airspace for many days, based on the guidance of the International Civil Aviation Organization (ICAO) that ash in the atmosphere should be avoided by aircraft. Information on eruption plume height, translated into estimates of mass eruption rate using an empirical relation, was used by the London VAAC to run models of transport and dispersion of the eruption cloud that formed the basis for their advisories of regions where ash was forecasted to be present (Webster et al., 2012). With this approach, a large part of European airspace became closed (Figure 4). During the eruption, a revised procedure was, however, agreed on in Europe, allowing aircraft to fly within the predicted volcanic ash cloud in regions with low levels of ash. The new limits are organized into three levels with a "no fly" high contamination zone for concentrations greater than 4 mg/m^3 (see, e.g., London VAAC, 2011; Hooper et al., in press). These zones apply in European airspace and have not been accepted for global use. These new rules imply that ash concentrations can both be measured, e.g., by using multispectral satellite measurements (Prata and Prata, 2012) and forecast, a major challenge for the response to future volcanic eruptions.

Definitions

Fault – a tectonic fracture in the earth's crust along which displacement (horizontal, vertical, or diagonal) of one side relative to the other has taken place. The fracture may be either a discrete plane or a zone containing multiple fracture planes. Cumulative displacement may be measurable from millimeters to kilometers.

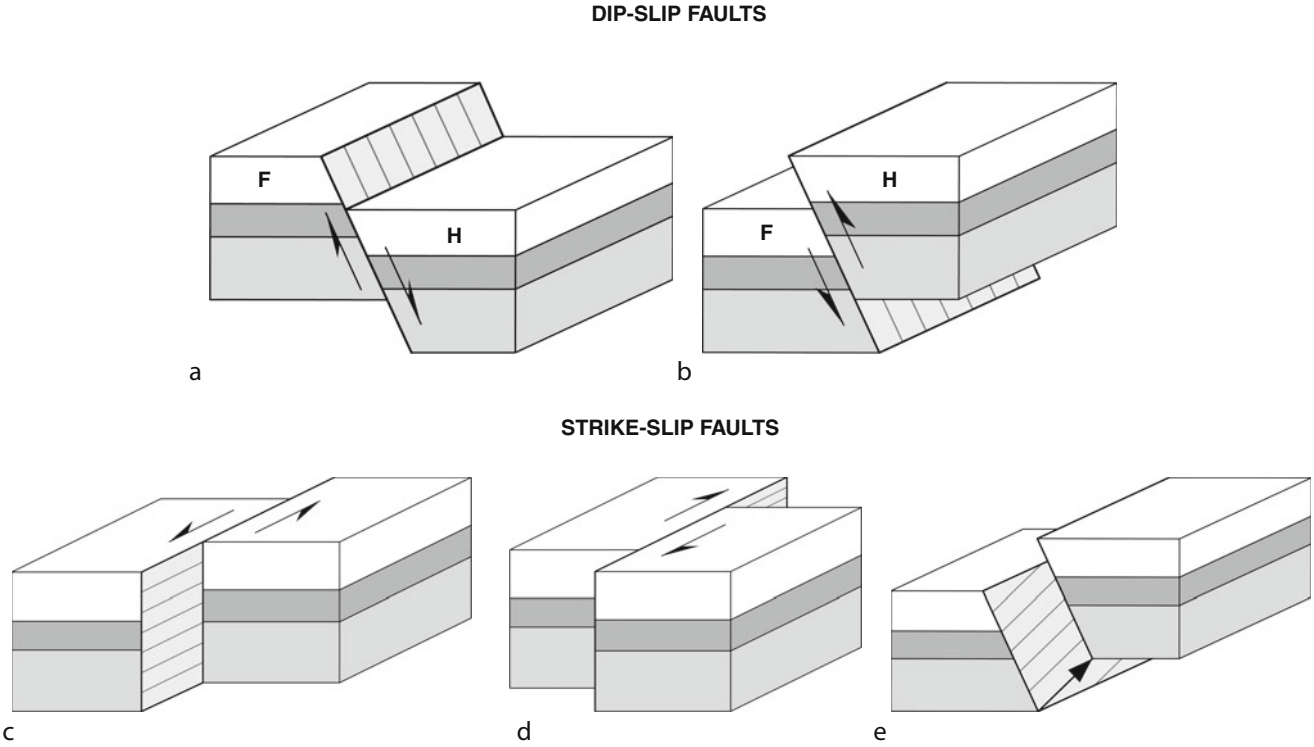
Slip – distance, measured on the fault plane, between two originally adjacent points situated on opposite sides of the fault. It would be represented by a straight line on the fault plane connecting these two points after displacement.

Introduction

The word fault was derived from a late eighteenth-century mining term used to describe a surface, or plane, across which coal layers were displaced (Twiss and Moores, 1992). Realization that sudden displacement along a fault produces earthquakes evolved from observations of four large events that ruptured the ground surface in the late nineteenth and early twentieth centuries: the 1888 Marlborough (New Zealand), 1891 Nobi (Japan), 1892 Tapanuli (Indonesia); and 1906 San Francisco (California) earthquakes (Yeats et al., 1997). Earthquakes are the dominant natural hazard associated with faults. Although strong ground shaking accounts for the vast majority of potential damage from earthquakes, significant damage to structures and infrastructure can result when the rupture of a fault at depth extends to and offsets the ground surface. Surface displacement can also disrupt drainage patterns, such as by damming streams, with resultant flooding and/or catastrophic breaching. Rapid uplift of the seafloor resulting from surface fault rupture is one of the ways seismic sea waves, or tsunamis, are formed.

Types of faults

Faults can be recognized by the juxtaposition of dissimilar rock types across a generally planar surface exhibiting textures and structures characteristically produced by shearing. A fault plane can be vertical, or inclined at an angle (dip) less than 90°. Dip is the acute angle between the fault plane and a horizontal surface. High-angle faults dip greater than 45°; low-angle faults dip less than 45°. Faults are classified according to the direction the bounding crustal blocks have been displaced parallel to the fault plane (Figure 1a–e). Dip-slip displacement is vertical movement oriented parallel to the dip of the fault plane. Horizontal offset parallel to the fault plane is known as strike-slip displacement. Oblique-slip faults will have components of both dip-slip and strike-slip displacement.



Dip-slip faults

Relative movement of crustal blocks bounding a fault plane determines whether a dip-slip fault is described as normal or reverse. The hanging wall is the structurally upper block bounding a dipping fault; the structurally lower block is the footwall. If the hanging wall has been displaced down relative to the footwall, the fault is considered a normal fault (Figure 1a). A reverse fault has the opposite sense of displacement: The hanging wall has moved up relative to the footwall (Figure 1b).

Normal faults

Normal faults generally form in response to extension of the earth's crust, and are found in regions such as oceanic

Fault, Figure 1 *Block* diagrams showing types of fault displacement. *Arrows* indicate direction of movement; *H* hanging wall, *F* footwall. Striations, or slickensides, on the fault plane generally denote direction of last displacement. (**a**) normal fault; (**b**) reverse fault; (**c**) left-lateral (sinistral) fault; (**d**) right-lateral (dextral) fault; (**e**) oblique-slip (sinistral-reverse) fault.

spreading centers and continental rift zones. The maximum principal stress axis (σ_1) is vertical and the minimum stress axis (σ_3) is horizontal. Although normal faults typically are steeply dipping (50°–70°), the dip angle of some normal faults decreases with increasing depth below the earth's surface (listric faults or low-angle detachment faults). Some earthquakes have been associated with low-angle normal faults, but there is still debate within the geologic community whether listric faults commonly produce earthquakes (Yeats et al., 1997; McCalpin, 1996). Normal faults vertically offset the ground surface and commonly are delineated by cliff-like features referred to as scarps. Examples of earthquakes produced by normal faults are listed in Table 1.

Reverse faults

Reverse faults are the result of compressive forces where the maximum compressive stress axis (σ_1, typically perpendicular to the fault's strike) is horizontal and the minimum compressive stress axis (σ_3) is vertical. Thrust faults are a subset of reverse faults where the fault plane dips less than 45°. Convergent plate margins (subduction zones and continent-continent collision zones) are the most significant and widespread compressional tectonic environments. Most major earthquakes have occurred along these convergent plate margins, contributing about 90% of the total energy released by earthquakes (seismic moment) in the twentieth century (Pacheco and Sykes, 1992). The devastating 2004 Mw 9.2 Sumatra-Andaman earthquake, and associated Indian Ocean tsunami, were the result of displacement along a 1,600-km section of the Sunda Megathrust Fault, an east-dipping subduction zone. The Himalayan Frontal Fault System is the locus of uplift of the massive Himalayan block resulting from the collision of the Indian and Eurasian plates (Nakata, 1989) (see Table 1 for selected reverse fault earthquakes). Surface traces of reverse faults typically are highly complex, irregular, and often are difficult to detect. This is especially true of thrust faults, which may form complex fault scarps, surface folding, and warping. Gordon and Lewis (1980) documented examples of variations in thrust fault scarp morphology.

Blind thrust faults

The blind thrust fault is a low-angle structure recognized as a significant seismic source in areas of active folding, including parts of Taiwan, Iran, Argentina, India, Algeria, and California (Stein and Yeats, 1989). The upper extent of the fault plane may terminate several kilometers below the ground surface. Surface expression of a blind thrust fault often is delineated by young folded terrain. Displacement along a blind thrust fault can deform overlying strata

Fault, Table 1 Representative historical earthquakes with surface faulting. Slip types: *RL* right-lateral, *LL* left-lateral, *R* reverse, *N* normal. Number in parentheses in Maximum displacement column is average displacement

Date and earthquake name	Fault	Slip type	Magnitude	Maximum displacement (m)	Surface rupture length (km)	Reference
1959 Hebgen Lake, Montana	Red Canyon, Hebgen	N	Ms 7.6	5.4 (2.5)	25	Myers and Hamilton (1964)

1980 El Asnam, Algeria	El Asnam	R	Ms 7.3	6.5 (1.5)	31	Philip and Meghraoui (1983)
1999 Chi Chi, Taiwan	Chelungpu	R	Mw 7.6	12.7 (3.5)	72	Lin et al. (2001)
1857 Fort Tejon, California	San Andreas	RL	Ms ~8.3	9.1 (4.7)	360	Sieh (1978)
1920 Haiyuan, China	Haiyuan	LL	Ms 8.5	10 (7.3)	220	Zhang et al. (1987)

in a number of ways, including fault-bend folds and fault propagation folds (Suppe, 1985). Recent blind thrust fault earthquakes include the 1983 Mw 6.4 Coalinga, California earthquake, and the 1994 Mw 6.7 Northridge, California earthquake.

Strike-slip faults

Strike-slip displacement results from a horizontal maximum compressive axis (σ_1) oriented at an acute angle to the fault's strike, vertical intermediate compressive stress axis (σ_2), and minimum compressive stress axis (σ_3) oblique to the fault's strike. By convention, a strike-slip fault exhibits left-lateral, or sinistral, displacement if the crustal block opposite the block on which an observer stands is offset to the observer's left (Figure 1c). A right-lateral, or dextral, offset occurs when the opposite crustal block is displaced to the observer's right (Figure 1d). Strike-slip faults often are the longest faults on continental landmasses, extending for hundreds to thousands of kilometers, and usually are delineated by prominent geomorphic expression (Weldon et al., 1996). Because strike-slip faults have steep to vertical dips, their surface trace is relatively straight, even through high-relief topography. Some of the most hazardous strike-slip faults form transform plate boundaries, such as the San Andreas Fault in California and the Alpine Fault in New Zealand. Table 1 lists representative strike-slip fault earthquakes.

Fault creep

Displacement that occurs in the uppermost part of the earth's crust without the occurrence of large earthquakes is known as fault creep. Fault creep was first recognized on the central part of the San Andreas Fault at a winery about 17 km south of San Juan Bautista, California (Tocher, 1960). Additional strike-slip faults of the San Andreas Fault System (Hayward, Calaveras, Concord-Green Valley, Maacama faults), the North Anatolian Fault in Turkey, and some reverse faults, such as the Buena Vista Thrust in central California and the Chihshang Fault in the Longitudinal Valley of eastern Taiwan, also exhibit fault creep. Displacement due to fault creep can be steady state, episodic, or episodic with steady-state background. Of critical importance is whether fault creep extends down along the entire fault plane, or whether the fault is locked below a certain depth. A fault that is locked through most of the seismogenic zone (typically 10–20 km below earth's surface) will be able to store seismic moment at a much faster rate, and can be more hazardous than a fault that slips freely from the surface to the base of the seismogenic zone. Some faults, such as the Hayward Fault in California, produce both fault creep and large earthquakes.

Active fault

The definition of "active fault" usually implies likelihood of future displacement that would constitute a geologic hazard. Wallace (1986) introduced the term "active tectonics" to denote "tectonic movements that are expected to occur within a future time span of concern to society." Most definitions of active fault have legal significance and vary according to the type of structure and the degree of acceptable risk. Jennings (1985) discusses the various definitions of active faults.

Seismic hazard assessment

The behavior of faults must be characterized in order to understand and mitigate earthquake hazard. Specific fault characteristics to consider include fault geometry (length, slip type, and dip), slip rate, recurrence interval of significant earthquakes, age of most recent event, and maximum earthquake magnitude (typically inferred from amount of displacement per event and expected rupture area of the fault). Slip rate is the displacement on a fault averaged over a time period usually involving several large earthquakes, and is typically expressed in millimeters per year. Recurrence interval is the elapsed time between earthquakes within a given magnitude range and can be measured by identifying geologic evidence of past seismic events (paleoseismology), or estimated using a fault's slip rate and expected slip per event. Ideally, paleoseismic investigations of faults can reveal the fault's geometry,

slip rate, recurrence interval (and dates of past earthquakes, including the most recent event), and amount of displacement during past earthquakes. Realistically, these data often are difficult to obtain and it is extremely unlikely, if not impossible, to obtain all of this information at an individual study site. The difficulty of characterizing blind thrust faults is much greater than surface faults due to the concealed nature of this type of fault.

Designing buildings to withstand surface fault rupture is particularly challenging and generally not cost effective. Mitigation of surface fault rupture over the past several decades has been by avoiding the placement of buildings across faults that have potential for surface rupture. California enacted the Alquist-Priolo Earthquake Fault Zoning Act in 1972 following the destructive 1971 Mw 6.6 San Fernando earthquake (Bryant and Hart, 2007). This law prohibits constructing most buildings for human occupancy across active fault traces (faults with evidence of surface offset in the last 11,000 years). Nevada (Nevada Earthquake Safety Council, 1998), Utah (Christenson et al., 2003), and New Zealand (Kerr et al., 2003) have developed similar guidelines for mitigating the hazard of surface faulting.

Summary

Understanding faults was one of the earlier concerns of applied geology that originated from the practical problem of tracing coal beds. During the nineteenth century, geologists recognized a correlation between large earthquakes and ground displacement caused by faults. The question of whether earthquakes produced faults, or faults caused earthquakes, was answered following the 1906 San Francisco earthquake. Investigation of faults remains an important task for geologists in order to better understand and quantify seismic hazards caused by sudden, catastrophic fault displacement. In the past 20 years several countries, including the United States (Machette et al., 2004), New Zealand (GNS Science, 2010), Italy (Basili et al., 2008), and Japan (AFRC, 2009), have compiled databases of essential fault parameters necessary for seismic hazard assessment. These databases are useful not only for cataloging data that can be used in earthquake forecast models, but also to quantify what geologists and seismologists know and do not know about potential seismic sources. This information can be used to better direct future paleoseismology research to address the uncertainties of critical seismic source parameters such as slip rate, timing of past earthquakes, and expected earthquake magnitude. Geologists also need to continue to develop geomorphic and stratigraphic models for active folds in order to better describe paleoearthquakes on blind thrust faults (McCalpin, 2009).

FEDERAL EMERGENCY MANAGEMENT AGENCY (FEMA)

Vincent R. Parisi
Park Ridge, IL, USA

Definition

The Federal Emergency Management Agency (FEMA) is part of the U.S. Department of Homeland Security (DHS) and coordinates response and recovery to disasters that occur in the USA and its territories. FEMA's mission is to support citizens and first responders to build, sustain, and improve capabilities to prepare for, protect against, respond to, recover from, and mitigate all hazards.

In 1979, FEMA was established by an executive order that merged many separate disaster-related responsibilities into a single agency, and on March 1, 2003, FEMA became part of the DHS. As of December 2009, FEMA has responded to more than 2,900 presidentially declared disasters. FEMA has more than 3,700 full time employees and over 4,000 on-call employees available to support disaster field operations. FEMA headquarters are located in Washington, D.C., with ten regional offices across the country (see Figure 1).

FEMA coordinates federal response and recovery efforts to disasters under the Robert T. Stafford Disaster Relief and Emergency Assistance Act (Robert T. Stafford Disaster Relief and Emergency Assistance Act, as amended, and

Federal Emergency Management Agency (FEMA), Figure 1 Regional office map.

Related Authorities as of June 2007). Once the President declares a major disaster, FEMA is authorized to provide disaster assistance and works in partnership with state and local emergency management agencies, numerous federal agencies, and the American Red Cross. FEMA provides assistance to individuals through grants for temporary housing and repair assistance when losses are not covered by insurance or other aid programs (Disaster Assistance Available from FEMA). FEMA also provides grant assistance to state, local, and tribal governments that is used to repair or rebuild public facilities damaged or destroyed by a disaster and to pay for debris removal and other emergency services (FEMA: Public Assistance Grant Program).

FEMA's other responsibilities include:

- Incident Management – FEMA works to respond swiftly and decisively to all hazards with around-the-clock support. The agency continues to professionalize its workforce by training and certifying staff in emergency management skills and techniques. FEMA also works closely with external partners to improve and update standards, and support the efforts of first responders (http://www.fema.gov/emergency/nims/index.shtm).
- Operational Planning – FEMA's Operational Planners assist state, local, and tribal jurisdictions with developing planning capabilities as well as write area- and incident-specific operational plans that will guide local response activities (FEMA: Plan).
- Integrated Preparedness – FEMA works closely with federal, tribal, state, and local governments; voluntary agencies; private sector partners; and the public to ensure the nation is prepared to respond to and recover from terror attacks, major disasters, and other emergencies. Preparedness information and tips can be found online at www.ready.gov.
- Hazard Mitigation – FEMA works proactively to reduce the physical and financial impact of future disasters through improved risk analysis and hazard mitigation planning, risk reduction, and flood insurance. FEMA helps implement effective hazard mitigation practices in order to create safer communities, promote rapid recovery from disasters, and reduce the financial impact at the federal, tribal, state, and local levels. Information about FEMA's mitigation efforts can be found online at www.fema.gov/government/mitigation.shtm.

FETCH

Norm Catto
Memorial University, St. John's, NL, Canada

Synonyms

Fetch length

Definition

Fetch is the linear distance of open, unobstructed water lying beneath a wind traveling with a constant direction.

Overview

Fetch is calculated by measuring the distance from a point across open water of suitable depth for allowing wave travel, unobstructed by land masses including islands and shallow banks. Fetch is directional, and hence should include both a distance and orientation. Commonly, the fetch specified for a port is the maximum open water distance associated with a prevailing wind direction.

The fetch length is directly related to the height of waves, which can be generated by wind. Formation of waves requires the wind to frictionally interact with the water, transferring energy and overcoming both the inertia of the water and any existing waves traveling in different directions. Thus, the height of the waves generated increases with the fetch distance, as the duration of the wind–water interaction increases.

The maximum height of waves in open water potentially generated by a wind of given velocity traveling across a fetch of given length can be calculated, giving an estimate of anticipated wave heights. However, the actual wave heights measured may differ considerably from this theoretical value, depending upon local weather conditions and nearshore bathymetry. Generation of maximum wave heights also depends upon maintenance of constant wind velocity, for periods ranging from hours for meter-high waves to several days for the largest waves.

For a specific wind velocity, greater fetch will result in higher, more powerful waves. A coast exposed to a long fetch is thus more susceptible to high energy wave conditions, posing a greater hazard to infrastructure and residents.

FIRE AND FIRESTORMS

John Radke
University of California, Center for Catastrophic Risk Management, Berkeley, CA, USA

Synonyms

Catastrophic wildfire; Conflagration

Definition

Fire is the result of combustion (a series of chemical reactions) between a fuel (an organic compound such as wood) and an oxidant (oxygen source) producing heat, light, and often sound. A firestorm occurs when uncontrollable combustion, a conflagration, impacts the wind system, exacerbates the flow of oxygen to the fire, and sustains the risk to humans and their habitat.

Overview

Fire is a natural phenomenon that controls vegetation growth in healthy landscapes. It becomes a natural hazard when it negatively impacts humans and their habitat. As human habitat continues to expand globally, the expansion of human communities into the surrounding landscapes serves to exacerbate conditions for this type of hazard.

The nature of humans to control and manage their environment has led to the evolution of a new class of landscape on the urban edge, the wildland–urban interface WUI (Radke, 1995; Cova, 2005; Radeloff et al., 2005; Stewart et al., 2006). Here, houses and wildland vegetation coincide to form a heterogeneous environment where fire suppression policies and misguided fuel management strategies have often resulted in extremely hazardous fire conditions (Russell and McBride, 2003). Such conditions have recently given rise to a new class of conflagrations that appear to be on the rise in number and intensity (Pagni, 1993; Hartzell, 2001; Rey, 2003; Radke, 2007).

Typical wildland fires consist of rapidly heated vegetation that undergo pyrolysis, emit flammable gases, mix with oxygen, combust, and spread. The speed and intensity of these fires vary as a function of vegetation type (fuel), topography, and weather conditions (Rothermel, 1972; Burgan and Rothermel, 1984). Such conditions are typically modeled and attempts are made to predict and mitigate fires (Radke, 1995; Finney, 1998; Finney et al., 2005). However, in the WUI, the mixing of houses and vegetation creates a new fuel condition where ignition and rate of spread is enhanced by vegetation, and fire temperature and intensity is exacerbated by the addition of extreme fuel loads in the form of houses and other structures. Add to this the decoration of individual properties with exotic plants to suit individual tastes and one gets a very unique, complex, and dangerous landscape where new predictive fire models are needed for mitigation (Radke, 2007).

Firefighting involves modeling, classifying, preventing, and ultimately extinguishing fire. Proficient firefighting in both urban and wildland environments requires very different strategies and skills. Although success at fighting fires has occurred in both urban and wildland regions, the WUI presents a hybrid environment where strategies and techniques are still evolving. WUI fires can quickly become catastrophic, escalating out of control and seemingly driven by, and sustaining their own wind systems. Such extreme fire behaviors, or uncontrollable firestorms (Radke, 2007; Cohen, 2008; Sommers, 2008), require a new breed of firefighters and fire models (Mell et al., 2007; Rehm and Mell, 2009), if we are to successfully control them in the rapidly expanding WUI (Stewart et al., 2006).

Fire knows no political or administrative boundary yet humans attempt to control and manage fire and their landscapes within politically defined or administrative boundaries. The WUI is no exception. As this human urge spreads globally, we continue to enhance this natural hazard.

FLASH FLOOD

Yang Hong[1], Pradeep Adhikari[2], Jonathan J. Gourley[3]
[1]Center for Natural Hazards and Disaster Research, National Weather Center, University of Oklahoma, Norman, OK, USA
[2]Atmospheric Radar Research Center, University of Oklahoma, Norman, OK, USA
[3]NOAA National Severe Storms Laboratory, Norman, OK, USA

Synonyms

Freshet; Huayco

Definition

A flash flood is a rapid flooding of water over land caused by heavy rain or a sudden release of impounded water (e.g., dam or levee break) in a short period of time, generally within minutes up to several hours, a timescale that distinguishes it from fluvial floods. It also includes freshet, which is a great rise or overflowing of a stream caused by heavy rains or melted snow and huayco or huaico (Quechua term waygu meaning "depth, valley") which are Peruvian terms referring to flash floods caused by torrential rains in high mountains.

Overview

Characteristics: Flash floods are typically characterized by raging torrents in response to heavy rainfall that rip through riverbeds, urban streets, or mountain canyons sweeping away large debris and sediment with them. The Federal Emergency Management Agency (FEMA) characterizes it as a flood with a quick rise in water surface elevation with abnormally high water velocity often creating a "wall" of water moving down the channel and floodplain (FEMA, 1981).

Causes: Heavy rainfall from convective thunderstorms and tropical cyclones are the main causes of flash floods in most parts of the world. The rainfall-producing storms are often intense and impact a given region repeatedly due to stationarity of the system, backward regeneration, or enhancement by steep relief. Impermeable surfaces in urban regions and hydrophobic soils from wildfire as well as high antecedent soil moisture conditions exacerbate flash flood impacts.

Occurrence: Flash floods typically occur in tropical, arid and semiarid zones. They can occur in developed urban zones, steep mountainous regions, canyons, dry washes in deserts, transitional areas, and coastal zones. The climatology of their occurrence is related to the seasonality of the rainfall-producing storms.

Impact on life and property: Flash floods are a major natural hazard throughout the world. In the United States, flash floods are the number one killer among all weather-related hazards with approximately 140 lives lost each year. A vast majority of deaths from flash floods, as high as 90% in tropical countries, are due to drowning from victims being caught by rapidly rising waters (Smith and Petley, 2008).

Prediction: Predicting flash floods requires accurate detection and estimation of rainfall events, which are typically intense and very localized. Operational prediction methods include flash flood monitoring and prediction algorithms (FFMPA) used in Europe and the United States. FFMPA alerts forecasters when flash flooding is imminent based on radar-estimated rainfall amounts compared to hydrologic model–based rainfall thresholds. Advancements in forecasting convective rainstorms help to improve the performance of FFMPA by providing a longer lead time of impending flash floods.

Mitigation: Reducing societal exposure to flash floods is a key to any mitigation measure. Preventive activities including open space preservation, planning and zoning, property protection such as relocation and insurance, public education, emergency services in the form of warning and evacuation, and structural engineering projects such

as levees, diversions, and channel improvements are some of the actions that mitigate the societal impacts of flash floods (Colombo et al., 2002).

Vertical-accretion deposits

Definition

Flood deposits are sediments derived from a running water source (river) and can consist of clay, gravel, sand, and silt. The sediments deposited are in an unconsolidated form until lithification.

Overview

Flood deposits are represented by channel deposits and overbank deposits associated with seasonal increases in river discharge caused by prolonged periods of snow melt, excessive rain, or monsoon conditions (Aslan, 2003). Lasting upward of several months, such "seasonal floods" are most typical of medium to large size rivers (e.g., Mississippi, Amazon, and Danube).

Subglacial outburst floods (jökulhlaup) that are episodic flood events accumulate *fluvial outburst flood deposits* (Duller et al., 2008). The structureless and diffusely stratified characteristics of depositional units are interpreted as the result of rapid deposition following flow deceleration at the stoss side of major antidunes, as well as at hydraulic jumps. This sedimentary evidence indicates that an outburst flood is a highly turbulent, sediment-charged flow (Duller et al., 2008).

According to Benito et al. (2003) and McKee (1938), *high-stage flood deposits* are characterized by a sheet-like layer of poorly sorted and relatively fine-grained material (pebble to silt size), directly overlain along a sharp contact by a well-sorted layer of cobbles and boulders. These two layers are interpreted to have been deposited in quick succession. The poorly sorted basal unit is deposited by a forward advancing stream flow that is losing turbulent energy and therefore also losing its suspended sediment load. This layer is in turn overlain by a slower advancing traction load of coarse boulders and cobbles. Late stage erosion, reworking of sediments, plus removal of fines typically occurs as progressively clearer flood waters wash over and dissect earlier deposited sediments.

In general, many floodplain deposits (channel and overbank deposits, or alluvium) are planar-stratified and small-scale cross-stratified, with fine to very fine sand interbedded with silt and clay (Aslan, 2003; Bridge and Demicco, 2008; Miall, 1996). The planar laminae are formed on upper-stage plane beds, and the small-scale cross strata are formed by current ripples. Small-scale cross strata are commonly of the climbing-ripple type and associated with convolute lamination. Ripples formed at the top of the sandy part of a strataset may be draped with mud that can show desiccation cracks. Wave-ripple marks can be superimposed on the ripples, representing the ponding stage of the waning flood. The upper parts of such stratasets are commonly bioturbated with root casts and animal burrows (Bridge and Demicco, 2008).

Synonyms

Deluge; Freshet; Spate; Inundation. The word flood comes from the Old English *flod*, a word common to Germanic languages (compare German *Flut*, Dutch *Vloed* from the same root as seen in *flow*, *float*). *Deluge* myths are stories of a great flood sent by a deity to destroy civilizations as an act of divine retribution and are featured in the folklore of many cultures.

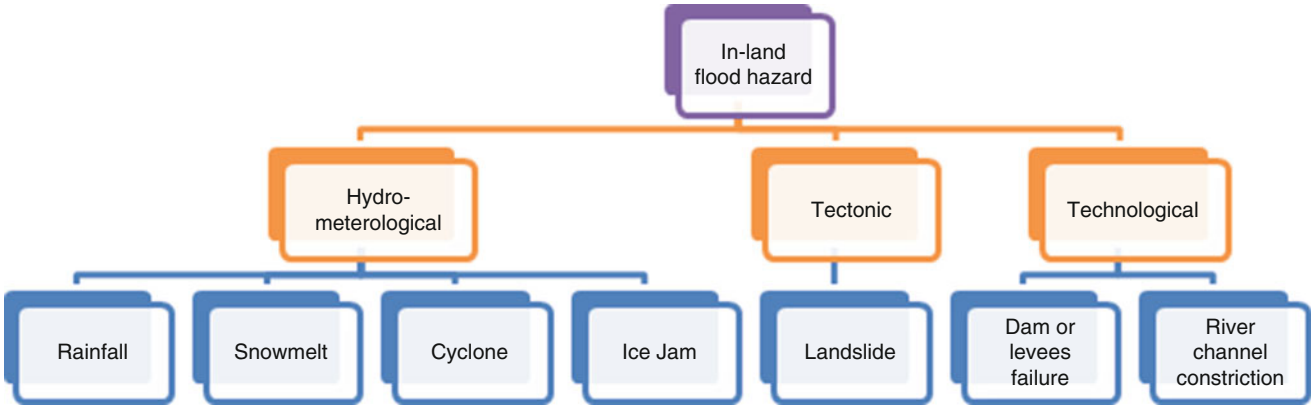
Introduction

Definition

Floods are an overflow or inundation that comes from a river or other body of water and often threatens lives and properties. Therefore, any relatively high streamflow overtopping natural or artificial banks (e.g., levees) in any reach of a stream can be termed a flood. Floods can happen when the flow capacity of river channels, streams, or coastal areas is exceeded due to heavy, intense, or continuous rainfall or when the absorptive capacity of the soils is exceeded. This causes water in a river channel to overflow its banks onto adjoining land area, known as a floodplain. Floodplains are, therefore, highly prone to flood. In addition, coasts and deltas, areas directly below dams, inland shorelines, and alluvial fans are vulnerable to floods (Smith and Petley, 2008).

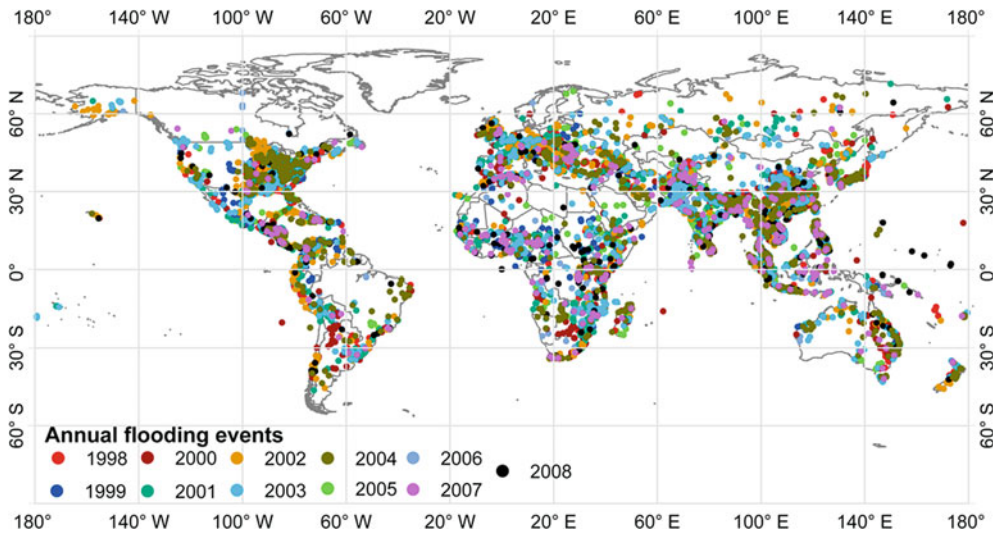
Flooding creates a significant threat to life and property. Communities situated near riverbanks or coastal zones are most vulnerable to flood, but many historic cities and towns have been built in such areas due to the conveniences of transportation, commerce, recreation, and pleasant scenery. Occasionally, flood hazard and flood risk are used interchangeably. Flood risk has the additional implication of the statistical chance of a particular flood actually occurring, whereas hazard is a naturally occurring or human-induced process which has the potential to create loss (Smith and Petley, 2008).

Generally, flooding invokes images of destruction and catastrophe. In contrast, floods also play an important role in the functioning of ecosystems, analogous to wildfire. Floodwaters bring many benefits such as increasing soil fertility by depositing nutrients from upstream and recharging ground water. Many aquatic species depend on normal flooding to wash debris into the water, which they subsequently use for shelter and food. Periodic floods also transport eroded soil and other materials that are essential for delta areas and coastal marshes to persist over time and sustain the wetland ecosystems. Freshwater floods in particular play an important role in maintaining ecosystems in river corridors and are a key factor in maintaining floodplain biodiversity (APFM, 2006). Many ecosystems develop with regular flooding as one of the key components to their existence. For example, the Sundarbans is the largest single block tidal forest of the world, located in the Ganges river delta. Similarly, it has been found that flooding was the key to the well-being and prosperity of ancient communities along the Nile, the Tigris-Euphrates, the Yellow, and the Ganges Rivers.



Flood generation

There are various factors that contribute to flood generation, with the primary ones being precipitation and snowmelt. In regions without extended periods of below-freezing temperatures, floods usually occur in the season of highest rainfall. The flood season is spring and early summer in regions where floods result from snowmelt, often accompanied by rainfall. Some other causes of floods include impediments to flood paths due to natural or man-made structures (e.g., ice jams, log jams, bridges, weirs), sudden dam failure and rapid snowmelt in the catchment basin (UNESCO, 2001). Because floods can transport large volumes of sediment and debris, they are often associated with landslides, mudflows, and debris flows. Figure 1 summarizes the causes of flood generation.



Flood measurement

Hydrologists generally quantify floods in two different ways. One is in absolute quantitative terms including discharge (m^3/s or ft^3/s), specific discharge (i.e., discharge normalized by catchment area or unit width of channel) or the height (stage) that the floodwaters reach (in m or ft). In contrast, a relative approach of quantifying flood is to express the magnitude of flood discharge or water depth based on the probability that the discharge or stage height will equal or exceed a certain level on a recurring basis, in terms of their statistical frequency. A "100-year flood" describes an event with a magnitude corresponding to a 1% probability of that flood occurring in any given year. This concept does not mean such a flood will occur only once in 100 years. Whether or not it occurs in a given year has no bearing on the fact that there is still a 1% chance of a similar occurrence in the following year. Any other statistical frequency of a flood event may be chosen depending on the degree of risk that is selected for evaluation; for example, 5-year, 20-year, 50-year, 500-year floodplain (DSD, http://www.oas.org/USDE/).

Frequency of flooding depends on the climate, the conditions of the banks of the stream, and the channel slope. Where substantial rainfall occurs in a particular season each year, or where the annual flood is derived principally from precipitation and snowmelt, the floodplain may be inundated nearly every year, even along large streams with

Flood Hazard and Disaster, Figure 1 Physical causes of in-land floods (Modified from Smith and Petley, 2008).

Flood Hazard and Disaster, Figure 2 Global flooding events 1998–2008 (Source: Adhikari et al., 2010).

very small channel slopes. The Yangtze River in China, the Ganges River in India and Bangladesh, and the Mekong River in Vietnam are some examples where flooding occurs annually, causing significant losses of life and property.

Spatiotemporal distribution of flood

Floods occur frequently in most parts of the populated world, inundating land and killing thousands of people annually. Figure 2 presents the distribution of annual floods for 1998–2008 based on the Global Flood Inventory (Adhikari et al., 2010).

A number of flood databases exist. The Emergency Disasters Data Base (EM-DAT) managed by the Centre for Research on the Epidemiology of Disasters (CRED) at the Catholic University of Louvain, Belgium, is a publicly accessible international database with information on natural and technological disasters including floods. The United Nations Office for the Coordination of Humanitarian Affairs (OCHA) through its portal ReliefWeb provides current disaster information on humanitarian emergencies and disasters relief works (ReliefWeb, http://www.reliefweb.int/). It does not intend to provide a comprehensive database of disaster events, but can serve as a valuable resource to verify current events and obtain additional disaster details for rapid response and humanitarian support. The Dartmouth Flood Observatory (DFO) compiled the Global Archive of Large Flood Events, which covers events from 1985 to the present in a simple Microsoft Excel spreadsheet format (DFO, http://www.dartmouth.edu/~floods/). This database also includes links to high-quality maps for selected events since 2006, showing the entire affected region. This database is exclusively dedicated for flood hazards. It has

Flood Hazard and Disaster, Table 1 Flood databases showing number of events and direct fatalities. Note that the variations among the database for the selected base period, 1998–2008

	Events		Fatality	
DATA Base	No. of events	Variation with respect to GFI (±)%	No. of fatality	Variation with respect to GFI (±)%
1. EM-DAT	1,796	−33	95,823 (96,000)	−61
2. DFO	2,132	−21	391,814 (392,000)	+60
3. GFI	2,700	N/A	246,087 (246,000)	N/A

Source: (Adhikari et al., 2010; DFO; and EM-DAT)

about 3,400 events recorded for 1985–2008. The Global Flood Inventory (GFI) has compiled global flood data for 1998–2008 from publicly available online resources, irrespective of their scale of impacts so as to have a comprehensive flood database. It has geo-referenced locations of all the flooding events for a period of 11 years. The Global Flood Inventory has record of approximately 2,700 events in total for the period, which is about 250 per annum (Adhikari et al., 2010). The discrepancies in the database discussed above are mainly due to the inherited biases as a result of the scope of the database. The entry criteria, sources of data, and definition of specific hazard terms differ amongst the databases. Table 1 shows an example of such variation in reporting the number of events and fatalities for the same time period of 1998–2008. It is obvious that analyses based on different database entries might result in contradicting conclusions.

It is important to note that some databases are impact-based making them potentially biased toward reporting more events in populated areas, whereas others are compiled from publicly available resources. The latter are prone to undermine the number of actual flooding events because only those floods that have significant effects on the community, local government, or national government are recorded. Therefore, a very careful interpretation of flood data is necessary before reaching conclusions regarding the number of events or their impacts to the people and the community. A more elaborate analysis on the different types of disaster databases and their scope and limitations can be found at Tschoegl (2006). Based on the GFI, it is found that the USA has recorded the highest number of flood events followed by China and India for the period 1998–2008. Table 2 gives the top ten countries which have witnessed the maximum number of flood events for the same period. In addition, the GFI shows a seasonal pattern in flooding, with the number of events increasing in May and peaking in the months of July to August (Figure 3).

In terms of the spatial distribution of flooding, Table 3 shows the percentage of reported flooding events for each region, sorted by year. Asia and Africa continuously recorded the highest percentage of events throughout the globe, followed by Southeast Asia, Central America, and the Caribbean.

Socioeconomic impact of floods

Flooding is one of the most destructive types of natural disasters. In the twentieth century, out of the top 100 most fatal natural disasters, 12 were associated to flooding. Floods resulted in the death of seven million people (EM-DAT; The Disaster Center, http://www.disastercenter.com). Out of the 12 most fatal flood events, 10 occurred in China alone (Table 4).

Natural disasters such as flooding have the potential to eradicate decades of investments in infrastructure and the personal wealth of a country, in addition to the insurmountable loss of lives. The situation is much worse for developing regions. The poor are the most severely affected by natural disasters including floods. According to UN/ISDR (2004), people from the low-income category accounted for approximately half of those killed in floods from 1975 to 2000.

For 1998–2008, North America, Europe, and Oceania experienced much fewer fatalities compared to the rest of the world (Figure 4), with the notable exception of North America in 2005 due to Hurricane Katrina. It is observed that almost 75% of the fatalities worldwide occurred in Asia and Southeast Asia combined. Specifically, Southeast Asia had the highest number of flood fatalities, mainly as a result of cyclone Nargis that hit Myanmar in May 2008. Totally, 247,000 people were killed worldwide from 1998 to 2008 (Figure 5). The seasonal trend of flood fatalities generally follows that of

Flood Hazard and Disaster, Figure 3 Seasonal variation flood events for each year of the GFI record.

Flood Hazard and Disaster, Table 3 Flooding events recorded for 1998–2008 (in percentage) across the regions

Region	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	Yearly average

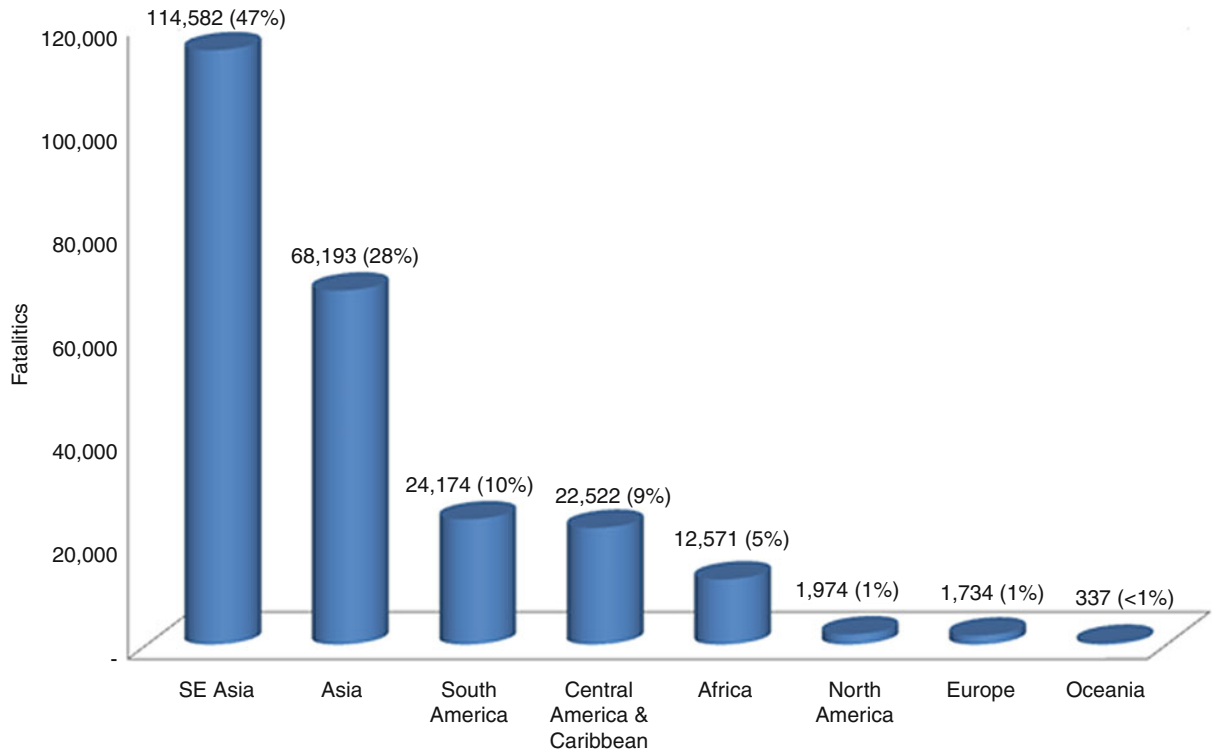
Source: Adhikari et al. (2010)

flooding events, but deaths extend into August through November. The month of May exhibited the highest fatality values; however, this may be skewed by the previously described tropical cyclone in Myanmar in 2008 (Figure 6).

Historical records show that the world has witnessed about 3,500 floods since 1900 till 2008 killing about seven million people globally. China is the country that witnessed the highest number of flood-related fatalities, a staggering 6.6 million during that time period (EM-DAT). Analyzing impacts for a longer duration from 1970 to 2008 based on the data from EM-DAT, it is observed that the world experienced total damages around 1.8 trillion USD from natural hazards, out of which 23% is attributed to floods alone. For the same time period, about three million people lost their lives; 8% of those were killed by floods (Figure 7).



It is clear from Figure 7 that, in terms of total fatalities for the 1970–2008 period, floods killed much less people in comparison to other natural hazards like storms, earthquakes, and droughts. But for the period 1985–1999 floods were the deadliest natural disaster followed by the earthquakes (Abramovitz, 2001). Irrespective of the discrepancies in the number of people killed or damages to local economies, the propensity of floods to harm human beings is very high and therefore requires attention from researchers, planners, and governments alike.

It is difficult to calculate an estimate of global economic impacts from floods alone. There is some information about the impact from all catastrophic natural hazards in which flooding is one of the major components. For 1985–1999, a total of US$920 billion were estimated to

Flood Hazard and Disaster, Table 4 Historical top 12 most fatal flood events

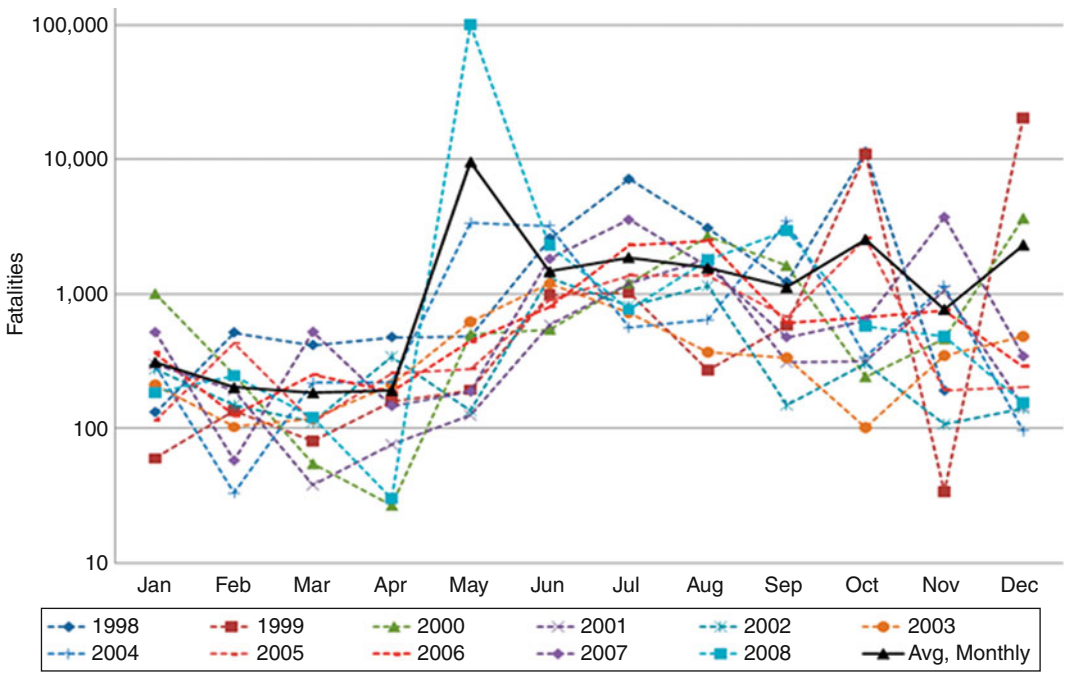
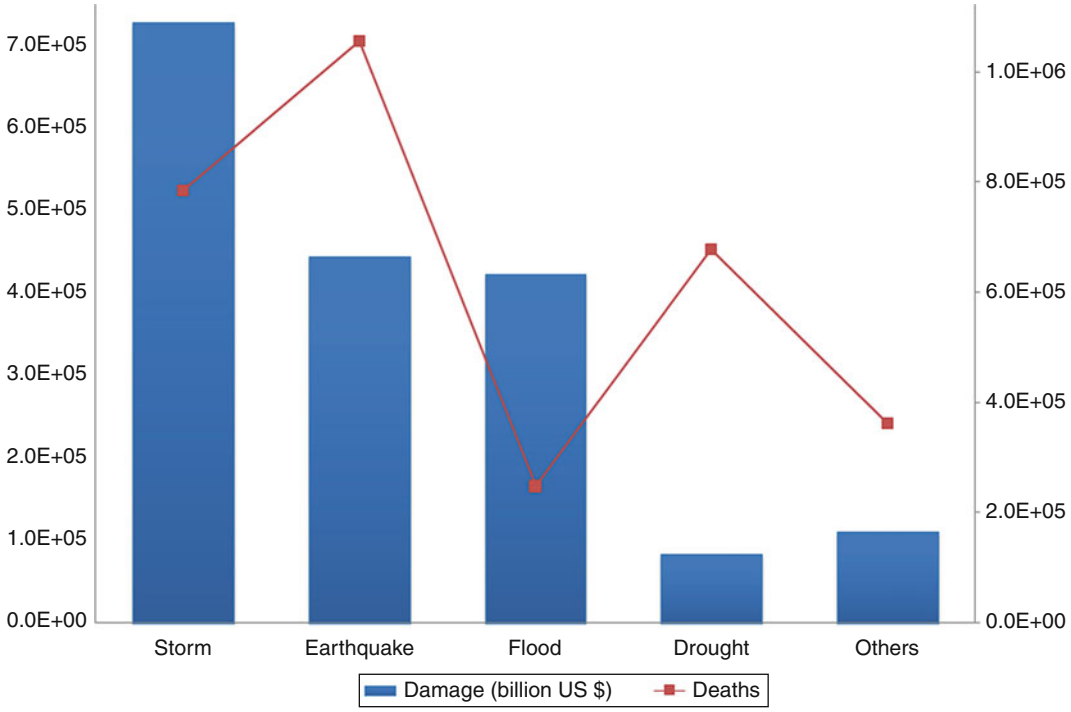
Flood Hazard and Disaster, Figure 4 Total fatalities for 1998–2008 segregated into regions. Southeast Asia witnessed the maximum fatality followed by Asia and South America.



have been lost from the natural hazards. The loss in richest and poorest countries is 57.4% and 24.4%, respectively. However, the loss in terms of Gross Domestic Product is 2.5% and 13%, respectively, in richest and poorest countries. This shows that disasters make the poorest countries even more vulnerable to future disasters (Abramovitz, 2001). The difference in loss from the disasters can be due to the phenomenal difference between rich and poor countries in infrastructure setup and better insurance coverage, which is the only reliable source of information to estimate the damages due to hazards.

Flood management



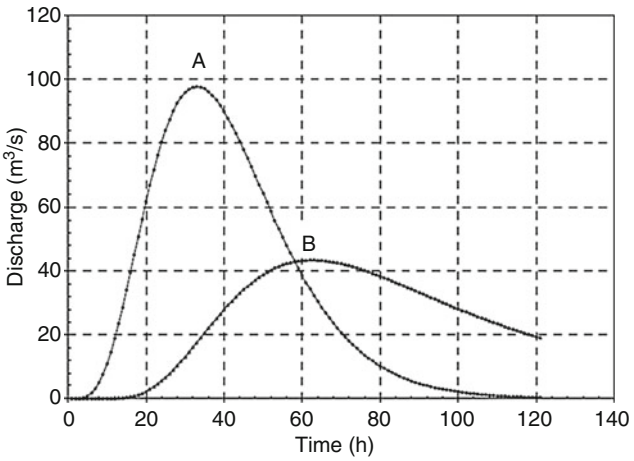
The ultimate objective of flood management is to minimize the destruction and damages that flood hazards can

Flood Hazard and Disaster, Figure 5 Total number of fatalities for 1998–2008. Results show that Asia, Southeast Asia, Eastern Africa, Central America, and the Caribbean and South America regions experienced the most fatal floods.

Flood Hazard and Disaster, Figure 6 Seasonal variation in flood fatalities for 1998–2008. Fatalities on vertical axis are in log scale.

Flood Hazard and Disaster, Figure 7 Flood impacts for 1970–2008. The primary y-axis on *left* shows the damage in billion US dollar while the secondary y-axis on *right* shows the deaths as a result of natural hazards (Source: EM-DAT).

inflict on human lives and society. Flood management comprises three major components: adaptation, protection, and mitigation. These can be categorized into structural and nonstructural measures. These measures have their own advantages and disadvantages.



Structural measures

Some of the major structural measures to control floods and protect communities are dams, levees, and river channel improvements. They have played a key role in protecting the people and property around the globe from floods for centuries.

Dams

Dams are constructed on many rivers around the world. They are constructed for irrigation, to store runoff and reduce flooding downstream. Dams attenuate flood peaks by storing water in reservoirs and releasing it when river levels have fallen (Figure 8).

There is no agreement on the number of existing dams in the world. The World Commission on Dams reports 45,000 large dams worldwide but the Global Reservoir and Dam database mentions only about 33,000 large dams (WCD, 2000; Lehner et al., 2011). Three Gorges in China, Syncrude Tailings in Canada, and Chapetón in Argentina are some of the largest dams in the world. Dams can serve multiple purposes in addition to flood control, such as water supply, irrigation, hydroelectric power generation, recreation, and fishing. Most dams are multipurpose

Flood Hazard and Disaster, Figure 8 Flood hydrograph. The point A is the peak inflow to the reservoir dam. Peak B is the regulated outflow from the reservoir. The difference in peak A and B is called attenuation which essentially reduces the flood peak downstream of the dam.

making them an economically attractive investment, although meeting the demand of competing uses makes their operation a very challenging task. At the same time, one should not minimize the negative impacts dams and levees have on riparian areas, forest land, and above all the displacement and resettlement of millions of people (WCD, 2000; Smith and Petley, 2008; Dixit, 2003;

Mishra, 2003). The World Commission on Dams (WCD) notes that large dams worldwide have led to the loss of aquatic biodiversity; upstream and downstream fisheries; and impacted the health of downstream floodplains, wetlands, estuaries, and adjacent marine ecosystems. Another negative consequence of dams is the displacement of people at the dam site and areas upstream that become inundated upon the completion of the dam. Globally, the total displacement from large dams could range from 40 to 80 million (WCD, 2000). In addition, dams have been connected to systematic changes in large-scale land use and land cover type, as they serve their multiple purposes possibly altering extreme precipitation patterns (Hossain et al., 2009).

Levees

Levees or dykes are artificial embankments built to control the spread of flood waters and to guide the river. Whereas dams are constructed across the river to impound the river water upstream and to regulate the downstream flow, levees are constructed laterally along the river banks. In low-lying areas or near deltas, levees are the main "protection" structure from floods. Historically, levees were constructed in the Indus Valley Civilization, as well as ancient Egypt, Mesopotamia, and China.

In modern times, levees play a major role to control floods. In the Upper Mississippi River basin of the USA alone there are more than 8,000 miles (~13,000 km) of levees (Interagency Floodplain Management Task Force, 1994). Levees are often part of a much larger project, such as the system of floodways along the lower Mississippi. However, environmentalists often challenge the notion of "safety" from the levees. Levees failed to protect vast areas in the Mississippi and Missouri River valleys during the record-setting floods of 1993 in which 1,600 levees were damaged (Wright, 2000). In 2005, levee and floodwall failures were blamed for the catastrophic inundation of New Orleans by Hurricane Katrina. Recently, in 2008, levees were breached by large floods in the Koshi River on the Nepalese-Indian boarder inundating vast settlements and killing hundreds of people.

River channel improvement

River channel improvement essentially enlarges and stabilizes the channel increasing the carrying capacity of the river and containing the floodwaters within its banks. During the channel improvement process, the channel bed is smoothened, which helps to clear the floodwaters faster downstream preventing floods in the upper reaches. But this type of intervention in the river channel potentially results in increased bank erosion raising the risk of embankment collapse, thus further exacerbating the problem (Smith and Petley, 2008). Sometimes channelization or dredging will aggravate flood problems downstream.

Therefore, a careful analysis of the situation is required before adopting suitable structural measures for flood control. Striking a balance between possible benefits and costs is a challenge to the water resources planning and engineering communities.

Nonstructural measures

In general, nonstructural measures of flood protection are of two types. The first one reduces the susceptibility to flood impacts including actions such as flood monitoring, forecasting and warning, and floodplain management. The second one reduces the impacts on individuals and the communities they live in. This includes flood insurance and relief and recovery aspects after the flood occurs.

Flood monitoring

Flood monitoring plays an important role in flood mitigation measures. Although flood monitoring cannot reduce flood incidence, it greatly reduces the loss to life and property. Monitoring river water levels and discharge are the major components of flood monitoring. Traditionally, river water levels were recorded only at limited in situ measurement stations, which failed to capture the spatiotemporal variability of a river's flow. Flood extents were usually derived from historical analysis of maps of past events or from model simulations based on in situ measurements. But with the latest communication technology, both recording and communicating a real-time water level or discharge measurements have become conventional. In addition, operational networks of stations are capable of capturing the spatiotemporal variability of river water levels along its reaches, significantly improving the efficiency of flood monitoring. Today, most of the developed countries have sophisticated systems of river water level and discharge measurements in place. For example, the United States Geological Survey (USGS) records and maintains a real-time water level and discharge network across the country. Similar examples can be found in Europe and Australia. Advanced remote-sensing technology has created a new opportunity for efficient flood monitoring even in ungauged basins of the least developed countries. Space-based rainfall monitoring has paved the way toward a global flood monitoring system (Hossain et al., 2007; http://trmm.gsfc.nasa.gov).

Flood forecasting

Flood forecasting is the capability to estimate, in real time, the future state of discharge and water levels at various sites in a river network as a result of observed or forecast rainfall, or from upstream streamflow measurements. An important aspect in flood forecasting is the lead time, which is the time between issuance of the forecast and the occurrence of the event. More lead time means ample opportunity to prepare and mobilize resources so as to evacuate people to a safer place and minimize the loss of life. Flood forecasting essentially includes three steps: getting real-time rainfall (and/or snowmelt) estimates or forecasts and streamflow observations; using these data in hydrological (rainfall-runoff and streamflow routing) simulation models; and forecasting discharge and water levels for periods ranging between a few hours and days,

depending on many factors such as the size and shape of the watershed. The rainfall and streamflow observations are collected using appropriate networks of instruments, through microwave, radio, or satellite communication systems. Numerical weather prediction models provide rainfall forecasts with global availability.

Over the last one and a half decade, the significant advancement of remote-sensing capabilities onboard space-borne platforms has yielded precipitation estimates and subsequent flood forecasts on a quasi-global scale. This major development has been made possible largely from the launch of the Tropical Rainfall Measuring Mission (TRMM) by NASA in 1997. These remotely sensed data have made it possible to predict floods even in the ungauged areas of the world.

Following estimation of rainfall, hydrological simulation models are needed to estimate the flood timing and severity. There are numerous hydrologic simulation models available that can be used for flood forecasting. Sometimes such models can be as simple as a statistical rainfall-runoff relation model or they can be much more sophisticated. Hydrological models have been classified according to their complexity in representing physical processes and by their handling of the spatial distribution of physical processes and parameters as either basin-integrated (or lumped), spatially distributed, or semi-distributed. The selection of a model often depends on the availability of input, output, basin characteristics data, the modeling objective, and the experience of the modeler. A lumped model generalizes a given watershed as a single unit for calculating runoff in response to basin-averaged forcing (i.e., rainfall) and rainfall-runoff processes. The calculations are statistically based and relate to the underlying hydrological processes as a spatially averaged process. Depending on forecast needs and the characteristics of the watershed, a lumped model may be sufficient. A distributed model simulates the key hydrological processes that occur in a watershed using spatially variable data inputs, parameters, and process representations. Distributed hydrologic models commonly use rainfall and evapotranspiration estimates as inputs and parameterize processes (e.g., rainfall-runoff generation, infiltration, channel routing, interflow, baseflow) using remotely sensed observations and in situ measurements of soil types and depths, land use and land cover types, and digital elevation models (and their derivatives). Distributed models require more data and knowledge of watershed processes than lumped models. Despite the increased complexity of physical process representation of a distributed model over a lumped one, data have often been the limiting factor to accurately calibrate and verify simulation results. Also, both types of models often require observations of system behavior (i.e., rainfall and runoff) for accurate estimation of model parameters and improved model skill.

Flood-forecasting systems are more common to developed countries like in Europe and the USA and have been found to be effective in large river basins like the Danube and Mississippi (Smith and Petley, 2008). Reasons for the lack of flood forecasting systems in lesser-developed countries can be attributed to the affordability of the technology and availability of precipitation and streamflow data in real time. Space-based rainfall, however, has paved the way for a global system of flood monitoring; results have shown improved flood forecasts and flood vulnerability reduction can now become a reality (Hong et al., 2007; Hong and Adler, 2008; Li et al., 2008). At present, the latest capabilities in remotely sensed forecasting and monitoring of floods have been in use in some of the most vulnerable areas of the world like Africa, Asia, and South America (http://www.servir.net; http://eos.ou.edu/; Begkhuntod, 2007; Islam and Sado, 2000).

Floodplain and wetland management

Floodplain management is the implementation of corrective and preventative measures for reducing flood damage to structures and properties in close proximity to a river. These measures generally include requirements for zoning, subdivision, or building, particularly applicable to new construction projects. According to the Federal Emergency Management Agency (FEMA) in the USA, over 20,100 communities voluntarily adopt and enforce local floodplain management ordinances that provide building standards for new and existing development to minimize flood losses. Although attempts are made to protect floodplains from encroachment (e.g., urbanization or agriculture) through regulations, it has a mixed success (Pinter, 2005). In less-developed countries, high population growth and poverty force people to encroach on the floodplains for shelter and cultivation, making flood mitigation a challenging prospect.

Wetlands, such as swamps, marshes, and lowlands along the rivers and coastal areas have saturated soils and support a wide diversity of vegetation and wildlife. Wetlands also serve as natural buffers to floods, especially in coastal regions where hurricanes make landfall. They store water from intense rainfall and release it more gradually into the groundwater or surface and thus attenuate the peak flows that would otherwise occur. Active management and conservation practices of wetlands benefits the water quality, local environment, and prevents impacts from floods.

Providing flood insurance, community involvement and increasing the resilience are all equally important aspects of flood preparedness and mitigation. Examples from Bangladesh, Philippines, and Indonesia where community involvement has been the core of the nonstructural measures at local levels have significantly improved the flood mitigation efforts to protect the lives of the people (Adikari and Yoshitani, 2009; Perez et al., 2007; BUDMP, undated).

Summary and conclusions

Flooding arises as a result of extreme hydrological events like heavy rainfall or snowmelt. It is one of the major natural hazards affecting the lives of millions of people around the world. Events such as the 1931 and 1938 flooding of the Yellow River in China, the great floods of the Mississippi in 1993, and flooding in Myanmar from Cyclone

Nargis in May 2008 serve as sobering testimonies to the significant effect floods can inflict on populations worldwide. Historically, it has been observed that floods have wiped out not only decades of investments for a country but they also have the capability to destabilize the economy of a nation and make them more vulnerable to future disasters. Flood impacts are most felt by the poor and marginalized communities in developing nations.

A spatial analysis of flood events indicates that almost all countries have experienced flood impacts unless they were situated at latitudes greater than approximately 60 °. When flooding reports were grouped by region, Asia and Africa regularly had the highest percentage of flood events per year, followed by Southeast Asia, Central America, and the Caribbean. While considering flood fatalities, almost 75% of the total worldwide deaths from floods occurred in Asia and Southeast Asia combined.

Due to the impact on human lives and property, investment in flood management strategies is a worthy enterprise. Flood forecasting and mitigation measures have contributed to the reduction in fatalities and economical damage as evidenced in Bangladesh (Adikari and Yoshitani, 2009). Globally, it is observed that each dollar spent on disaster preparedness has saved $7 in disaster-related economic losses, an impressive return on the investment (Abramovitz, 2001). Flood prediction and forecasting of impending floods at national and global levels look even more promising due to innovation in information technology and remote-sensing techniques over the past one and half decades. However, continued investments to reduce the flood vulnerability of the world's poorest and marginalized people are needed given anticipated hydrologic responses to climate change.

Synonyms

Flood control; Flood defense; Flood management

Definition

Flood protection refers to the human-made and natural structures, strategies, and actions undertaken to prevent, manage, control, and mitigate the social, economical, and physical impact of floods.

Overview

The protection of a territory from floods is achieved by means of structural and nonstructural measures. Structural measures are physical features, devices, and operations that directly impact flood waters dynamics at different scales – from a river basin to river transects and a single building. Nonstructural measures are legislative and regulatory policies formulated to plan, manage, and identify the flood risk – *floodplain* and *floodways* – at the river basin scale.

Structural flood protection is generally achieved by means of artificial hydraulic structures, land surface modifications, and maintenance activities specifically designed to control, store, convey, and attenuate the inundation process as well as the adoption of flood proofing techniques to prevent storm waters from entering predefined urban areas and properties. Nonstructural flood protection is achieved by strategic activities and, in particular, by river basin zoning and planning, actions aimed at increasing humans preparedness and/or to minimize the presence of humans and valuables in flood-prone urban and rural areas. In other words, structural methods interact with the inundation phenomenon by interventions that directly modify the flood whereas nonstructural methods act indirectly by means of spatial organization of urban and rural areas, steering toward safer land use planning and managing real-time flood forecasting-warning systems with the objective of avoiding people and properties to be exposed to flood-induced hazard.

Flood protection structural systems include flood and *debris flow* barriers, *levees*, floodwalls, dams, embankment and dykes, detention basins and reservoirs, artificial channels, diversions, and bypasses. Structural measures also include the human-made landscape modifications such as channel geometry reshaping and floodplain maintenance operations (e.g., vegetation cleaning) that modify river hydraulics and surface roughness conditions, and also the flood proofing activities that are part of interventions aimed to prevent (dry flood proofing) or control (wet flood proofing) the damages due to the passage of flood flows through private properties.

Flood protection nonstructural systems include flood-induced hazard and risk assessment, hydrologic and hydraulic modeling for floodplain mapping, law and regulations by policy makers, land use planning, soil and vegetation management, real-time online flood forecasting and warning systems, as well as human preparedness to floods.

FLOOD STAGE

Fernando Nardi
University of Tuscia, Viterbo (VT), Italy
Hydraulics Applied Research & Engineering Consulting S.r.l., Rome, Italy

Synonyms

Flood (plain) flow height; Flood (water) level

Definition

Flood stage is the depth of the inundated areas in fluvial and coastal environments that is generally originated by an unusual and abrupt increase of river flow and tidal level during severe storm events.

Discussion

In river basins, the flood stage is that specific *floodplain* flow depth that corresponds to the exceeding of the maximum conveyance and storage capacity of natural or artificial water systems – channels and water bodies – which results in the flooding of usually dry lands.

At the watershed scale, the concept of flood stage is often associated to a predefined *floodplain* cross section of the river reach, where a flow gauge is usually located, in order to monitor, identify, and map the corresponding downstream flood hazard. The analysis of downstream inundated areas corresponding to the increasing flood stage of the upstream floodplain river station is the core information of nonstructural *flood protection* methods (e.g., flood hazard mapping, flood forecasting and warning systems). In fact, the real-time monitoring and forecasting of the flood stage of gauged river stations, located upstream of flood-prone areas, is regularly used for preparing and organizing the evacuation plan for a population situated in downstream valleys/regions.

FLOODPLAIN

Klement Tockner
Leibniz Institute of Freshwater Ecology and Inland Fisheries, IGB, Berlin, Germany

Synonyms

Riparian zone

Definition

Floodplains are low-relief Earth surfaces positioned adjacent to freshwaters and subject to flooding (fringing floodplains of lakes and rivers, internal and river deltas). Similarly, riparian zones are transitional semi-terrestrial areas that extend from the edge of permanent water bodies to the edge of uplands and are influenced by freshwater (Junk et al., 1989; Naiman et al., 2005; Tockner et al., 2002, 2008).

Overview

Floodplains are distributed worldwide and cover about 2% of the land surface. Floodplains are particularly abundant adjacent to large rivers including their deltaic areas. The Amazon, the Brahmaputra, the Nile, the Niger, the Zaire, and the Siberian Rivers, among others, are still fringed by extensive floodplains that are regularly inundated. Floodplains are disturbance-dominated ecosystems tightly linked to fluvial and geomorphic dynamics. As expanding and contracting ecosystems, they are among the most complex, dynamic, and diverse ecosystems globally. Because of their unique position at the lowest location in the landscape, floodplains integrate and accumulate upstream processes. They offer a remarkable diversity of ecosystem services including flood retention, recharge of ground water, biomass production, nutrient removal, as well as aesthetic and cultural values. Worldwide, floodplains provide approximately 25% of all continental ecosystem services, more than any other ecosystem type. Such multiple services favored the development of modern civilizations along the Nile, Euphrates, Indus, Amazon, Yangtze, or Mississippi rivers; and many present indigenous human societies are well adapted to the unique conditions of floodplains. Today, about half of the human population of Europe and Japan live on (former) floodplains. About 80% of Bangladesh, the most densely populated country worldwide, is covered by floodplains. At the same time, floods are among the most costly natural disasters worldwide. Between 1900 and 2004, almost 3 billion people were affected by floods, causing 2.9 million human deaths, and making more than 130 million other people homeless. At the same time, floodplains are among the most threatened ecosystems. In Europe and North America, more than 90% of the former floodplains are functionally extinct or have been converted into cropland and urban areas. Habitat degradation, species invasion, pollution, and climate change are among the most important pressures threatening floodplain ecosystems and their rich biodiversity. Therefore, conserving the remaining intact floodplains as strategic global resources and restoring degraded floodplains poses highest priority for future ecosystem management. However, floodplains designated for restoration and conservation must be large enough to support its native plant and animal communities and to perform key ecosystem functions.

FLOODWAY

Armand LaRocque
University of New Brunswick, Fredericton, NB, Canada

Synonyms

Regulatory floodway

Definition

A floodway is defined as a man-made diversion channel that is created for the discharge of river flow during flood events, without increasing the water surface elevation more than a particular reference level, usually the 100-year flood level. For the US Federal Emergency Management Agency (FEMA), the floodplain includes also the channel of a river or another watercourse, with the adjacent portion of the floodplain being used for the discharge of flood water (FEMA, 2002).

Floodways are among the protection systems that are built to avoid the catastrophic floods that occur annually in many densely populated floodplains. A floodway includes not only the diversion channel, but also any adjacent areas of the floodplain that can carry overflow. The floodway can be delineated by dikes that are built on both sides of the adjacent overbanks and by other control structures that regulate the water flow, at both ends of the diversion channel. At the inlet of the floodway, the control structures may include control gates which are built to redirect the overflow from the river to the diversion channel, at the beginning of flood occurrences. The implementation of a floodway can be a very complex project, including excavation of earth, construction of dikes, building or redesign of highway and railway bridges, and modifications to utilities and services (e.g., power and sewer lines) which are already in place.

One example of a floodway is the Red River Floodway that was built to protect the city of Winnipeg (Manitoba, Canada) against catastrophic floods that occur regularly in the Red River valley. The floodway consists of an artificial 47 km (29 mi) long channel that diverts a portion of the Red River's flow during flood periods along the eastern edge of the city of Winnipeg. This system also includes a network of dikes and hydraulic structures controlling the water flow. Constructed between 1962 and 1968 at a total cost of $63 millions (CAD), this floodway was used over 20 times until 2005 and has resulted in savings estimated to be $10 billion (CAD). The original floodway was built following the 1950 flood, but the "Flood of the Century" (Spring, 1997) showed that there was a need to improve the flood protection of the valley. Once completed in 2010, the new expansion of this floodway will prevent floods having a 700-year probability of recurrence, by increasing the capacity of the floodway from 1,700 m^3 (60,000 ft^3) of water per second to 4,000 m^3 (140,000 ft^3) of water per second.

FOG HAZARD MITIGATION

Steve LaDochy[1], Michael R. Witiw[2]
[1]California State University, Los Angeles, Los Angeles, CA, USA
[2]Embry-Riddle Aeronautical University Worldwide, Everett Campus, Everett, WA, USA

Synonyms

Haze; Mist; Smog

Definition

Fog is a cloud consisting of minute droplets or ice crystals that is in contact with the surface of the Earth. Horizontal visibility is reduced to less than 1 km, according to international standards (George, 1951).

Dense or heavy fog. When visibility is less than 5/16ths of a mile (less than 400 m) fog is dense or heavy.

Mitigation is efforts to lessen the negative effects of a natural hazard such as fog on society and the natural environment.

Introduction

Despite its beneficial impacts including moisture for forests and plants and the ability to collect fog to be used as a water source in otherwise arid regions, fog has been

a hazard probably for as long as humans have inhabited Earth. It is the reduced visibility which makes fog a hazard. The hazards of fog can be epitomized by the sinking of the RMS Titanic in 1912, when on its maiden voyage it became enshrouded in fog, hit an iceberg, and sank into the cold North Atlantic (see *Marine Hazards*). In some years fog causes more deaths in the USA than tornadoes and hurricanes combined. Most of these deaths are caused by auto accidents in poor visibility. For these reasons, in many areas, humans have made the attempt to mitigate the effects of fog, by either modifying the fog itself or devising ways to cope with it.

Road transport

Fog lights

A good fog lamp or lights produces a wide, bar-shaped beam of light with a sharp horizontal cutoff (dark above, bright below) at the top of the beam, and minimal upward light above the cutoff. Studies show that in North America, more people inappropriately use their fog lamps in dry weather than for poor weather (Sivak et al., 1997). The effectiveness of fog lights decreases when drivers do not slow down.

Fog visibility sensors

A nephelometer is an instrument that measures light scattering in the forward direction by fog particles. Normally found with weather stations at an airport, these instruments can also detect patchy or dense fog along a highway (FHA, 1999). In 2006, the USA employed over 7,000 closed circuit televisions (CCTV) to monitor traffic nationwide. The Federal Highway Administration uses CCTV along with nephelometers in developing road weather management strategies aimed at mitigating weather impacts by advising motorists of prevailing and predicted conditions. Part of this program employs the 511 national travelers information telephone number (DOT, 2009).

Fog road warning systems

In 1995, the California Department of Transportation (Caltrans) installed an automated fog warning system that uses nine roadside weather and visibility monitoring stations and 36 detectors lodged in the pavement. Motorists are advised of prevailing conditions via flashing beacons atop static signs, information broadcast over advisory radio frequencies, and messages posted on dynamic message signs. Success was seen in a 70% reduction in incidents where the system was installed. Because of this success, the system was expanded in 2005 (Traffic Technology Today, 2010). A similar system was installed in Tennessee after a chain-reaction collision of 99 vehicles occurred in 1990 (Robinson et al., 2002).

Driver's behavior

Even with advanced warning systems, it is often driver's behavior that determines accidents. In a recent study in California, it was noted that although the advised speed during fog was lowered to 30 mph, the mean speed of drivers averaged 61 mph (MacCarley et al., 2007).

Widespread dense fog can have large socioeconomic impacts through disruption of commerce as well as in injury and death. Data obtained from the Illinois Department of Transportation indicate that between 1975 and 1995 some 4,000 collisions occurred annually under foggy conditions in Illinois, excluding the city of Chicago, resulting in an average of 30 deaths per year and millions of dollars in damage (Westcott, 2007). Accident reports from 1992 to 1995 indicate that, on average, at least two fog-related traffic accidents occur somewhere in Illinois, excluding Chicago, on 288 days per year.

Dense fog with reduced visibility slows traffic and causes costly accidents. Long traffic delays may be harmful to perishable food, especially fresh fruit, vegetables, and sushi. A 1960s report from the British Transport Commission, London, said that one fog day caused them additional costs of about $10,000 due to loss of income or pay for extra personnel.

The National Transportation Safety Board found that between 1981 and 1989, accidents where fog was present on highways resulted in more than 6,000 deaths in the USA (NCHRP, 1998). On average, dense fog is present during 680 fatalities per year in the USA (NTSB Highway Accident Report, 1992). In 2001, fog was associated with 43,792 crashes; over 670 people were killed and more than 19,000 people were injured (Goodwin, 2003). In Canada, approximately 50 people per year die because of motor vehicle accidents in which fog was a contributing factor (Wiffin et al., 2004). In Europe, a fog chamber, with the capability of simulating different visibilities, was built in Clermont-Ferrand, France. This chamber is used to simulate fog with a goal of improving transport safety (Andre et al., 2004; Colomb et al., 2004).

Marine transport

Fog horns

Lighthouses use high-powered lenses to warn ships of coastlines or islands. But as in the case of Alcatraz Island, the San Francisco fog made the light ineffective and a fog bell was needed (Veronico, 2008).

A foghorn or "fog signal" or "fog bell" is a device that uses sound to warn vehicles of hazards (or of the presence of other vehicles) in foggy conditions. The term is most often used in relation to marine transport. When visual navigation aids such as lighthouses are obscured, foghorns provide an audible warning of rocks, shoals, headlands, or other dangers to shipping.

Since automation of lighthouses became common in the 1960s and 1970s, most older, manual foghorn installations have been removed and have been replaced with electrically powered diaphragms or compressed air horns. Activation is completely automated using a laser or photo beam that reflects back due to the fog. The sensor tells a computer to activate the foghorn. In many cases, modern

navigational aids have rendered large, long-range foghorns completely unnecessary (Noble, 2004).

Foghorns have very low pitches because sounds with low pitches have a long wavelength. This is important because a long wavelength means that the sound wave can pass around barriers, like rocks, easily (Young, 2010).

Radar

Modern shipping relies less on lighthouses and fog horns and more on technology, such as sonar and radar to avoid objects in dense fog (Amichai, 1978).

Aviation

Fog also greatly impacts the aviation community, that is, closing some airports as well as keeping VFR (Visual Flight Rules) pilots on the ground (see *Aviation (Hazards to)*). Aviation is directly impacted by fog as visibility is critical for landing and takeoffs. Elevated risk of a fog event is defined as ceiling/visibility less than 200 feet/½ mile (60m/800m). In New Delhi, where pollution has led to increasing fog, flight delays and cancellations due to fog during the winter cost airlines millions of dollars while stranding thousands (Air Transport Association, 2002). Efforts are being made on improving forecasting techniques (Whiffen, 2001).

Fog seeding

At Fairchild Air Force Base, near Spokane, Washington, cold fog (that which forms at subfreezing temperatures) has been routinely dispersed through the use of liquid propane dispensers for years. Liquid propane is dispensed into the foggy air. The vaporized propane results in very low temperatures (<-40 C). The super-cooled water droplets become glaciated. The resultant ice crystals initiate the ice crystal process, causing the fog to dissipate. Visibility improves as the ice crystals grow and fall out as snow (Vardin et al., 1971).

Cold fog is easier to disperse, using seeding techniques than warm fog (which forms at temperatures above freezing). But most mid-latitude airports have to deal with warm fog. Since fog droplets are found in a narrow size range of about 4–10 μm, dissipation can be achieved through coalescence processes. Houghton and Radford (1938) were the first to use hygroscopic particle (NaCl, $CaCl_2$) seeding to dissipate fog droplets. Giant hygroscopic nuclei seeding, NaCl, was used by Jiusto et al. (1968) to improve visibility.

Successful programs of fog dissipation have been carried out in Korea (Oh et al., 2008) and Germany (Moller et al., 2003) and Iran using liquid carbon dioxide (Jamali et al., 2005).

Heat

FIDO (Fog Intensive Dispersal Of) was a successful program using burners to heat the air in fog during WWII in England. A similar program was installed at Paris. (Fabre, 1971) showed that the use of heat and turbulence from jet engine exhaust could improve visibility on runways in Paris.

Turbulent mixing

Another method for dispersing ground fog is by turbulent mixing of saturated surface air with drier air aloft. Airports have used helicopters to mix dry air into the fog layer by the helicopter's downwash (Plank et al., 1971). Heat from jet engines also produces convection and turbulent mixing.

For aviation, fog is the only weather hazard that can be mitigated by technical means. Enhanced vision systems and space and ground-based navigation and augmentation systems will allow automated landings and takeoffs also under very reduced visibility conditions.

Forecasting

Better forecasting/nowcasting skills can help reduce financial losses arising from road, air, and marine transport systems that can be significantly impacted by unpredicted low-visibility conditions (Gultepe et al., 2009). In Europe, a major fog project called Cooperation in Field of Scientific and Technical Research (COST-722), with objectives of reducing economic loss and fatalities, was also created to develop advanced methods for very short-range forecasts of fog and low clouds (Jacobs et al., 2007).

Remote sensing

Satellites are used operationally to monitor developing fog and to verify forecasts. The use of satellite observations for fog studies has been discussed in many earlier studies (Ellrod, 1995; Bendix, 2002). In these studies, differencing between channel 2 (ch2; 3.9 μm) and channel 4 (ch4; 11.2 μm) from Geostationary Operational Environmental Satellite (GOES) observations, and between the channel-3 IR component (3.7 μm) and ch4 (11.0 μm) data from National Oceanic and Atmospheric Administration Advanced Very High Resolution Radiometer observations, has been used to detect fog regions. The discrimination between fog and other surfaces is due to the low emissivity of fog in channel 3 at night and the high reflectivity in channel 3 during daylight (Bendix, 2002). In Switzerland, ground-based cloud radars and ceilometers were used to detect low clouds and fog (Nowak et al., 2008).

Laser telecommunications

Since the 1990s, laser telecommunications, also called free space optical (FSO) communications have been used to transmit large amounts of data in a line of site fashion over distances that range up to 2,000 m. Wavelengths that are less susceptible to atmospheric attenuation are chosen. However, attenuation due to absorption by fog droplets remains an issue. To mitigate this problem, laser communications companies have done studies on attenuation caused by fog. Basically, to maintain an average downtime

of the communications equipment due to low visibility to less than 0.1%, a climatological study of the fog regime at the location is made. Receiver and transmitter are then spaced apart accordingly. In a relatively foggy area, like Seattle, depending on the power and wavelength chosen, transmitter and receiver may need to be separated by no more than 500 m. On the other hand, a place like Phoenix, Arizona, may sustain downtime less than 0.1% with transmitter and receiver separated by a distance of 2,000 m (Fischer et al., 2008, 2004).

Health

Air pollutants, especially particulate matter, are also known to enhance the reduction in visibility resulting from fog. The famous Killer Smog (smoke and fog) of London in December of 1952 not only reduced visibility but resulted in an estimated 4,000 deaths (Bach, 1972). The Donora Pennsylvania fog of 1948 also led to many deaths but occurred in a much less populated area (Pennsylvania Department of Environmental Protection, 1998). These two events helped lead to the clean air acts that were subsequently passed in the UK and USA. Largely as a result of the clean air acts, the health hazards posed by fogs of the past have greatly diminished. Visibility has also improved. For example, since 1980, Los Angeles International Airport (LAX) has only experienced 1 year where dense fog occurrence exceeded 50 h and, in fact, in 1997, no dense fog was reported at LAX. This contrasts to the years prior to 1980, when more than 50 h of dense fog per year were routinely reported, peaking at over 300 h in 1950 (Witiw and LaDochy, 2008) (see *Acid Rain*).

Summary

Fog is an underrated natural hazard that takes a large toll in lives every year from accidents mainly in transportation (road, air, and marine). Fog also disrupts transport, communications, and construction on a global scale impacting economies with billions of dollars (US) in losses, although total impacts may not be calculable. Mitigation efforts at dissipating fog, providing accurate and early forecasts, and devising successful warning systems have a long and successful history. The continued list of international accidents shows that further efforts are needed to make these efforts universal.

FOG HAZARDS

Paul J. Croft
Kean University, Union, NJ, USA

Synonyms

Cloud; Ice particles (suspended); Mist; Nebulosus; Rime; Water droplets

Definition

Fog. Cloud at or near the surface. Word origin may be primarily from northern latitude countries to describe small/fine rain sometimes with wind obscuring visibility. After the Greek (nephele) or Latin (nebula) for cloud.
Nebulosus. Veil of clouds without definition as a stratus layer or sublayer.
Water droplets. Suspended above or near the surface.
Ice particles. Suspended above or near the surface.
Mist. Suspended and falling liquid hydrometeors.
Rime. Suspended and falling solid hydrometeors.

Internationally, fog is known by a variety of names (see Table 1) and is reported operationally (and for climatic purposes) according to WMO criteria (e.g., see WMO-No. 485, Geneva; World Meteorological Organization, 1992) and coding symbols (i.e., 10–12, 28, 40–49).

Fog impact

Fog is observed worldwide at all locations and elevations under substantially variant synoptic, mesoscale, and microscale conditions of the atmosphere. As such, its formation and intensity – and thus hazards posed – may occur any time or day of the year, and its coverage may be widespread, regional, or highly localized. Although fog is often very shallow in the vertical layer, it is very often in close proximity to the surface (e.g., see the COMET MetEd online learning module "Fog: Its Processes and Impacts to Aviation and Aviation Forecasting" revised 2010; https://www.meted.ucar.edu/ – user registration is required). The production, maintenance, and dissipation of fog pose significant risks and hazards for multiple modes of transportation, and thus these show the greatest impacts in terms of total populations affected (i.e., by populations and costs; e.g., see Encyclopedia of Atmospheric Science, 2003). For example, the Bosphorus and Dardanelles Straits experience closures in Turkey due to dense fog, and the closures impact the flow of oil and grain from ports in the Russian Black Sea.

Multiple vehicle collisions and chain-reaction crashes are the most common and may be exacerbated when ice fog (or riming) also takes place. Marine, rail, and aviation impacts tend to produce more of an economic impact due to delays but on occasion, have led to serious accidents (or significant delays) with loss of life and property (e.g., Croft et al., 1997; Chagnon, 2006). This is also true in some instances of search and rescue operations. Notable transportation-related disasters have included the highway chain-reaction crash on the Mobile Bayway (1993) in

Fog Hazards, Table 1 Fog terms by country or language of origin with some locally known names

Fog Name/Definition	Origins/Language	Local names and meanings
la niebla	Coastal Chile/ Spanish	Gorua
le brouillard (or brouiller)	French	To blur; cloud over
nebel	German	
megla	Slovene	
雾	Chinese	"Fog City" (Chongqing)
안개	Korean	
la niebla (a neblina)	Spanish	Chilean coastal town
Tage	Danish	
بابضلا	Arabic	
Dimma	Swedish	
mgla	Polish	
mist	Dutch	
霧	Japanese	
nevoeiro	Portugese	
sumutusjärjestelmiä	Finnish	
nebbia	Italian	
tåke	Norwegian	

Mobile, Alabama; the shipping collision of the Andrea Doria with the MS Stockholm (1956); and the Tenerife airport disaster (1977). Other collisions with loss of property and life, or with significant damages, have also occurred between transportation vehicles and fixed structures (e.g., buildings, bridges) and even mountains. The majority of transportation impacts have resulted from obstructed visibility and the lack of adequate instrumentation or warning systems. However, while such systems have been used, fog-related accidents still occur often due to human error or poor judgment of the conditions or their seriousness.

In combination with other atmospheric constituents (natural or anthropogenic), fog also has the potential to damage the health and welfare of human, plant, and animal communities as well as insect populations. These may occur in the air, within the ground surface layers, or the water cycle components. When these constituents include noxious (and/or irritant) aerosols and chemicals, the impact may be deadly (e.g., the Donora Episode of 1948 and the London Fog Event of 1952) or lead to chronic illnesses and thus represents a significant but less common and more isolated hazard. The occurrence of smog, a term first used circa 1905 in London, dates back to the burning of coal reserves to at least the thirteenth century. Similar smog episodes occur around the world including Mexico City, Tehran, Los Angeles, and in many portions of Southeast Asia.

In cases where fog is harvested, risks exist in the use of fog-water in terms of its composition, contamination, and storage. It has been suggested that the generation of mists by fog machines for entertainment purposes may also pose health risks. There is also some concern for the use of various chemicals used for fog dispersal (seeding) that may have short-term impacts on those communities exposed to the application and dispersion of the chemical treatments. Fog has also been popularized with regard to film (often as mystical and menacing), music, and artwork, as well as for industrial, commercial purposes, and marketing (e.g., clothing or manufacturing, anti-fog devices). In some instance, fog has had a negative, but not critical impact, with regard to sporting and other outdoor events (e.g., the "Fog Bowl" in the United States, or impacts on ski slope operations).

Fog investigation

The advent of a more scientific and structured observational (or empirical) study of fog followed cloud classification schema and the development of more sophisticated instrumentation for study of the atmosphere, particularly on more localized scales (e.g., Sutton, 1953; Geiger, 1965). This phase of exploration led to improved understanding of the observed properties and behaviors of fog based on weather observation data and fog's associated characteristics as a function of dynamic processes in the atmosphere. This linkage afforded the first efforts at fog prediction in order to provide opportunity for the avoidance, mitigation, or prevention of its impacts. Based upon numerous studies in this regard, fog has since typically been classified by its formative method (e.g., radiative), location (e.g., sea fog), or atmospheric processes (e.g., frontal fog) and has led to many types being recognized internationally as well as locally named fogs (Table 2). In the latter case, these processes provide explanation of the movement or evolution of fog and thus allow for an "entity-following" method to study an evolving phenomenon.

Further development of these methods have included statistical and time series analyses to produce simple conditional climatologies of fog occurrence, intensity, and tendencies, as well as Markov Chain and other analytic techniques to more accurately assess fog occurrence and probability distributions for specific locations or regions (and intensity). In any of these cases, the specificity of the information is limited to the period of record and how representative each location is with regard to its surrounding area. Further specification of fog occurrence is possible when these techniques are linked to the synoptic setting or when statistical or climatic values are mapped across a region in order to infer the frequency of occurrences, intensities, and fog coverage or behavior. However, while such findings may be applied in a predictive (or diagnostic) manner, they are limited according to an observational framework and time scale (e.g., hours or days) without full consideration of the process-oriented nature of fog formation, maintenance, evolution, and dissipation.

As the observational study of fog has matured, the study of cloud physics and the microphysical processes

Fog Hazards, Table 2 Fog types, names, or classifications and key formation mechanisms and common locations

Classification/type of fog	Formation	Locations
Radiative fog	Thermal loss	Particularly low elevations
Advective fog	Transport and/or mixing	Ocean/coastal;
Advective-radiative fog	Delayed cooling modified air	Inland and isolated areas
Precipitation fog	Associated with synoptic pattern	Anywhere
Steam fog	Air-sea differential	Ocean, lakes, rivers
High-altitude fog	Cloud formation processes	Mountains
Upslope fog	Mechanical lift	Mountains
Frontal fog	Mechanical lift and instability	
Mixing fog	Convective/advective mixing	
Ocean fog	Evaporation, cooling	Fog bank formation
Valley fog	Cold air drainage	Depressions
Freezing fog	Thermal loss	
Hail fog	Rapid cooling (thunderstorm)	
Ground fog	Moist ground and rapid cooling	

involved in cloud growth provided distinct thermodynamic information as to the internal mechanisms and factors associated with fog formation (and dissipation) as well as its radiative impacts (as recognized many years before). This much more comprehensive insight of fog as an "entity" phenomenon to observe and follow was also assisted by the modern development of more sophisticated instrumentation (e.g., transmissometer) to measure cloud (or fog) properties and to monitor subsequent development (or dissipation) for shorter time scales and across shorter distances. These help to establish the sensing of fog's presence and the impact of fog intensity according to visibility criteria as linked to arbitrary interrogations versus one based on more defined impacts or meaningful thresholds. This provided more distinctive identification of fog and its variations in terms of visibility, or depth/thickness, beyond simple measurements of visual range according to predetermined target ranges. Microphysical studies have also provided sufficient evidence to explain variations in fog behavior based upon its phase composition (i.e., liquid, solid, or mixed) and its subsequent evolution.

Fog drop-size distributions have been determined to range from 1 to 10 μm according to the aerosol (or particulate) matter and the availability of moisture (e.g., mixing ratio of the atmosphere) and condensational processes. Larger sizes are preferred as fog increases during condensation processes, while smaller drops dominate in dissipation. While these also have obvious synoptic signatures as found through observational studies, they are also driven by interactions between fog and the local landscape, including local sources and sinks acting on the micro- and mesoscale. These act to contribute to locally preferred drop-size distributions with specific precipitation or deposition (or terminal velocity) tendencies. An understanding of the dependence and interaction of fog on local features has been aided by air quality and atmospheric chemistry studies (for near-surface locations) as well as the emergent air-surface and air-sea studies (over the last 20 years) that focus on boundary layer exchanges and flux behaviors. These allow a more precise explanation of fog's physical and chemical characteristics (or the statistical family of these) which modulates evolution of fog in time and space – and that create regional and local differences. Due to the physical-chemistry associated with fog events, their electrical, radiative, optical, and acoustical properties also necessarily show variation.

Fog mitigation and applications

More recent investigations have focused on the physical-chemistry involved in cloud (and thus fog) processes as well as techniques for fog dissipation or dispersal based on the foregoing knowledge of fog's physical, chemical, radiative, and internal properties. Other work has been focusing on the chemical mixture of species present in fog in terms of its impacts on human (or animal/plant) respiration (e.g., acute or chronic, mortality), external contact (e.g., surface of the skin or leaf contact), and ingestion (e.g., mucous membranes or eyes, fog-water consumption, or irrigation). In tandem with prior empirical and statistical study, these are assisting in the development of a more comprehensive conceptual model of fog in terms of its characteristics, physical and chemical attributes, and behaviors. Together these provide for integrated numerical modeling of fog with regard to its formation mechanisms, maintenance, intensity, evolution, and dissipation – particularly as related to fog's physical-chemistry and its attendant optical and radiative effects. The ability to quantify these will provide an enhanced ability to model the interactions between atmospheric systems producing fog and the systems impacted by fog (i.e., human and other populations). To best represent and visualize such systems and their interactions, current work has focused on artificial intelligence, impact-response models, and the use of GIS systems.

Presently, fog is known to be formed through three basic mechanisms, each of which are found to a lesser or greater extent in the creation of each fog type or classification. The basic processes are radiative (cooling), advective (cooling and/or lift), and mixing (thermodynamic). Making use of the historical empirical evidence, statistical evaluations, and the principles of physical-chemistry, researchers and application-specialists have used this information to enact two basic types of mitigation or prevention strategies with regard to fog hazards and a third option for use in other cases: (1) fog dispersion, (2) air quality management, and (3) special cases. In the first case fog dispersion has focused on relatively costly mechanical

means (i.e., bulk mixing) as opposed to thermodynamic and physical methods (i.e., heating and/or seeding) that have been applied predominantly at aerodrome locations. For air quality issues, emphasis has been placed on reduced exposure (e.g., avoidance by remaining indoors or masking through the use of personal filters), reduction of contributing sources, or ventilation (similar to bulk mixing) and is often a function of the population affected (i.e., receptors) and the resources required for cost-effective implementation and the likely effectiveness.

The third aspect (special cases) typically offers a mix of the foregoing methods, requires other techniques, or is not well known. These would include situations of ice or acid fog, fog-water collection, smog, or fogs occurring with smoke and haze. Related to these anthropogenic issues are the creations of artificial fogs by cooling towers and other industrial processes or those fogs made for use "on stage" or for entertainment purposes. While most of these make use of simple ventilation techniques or equipment, these environments are often complicated due to the presence of other airborne aerosols which may be more readily deliquesced and thus affective for the population that is present. Impacts may range from ear, eye, nose, or throat ailments or chronic exposure that may need to be treated on an individual basis. Secondary impacts may be wet or dry deposition from fog on plants, buildings, statues, and other surfaces causing damage due to chemical interactions (or scalding).

Operational support

In support of the avoidance, mitigation, or prevention of fog hazards, a variety of operational support and decision-making tools and information is available to forecasters as well as the affected and responding communities (e.g., aerodromes, emergency managers, or similar personnel). In some cases, these are also linked to, or provide data ingest for, numerical or statistical guidance packages. These are particularly effective when tied to GIS databases and decision-support software (or artificial intelligence) and are more commonly used in a military (e.g., transmittal or blockage of select frequencies of communication, visible light and infrared/thermal sensors) or disaster-related type of response (e.g., applications in catastrophe modeling). The additional deployment of meso-and microscale surface-based observing networks will increase the spatial and temporal acuity of data as related to fog occurrence and its evolution so that it may be more accurately detected, assessed, and compared with forecasts (e.g., the National Digitized Forecast Database as per the United States: NOAA/NWS). In some instances, highway systems have been deployed to provide "instant" warning signs to alert drivers to rapidly changing visibility in fog-prone regions.

Satellite and similar remote sensing platforms offer a variety of products (e.g., the website of "Nighttime Fog and Low Cloud Images" as produced by NOAA-NESDIS, USA: http://www.orbit.nesdis.noaa.gov/smcd/opdb/aviation/fog.html) and provide a gross estimate of fog occurrence, intensity, and coverage by channel differencing as well as through examination of sounder data to construct vertical and near-surface profiles of temperature and moisture in the atmosphere. While useful, these products only provide information after fog has formed and thus allow tracking its movements and evolution. While other parameter fields are available through satellite imagery, none presently provide estimates of fog precursors for predictive purposes (or for the assessment of the pre-fog environment). Although microwave sensors and ground-based radar, lidar, and profiler platforms may offer additional information and operational support, none are presently suited to fog detection or prediction (with the exception of automated highway alert systems). Additional information on atmospheric chemistry and structure is now available through several remote sensing platforms, and these will provide a real-time observation profile of the physical-chemistry of the atmosphere as related to fog and other phenomena or conditions in the atmosphere (including the diagnosis of the pre-fog environment).

Summary

Continued progress in understanding the physical and chemical attributes and behaviors of natural and artificial fogs will provide for localized modeling. When these are integrated with community or population-impact models the prediction of fog occurrence, intensity, evolution, coverage, and impacts will be further enhanced. These will require the use of emerging decision-making tools, visualization environments, additional observational networks, and the development of advanced warning systems that monitor the pre-fog environment in order to provide real-time updates and automated advisories. Further work on the mitigation and prevention of fog will proceed from these efforts in order to enhance operations while reducing impacts and costs to the safety and health of select populations as well as economic sectors.

Fohn

FÖHN

Anita Bokwa
Jagiellonian University, Kraków, Poland

Synonyms

Aspre; Austru; Berg; Chinook; Favogn; Halny; Nor-Wester; Samun; Santa Ana; Zonda

Definition

Föhn is a warm, dry, strong, and gusty wind descending down on the leeward side of a mountain range, as a result of a synoptic-scale, cross-barrier flow over the mountain range.

Föhn winds occur along the leeward slopes of mountains in various regions of the world and they have regional names, such as *zonda* in Argentina, *halny* in Poland, *austru* in Romania, *favogn* in Switzerland, *aspre* in France, *chinook* and *Santa Ana* in USA, *berg* in South Africa, *Nor-wester* in New Zealand, and *samun* in Iran. The particular term *föhn* is associated with the Alps. When moist air is forced to rise over the mountains, it cools at the saturated adiabatic lapse-rate ($0.5°C \cdot 100\ m^{-1}$). The humidity increases until the condensation begins. Precipitation may occur and föhn clouds can be formed. Föhn clouds are either orographic clouds or mountain wave clouds. Orographic clouds may include crest clouds and the föhn wall (föhn bank), that is, clouds that form along a mountain range, either on the ridge or slightly above and to the lee of it, and which present, to an observer downwind from the ridge, the appearance of a vertical wall. The most distinctive wave clouds are altocumulus lenticularis clouds. Subsequently the air descends along the leeward side of the ridge and warms at the dry adiabatic lapse-rate ($1.0°C \cdot 100\ m^{-1}$), which generates a rapid rise of air temperature, as high as 20°C (36°F) in 1 h and a decrease in relative air humidity, possibly to less than 5%. Föhn can cause dangerous avalanches and sudden snowmelt in the mountains, which may result in floods. The extreme dryness of air can lead to dangerous fire weather conditions. Föhn has a negative impact on bioclimatic conditions for humans; it increases cardiovascular problems and affects the symptoms of some mental illnesses.

Sometimes before the occurrence of a föhn wind, a high föhn (free föhn) can be observed. The latter are föhn-like conditions at higher elevations, while the lower elevations are under a cold air mass. The mountains are then often warmer than the lowlands. The warming is attributed to subsiding air in a synoptic anticyclone above the cold surface air. The high föhn does not necessarily have strong, gusty winds.

FOREST AND RANGE FIRES

George Eftychidis
Algosystems S.A, Kallithea, Greece
Pangaiasys Ltd., Pikermi, Greece

Synonyms

Forest fires; Range fires; Wildfires

The forest fire problem

Fires have been a major ecological factor that shaped and continue shaping the earth landscape and vegetation along centuries and across the entire globe (Trabaud and Prodon 1992). There have been wildfires long before *Homo sapiens* evolved. One main component of carboniferous and north hemisphere coal is charcoal left over by forest fires. Being an intrinsic factor of the ecosystem, fire occurs where and when the conditions favor ignition. Wildfires are common in many places around the world, where the climates are sufficiently moist to allow the growth of trees, but feature extended dry, hot periods when fallen branches, leaves, and other material dry out and become highly flammable. Wildfires are also common in grasslands and scrublands.

In the Mediterranean region, as well as in areas with a Mediterranean climate type (hot dry summer combined with cold and rainy winter) worldwide, vegetation is considered the result of competition and adaptation to fire of the forest species. Plants use a variety of strategies from possessing reserve shoots that sprout after a fire, to fire-resistant seeds for surviving fire, and they even encourage fire (e.g., eucalypts contain flammable oils in the leaves) as a way to eliminate competition from less fire-tolerant species (http://www.sciencedaily.com/articles/b/bushfire.htm).

In 2004, researchers discovered that exposure to smoke from burning plants actually promotes germination in other types of plants by inducing the production of the chemical butenolide (Dawsa et al., 2004). Most native animals in fire-prone regions are also adapted to surviving wildfires.

The ecological role of the fire in the natural ecosystems can be compared to the role of fever as a protective response to human diseases. According to the circumstances both can be a healthy systemic reaction or a lethal upshot. Thus, small-scale fires or fires in old, mature forest stands can be part of the natural dynamics of the ecosystem and, therefore, beneficial to the health of the vegetation from the ecological point of view. On the contrary, frequent, repetitive fires which prevent the stands from maturity and suppress the regeneration capability of the forest or large-scale fires that consume the tree seeds due to high fire intensity can be catastrophic or leading to a permanent impair of the ecosystem.

Although the vast majority of fire ignition is due to human activity or is intentionally set, there are fires that start from natural causes such as lightning or self-ignition. Rapid land-use changes, socioeconomic conflicts, and competing interests, which are quite typical in the regions threatened by forest fires, contribute to increasing their occurrence and tend to aggravate their effects. With extensive urbanization of wild lands, fires often involve destruction of suburban homes located in the surroundings of large cities and in the zone of transition between developed areas and undeveloped wild land, the so-called wildland urban interface. The problem of fire in the wildland urban interface increased greatly over the last decades due to lack of management of nonproductive forests and the extensive use of forests as recreation and residence areas. The combination of flammable vegetation and human activity in the same area fanned most of the large disastrous fires in Greece in 2007 (Peloponnesus) and 2009 (Attica), Portugal in 2003, Australia in 2009 (Victoria), USA in 2003 and 2008 (California), etc.

Every year, 9,200 million tons of biomass are burnt globally for energy generation. Wildfires consume over half of this – some 5,130 million tons of biomass. At the same time, they release 3,431 million tons of CO_2 into the atmosphere, contributing to global greenhouse gas emissions and thus to climate change (FAO, 2007).

Although the main reason for increased fire occurrence over the last decades is land-use change, climate change plays a very important role in modifying forest fire regimes worldwide. The fire-prone Mediterranean landscapes in Europe are likely to be affected by regional climate change that may exacerbate the current fire conditions. Recent assessments on climatic changes in the Mediterranean Basin show that air temperature increases while summer rainfall is reduced, which leads to an increase in the soil water deficit and the vegetation water stress (Dimitrakopoulos and Mitsopoulos, 2006). As vegetation burns, it releases stored-up carbon into the atmosphere, speeding global warming and thereby exacerbating conditions that may lead to extreme behavior and generate a greater incidence of wildfires in the coming years (Flannigan et al., 2005). This phenomenon can be further engraved by the use of fire on a massive scale as a cheap and efficient way to clear forests for agriculture or development. In fact, deforestation fires alone have contributed 20% of the total greenhouse gases that humans have contributed to the atmosphere since industrialization (Scientific American, 2009).

The fire season

Fire season is defined as the period or periods of the year during which wild land fires are likely to occur, spread, and do sufficient damage to warrant organized fire-suppression activities.

Naturally caused fires are more frequent as the dry and warm season advances, due to the cumulative decrease of moisture in the soil and the limited rainfall. Geographically the number of fires increases as we move from smaller to greater latitudes and from higher altitudes to the sea level. The fire season typically starts after the end of the winter rainfall and finishes following the first rains in autumn.

Types of fire

It is quite usual to describe the type of a fire burning in natural surroundings in terms of the main form of supporting vegetation. A forest fire, often termed as "wildfire" in the US literature, and "vegetation fire" or "bushfire" in Australasia, is an uncontrolled fire in tall, closed forests, ignited by natural or human causes. The term is commonly used referring to any fire event burning in wildland areas. Grass fire is a relative term referring to fire burning herbaceous vegetation, which may be substituted by the terms prairie, rangeland, or veldt (similar to savanna areas in African regions) fire (Luke and McArthur, 1986). There can be also tundra fires, moor or muir (poorly drained areas with patches of heath and peat bogs) fires, and peat fires which usually burn underground. In North America, the term "brushfire" is used if the main fuel is a low, scrubby vegetation, whereas in Australia such type of fire is called scrub fires. Rural fire is also used to describe fires burning in the countryside in a mosaic of agricultural cultivations.

All grass species have a lifestyle where the grass grows, flowers, and dies. This process is called curing. Due to curing, grasslands and rangeland fires can occur earlier than fires in shrub lands and forest stands, according to the degree of curing of grass along the fire season. Brush and chaparral (maquis) fires usually start somewhat later in the season than the first grass fires, and they normally have more intense, longer lasting impacts.

Furthermore fires can be characterized based on the vegetation layer in which they burn or propagate. We may then distinguish ground, surface, and crown fires, whereas the term "spot fire" is used to denote a secondary fire which has been ignited ahead of the main fire by an airborne firebrand or ember.

Overall, the types characterized by the vegetation layer carrying the fire include the following:

- *Ground fires* which burn below the surface or the ground in deep layers of organic material such as peat bogs, fed by subterranean roots, duff, and other buried organic matter. This fuel type is associated with smoldering combustion and is particularly susceptible to ignition due to spotting. Ground fires can be caused due to inadequate vegetation management, such as peat fires in Kalimantan and Eastern Sumatra, Indonesia, which resulted from a rice land creation project that unintentionally drained and dried the peat.
- *Crawling or surface fires* are fueled by low-lying vegetation such as leaf and timber litter, debris, grass, and low-lying shrubbery without extending into the tree crowns. In this category we include grass, brush, and shrub fires.
- *Crown, canopy, or aerial fires* burn tree crowns and suspended material – called ladder fuels – at the canopy level, such as tall trees, vines, and mosses. The ignition of a crown fire, termed "crowning," is dependent on the density of the suspended material, distance of the canopy base from ground, canopy continuity, and sufficient surface and ladder fuels for the flames to reach the tree crown.

Crown fires evolve often to extremely violent fires that are described as conflagrations or blow-up fires, meaning fires having "assumed three-dimensional characteristics" (Luke and McArthur, 1986).

Fires are also characterized according to the combustion phase as flaming, creeping, and smoldering. Flaming is normally associated with the front of the fire propagation. A creeping fire is a low-intensity fire with a negligible rate of spread whereas a fire burning without flame and barely spreading is characterized as smoldering. Smoldering combustion of biomass can linger for days or weeks after flaming has ceased without having any visual impact; however, it has important consequences for the forest ecosystem resulting in large quantities of fuels consumed and becoming a global source of emissions to the atmosphere. The slow propagation during the smoldering phase of combustion leads to prolonged heating and might cause sterilizations of the soil or the killing of roots, seeds, and plant stems at the ground level.

Detection

Fast and effective detection is a key factor in wildfire fighting. Early detection and relevant warning of the protection authorities aim to early response for limiting the fire size and thus require accurate location of the fire spot in relation to topography, day and nighttime operation, and ability to prioritize fire danger (Hirsch, 1964).

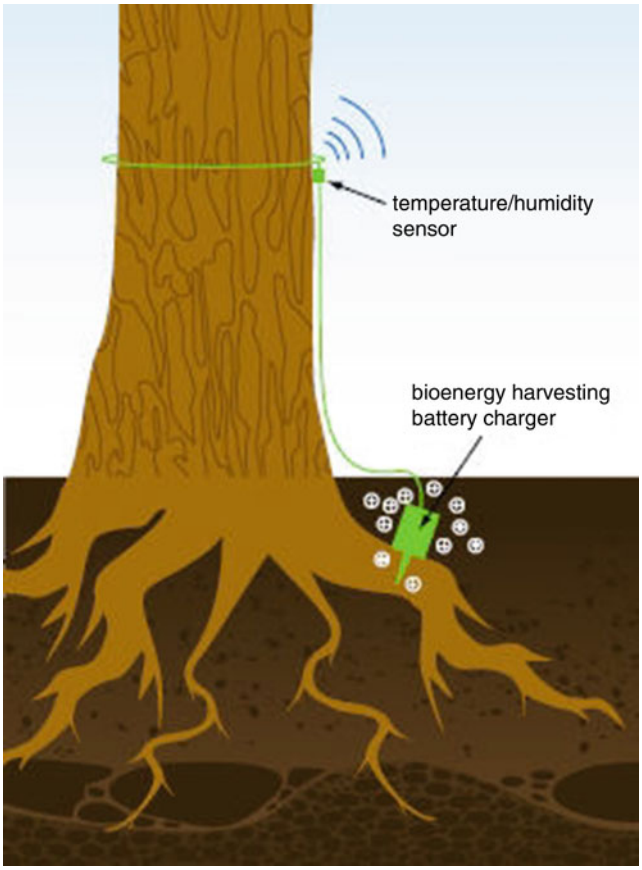
Fires were detected systematically from observers in lookout towers since the beginning of the twentieth century. Most of these towers were more than 30 m tall with views reaching up to 50 km. However, forest authorities limited such high towers later being concerned that people might climb up and injure themselves (CBC Digital archives). Before radio contact was possible, observers reported fires using telephones, carrier pigeons, and heliographs (a heliograph operator uses Morse code to communicate by tilting a mirror to reflect sunlight). Aerial and land photography using instant cameras were used in the 1950s until infrared scanning was developed for fire detection in the 1960s. However, information analysis and delivery was often delayed by limitations in communication technology. Early satellite-derived fire analyses were hand-drawn on maps at a remote site and sent via overnight mail to the Fire Manager.

In the last decades, public hotlines, fire lookouts in towers, and ground and aerial surveillance platforms have been used as means of early detection of forest fires. However, since accurate human observation may be influenced by operator fatigue, time of day, time of year, and geographic location, electronic systems have gained popularity in recent years as a possible alternative. The layout of a network of fire detection stations is defined based on the results of visibility analysis and fire risk assessment of the envisaged area performed using GIS technology. Alerts from fire detection systems are normally merged by the Fire Manager together with satellite data, aerial imagery, and personnel position, available via Global Positioning System (GPS), into a response module of an Integrated Forest Fire Management system. There are currently systems under development which consider broadcasting of fire detection alerts to local population using SMS messaging (ESS project, 2009).

Small, high-risk areas that feature thick vegetation, a strong human presence, or that are close to a critical urban area can be monitored using a local wireless sensor network in order to overcome privacy problems associated with the use of visual cameras (Dubbeld, 2005). These networks act as specific automated weather systems: detecting temperature, humidity, and smoke. This is a modern approach for detecting fire ignition and monitoring its propagation using dispersed wireless temperature sensors, fixed on trees (Figure 1), which communicate to each other their status and measurement, broadcasting alerts to long distances if a fire occurs.

Wireless sensors are normally powered by batteries, since their size is rather small and forest conditions are not favorable for using solar energy. A major environmental issue regarding this technology is the dispersal of the batteries in the forest. This problem requires the monitoring of the sensors at the physical level, which in fact downgrade the performance of the solution and prevent its safe use in natural environments. Recent developments consider the use of bioenergy-harvesting technology (tree-supplied energy) for recharging batteries using converted metabolic plant energy into usable electricity, which can be a relevant solution in the future (Figure 2).

Larger, medium-risk areas are usually monitored by scanning towers that incorporate fixed cameras and sensors to detect smoke or additional factors such as the



Forest and Range Fires, Figure 1 Wireless fire sensors (Photo courtesy Enveve SA).

infrared signature of carbon dioxide produced by fires. Brightness and color change detection and night vision capabilities may be incorporated also into sensor arrays.

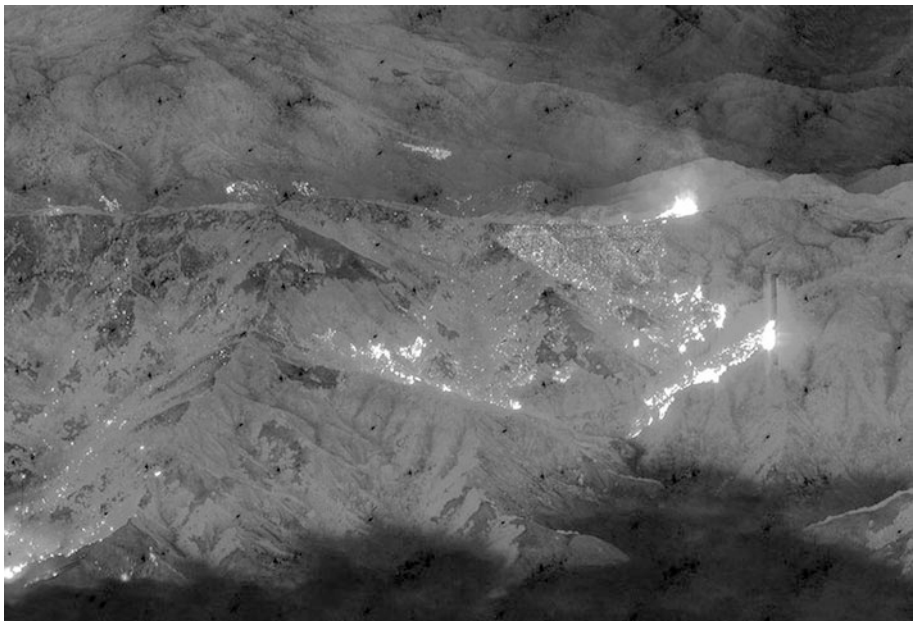
A particular solution is considered to be the use of mobile fire detection and monitoring stations which can be deployed in an area only during the fire season and moved easily in other areas during the rainfall period in order to be used, for example, for flood monitoring (Figure 3).

Satellite and aerial monitoring can provide a wider view and may be efficient to monitor very large, low-risk areas. Properly equipped unmanned aerial vehicles (UAV) are used for such purpose. These more sophisticated systems employ GPS and aircraft-mounted infrared or high-resolution visible cameras to identify and target wildfires (Figure 4).

Satellite-mounted sensors, such as Envisat's Advanced Along Track Scanning Radiometer and European Remote-Sensing Satellite's Along-Track Scanning Radiometer, can measure infrared radiation emitted by fires, identifying hot spots greater than 39°C. The National Oceanic and Atmospheric Administration's Hazard Mapping System in the USA combines remote-sensing data from satellite sources, such as Geostationary Operational Environmental Satellite (GOES), Moderate-Resolution Imaging Spectroradiometer (MODIS), and Advanced Very High Resolution Radiometer (AVHRR), for detection of fire and smoke plume locations. However, satellite detection is limited so far for operational use in the conditions of the European forests. This is due to the fact that satellite detection of fires is prone to offset errors, anywhere from 2 to 3 km for MODIS and AVHRR data and up to 12 km for GOES data. Satellites in geostationary orbits may become disabled, and satellites in polar orbits are often limited by their short window of observation time. Cloud cover and image resolution may also limit the effectiveness of satellite imagery. On the contrary,

Forest and Range Fires, Figure 2 Voltreebioenergy harvesting system (Photo courtesy Voltree power).

satellite technology can be very helpful for monitoring very large fires, detecting fires in isolated vast forest areas as well as for supporting post-fire management decisions (Figure 5).



Prevention

Since most of the fire events recorded in the various regions of the planet are caused by human activity it is expected that fire ignition can be prevented. Similarly measures can be taken for mitigating the impact of a fire in order to keep its size within the boundaries of the fire control mechanism. This is the main objective of the fire prevention planning worldwide.

While considered global the wildfire problem appears different due to the diversity of the ecological factors and the existing variety of land-use patterns, the environmental awareness, the fire culture, and the forest management practices across the globe. Thus, the percentage of human-caused fires can differ from as low as 60% in the Northern American continent (except Mexico) up to 95% in the Mediterranean region (FAO, 2007). However in Mexico and Central America, this percentage raises to 97% since several fires are intentionally set for

Forest and Range Fires, Figure 3 Mobile fire detection station installed in the island of Karpathos in Greece (Photo courtesy Faenzi Srl).

Forest and Range Fires, Figure 4 A photo of the wildfires in Northern California taken by the RQ-4 Global Hawk (UAV).

agricultural purposes. In countries such as Canada and the Russian Federation, lightning is a major cause of starting a fire in the forest. In Canada, for instance, 35% of the total number of fires is caused by lightning compared with the 60% of fires ignited by human activity. On the contrary, in southern EU countries (Portugal can be an exception here), although being the main natural factor, lightning causes less than 5% of the fire starts (Kettlunen et al., 2008). Fire is also used as a forest management tool for eliminating competition between species, reducing fire hazard, improving the recycling of nutrients of the soil, etc. Although prescribed fire is normally practiced since

Forest and Range Fires, Figure 5 Wildfires across the Balkans in late July 2007 (MODIS image).

several decades in the USA and Australia, it is slowly progressing in Europe as a Forest and Fire Prevention Management practice.

Wildfire prevention refers to the preemptive methods of reducing the risk of fires as well as lessening its severity and spread. Effective prevention techniques allow supervising agencies to manage air quality, maintain ecological balances, protect resources, and limit the effects of future uncontrolled fires. However, prevention policies must consider the role that humans play in wildfires, since, for example, only 5% of forest fires in Europe are not related to human involvement. Sources of human-caused fire may include arson, accidental ignition, or the uncontrolled use of fire in land-clearing and agriculture such as the slash-and-burn farming in Southeast Asia.

Fire danger rating systems are used by national authorities in most countries for producing qualitative and/or numeric indices of fire potential, based mainly on fuels, topography, and weather. These rating systems allow Fire Managers to estimate present and future fire danger for a given area.

From the management point of view, the risk of major wildfires can be reduced by reducing the amount of fuel present. In wild land, this can be accomplished by either conducting "controlled burns" – deliberately setting areas ablaze under less-dangerous weather conditions in spring or autumn – or physical fuel removal by removing some trees or shrubs beneath the forest stands. Multiple fuel treatments are often needed to influence future fire risks, and wildfire models may be used to predict and compare the benefits of different fuel treatments on future wildfire spread. Both approaches are controversial with some environmentalists, who regard them as tampering with the forest ecosystem.

Beyond the operational management of fires, major issues for preventing catastrophic events are education of the population and reasonable planning of land development in particular in the wildland urban interface.

People living in fire-prone areas typically take a variety of precautions, including building their homes out of flame-resistant materials following particular national codes, reducing the amount of fuel within a prescribed distance from their home or property (including *firebreaks* – their own miniature control lines, in effect), and investing in their own firefighting equipment. Communities in the Philippines maintain fire lines 5–10 m wide between forests and villages, and patrols along these lines are set during summer months or seasons of dry weather. In Switzerland, agricultural zones are planned between settlements and forests for reducing the risk and providing defensible space to address a fire approaching the village.

Rural farming communities are rarely threatened directly by wildfire. These types of communities are usually located in large areas of cleared, usually grazed, land, and during the drought conditions that prevail in the wildfire years, there is often very little grass left on such grazed areas. Hence the risk is minimized. However, urban fringes spread in and communities have literally built themselves in the middle of highly flammable forests. These communities are at high risk of destruction in the case of forest fires.

Wildfire mitigation is accomplished through the assessment of fire risks, the reduction of fire risks, and the prevention of unwanted fires. Loss of life, property, and resources can be reduced if planners, developers, fire agencies, and homeowners work together to define, enforce, and maintain reasonable fire safety standards.

The fire paradox

Since a great percentage of fires are due to the human activity and carelessness, for many decades the fire management policy was to suppress all fires. In 1937, US President Franklin D. Roosevelt initiated a nationwide fire prevention campaign, highlighting the role of human carelessness in forest fires. Sixty years after implementing aggressive fire-suppression programs they realized that no new sequoias had been grown in the redwood forests of California, because fire is an essential part of their life cycle. This situation led to including controlled burns in the fire management policy for reducing much of the forest undergrowth which is the main stratum supporting the propagation and growth of the fire. Therefore in North America, current firefighting policies may permit naturally caused fires to burn to maintain their

ecological role, so long as the risks of escape onto high-value areas are mitigated.

It was in the mid-1800s when explorers from the HMS Beagle (the ship of Charles Darwin mission) observed Australian Aborigines using fire for ground clearing, hunting, and regeneration of plant food in a method called fire-stick farming. Such careful use of fire has been employed for centuries in the lands protected by Kakadu National Park in Australia to encourage biodiversity.

In Europe, fire management practice continues to be closer to the fire suppression, although there are efforts to consider the use of fire as a tool for managing wild land fires. However, the human activity continues to be the center of any fire management policy, trying to combine easier access to the forest while reducing the risk of dangerous high-intensity fires caused by many years of fuel buildup. Although not a European peculiarity, there are fire management policies that are still missing which can address fire prevention with the objective to ensure sustainability, biodiversity, and community-based protection of the forests (Figure 6).

The fire-exclusion policy results also in the buildup of forest fuel resulting in large and severe fires in all countries where the policy proved to be successful for several years in the past. This is known as the fire paradox, which put on evidence that efficient fire suppression leads after years to bigger fires if not accompanied with other forest management measures. Large fires, the so-called Megafires, were the result of this policy in the Yellowstone National Park in 1988, the fires in Greece during the summer of 2007, and many others. Urbanization of forested areas is another factor resulting in fuel buildup and devastating fires, such as those within the California cities of Oakland and Berkeley (1991, 2003), all over Colorado (2002), in Attica region (Greece 2009), in Guadalajara (Spain 2005), etc.

Forest fuels and fuel management

In wild land fires, fuel corresponds to all combustible plant-derived material including grass, litter, duff, down dead woody debris, exposed roots, plants, shrubs, and trees. This plant-derived material can be dead or alive. Thus, a significant difference between fuel and vegetation is that fuel refers mainly to small- and medium-sized combustible material including dead vegetative material, while vegetation refers to the living plant components of any size. Plant parts that are not consumed, such as the trunks of live trees, are not considered fuel.

The forest fuel concept, as used in fire behavior modeling, includes further the horizontal and vertical distribution of the combustible material in the forest. Thus, the spread of wildfires varies based on the quantity and distribution of the flammable material present in the forest fuel bed and its vertical arrangement.

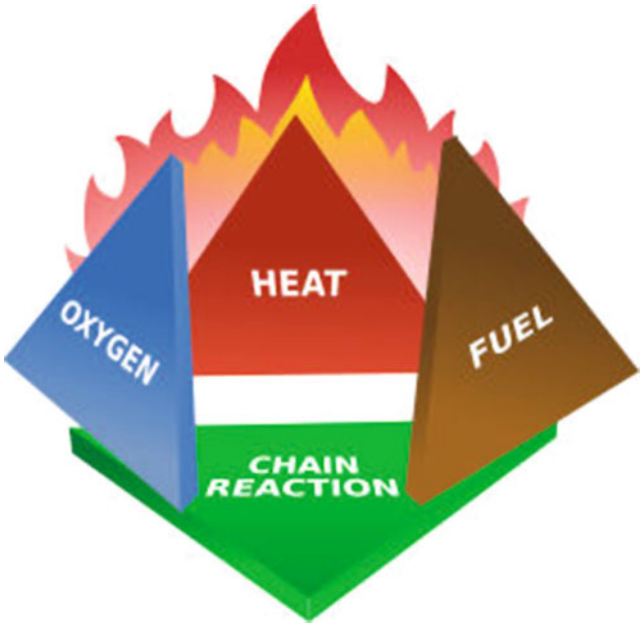
Fuel status is influenced not only by the weather but also due to the topographic conditions in the fire scene. For example, fuels uphill from a fire front are more readily dried and warmed by the fire than those downhill, yet burning logs can roll downhill from the fire to ignite other fuels. Fuel arrangement and density is governed in part by topography, as land shape determines factors such as available sunlight and water for plant growth.

Fuels can be produced or modified by the human activity in the forest. Fuels resulting from, or altered by,

Forest and Range Fires, Figure 6 Controlled burning in Portugal.

forestry practices such as timber harvest or thinning, as opposed to naturally created fuels are called Activity fuels. Branches and other noncommercial wood left on site after timber harvesting (slash) is the quintessential activity fuel. Other land management and activity, such as pruning, herbicide application, noncommercial thinning of forest stands, and even controlled burning (killing tree branches or whole trees) for silvicultural purpose, can create activity fuels.

A series of fuel classification systems have been historically developed taking into account the needs of fire management and fire modeling. In the traditional sense, fuel models are a set of parameters that describe vegetation in terms that are required for the solution of a mathematical rate-of-spread model. Fuel models were thus defined initially as input to fire growth simulation models, such as Rothermel's surface fire behavior and spread model (Rothermel, 1972), BEHAVE (Burgan and Rothermel, 1984; Andrews et al., 2005), FARSITE (Finney, 2006), FlamMap fire potential simulator (Finney, 2006), and Canadian Wild land Fire Growth Model (CWFGM) Prometheus (Prometheus, 2000). Nowadays, it is recognized that solid fuel classification systems are also essential tools for fuel mapping, hazard assessment, evaluation of fuel treatment options, and monitoring fire effects (Sandberg et al., 2001).

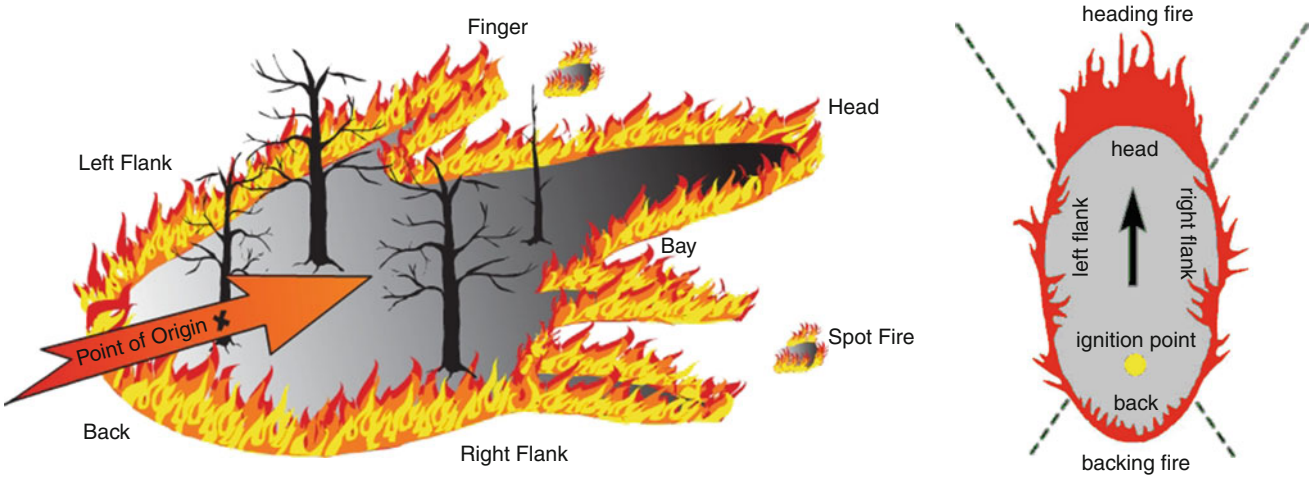


Fuels are the main component of the fire triangle which fire management can influence directly. Fuel management projects are prepared on a regular base, including thinning and pruning of vegetation, partial removal of understory shrubs, construction of fuelbreaks and control lines, etc. The objective of the fuel management is to keep fire behavior corresponding to predefined environmental scenarios within the limits of the fire-suppression mechanism. Fuel typology is useful for supporting planning of forest fuel management projects.

Fire behavior

Wildfires occur when fuel, heat, oxygen, and the chain reaction occur in a wooded area. The fire occurrence is modeled as a tetrahedron having in each of its sides one of the aforementioned elements as shown in the "Figure 7".

The time of burning is considered an additional dimension to the traditional fire triangle since longer fire duration can release additional energy, increase the potential of the fire, and cause extreme or erratic behavior.



Wildfire behavior and severity result from the combination of factors such as available quantity of burnable material (fuel load); physical setting, that is, topographic conditions; and weather. Based on these conditions the size of the fire can vary greatly. Wildfires can be kept small if wind strength, fuel quantity, and distribution (sparse vegetation) prevent its propagation. Fires are also kept small if they are suppressed at a very early stage before gaining significant size and releasing energy that supports their propagation and outweighs the suppression efforts.

Forest and Range Fires, Figure 7 The fire tetrahedron.

An ignition source is brought into contact with a combustible material such as vegetation, which is subjected to sufficient heat and has an adequate supply of oxygen from the ambient air. High quantity of water in the burnable material (fuel moisture content) usually prevents ignition and slows propagation, because higher temperatures are required to evaporate any water within the material and heat further the material to its ignition point. Dense forests usually provide more shade, resulting in lower ambient temperatures and greater humidity, and are therefore less susceptible to wildfires. Less-dense materials, such as grasses and leaves, are easier to ignite because they contain less water than denser materials, such as branches and trunks. Plants continuously lose water by evapotranspiration, but water loss is usually balanced by water absorbed from the soil, humidity, or rain. When this balance is not maintained, plants dry out and are therefore more flammable, often a consequence of droughts.

Occasionally fires spread outward at an equal rate in all directions and assume a circular form. This is more probable in grass fires burning a homogeneous fuel bed, in calm conditions and in rather plain areas. Forest fires burn and grow according to the availability of the material that they consume, the prevailing wind, and the landscape topography. Therefore, they normally become irregular or elongated in shape when spreading. For supporting fire suppression, specific names are assigned to the different parts and sectors of a spreading fire as shown in the Figure 8.

Forest and Range Fires, Figure 8 The parts of a forest fire.

A wildfire front is the portion sustaining continuous flaming combustion, where unburned material meets active flames, or the smoldering transition between unburned and burned material. As the front approaches, the fire heats both the surrounding air and woody material through convection and thermal radiation. First, wood is dried as water is vaporized at a temperature of 100°C. Next, the pyrolysis of wood at 230°C releases flammable gases. Finally, wood can smolder at 380°C or, when heated sufficiently, ignite at 590°C. Even before the flames of a wildfire arrive at a particular location, heat transfer from the wildfire front warms the air to 800°C, which preheats and dries flammable materials, causing materials to ignite faster and allowing the fire to spread faster. High-temperature and long-duration surface wildfires may encourage flashover or torching: the drying of tree canopies and their subsequent ignition from below.

Wildfires have a rapid forward rate of spread when burning through dense, uninterrupted fuels. They can move as fast as 10.8 km/h in forests and 22 km/h in grasslands. Wildfires may spread by jumping or spotting as winds and vertical convection columns carry firebrands (hot wood embers) and other burning materials through the air over roads, rivers, and other barriers that may otherwise act as firebreaks. Torching (an intermittent ignition of tree crowns as fire advances) and fires in tree canopies encourage spotting, and dry ground fuels that surround a wildfire are especially vulnerable to ignition from firebrands. Spotting can create spot fires as hot embers, and firebrands ignite fuels downwind from the fire. In Australian bushfires, spot fires are known to occur as far as 10 km from the fire front.

Large wildfires may particularly affect air currents in their immediate vicinities by the stack effect: Air rises as it is heated, and large wildfires create powerful updrafts that will draw in new, cooler air from surrounding areas in thermal columns. Great vertical differences in temperature and humidity encourage the formation of pyrocumulus clouds, strong winds, and fire whirls with the force of such tornadoes to reach speeds of more than 80 km/h. Rapid rates of spread, prolific crowning or spotting, the presence of fire whirls, and strong convection columns define extreme conditions of fire behavior.

Fire intensity increases during daytime hours. Burn rates of smoldering logs are up to five times greater during the day due to lower humidity, increased temperatures, and increased wind speeds. Sunlight warms the ground during the day which creates air currents that travel uphill. At night the land cools, creating air currents that travel downhill. Wildfires are fanned by these winds and often follow the air currents over hills and through valleys.

From the chemical point of view, fire is an oxidation process that rapidly transforms the potential energy stored in chemical bonds of organic compounds into the kinetic energy forms of heat and light. Like the much slower oxidation process of decomposition, fire destroys organic matter, creating a myriad of gases and ions, and liberating much of the carbon and hydrogen as carbon dioxide and water. A large portion of the remaining organic matter is converted to ash which may go up in the smoke, blow or wash away after the fire, or, like the humus created by decomposition, be incorporated into the soil.

Fires in shrub lands compared to grasslands burn with much greater thermal output because their fuel loading can be 5–50 times greater than that in grasslands. Similarly, the fuel in a mature forest, which may be 100 times greater than that of a medium density shrub land, requires more time to dry and become available for combustion.

The state of grassland curing is critical to the initiation and spread of grass fires. The proportion of dead grass in a pasture has a major effect on grassfire behavior. Thus, the fire is spread fast in grasslands even in cases where the grass is cured barely more than 50% and despite the presence of several green shoots.

Fire is traditionally used worldwide as grassland management tool and several wildfires start from grasslands burning for soil improvement (fertilization).

Fire modeling

Fire modeling is concerned with numerical simulation of wildfires in order to comprehend and predict fire behavior. Models are helpful tools for scientists and engineers. Fire models are used for organizing prevention, training firefighters, and supporting the coordination and decisions during the fire-suppression operations.

Existing models used for fire modeling are usually classified into the following: empirical models which are based primarily on statistics collected by observation of experimental or historical fires; physical models based on physical principles of fluid dynamics and laws of conservation of energy and mass; and semiempirical models based on physical laws, but enhanced with some empirical factors.

Various wildfire propagation models have been proposed in the past, including simple ellipses and egg- and fan-shaped models. Early attempts to determine wildfire behavior assumed terrain and fuel uniformity in space. However, the exact behavior of a wildfire's front is dependent on a variety of factors, including wind speed and slope steepness. Modern growth models utilize a combination of past ellipsoidal descriptions and Huygens' Principle to simulate fire growth as a continuously expanding polygon (Finney, 1998).

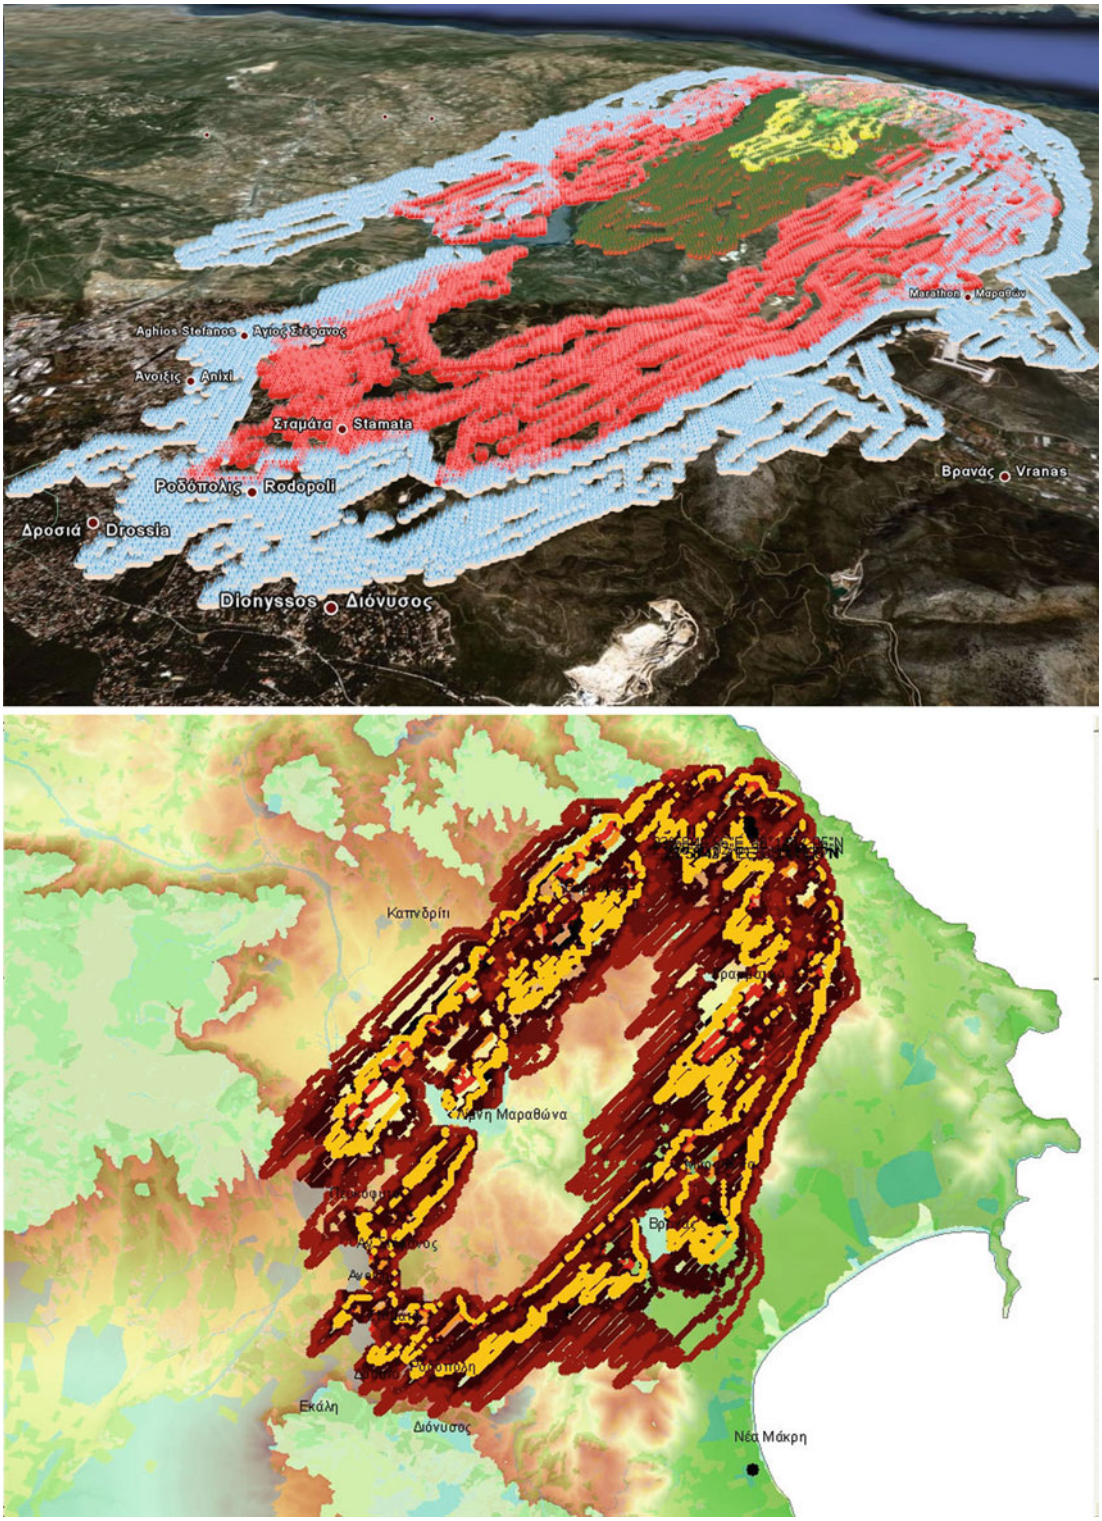
Computer models help predicting the propagation of a fire under varying fuel, weather, and topographic conditions. The most known modeling system for assessing wildfire is BEHAVE, which is a wild land fire behavior and fuel modeling system developed by the US Department of Agriculture Forest Service (Andrews et al., 2003). Numerous information systems have been developed based on BEHAVE and are currently in use for supporting operational fire management decisions worldwide (Farsite, Flamap, CARDIN, GFMIS, Fire tactics, Fire station, etc.) (Figure 9).

Fire suppression

Although fire is vital to the long-term health and sustainability of many ecosystems, wildfires take numerous human lives and cause damages in the range of several millions of euro per year.

Suppression includes all the procedures which start on, or after the fire alarm. Fire-suppression efforts are based on the fact that any fire requires three things: heat, fuel, and oxygen. Together, these make up the three legs of the so-called fire triangle known to all firefighters. The strategy in all firefighting is to extinguish the blaze by breaking one of the legs of this triangle. An entire science has developed around fire behavior and the effects of changing weather, topography, and fuels on that behavior.

There are several techniques for controlling the fire propagation in the forest. Fuelbreaks are 20–300-m-wide strips of land on which the natural vegetation has been permanently modified so that fires burning into it can be more readily controlled (Heikkila et al., 1993). Fuelbreaks are created as a prevention and mitigation measure before the start of any fire event in the area. They can include roads, streams, or rivers for extending the width of the fire barrier. During the fire event, firebreaks, which are strips from which all fuel is removed, are created and they are used as a control line for suppressing an approaching fire front. Existing natural or constructed fire barriers in the direction of the fire propagation are used as firebreaks as well.



Most fire-prone areas are served by fire authorities aiming to protect them from forest fires. Similarly to the water-spraying fire trucks used in urban fires, forest fire services use a variety of alternative firefighting techniques. These may refer to a variety of tools and technologies including chain saws and hand tools, all terrain fire-engines using water and foam, water-bombing air planes using sea- or lake-water and fire-retardants, helicopters with water bucket, etc. Sophisticated firefighting technology can consider edge techniques, such as the use of cloud seeding with silver iodide, full-scale aerial assaults by UAVs, establishment of fire control lines using water mist, use of explosives, etc. However, large fires are often of such a size that no conceivable firefighting service could attempt to douse them efficiently, and so alternative techniques are used.

Normally forest firefighters attempt to control the fire by controlling the area where it is spread, by creating firebreaks as control lines. These control lines can be produced by physically removing fuel (e.g., using bulldozers), or by "backburning," which refers to small, low-intensity fires that are set by the fire authorities in order to burn the flammable material between the fire front and the control line in a (hopefully) controlled way. These fires may then be extinguished by firefighters, or, ideally, directed in such a way that they meet the main fire front, at which point both fires run out of flammable material and are thus extinguished (Figure 10).

Unfortunately, such methods can fail in the face of wind shifts causing fires to miss control lines or to jump over them (e.g., because a burning tree falls across a line, burning embers are carried by the wind over the line, or burning tumbleweeds cross the line).

The actual goals of firemen during wildfire fighting vary. Protection of life (both of the firefighters and the "civilians") is given top priority, then follows private property according to economic and social value and also to its "savability" (structure triage), that is, to give an example, in a wildland urban interface fire, more effort will be dedicated towards saving a house with a tile roof than one with a wooden shake roof.

The usual firefighting tactic is the creation of control lines, that is, to create a defense line by removing fuels very far from the moving fire front. The control line is decided based on the estimation of the fire propagation according to the wind, topography, and forest fuels ahead

Forest and Range Fires, Figure 9 Simulation of a fire propagation using the GFMIS forest fire simulator.

Forest and Range Fires, Figure 10 Backburning.

of the front. Preventing the burning of publicly owned forested areas is in some countries (e.g., in Australia) of least priority, and it is quite common for firefighters to simply observe a fire burning toward control lines through forest rather than attempt to put it out more quickly – it is, after all, a natural process. This is not, however, the case in wildland urban interface or rural fires where the firemen have to protect the residents, their property, and the threatened infrastructures. In such cases, life protection comes first, whereas protecting houses is regarded as more important than, say, farming machinery sheds, although firefighters, if possible, try to keep fires off farmland to protect stock and fences (steel fences are destroyed by the passage of fire, as the wire is irreversibly stretched and weakened by it).

During the first stage of the fire evolution suppression can be performed using back-pack pumps and hand tools. As the fire grows mechanical means like chain saws and equipment (dozers, etc.) are required. The last stage of a controllable wildfire is addressed using aerial means. Despite the fact that aerial firefighting is considered by the public the most efficient practice for extinguishing wildfires, the fire propagation can be efficiently stopped by ground crews creating appropriate control lines (removing fuels). It is true that large fires and conflagrations cannot be distinguished from the ground. However, very large fires (so-called Megafires) burning with extreme weather conditions cannot be extinguished by aerial means either.

Fire effects

The aftermath of a wildfire can be as disastrous if not more so than the actual fire itself. A particularly destructive fire burns away plants and trees that prevent the forest soil from erosion. If heavy rains occur after such a fire, landslides, debris flows, and flash floods can occur. This can result in property damage in the immediate fire area and can affect the quality of water in streams, rivers, and lakes. Thus, soil erosion and flooding are the main effects expected following a wildfire.

Fires of both natural and anthropogenic origin have generated biotic and abiotic effects on ecosystem properties and the environment. The biotic effects of fire include changes in vegetation composition and subsequent impact on wildlife. Abiotic effects include changes in soil properties, nutrient cycling, water quality, and air quality. The quality of life experienced by human populations near the burned area is also impacted.

When the forest burns, the ground may or may not be intensely heated, depending on the arrangement of fuels from the ground to the forest canopy. Under a hot burn with the heavy ground fuel found in some forests, heat can penetrate mineral soil to a depth of tens of centimeters, significantly altering the physical, chemical, and biological properties of the soil. When the soil is heated, water is driven out; soil structure, which is the small aggregations of sand, silt, clay, and organic matter, may be destroyed, leaving a massive soil condition to a depth of several inches.

Forest and shrub lands soils often become hydrophobic or water repellent after the fire passage. A hydrophobic layer of a few centimeters thick commonly develops just below the burned surface. This condition is created because the fire's heat turns organic matter into gas and drives it deeper into the soil, where it then condenses on cooler particle surfaces. Under severe conditions, water simply beads and runs off this layer, like water applied to a freshly waxed car. Soil above the hydrophobic layer is highly susceptible to erosion during the first rains after a fire. Fortunately, the hydrophobic layer is soon broken

by insects and burrowing animals, which have survived the fire by going underground; they penetrate the layer, allowing water to soak through.

Forest fires decrease soil acidity, often causing pH to increase by three units before and after the fire (e.g., from 5 to 8). Normally, conditions return to pre-fire levels in less than a decade. Fires also transform soil nutrients, most notably converting nutritive nitrogen into gaseous forms that go up with the smoke. Some of the first plants (legumes) to recolonize a hotly burned area are those whose roots support specialized bacteria that replenish the lost nutritive nitrogen through a process called nitrogen fixation. Large amounts of other nutrients, including phosphorus, potassium, and calcium, remain on the site, contributing to the so-called ashbed effect. Fires convert through burning organic vegetative material that could not before be used by the plants to a fertile ashbed. Plants that colonize these fertile ashbeds tend to be more vigorous than those growing outside of them. When heating has been prolonged and intense in areas such as those under burning logs, stumps, or debris piles, soil color can change from brown to reddish. Fires hot enough to cause these color changes are hot enough to sterilize the soil, prolonging the time to recovery. In the absence of heavy ground fuels, so much of the energy of an intense forest fire may be released directly to the atmosphere that soils will be only moderately affected.

Competing conceptions of the costs and benefits of wildfires have led to conflicting fire management and suppression objectives, most notably in the national parks and national forests. The debate on which fires should be allowed to burn and which should be suppressed undoubtedly will continue for some time.

Summary and conclusions

Forest fires are a major environmental issue worldwide. Despite the progress of the fire-suppression technology and the advances in fire science, the results in terms of burned area and damages still remain poor. People have now exposed a wealth of assets in fire-prone forest areas which competes with forest downgrading its environmental services. The policy of aggressive fire suppression is to limit the number of fires and to control the small- to medium-sized fires. However, the size of large and very large fires, fanned by global warming, exceeded all the previous records in the last decade and threatens the forest sustainability in the future if economic growth will continue feeding human activity in the forest without revising citizen's fire culture and creating rational plans of land development.

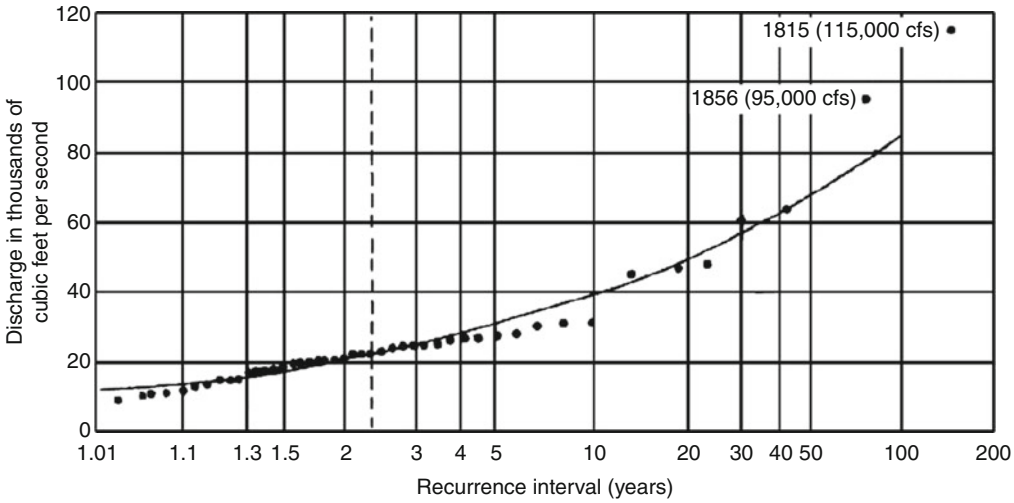
FREQUENCY AND MAGNITUDE OF EVENTS

Lionel E. Jackson, Jr.
Geological Survey of Canada, Vancouver, BC, Canada

Definitions

Frequency. The frequency of a natural hazard event is the number of times it occurs within a specified time interval.
Magnitude. The magnitude of a natural hazard event is related to the energy released by the event. It is distinguished from *intensity* which is related to the effects at a specific location or area.

Introduction



The magnitude of a natural hazard event varies in its frequency of occurrence over time in an inverse power relationship. The relationship is often depicted as log-normal (Figure 1) where the magnitude increases linearly (e.g., 1, 2, 3, . . .) whereas the frequency decreases as an inverse power function (e.g., 1/3, 1/9, 1/81) with increasing magnitude (Keller et al., 2008, p. 23). In other words, the larger and the more energetic the event, the rarer it is in time.

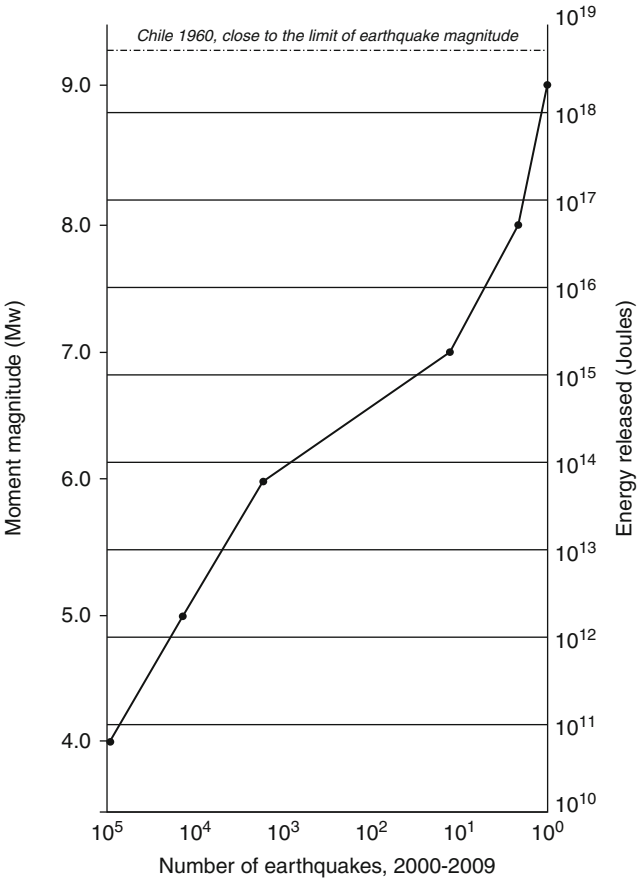
Linear magnitude scales or proxy indicators are logarithmically related to exponential increases in energy as events increase in size. Log-normal plots are useful to engineers and scientists because, given a linear magnitude scale, magnitude-frequency data approximate a straight line on this type of plot and are relatively easy to visualize and compare. Magnitude values are explicitly or implicitly related to the energy released during an event. The Moment Magnitude (M_W) scale is used by seismologists to rate earthquake magnitude (Hanks and Kanamori, 1979). It increases linearly (i.e., 1, 2, 3, . . .) in relation to the exponential increases in the energy released by earthquakes. For example, an earthquake of M_w 6 releases an energy equivalent to approximately 32 times more than the energy released by an earthquake of M_w 5 and 1,024 (32 × 32) times more than that of an earthquake of M_w 4 (Figure 2). Proxy indicators of magnitude may have various dimensions or be dimensionless. Peak stream discharge in cubic metres/second (m^3/s) is used as a measure of magnitude in flood frequency analysis (Figure 1). The total volume discharged (m^3) is used as a measure of magnitude in the case of the debris flow magnitude scale of Jakob (2005) or for other types of landslides. The moment magnitudes of earthquakes (M_w) are dimensionless as are the units (0-7) used in volcanic explosivity index (0-7) (Newhall and Self, 1982) are dimensionless but are related to energy released in Joules and volumes of tephra erupted in cubic kilometres, respectively. The relationship between magnitude and frequency is not open-ended: magnitude of events is limited by physical limits to the energy that can be liberated during an event within the context of such variables as plate interactions in the solid earth (earthquakes), the relative relief between mountains and valleys (landslides), and ocean-atmospheric circulation (floods).

Global earthquake magnitude and frequency records 2000–2009

Earthquakes are among the best phenomena to illustrate the magnitude-frequency concept as they occur frequently and are globally monitored. Also the largest earthquakes can be expected to occur several times along earth's seismically active belts during an average human lifespan. Figure 2 is a plot of the frequency of earthquakes above M_w 4.0 for the decade 2000–2009 from data posted on the United States Geological Survey website http://earthquake.usgs.gov/ (February 2010). The log-log plot groups earthquakes in M_w classes 4.0–4.9, 5.0–5.9, etc. up to 9.0+ against their frequency over the decade. The data points are plotted at the lower limit of their class range. The period includes the great Andaman-Nicobar earthquake (26 December, 2004) that was rated as M_w 9.1 (the only one in the 9.0+ class that occurred during the observation period). It is interesting to note that this value approaches the upper limit of earthquake magnitude: the energy released during an earthquake is determined by area of the rupture along the source fault. Subduction zones, where one tectonic plate overrides another, such as those along the coasts of Chile, Sumatra, and northwestern North America, are regarded as producing the largest earthquakes because they have the largest potential rupture areas with lengths over 1,000 km and down-dip widths up to 100 km (Wells and Coppersmith, 1994). The great 1960 earthquake that occurred along the subduction zone along the coast of Chile (M_w ~9.5) is regarded as being close to the ultimate limit of earthquake magnitude. This is because the rupture surface area approached the largest potential rupture surface existing in any subduction zone on the planet.

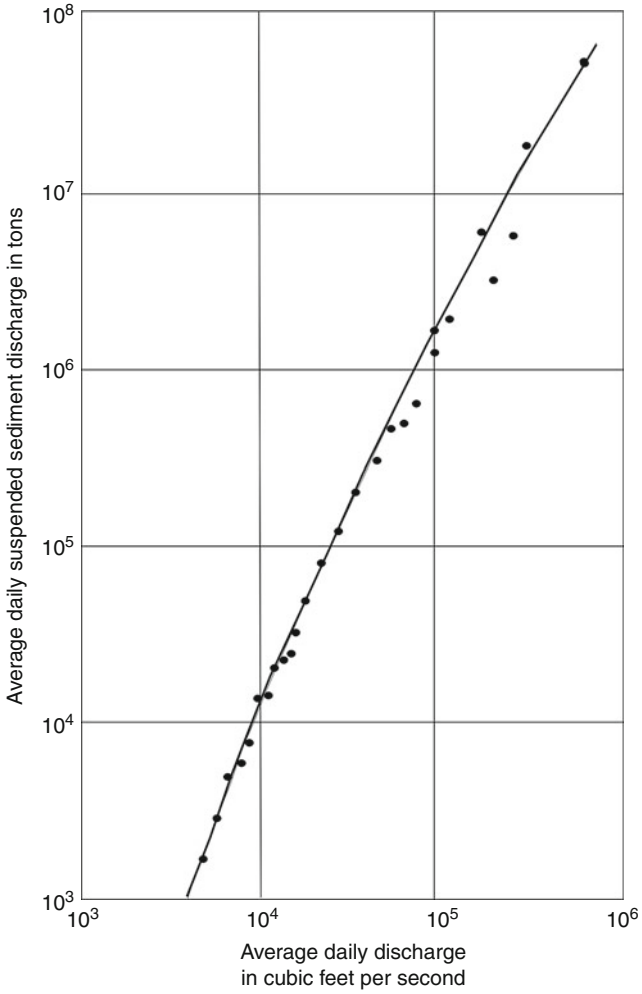
The frequencies of earthquakes increase exponentially with decreasing magnitude in Figure 2. The asymptotic trends of the curve at extreme values of magnitude and frequency give it a sinusoidal shape. This is typical of the relationship between magnitude in terms of energy released and frequency of natural hazards. No data were

Frequency and Magnitude of Events, Figure 1 A log-normal frequency plot showing variation between maximum instantaneous stream discharge and flow recurrence in years for the Skagit River at Newhalem, Washington (From Stewart and Bondhaine, 1961). The *vertical dashed line* is mean annual discharge. The *trend line* is hand-fitted to values from the instrumental gauge record. This plot was used by Baker (2008) to illustrate the nonconformity of extreme flood values (1815 and 1856) with the extrapolation of more frequent peak flows. The extreme flood values were defined by paleohydrologic flood-stage indicators identified in the field.



plotted for earthquakes with M_w values below 4.0 in Figure 2. Had they been plotted, they would have taken several more log cycles and accentuated the asymptotic shape of the curve for high frequency events.

Applications and limitations of magnitude-frequency in flood frequency analysis



The magnitude-frequency relationship of natural events is most widely applied in the field of flood frequency analysis which spans fields of hydrology, civil engineering, and geomorphology. Water and suspended sediment discharge data are routinely collected through stream gauging and water sampling worldwide. These data are used to construct stream flow frequency plots (Figure 1) and sediment transport plots (Figure 3). Magnitude-frequency plots are valuable in understanding the relationship between magnitude and frequency of relatively common peak flows and the amount of sediment transported by them. This led Wolman and Miller (1960) to conclude that intermediate ranges of stream discharge (intermediate magnitudes and frequency) can be more significant for transporting sediment and shaping river channels over long periods of time than those of low frequency/high magnitude discharge rates (see example of the Eel River, Figure 3). Over the 10-year record period (1957–1967), the stream transported an average suspended load of 2.8×10^7 tons per year past the Scotia gauging station with 50% of the sediment transported by high flows during 6 or fewer days per year. The period of record included a very high magnitude low frequency flood in 1964 (probability of occurring in a given year has been estimated as low as 0.003 (Helly and LaMarche, 1968)). This transported 51% of the entire suspended sediment for the 10-year period. However, because of the rarity of such a flood event, more frequent yearly peak stream flows will transport much more sediment in the course of a few decades.

Extremely low frequency/extreme magnitude floods bring effects that are not associated with more frequent peak flows: they can cause major and permanent changes to stream channels and landscapes through permanent channel modification, establishment of new stream channels, and abandonment of old ones (stream avulsion). In mountainous landscapes, prolonged and intense rainfall associated with extreme floods can trigger landslides over large parts of drainage basins which in turn create debris flows. Such extreme floods are capable of transporting large boulders that are stable during all but the most extreme flood events. The disastrous flood in the Vargas area along the northern coast of Venezuela in December 1999 is a good example of such an extreme flood (García-Matinez and López, 2005). It killed tens of thousands of people and boulders driven by torrents severely damaged multistory buildings.

Attributes and understanding of extreme flood events have not been reliably captured or their frequencies reliably estimated by extrapolating flood frequency from intermediate and low frequency events (Baker, 1994). Baker (2008) originally used the plot in Figure 1 (after Stewart and Bodhaine, 1961) to illustrate this point: the outlying values in the extreme upper right of the plot represent peak discharges reconstructed for ungauged historical floods of 1815 and 1856 on Skagit River, Washington State, USA. They lie outside of the trend line based on stream gauge records. Understanding of extreme

Frequency and Magnitude of Events, Figure 2 Log-log plot of earthquake energy and frequency for global earthquakes >M_w 4.0 for the decade 2000–2001. The moment magnitude (M_w) scale is shown along the left side of the plot to illustrate the relationship between the moment magnitude scale and energy released by earthquakes (scale on the right side). The earthquakes are grouped in M_w classes 4.0–4.9, 5.0–5.9, etc. up to 9.0+. Points are plotted at the lower limit of their class for the sake of explanation. The great 1960 earthquake along coastal Chile approached the upper limit of the energy that can be released in an earthquake. The sinusoidal shape of the curve is typical of the magnitude-frequency relationship for natural hazard events.

Frequency and Magnitude of Events, Figure 3 Log-log plot of average daily water discharge versus average daily discharge of sediment for the Eel River at Scotia, California, for the period October 1957–September 1967 (Redrawn from Brown and Ritter, 1971). Such plots are used when two variables change exponentially. Data spanning many orders of magnitude can be depicted in a single plot. The period includes the great flood of December 1964 that was estimated to have a 400-year return period based upon paleoflood indicators analysis (Helly and LaMarche, 1968).

past flood events requires their reconstruction and modeling based upon geological evidence. This has led to the development of paleohydrology as a discipline (Baker, 2008).

Applications of magnitude and frequency to landslide-type hazards

The magnitude-frequency concept can be applied regionally to landslides (Guthrie and Evans, 2005) and is the basis of landslide risk management (Fell et al., 2005). Landslides encompass a spectrum of mass wasting phenomena including translational or rotational failures and mass flow (Cruden and Varnes, 1996; Hungr et al., 2001). Separate magnitude-frequency relationships will exist for each type of landslide within a given region with similar climate, physiography, and geological substrate (Picarelli et al., 2005). For example, the magnitude and frequency of debris flows (lahars) in volcanic terrain are typically much higher than in non-volcanic mountainous areas (Vallance, 2005).

The frequency of an event of a given magnitude may vary with time where climate-driven cycles operate on the landscape. For example, based upon indicators of relative rates of sedimentation on flood plains and alluvial

fans, Jackson et al. (1982) concluded that the frequency of debris flows in the southern Canadian Rocky Mountains was greater following deglaciation at the end of the last glaciation about 10,000 years ago than they have been during the last 5,000 years. An analogue is occurring globally in contemporary mountain-glacier regions in response to climatic warming: rapid retreat of glaciers is leaving unstable moraines and moraine-dammed lakes resulting in landslide-failure of slopes and outburst floods (Jackson et al., 1989; Evans and Clague, 1994). The magnitude-frequency relationship for debris flow and outburst flood hazards in a given mountain-glacier region would have been different before the current period of climatic warming that began in the latter part of the nineteenth century (Mann et al., 1999). Concerning landslide frequency over a similar time period, Jackson (2002) postulated that the frequency of large rockslides and rock avalanches in glaciated mountains is highest following deglaciation and decreases and becomes asymptotic toward a basal rate determined by structural and lithologic architecture and regional rates of uplift and stream incision. Similar relationships may prevail in the magnitude and frequency of submarine landslides: the Storrega landslide west of Norway on the floor of the North Atlantic Ocean is one of the largest known on earth (volume >3,000 km^3; Nadim and Locat, 2005). Its failure 8,500 years ago (which produced a tsunami) was conditioned partly by rapid deposition of sediment along the edge of the Norwegian continental shelf during and immediately after the last glaciation. Such high rates of sedimentation associated with deglaciation are no longer in operation today in that region. Consequently, the frequency of events of that size in shelf areas is likely less at present than it was the end of the last glaciation.

Summary

The frequencies and magnitudes of potentially hazardous geophysical and hydro-meteorological events have an inverse power relationship: the larger and more energetic the event, the rarer it is in time. The relationship is not open-ended but is limited by physical limits dictated by such factors as plate tectonics and climate. The magnitude-frequency relationship can imply that events of intermediate frequency and magnitude may be the most significant in shaping aspects of the earth's surface. However, rare extreme events can cause permanent changes to fluvial systems and other aspects of the landscape that would not have occurred under the regime of more frequent and less energetic events. The attributes and frequencies of extreme floods are unlikely to be predicted by analysis of more frequent and lower magnitude stream flow data. For natural hazard processes that are influenced by climatic change, the frequency of an event of a given magnitude can vary depending on the length of time and the specific time interval considered with respect to climatic variation.

Synonyms

Freeze hazard; Freezing injury; Frost damage

Definition

A frost event occurs when air temperature falls to 0°C or lower, measured at a height of between 1.25 and 2.0 m above soil level, inside an appropriate weather shelter. In meteorology, *frost* refers to the formation of ice crystals on surfaces due to deposition, that is, a phase change from vapor to ice. In agriculture or biology, however, *frost* refers to an event where temperature falls to the point where ice forms inside plant tissues and causes damage to the cells. *Frost hazard* is the potential for damage or negative impact caused by freezing temperature or frost.

Introduction

Frost hazard, as it relates to the potential for plant damage (or injury) caused by freezing temperature is discussed in the following description. Although other impacts through freezing conditions may occur, for example, road or infrastructure damage or soil heaving (e.g., Knollhoff et al., 2003; Little et al., 2003; Greenfield and Takle, 2006), these have not been addressed in detail here.

Frost events can be described as advective or radiative (Kalma et al., 1992). Advective frosts are associated with large-scale incursions of cold air with a well-mixed, windy atmosphere and a temperature that is often below zero, even during the day. Radiative frosts are associated with clear night-time skies and calm winds, where more heat is radiated away from the surface than is received, so that the temperature drops. In some cases, a combination of both advective and radiative conditions occurs. For example, it is not uncommon to have advective conditions bring a cold air mass into a region, resulting in an advection frost. This may be followed by several days of clear, calm conditions that are conducive to radiation frosts.

There are two subcategories of radiation frosts. A "hoar frost" occurs when water vapor deposits onto the surface and forms a white coating of ice that is commonly called "frost." A "black" frost occurs when temperature falls below 0°C and no ice forms on the surface. If the humidity is sufficiently low, then the surface temperature does not reach the ice point temperature and no frost forms. When the humidity is high, ice is more likely to deposit and a "hoar frost" can occur. Because heat is released during the ice deposition process, hoar frosts usually cause less damage to vegetation than black frosts.

The average length of the frost-free period, measured in days, varies across the world through latitudes, continentally and topographically (Kalma et al., 1992). The length of the frost-free period can be used as a general guide to the agro-climatic suitability of a region, though as explained subsequently, this also depends on the crop sensitivity.

Frost conditions can result in losses to crops through damage to plant tissue. The extent of damage can be significant and is influenced by many factors. These include the location of the crop, the time of the frost event in relation to the developmental stage of the plant, the severity of the frost event, plant nutrition, the type of plant, and the conditions leading up to the event (e.g., cold hardening or acclimation). Ice-nucleating bacteria promote the initiation of freezing so their presence also influences damage levels.

Frost causes significant damage to agricultural products in both commercial and noncommercial enterprises. Freezing accounts for greater economic losses of fruits and vegetables than any other environmental or biological hazard (Rieger, 1989). Frosts severely affected coffee in Brazil and Africa in the 1960s and 1970s (Hewitt, 1983), and, with losses amounting to US$3.5 billion in 1989/90, citrus in Florida (Kalma et al., 1992). Annual crops (e.g., wheat, barley, sorghum) are also vulnerable; though

sowing dates can be selected to reduce risk of frost exposure (Gomez-Macpherson and Richards, 1995).

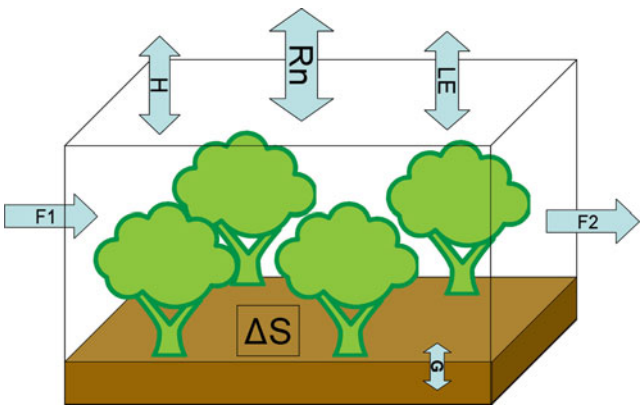
Depending on the type of frost event (advective or radiative) either passive or active protection methods are employed to reduce the potential hazard (Kalma et al., 1992). The risk and the relative benefit and cost need consideration to ensure effective strategies are implemented for hazard reduction.

Frost hazard: biological impact

Low temperature freeze injury can occur in all plants, but the mechanisms and types of damage vary considerably. Crop plants that develop in tropical climates often experience serious frost damage when exposed to temperature slightly below zero, whereas most crops that develop in colder climates often survive with little damage if the freeze event is not too severe. The temperature at which plant tissue damage occurs is correlated with air temperatures called "critical temperatures" and these are specific to particular plant species. In addition to species differences in susceptibility to low temperatures, some species or varieties can exhibit different frost damage at the same temperature and phenological stage, depending on antecedent weather conditions. During cold periods prior to the frost event, plants tend to harden against freeze injury, and they lose the hardening during warm spells.

Direct frost damage can occur when ice crystals form inside the protoplasm of cells (intracellular freezing), whereas indirect damage can occur when ice forms inside the plants but outside of the cells (i.e., extracellular freezing). Levitt (1980) reports that, in nature, freeze injury results from extracellular ice crystal formation and there is usually no evidence of intracellular freezing. It is not cold temperature but ice formation that actually injures the plants. The extent of damage due to extracellular freezing depends mainly on how fast the temperature drops and to what level it supercools before freezing. There is little or no evidence that the duration of the freezing affects damage levels (Levitt, 1980). In fact, Levitt (1980) states that extent of freeze injury is independent of time, at least for short periods (e.g., 2–24 h).

Levitt (1980) proposed that cells were gradually damaged as a result of growth of the extracellular ice mass. As a result of extracellular ice formation, water evaporates from the liquid water inside the cells passing through the semipermeable cell membranes, potentially causing cell desiccation, to deposit on the ice crystals outside of the cells. As water is removed from the cells, the solute concentration increases and reduces the chances of cell freezing. Therefore, the main cause of frost damage to plants in nature is extracellular ice crystal formation that causes secondary water stress to the surrounding cells. In fact, there is a close relationship between drought-tolerant plants and freeze-tolerant plants.



Protection from frost hazard

Farmers can elect to passively protect their crop from frost or employ more active protection measures to reduce frost hazard. Passive methods are usually less costly than active methods and often the benefits are sufficient to eliminate the need for active protection. The overall aim of both types of strategy is to maintain plant temperatures high enough to minimize extracellular ice formation. Critical air temperatures, which provide a guideline when frost damage is likely to occur, vary with crops described as either tender, slightly hardy, moderately hardy, and very hardy (Levitt, 1980). These temperatures have been quantified in growth chamber studies for many crops (Snyder and Paulo de Melo-Abreu, 2005).

Energy transfer rates determine how cold it will get and the effectiveness of frost protection methods. The four main forms of energy transfer that are important in frost protection are radiation; conduction (or soil heat flux); convection (i.e., fluid transfer of sensible heat), and phase changes associated with water (latent heat). For all nonbiological methods of frost protection, the goal is to minimize losses or maximize gains of energy from one or more of the energy balance components (Figure 1).

Humidity is an important factor in freeze protection because of phase changes which convert sensible to latent (evaporation) or latent to sensible (condensation) heat and because moist air absorbs more long-wave radiant energy. When the surface temperature drops to near the dew point temperature, condensation can occur releasing latent heat and reducing the rate of temperature drop. Also air with higher humidity cools more slowly than drier air (as it absorbs more long-wave radiation).

Both passive and active protection methods (Table 1) are more effective during radiative than advective frost events. Active methods, for example, heaters and wind machines, often use the presence of a temperature inversion near the ground to enhance heat transfer to the plants. Inversions, however, tend to be weak or absent during advective freezes. Protection methods that use water are

Frost Hazard, Figure 1 A *box* energy diagram showing possible sources and losses of energy from a crop represented by the *box*. Net radiation (Rn), sensible heat flux (H), latent heat flux (LE), soil heat flux or conduction (G), sensible heat advection in (F1) and out (F2), and energy storage in the crop (ΔS) (Adapted from Barfield and Gerber, 1979).

more effective when evaporation rates are low, that is, when the humidity is higher and the wind speed is lower. Advective frosts are associated with low humidity and high wind speeds, so using water for protection is more problematic during advective frost events. Passive methods, for example, cover cropping and soil moisture management, are beneficial for both types of frosts, but they are less effective for advective frosts because air turbulence tends to dominate energy transfers. Avoiding low spots, where cold air accumulates, is advisable for locations with radiation frost, but avoiding hilltops is more prudent in regions characterized by advective frost. If the risk is high for advective frosts, it might be best to select a different region for growing sensitive crops. A good example is the citrus industry in the southeastern USA that, 200 years ago, extended north to South Carolina but is now restricted to southern Florida (Attaway, 1997) because of advective frost. While most protection methods attempt to optimize energy transfer and maintain higher plant temperatures, passive methods also include biological factors such as plant selection, hardening, and reduction of ice nucleating bacteria concentration (Lindow, 1983), which reduce the chances for ice formation and/or cell damage.

A wide range of simple to sophisticated frost protection technologies are used around the world. The main determining factors depend on local availability and costs. For example, liquid-fuel heaters are widely used in Mexico because low-cost fuel is available, but not used where costs are higher. Of course, protection methods vary depending on the size and wealth of the farming operation as well as government support. Each protection method must be considered on its own merits and an economic evaluation should be performed to determine whether or not the method is cost-effective (Snyder et al., 2005).

Probability and risk

Remote sensing, for example, aircraft or satellite thermal imagery, can be employed to produce both frost risk maps and to improve frost prediction services (Kalma et al., 1992). Maps indicating frost risk incorporate both climate and topography data (Laughlin and Kalma, 1990) and, more recently, have been produced through GIS-based studies, for example (Lindkvist et al., 2000; Geerts et al., 2006). Due to the importance of frost hazard to agricultural economies, frost risk maps are produced by many governmental meteorological departments around the world, for example, http://www.ncdc.noaa.gov/oa/climate/freezefrost/frostfreemaps.html.

As frost damage can occur in almost any location in temperate and arid climates, and even in tropical zones at elevated sites, minimum temperature forecasting techniques were developed and are used extensively by farm managers (Kalma et al., 1992). Empirical formulae employing meteorological variables such as air temperature, various measures of humidity, wind speed, and cloud cover are used in combination with local conditions and topography to develop these forecasts.

Future climate

In changing global conditions, the risk of frost incidence is likely to change. Future temperature projections indicate fewer frost days so it might be expected that horticulturists would experience less frost damage. This may be the case with annual cropping systems where planting/sowing dates can be managed, but the timing of budburst for perennial crops is controlled by temperature. Budburst will likely occur earlier, and therefore frost risk may not be reduced (Hanninen, 1991; Nemani et al., 2001). In some regions, projections of lower rainfall in spring and associated drier soils, fewer clouds and lower dew points may even increase frost risk. Furthermore, an increase in day-to-day climate variability may lessen any "positive" impact of mean warming on reducing frost frequency (Rigby and Porporato, 2008). Further, increasing concentrations of carbon dioxide in the atmosphere have been found to render plants more susceptible to potential frost hazard (Woldendorp et al., 2008).

Summary

Frost damage to plants is a widespread serious economic problem for agricultural and horticultural producers and the public at large. While global warming may elicit some benefit, it is unlikely that the problem will diminish greatly. Here, the frost hazard to plants is defined and discussed in terms of the physical and biological processes involved. Both passive and active methods of protection against frost damage are presented and discussed. Frost hazard is also discussed in terms of the probability and risk of occurrence.

EF2	111–135, 50–60
EF3	136–165, 61–74
EF4	166–200, 75–89
EF5	Over 200, over 89

Definition

Enhanced Fujita Tornado Scale: A system for classifying *tornadoes* intensity in the United States according to six categories from EF0 to EF5 based on the degree of damage to one or more of 28 damage indicators, such as various types of buildings, towers, and trees.

Dr. T. Theodore Fujita introduced the Fujita Scale, or F-scale, in 1971. Dr. Fujita (1920–1998) was a professor of meteorology at the University of Chicago. His goals were to categorize each tornado by its intensity and area as well as estimate a wind speed associated with the damage caused by the tornado. He surveyed every tornado from the Super Outbreak of April 3–4, 1974 and the F-scale became the official basis for rating tornadoes in the United States. The F-scale contained six categories from F0 to F5 and ranked tornadoes based on damages to homes and other buildings. A range of wind speeds was associated with each damage category.

In the late 1990s, engineers from Texas Tech University and others who studied tornado damage questioned whether the wind-speed ranges associated with the stronger categories in the F-scale were appropriate for the damage descriptions. Meetings between meteorologists and engineers resulted in an Enhanced Fujita Scale, or EF-scale, that was adopted for use in the United States in February 2007. The EF-scale maintained the EF0 to EF5 categories of the original F-scale, but wind-speed ranges associated with the categories were changed (Table 1). In addition, 28 damage indicators were identified and an accompanying guide was developed to associate the degree of damage on each damage indicator with EF-scale and respective wind speed. Wind speed in the EF-scale is taken to be the 3-s gust (mph) at 10 m height. The relationships between degree of damage and wind speed continue to be discussed and revisions of the EF-scale may occur as more information becomes available.

FUMAROLE

Travis W. Heggie
University of North Dakota, Grand Forks, ND, USA

Synonyms

Mofette; Solfatara; Volcanic fumarole

Definition

A fumarole is a vent in the Earth's surface from which steam and *volcanic gas* are emitted.

Distribution and origins: Fumaroles are generally found in the vicinity of volcanoes and are active during and between periods of volcanic activity. Fumaroles occur along cracks and fissures in the Earth's surface. They also appear in clusters or fields and on the surface of lava flows and thick deposits of *pyroclastic flow*. Emissions from fumaroles may continue over long periods of time if they are situated above a continuing heat source or they may stop after a short period of time if they occur atop a volcanic deposit that quickly cools.

Fumaroles may appear in different shapes and forms such as a fissure, a phreatic explosion crater, a single or multiple oval opening, and a diffuse, multiple opening. Gases emitted from fumaroles include carbon dioxide (CO_2), sulfur dioxide (SO_2), hydrogen (H_2), hydrochloric acid (HCl), hydrogen sulfide (H_2S), methane (CH_4), and helium (He) (Heggie, 2009). Fumaroles that emit sulfurous gases are sometimes referred to as solfatara. A fumarole that is rich in CO_2 may be called a mofette. The primary source of water vapor (steam) emitted from fumaroles is groundwater heated by magma situated close to the surface. Hence, fumaroles are often considered related to hot springs and geysers. Gas emissions from fumaroles such as CO_2, SO_2, and H_2S are usually directly emitted from magma sources. A gas such as H_2S that is commonly emitted from fumaroles oxidizes to sulfuric acid (H_2SO_4) and native sulfur (a bright yellow crystalline solid). This accounts for much of the brightly colored rocks in thermal areas.

Hazards: The hazards related to fumaroles are similar to those presented by volcanic gases in that they can be harmful to humans, animals, plants, agricultural crops, and property. An example is the death of four skiers (via asphyxiation) exposed to fumarole emissions on Mammoth Mountain, California, USA, and the death of two children and animal stock in Italy (Hill, 2000; Beaubien et al., 2003; Cantrell and Young, 2009). Central Italy (Alban Hills area), in particular, is an example of one region where a large human population is threatened by fumarole emissions. Elevated SO_2 levels near fumaroles in the Azores have also been identified as a potential hazard for those with asthma (Baxter et al., 1999).

Summary points

Galeras Volcano, Colombia: Volcano Crises, 1988–2010+: Adverse Impacts without a Major Eruption

- Lava dome growth with strong seismic, deformation and gas precursors
- Vulcanian explosions with very subtle precursors and strong shocks
- Fears of population early in crisis magnified by 1985 Nevado del Ruiz catastrophe
- Lack of a pre-crisis hazard map led to a *chain-reaction* of events that culminated in an economic crisis, hostility of authorities and loss of credibility of the scientists
- Important lessons for safety of volcanologists from 1993 tragedy
- Continuing difficulty of compliance to evacuation recommendations

Introduction

Located in southwest Colombia, 4,270-m high Galeras Volcano rises 1,600 m above Pasto, the capital city and economic nucleus of Narino Province (Figure 1). It is the most active volcano in Colombia. Pasto is located on the eastern slope of the volcano, about 7–11 km from the crater. Its population is about 350,000, and over 50,000 more people reside in neighboring villages.

Activity at Galeras Volcano extends back about 4,500 years and included six major eruptions before the most recent episode of activity (Calvache, 2000; Stix et al., 1997). It consists of an active cone some 100–150 m high and 500 m diameter, nested inside a horseshoe-shaped amphitheater created by a prehistoric cone collapse.

About 50 periods of unrest have been described in the 500 years of recorded history at Galeras, of which 27 have proceeded into eruptions. Twelve of these episodes were brief and included small explosions, and the remainder were more notable but still modest. Pyroclastic currents of mixtures of blocks, ash, and gas generated by a collapsing eruption column descended beyond the crater rim in 1580, 1616, 1641–43, and 1936, and represent the most serious current potential hazard. The effects on Pasto in historic events include ash deposits of 4 cm or less and shock waves breaking windows. Incandescent ballistic blocks have reached about 3 km from the crater rim. Some building damage and a few fatalities have been caused by strong volcanic earthquakes. The towns of Consaca and Bambona, 12 km west of the active cone, have reported heavier ash falls and stronger earthquakes. Historic loss of life has been limited to tourists and scientists in and near the active cone (Munoz et al., 1993), and several deaths in Pasto due to earthquake-induced building collapse.

This case history reviews activity since 1989, and underscores the severe and complex problems that can emerge when no hazards assessments, emergency preparedness plans, or mitigation plans are available at the start of a crisis – such as at Galeras in 1989 and early 1990s. The contribution also examines background information on nine deaths within the crater from an explosion in January 1993.

Post-1988 activity and deadly explosions

In general, volcano monitoring is carried out to improve understanding of volcanic processes and to identify times of enhanced risk of eruption. Most techniques utilize

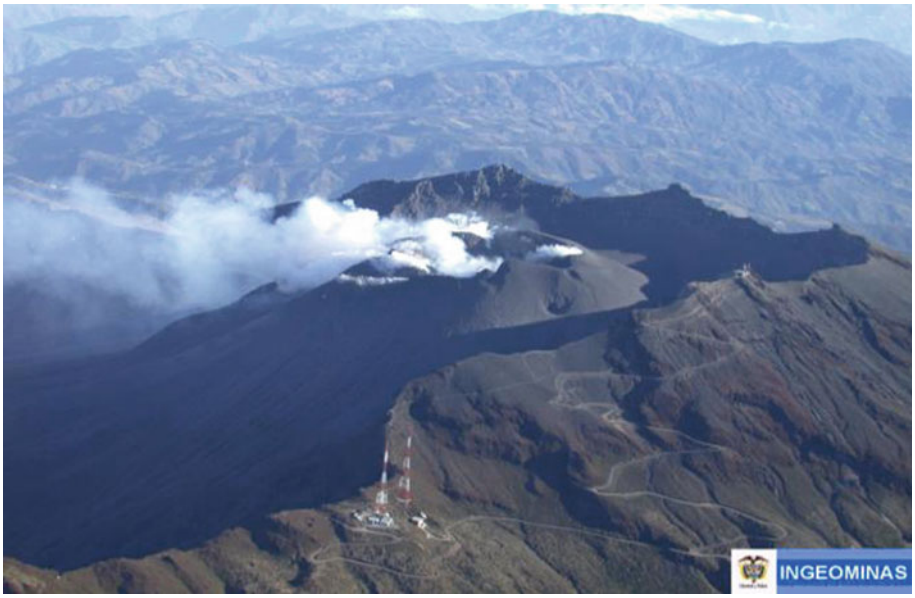
Galeras Volcano, Colombia, Figure 1 Location map of Galeras and other major volcanoes in Colombia (After USGS).

sophisticated equipment and require trained specialists to acquire, process, and interpret the data. Typical indicators include seismicity, changes in gas flux or temperature, and deformation of the edifice linked to observations of activity. Seismic indicators are particularly important, with one family of events consisting of volumetric sources involving flowing gas and/or magma, and another family involving rock breakage (Chouet, 1996). *Long-period (LP)* events and *tremor* are examples of the former, and *volcano-tectonic (VT)* events are an example of the latter. These types of events were involved in the debates which occurred after the fatal incidents in 1993.

Following recognition of anomalous fumarole activity in 1987–1988, continuous monitoring began in February 1989 (Cortes and Raigosa, 1997). Seismic activity accelerated in the next months, and between 4 and 9 May 1989 explosions occurred and eruption plumes rose as much as 3.5 km high (Figure 2). Ash deposits around the crater were as much as 6 m thick and a thin ash blanket covered a region 35 km^2.

After the May eruption, seismicity continued at a moderate level and SO_2 emissions increased, several times exceeding 5,000 t/day (Zapata et al., 1997). After June 1990, an increase in CO_2/SO_2 ratio was observed, suggestive of rising magma. After July 1991, an extended period of long-period (fluid-flow) seismicity occurred, with very large tilt inflation, and in October fresh andesite lava extruded. The lava was stiff and developed the shape of a dome, and grew for about a month, with 400,000 cubic meters emplaced in the first 2 weeks. Throughout this active period, VT (rock breakage) seismicity was low. From December 1991 through June 1992, LP seismicity reduced to moderate levels, tilt stabilized, gas emissions remained moderate, and VT seismicity remained very low (Figure 3).



Daily occurrences of LP events halved by June 1992, and continued to decrease in early July. However, a relatively new type of long-period signature (a few had been noted in March 1989) was observed on 11 July (Narvaez M. et al., 1997; Gomez and Torres, 1997), characterized by low-frequency, decaying signal with long duration (Figure 4). This type was described as a *tornillo*, Spanish for *screw*, and nine such events occurred between 11 and 16 July. On 15 July a swarm of small high-frequency events occurred and were interpreted as VTs (Cortes and Raigosa, 1997); much later they were reinterpreted as events of intermediate (hybrid) character between LP and VT events (Gil Cruz and Chouet, 1997). The last tornillo event occurred 1 h before an explosion on 16 July 1992 which destroyed about 90% of the lava dome.

Other possible eruption precursors for 16 July included SO_2 gas flux, variable for a month prior to the eruption, from ~300 to 3,500 t/day (Zapata et al., 1997), and minor tilt changes possibly indicating localized pressure buildup. The explosion generated a shock wave felt in local villages (Cortes and Raigosa, 1997), ejected blocks over 3 m diameter, and produced a 4-km high plume; its signal lasted about 9 min.

Monitored activity remained at low levels into 1993, when five small (Volcano Explosivity Index, VEI 1) explosions occurred on 14 January, 23 March, 4 and 13 April, and 7 June. The explosions were similar in style, volume of incandescent lava blocks and ash ejected, and similar activity preceding and following each explosion (Cortes and Raigosa, 1997; Zapata et al., 1997).

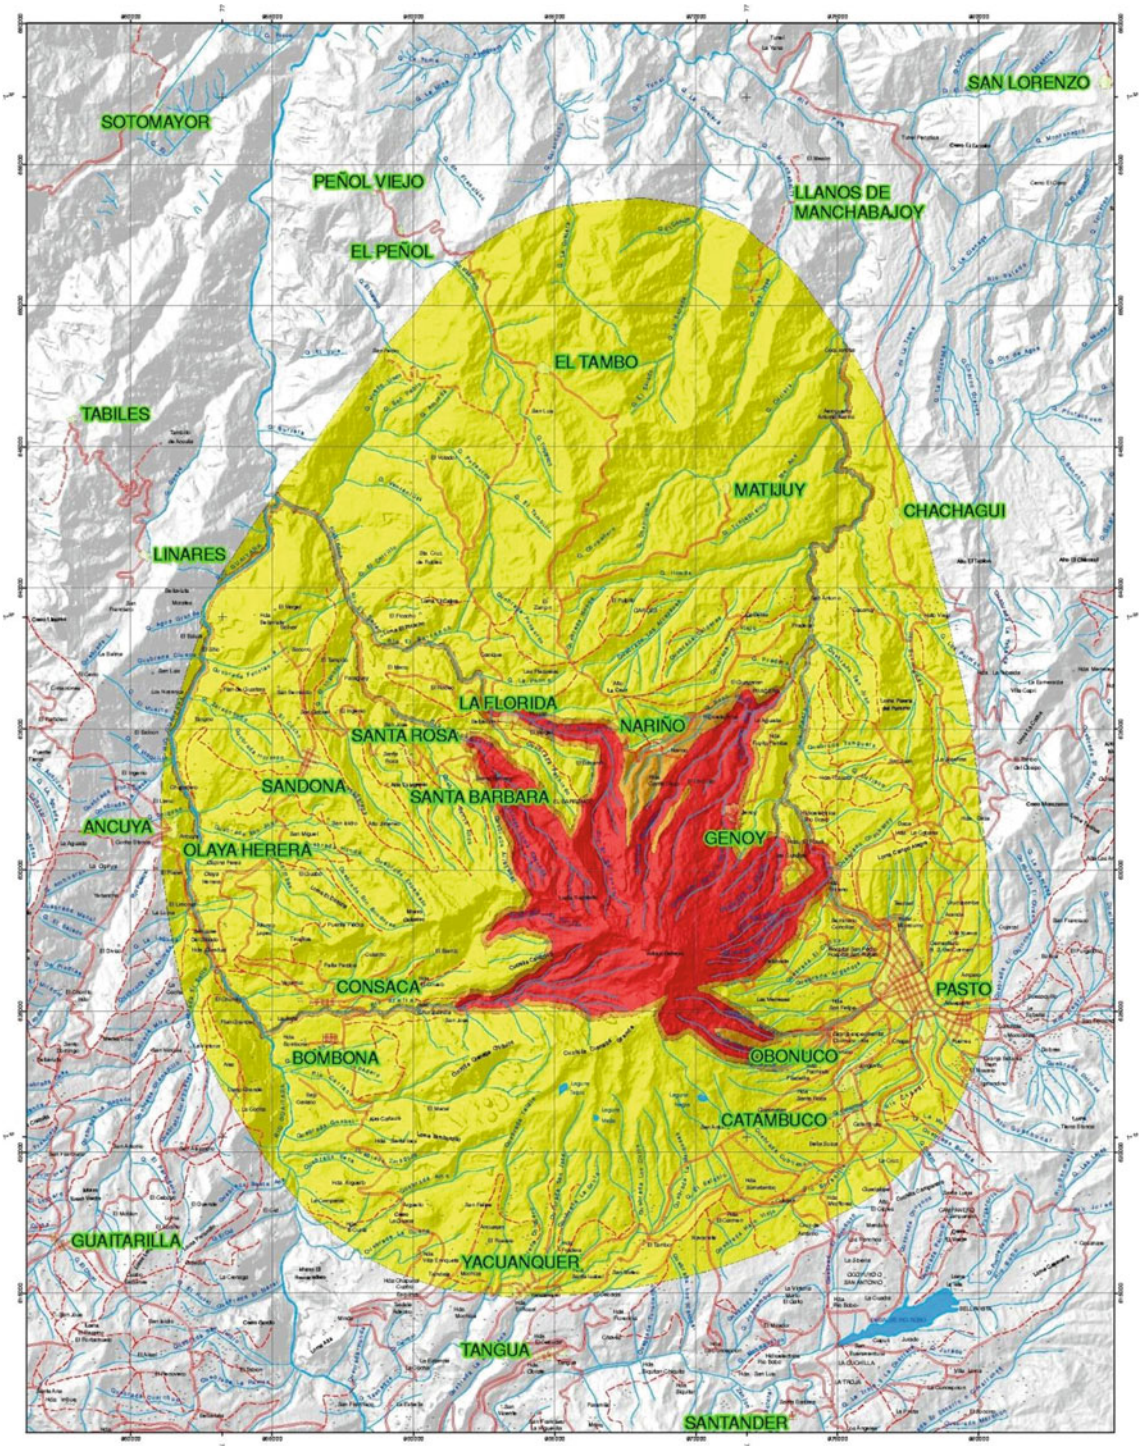
The 14 January explosion, which lasted 15 min, caused the deaths of six scientists participating in a scientific workshop, and three others, all near the active cone inside the amphitheater (Munoz et al., 1993; Baxter and Gresham, 1997). The imminence of the explosion was not recognized by the scientists. Seismicity was low before the explosion (Cortes and Raigosa, 1997). A total of 12 tornillo signals were recorded from 23 December to 14 January (about one event per day), but no swarm of high-frequency events occurred as in July 1992. Gas flux had been low in December although no data were recorded for 3 weeks prior to the explosion (Zapata et al., 1997). No precursory deformation was detected. An intense LP swarm occurred for 18 h after the eruption, but thereafter the rate declined to <10 events per day, a background level comparable to that before the eruption.

The other explosions were similar to the one of 14 January (Cortes and Raigosa, 1997), and by then the tornillo signals had acquired importance as an eruption precursor.

Galeras Volcano, Colombia, Figure 2 Galeras volcano, showing large amphitheater-like crater, and the active vent inside the crater. The amphitheater gives a measure of protection to Pasto and neighboring villages, because pyroclastic flows must surmount the rim to descend into the nearest populated areas.

Seismicity was low before the explosions (<100 long-period events/month), with a sparse number of tornillos generally recorded, ranging from zero before 4 April, to 103 in the 50 days preceding 7 June. Intense LP swarm activity and tremor occurred for a few days immediately following the explosion but seismicity then returned to low levels. Deformation showed no significant changes before, during or after the explosions. Gas flux (SO_2) was generally low before and after the explosions, apart from a short-lived increase associated with the explosions themselves. An exception is for the period preceding 7 June, when variable SO_2 flux was recorded, reminiscent of 16 July 1992. Authorities were alerted on 17 May for a possible sudden explosion (Narvaez et al., 1997), and the explosion occurred on 7 June, expelling 1.3 million cubic meters of material. This was the largest of the 1992–1993 explosions (Cortes and Raigosa, 1997). The various explosion signals had lasted 2–17 min, and eruption plumes reached 2–8 km above the vent.

Between July and November 1993, 94 tornillo-type events were recorded, without being followed by an explosion (Cortes and Raigosa, 1997). Likewise sporadic tornillos occurred in January, March, and May 1994, without explosions. Between 9 August and 23 September 1994, 31 tornillos preceded a long-period swarm with a minor gas emission; after 20 October 1994, 89 tornillos occurred, prior to a minor gas release on 9 January associated with LP events. The event type continues to be recognized in sparse numbers and is postulated to reflect pressurized fluids at shallow depth.

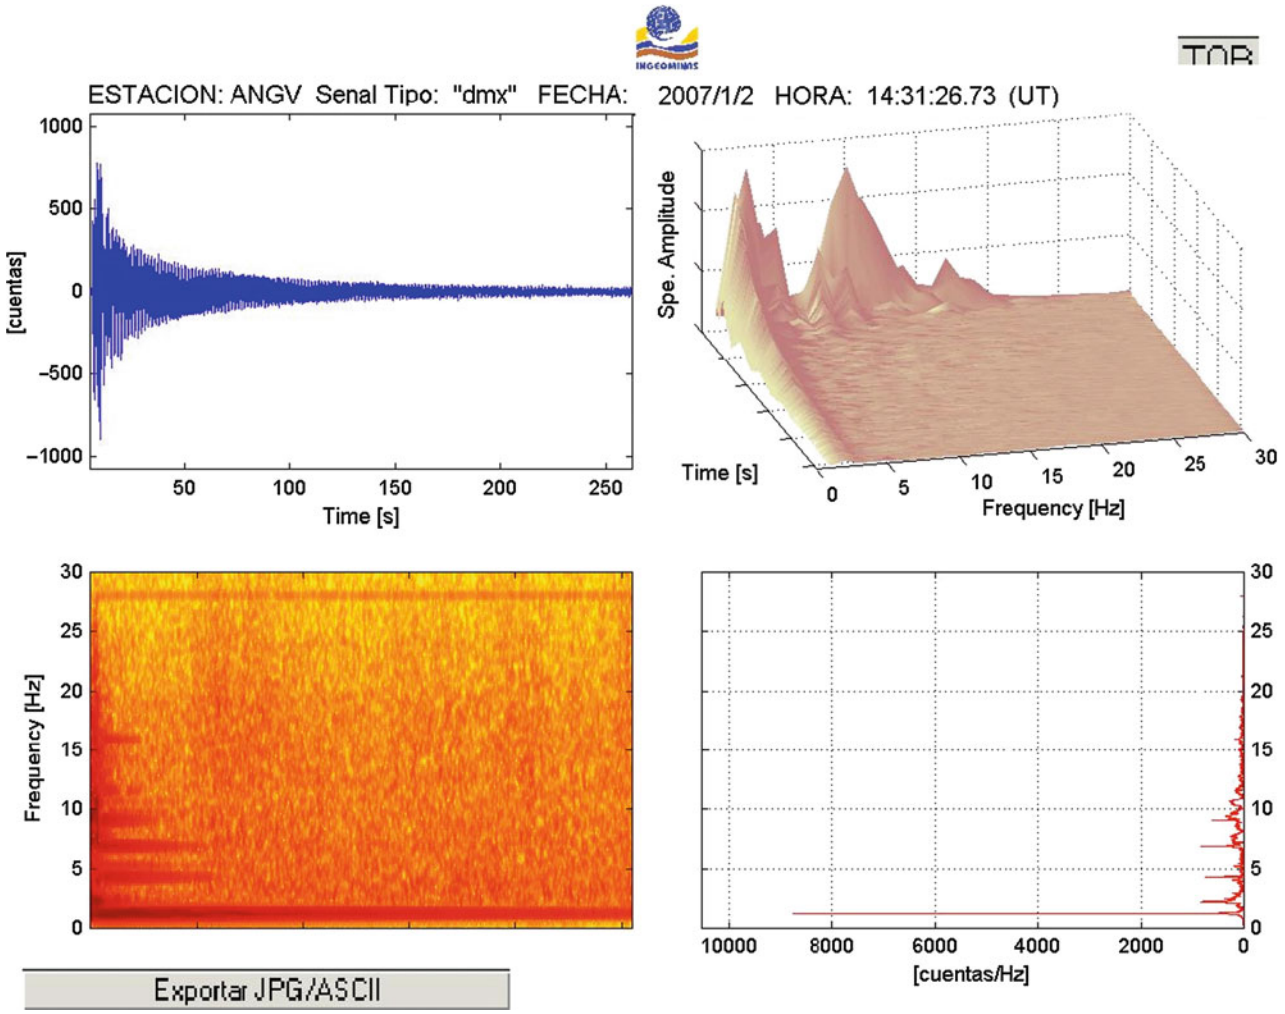


Activity and monitoring continues to present (e.g., Smithsonian BGVN, 2009).

Crisis response and management

Institutional structure and political reactions

The catastrophe caused by the Nevado del Ruiz eruption in 1985 (*see entry Nevado del Ruiz Volcano, Colombia 1985*) led the Government of Colombia in 1988 to create a national system for risk mitigation and disaster preparedness. Its responsibilities were defined at national, regional, and local levels. It incorporated public and private organizations that already existed and was designed such that decisions would be decentralized through Regional and Local Risk Committees, headed by the Governor at regional level and the mayors of municipalities at local level (Cardona, 1997). Coordination was provided by a National Office for Emergency Prevention and Assistance of the Office of the President (ONAD).



The study of Galeras by INGEOMINAS (the geological survey of Colombia) was initiated in 1988, in response to a request by ONAD to evaluate all active volcanoes of Colombia. In February 1989, enhanced fumarolic activity at Galeras was reported to the newly created Regional Risk Committee for Narino Province, and ONAD then provided funding for continuous monitoring by INGEOMINAS. With the first eruptive events in May 1989, intensive work began at all Risk Committee levels to provide emergency and contingency plan, prompted by fear based particularly on the recent horrible outcome at Nevado del Ruiz and Armero. Although significant progress was achieved in this planning, the "community was in large part isolated from the preparedness process" (Cardona, 1997). For example, videos from the 1980

Galeras Volcano, Colombia, Figure 3 Hazard map of Galeras in 2009, relation to surrounding region. Pasto is located to the east. *Red* indicates flowage hazards; *yellow* is area of lesser hazard including ash fall (INGEOMINAS).

Mount St Helens eruption were used for public education, but these were criticized for generating undue fear and alarm, because some of the processes illustrated were different from what was possible at Galeras.

In 1989, some unfortunate events generated strong dissatisfaction within economic organizations and the population. For example, the Mayor of Pasto promoted "voluntary preventive evacuations" that alarmed

Galeras Volcano, Colombia, Figure 4 Seismic record with tornillo-type event, with frequency spectra.

inhabitants (Cardona, 1997). On 8 May, during the eruption, an evening "emergency meeting" was held in Pasto to advise the Governor and Mayor; the meeting was attended by INGEOMINAS staff, the Director of ONAD, and several volcanologists acting as advisors to INGEOMINAS. The possibility of cyclic eruptive activity, the gradational nature of hazard zone boundaries, the uncertainties regarding precursors, and the uncertain probabilities of pyroclastic flowage hazards were discussed, and the government officials displayed impatience and frustration concerning the uncertain information received by them. A few days later, on 10 May 1989, taking into account the concern of volcanologists regarding the status of activity, ONAD in Bogota unilaterally declared an "orange warning" (second-highest warning level). The volcanologists, influenced by the uncertain and insufficient knowledge of Galeras, were concerned about potential large eruptions and the potential for pyroclastic currents in some drainage channels. However the "orange warning" promoted sensationalism by the media, particularly at the national level, in exaggerated reports on the evolution of activity at Galeras. These media pressures aggravated the relationships between scientists and the new Mayor of Pasto and the Governor of Narino (Cardona, 1997).

Also, on several occasions when changes in activity were noted, the national media used archival eruption images of other volcanoes that were spectacular but unrepresentative of Galeras activity. Such instances enhanced concerns and stress levels for local inhabitants and relatives living in other areas. The national government held seminars for the media with the aim to minimize distortional reporting and to emphasize the social responsibility of media toward inhabitants in affected areas, but these goals were not achieved and sensationalized reporting continued. The problem was exacerbated when regional and local officials impeded the flow of information in an attempt to exert control on media.

In late 1991, about the time the new lava dome was emplaced, a new Governor and Mayor were elected for the term of office 1992–1994. The election campaigns featured criticism of the previous administration's management of the May 1989 volcanic crisis and the subsequent directly related economic crisis. The governments had been asked several times by ONAD to restrict tourism near the crater and to establish better security against theft or damage for volcano monitoring equipment. These requests to the old governments had been ignored, and the new governments proved even more unwilling to support hazards work. After the explosion of July 1992, the national government was asked by the Governor to restrict information releases to the public from national offices, including ONAD, about the activity of Galeras – despite the explosive destruction of the dome in July 1992 that hurled ballistic fragments several kilometers, damaged telecommunication facilities high on Galeras, and generated a strong shock wave. The minister reiterated the constitutional obligation of authorities to inform citizens in risk zones. The same Governor ridiculed the activities and ignored the monitoring of the Pasto observatory scientists, and appointed an independent geologist as his scientific advisor. During this period, local media began to claim that information was being concealed. The Governor's attitude finally led to an investigation by the Attorney General of Colombia.

The deaths to scientists and tourists in January 1993 generated a confrontation between national and regional authorities, each blaming the other (Cardona, 1997). The national level of government had to address the emergency, as the local and regional governments through lack of preparation exhibited inadequate procedures and coordination. Although the disaster generated new meetings at local and regional level, the debate instead led to requests to the President of the Republic to declare an economic emergency, and to invest resources from the national budget into the local economy. Although not unsuitable, the requests bore no direct relation to improving risk management.

During 1994 and 1995, seismic swarms and damage-causing earthquakes occurred. The emergency caused by the March 1995 earthquake, which resulted in six deaths, was dealt with by yet again a new Mayor and Governor. Despite their positive attitudes toward preparedness, resources available for mitigation were limited. Yet between 1989 and 1994, almost two million dollars was made available through ONAD and related entities, and used for volcano monitoring, hospitals, communications, and public education.

Hazards assessments and the role of scientists

Most Colombian volcanologists assigned to Pasto in 1989 had some experience from the Nevado del Ruiz emergency (there were *no* trained "volcanologists" in Colombia before Ruiz). Despite this limited experience, they were disconcerted by the rapid buildup of volcanic activity, and were under pressure from national and regional authorities to accurately forecast future developments, and simultaneously to determine zones of volcano hazard to aid emergency preparations.

The first official hazard map, released 3 May 1989 by the Regional Risk Committee, was essentially a "bullseye" map with five concentric zones. Its necessarily rapid preparation, the lack of basic knowledge about Galeras, and the Ruiz experience, collectively contributed to an overestimation of the extent of hazardous zones. Western Pasto was mapped as high hazard, and the main part of the city was in a medium-high hazard zone.

In addition to the map, alert levels concerning the volcano's activity were being discussed. In late March 1989, INGEOMINAS volcanologists recommended consideration of issuing a "white warning" of increasing activity, with the intention of using this unconventional color code to avert undue alarm. Days later, a "yellow warning" was declared by the Regional Risk Committee. However, concern at national level prompted ONAD in Bogota to declare an "orange warning" to the media, without the input of the regional and local committees who should have been the source of information (Cardona, 1997). The orange alert was noted on the front-page headline in the Pasto newspaper *Diario del Sur* on 10 May, along with the colored hazard map. This action led to some exaggerated media reports and a deterioration in scientist-government relations at regional and local levels, as mentioned earlier.

Meanwhile several experts from the USA arrived in early May to assist the Colombians, and a second, unofficial hazard map was prepared and with a summary distributed to authorities and DN-PAD by 30 May 1989; a report was issued the next month (Janda and Voight, 1989). The map considered the influence of valley topography on potential flowage hazards and showed that Pasto was under much less risk than indicated in the first map.

An international workshop on volcano emergencies was held in Pasto between 8 and 28 May 1989, sponsored by UNESCO, USGS, and USAID, and attended by foreign scientists and trainees. The hazards were being discussed at this time, and more monitoring instruments were installed by USGS. At about the same time, a decision was made by the National Emergency Committee (NEC) to completely and quickly evacuate Pasto and neighboring towns in order to conservatively prevent loss of life. The decision was reversed when the eruptive scenarios were presented to NEC in probabilistic terms, along with concepts of acceptable risk, "that should be considered to avoid a social and economic disaster in the absence of a volcanic event" (Cardona, 1997). This information was received by local and regional governments as more suitable than the existing official hazards map for planning purposes.

Other problems were recognized. Maintaining an "orange warning" for a long time had led to loss of its effectiveness, and the population drifted back to the same mind-set as had existed before the warning. Thus some

thought was given to restructuring the criteria for warnings and the actions implied.

The second "official" hazard map was issued December 1989. This version considered the eruptive potential during the last 10,000 years, the runouts of hazardous flows, and their probabilities. The result was three zones with Pasto in a low hazard zone. But in a contrary development in 1990, the Pasto Chamber of Commerce and Mayor encouraged the involvement in the crisis of the director of the geophysical institute at a local university. The institute had no credentials in volcanology, but their optimistic and reassuring opinions on the volcano were desired by the Chamber of Commerce. For example, the institute denied that pyroclastic currents had occurred in the past, despite proof to the contrary recognized by INGEOMINAS.

When the lava dome appeared in 1991 the observatory in Pasto was strengthened further, and a two-man USGS seismology team provided technical assistance on 8–15 November. Because of the political situation, the team was instructed to maintain a low profile and not to offer public opinions on volcano status or other actions. A meeting that included regional and local authorities and INGEOMINAS was held on 17 November, and appeared to be positive in the limited sense that the Governor and Mayor agreed to the necessity of having an emergency plan (USGS file information).

Clearly the nadir for those who had insisted on strengthening preparedness was the eruption of 14 January 1993. Not only were valued colleagues lost, but some inhabitants were shocked by the accident and later ridiculed it, deteriorating the credibility of the scientists still further (Cardona, 1997). Some recognized that the eruption was proof that the volcano was dangerous and a threat to the community, but some poorly educated persons believed that the volcano was venting anger only at foreigners that disturbed it (Calvache, 2000). Years later this accident was sensationalized in nonscientific reporting, with personality issues emphasized and the field trip leader vilified. But before 14 January there was a paucity of experience with which to assess a conjectured link between tornillos and dome-destroying eruptions at Galeras, and other potential precursors were then at a low level. In the few days preceding the eruption, "It is important to mention that at that time no special or clear indications of these signals as precursors was seen. . .in the sense to have a real premonition of the incoming eruption" (R. Torres and D. Gomez, Observatory Seismologists, written communication to BV). Several experienced volcanologists have also judged the January 1993 situation as manifestly unclear: from S. McNutt, ". . .based on my experience elsewhere, it was not obvious"; and from B. Voight, ". . .before hindsight entered the picture, there was plenty of room for alternative interpretations regarding the hazard implications of the signals" (Monastersky, 2001). In a detailed assessment of the precursory evidence using probability theory, Aspinall et al. (2003) concluded: "With the benefit of hindsight, it would be invidious to criticize an expedition leader for taking with him or her other scientists who were keen to enter the crater and whose posterior odds of imminent explosive activity were probably 'professionally acceptable.'"

The incident also prompted consideration of general safety recommendations for volcanologists and the public (Aramaki et al., 1994). Precautions had been followed by the Pasto observatory during (and even before) January 1993, limiting the personnel entering the crater area, minimizing exposure time, and keeping radio contact with Pasto. Certainly, their standard of safety practice was no worse than that observed at most other observatories in the 1990s, but a raised worldwide standard was deemed desirable.

Only after four eruptions and two seismic crises (clearly felt by the population) had occurred in 1993 was it finally accepted by government officials and the community that Galeras was a genuine threat. The seismic crises particularly affected the population, and even the Governor "decided to believe" the volcano was active (Calvache, 2000). Gradually, after political resistance waned, the observatory scientists began to develop more advanced procedures for communicating information to authorities and the community. Several strategies were used to make the scientist's work and tools more accessible to the public, including student tours to the observatory, scientist interviews on local television, preparation of educational materials using easy-to-understand language, and production of videos on volcano hazards and monitoring. Nevertheless, as recently as 2009, recommended evacuations have not been generally met with compliance.

Social and economic impacts and feedback to the crisis

Many people left Pasto c.1990 and some property was sold at very low prices. A recession occurred in construction, because the Mayor prohibited construction in western Pasto (where the hazard was originally perceived as high), and in turn this fuelled unemployment. Financial and business concerns suspended or tightened credit and debtors failed their obligations. Transportation companies were unwilling to send freight and passengers to the area, leading to a severe problem of supplies and food. Tourism ceased and businesses were significantly affected.

When the volcano failed after many months to generate a significant eruption, doubts of a large eruption arose among both authorities and scientists. The events that had occurred were within the range encompassed by oral tradition and history, over a time span that seemed long to nonscientists but brief to volcanologists. The political campaigns of 1990–91 focused on meeting the economic crisis, and on criticism of the incumbent authorities' management of it.

Acceding to pressure from the economic guilds, the Mayor of Pasto promoted a "Meeting of the Volcanic Risk Situation and its Socioeconomic Consequences" in July 1990, whose purpose was the "*de-galerasization*" of

Pasto. At this meeting, attended by representatives of INGEOMINAS, ONAD, the Regional Risk Committee, and the economic guilds, it was suggested to de-emphasize the importance of volcanic activity to the city. The main speaker was the director of the Jesuit geophysical institute mentioned earlier, and, with misleading evidence and logic, he minimized the risk posed by Galeras. As a result, information concerning volcanic activity was almost totally restricted. There were no interinstitutional, educational, or public information actions, and information issued by scientists were undermined. Statements made by ONAD at national level were ignored.

The Governor and several parliament members later (in 1992) asked the President of the Republic to declare an economic emergency, but this was denied. The attitudes of most inhabitants evolved from one of extreme stress to complete apathy or denial of risk (Cardona, 1997). The lack of an alternative to coexistence with the risk prompted a collective psychological attitude of simply ignoring the volcano. Elements of that attitude exist to the present time and are a factor in poor compliance to evacuation recommendations.

Summary of crisis management issues

Because of a lack of available detailed knowledge about the volcano and no previous hazards mapping or emergency preparedness plans, the initial, necessarily rushed hazards assessments by Colombian scientists overestimated the extent of the hazard zones, and the first official hazard map in 1989 showed the densely populated city of Pasto within a zone of high to medium-high hazard.

This initial, appropriately cautious attitude of scientists on the risk posed by Galeras was translated, in the post-Armero environment, by political authorities at local, regional, and national levels into extreme alarm – because if a serious eruption were to occur, they would be held responsible due to a lack of recommendation for evacuation. This alarm overrode considerations of social impacts which might be produced by a false alarm or an unnecessary evacuation. Although a formal evacuation was not instituted, the way information was managed also contributed to problems in the fragile economic environment of southern Colombia – even though it would have been difficult to eliminate such problems.

Given the negative implications from the 1989 crisis, the local and regional political authorities focused on the economic problems and were thereafter reluctant to promote risk reduction activities. Further, since the Governor and Mayor were automatically the designated chairpersons for the regional and local risk committees, respectively, progress on these committees was negligible. Exemplified by the "*de-galerasization*" of Pasto, and fearing that the media would spread alarm and thereby affect the economy, information concerning volcanic activity was almost totally restricted. There were no inter-institutional, educational, or public information actions, information issued by scientists were consistently undermined, and statements from ONAD at national level were ignored. More than four Governors and four Mayors had dealt with the crisis in the period to c.2000, and such lack of continuity (and related politicization of the crisis) affected hazards management. The problem of continuity is typical for long-lasting crises, e.g., at Montserrat.

Conclusions – the lessons learned

1. The lack of precrisis scientific knowledge of the volcano contributed not unreasonably to an assessment that overemphasized the hazards, but this in turn led to a *chain-reaction* of serious problems – undue extreme alarm by civil authorities, the spreading of alarm nationally by media, deterioration of a fragile regional economy, loss of credibility of the scientific team with authorities and the public, and adverse politicization of the crisis which lasted many years.
2. The Galeras example shows how a potentially active volcano can lead to serious economic and social problems without accompanying serious volcanic activity, and indeed even without an evacuation. Much depends upon the way the emergency is managed, although some aspects of the problem can develop irrespective of management skills. Such situations are dangerous because they may lead to a state of denial of risk, with potentially disastrous consequences.
3. Scientists, risk committees, and civil authorities must learn how to work together, in order to maintain credibility of the public and to protect the public interest. Lacking such credibility, effective communications with the public will be impossible, and the implementation of effective mitigation measures will be severely hindered.
4. Despite management problems, the scientific achievements from Galeras have been notable in multiparameter monitoring, detection of strong precursors to lava dome emplacement, LP seismicity as indicators of gas pressurization, and interpretation of gas flux fluctuations. Interpreting explosion precursors was for a time problematic, given the subtle nature and limited understanding (pre-January 1993) of the precursors.

Acknowledgments

We thank our highly dedicated colleagues at OV Pasto for much support, notably F. Munoz, H. Cepeda, E. Parra., D. Gomes, R. Torres. The 1989 mission to Galeras by BV, R. Janda and D. Harlow was supported by USGS and United Nations (UNDRO) funds. C. Cardenas and O.D. Cardona of ONAD provided assistance and insight. We recall the memory of colleagues and friends killed in the 1993 eruption, Geoff Brown, Fernando Cuenca, Nestor Garcia, Igor Menyailov, Carlos Trujillo, and Jose Arles Zapata, and of Bruno Martinelli, dear friend and wise advisor to the Pasto observatory scientists.

GAS-HYDRATES

Harsh K. Gupta[1,2], Kalachand Sain[2]
[1]Government of India, NDMA Bhawan, New Delhi, India
[2]National Geophysical Research Institute, Hyderabad, India

Synonyms

Clathrates; Methane-hydrates

Definition

Gas-hydrates, also called clathrates, are ice-like crystals of hydrocarbons (mainly methane) and water, which are found in shallow sediments of deepwater and permafrost regions, controlled by high-pressure and low-temperature regimes.

Discussion

The origin of methane can be either biogenic or thermogenic or a mixture of both. The estimated global reserve of methane (2×10^{16} m^3) within gas-hydrates is believed to exceed the equivalent amount of gas in total fossil fuels, and is roughly 3,000 times the amount present in the atmosphere. The carbon in gas-hydrates is speculated to be 10,000 gigatons, which is roughly two times the carbon content in global fossil fuels (Milkov, 2004).

Methane is the cleanest fuel of all hydrocarbons and is 20 times more potent as a greenhouse gas than carbon dioxide. Therefore, a large release of methane from this source may have a significant impact on climate change. Destabilization of gas-hydrates weakens the host sediments influencing the occurrence of submarine *Landslide*. The study of gas-hydrates has attracted the attention of researchers because of their (1) potential submarine geohazards, (2) likely role in global climate change, and (3) future fuel resource. The first two aspects are dealt with here.

Periodic tidal loading and unloading, and an increase in bottom-water temperature can change the

pressure–temperature regime of a gas-hydrate stability field thereby leading to dissociation of gas-hydrates, and consequently causing sediment instability. The tectonic disturbances may lead to explosive dissociation of massive gas-hydrates, which can trigger large submarine landslides that can damage oil platforms, coastal installations, and fishing networks. Due to a decrease in permeability, the hydrate-bearing sediments can trap free-gas underneath. The association of gas-hydrates with active mud volcanoes enhances the chances for flaming eruptions.

Deepwater drilling operations may melt the gas-hydrates that can cause sediment mass movement, borehole collapse, gas blowouts, etc. The clogging of pipelines by the formation of gas-hydrates also poses a threat to transmission. Since a depressurizing hydrate plug can travel at ballistic speeds, it has the potential to injure workers and rupture the pipelines, and thus this type of dislodging can be dangerous.

The dissociation of gas-hydrates may add a large volume of methane to the atmosphere, which is known to contribute to climate change. This also causes an uncontrolled release of over-pressured gas trapped underneath, which also represents a significant hazard. Global warming could melt gas-hydrates, causing methane release into the atmosphere and enhanced warming. This raises the risk of more extreme events such as floods, droughts, and wildfires.

There is a need to develop an environment-safe technology for commercial production of gas-hydrates, avoiding possible hazards and meeting the enormous global energy deficit. It is essential to recognize the prospective places of gas-hydrates' occurrences for evaluating the resource potential and impact of environmental hazard for further advancement. The identification and quantification (Sain and Gupta, 2008) of gas-hydrates is a prerequisite for exploration of conventional oil and gas in the deepwater regions.

GEOGRAPHIC INFORMATION SYSTEMS (GIS) AND NATURAL HAZARDS

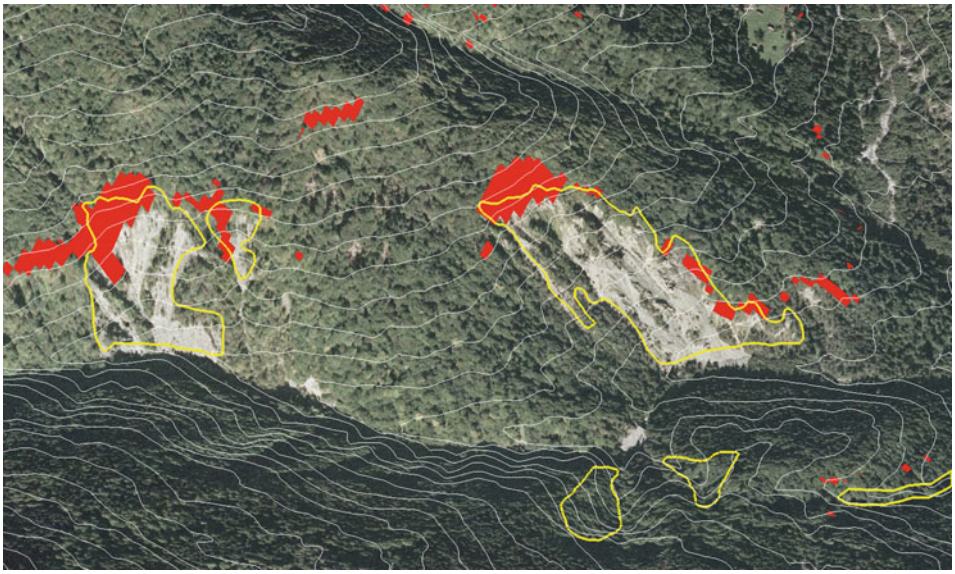
Definitions

Geographic Information Systems (GIS). GIS is a computer-based information system designed for capturing, storing, analyzing, managing, and displaying spatial data representing human and natural phenomena from the real world. It may include application to remote sensing, land surveying, mathematics, and geography.

Natural Hazard. Any natural phenomenon that poses a threat to human life or properties.

Introduction

Natural hazards include geological (e.g., earthquakes and landslides) and meteorological events such as cyclones, tornadoes, hailstorms, floods, droughts, and wildfires (Chen et al., 2003). Natural hazards are deeply linked to the concepts of *magnitude*, *geographical location*, and *time recurrence* which denote intensity, place of potential occurrence, and frequency of the natural phenomenon, respectively. Since many factors can play an important role in the occurrence of a natural disaster and their spatial information is crucial to risk assessment and management, the analysis of natural hazards greatly benefits from GIS. The use of GIS to manage and understand complex natural hazards in spatial and temporal contexts is nowadays essential (e.g., Chen et al., 2001; Zerger, 2002; Gamper et al., 2006; Fernández and Lutz, 2012), since many issues related to hazard assessment and mitigation have a strong spatial component and their combination can provide valuable information for decision making. For example, in the case of hazard assessment and risk mitigation of diseases such as malaria and cholera, mapping the spatial distribution of incidence or space-time evolution, and merging these maps with land-use and land-cover layers and population density is really useful and represents a precious tool for decision making, method preparedness, and early warning system for malaria or cholera control (Bertuzzo et al., 2008; Hanafi-Bojd et al., 2012). Even in the case of destructive phenomena, such as hurricanes and wildfire, GIS tools are essential to store and manage geographical data in order to study effective mitigation measures (Castrillón et al., 2011; Krishnamurthy et al., 2011). In the frame of a joint analysis of several natural hazards via GIS, the combination of multiple hazard maps related to the individual phenomena can lead to the creation of a composite "multi-hazards" map (Schneider and Schauer, 2006; Reese et al., 2007; Kappes et al., 2012).



In recent years, GIS technology has allowed individuals to store and manipulate earth surface data in more efficient and innovative ways. Considering the topography, morphological factors, such as slope, landform curvature, flow direction, and drainage area, play a key role in flood and landslide hazard assessment. During the last decade, a range of new remote sensing techniques have led to a dramatic increase in terrain information, both in terms of quality and amount of topographic data (Tarolli et al., 2009). Both Terrestrial Laser Scanner (TLS) and Airborne Laser Swath Mapping technology (ALSM), using LiDAR (Light Detection And Ranging) technology, now provide high-resolution topographic data with notable advantages over traditional survey techniques (Slatton et al., 2007; Tarolli et al., 2009). A valuable characteristic of these technologies is their capability to produce sub-meter resolution Digital Terrain Models (DTMs), and high-quality land cover information (Digital Surface Models, DSMs) over large areas (Tarolli et al., 2009; Cavalli and Tarolli, 2011). With the use of GIS, it is possible to combine topographic information with other land surface data (e.g., geology, land use, location of buildings and roads) to improve the natural hazards assessment (Ayalew et al., 2004; Ho and Umitsu, 2011; Guzzetti et al., 2012), and to increase the effectiveness of decision-makers for natural hazards mitigation and preparedness (Rashed and Weeks, 2003; Malczewski, 2006; Ballesteros-Cánovas et al., 2012; Yang et al., 2012). In order to assure the effectiveness of a GIS model, all the data layers must be periodically updated and the analysis repeated with new data (Cubellis et al., 2004; Tropeano and Turconi, 2004).

At present, there is a great variety of GIS software, such as packages developed by academic institutions, commercial software, and, especially in the last few years, many widely spread open-source software systems (Steiniger and Bocher, 2009), that can be used in different operating systems (OS). In addition, they are developed in various languages: Java, C++, C#, VB.Net, etc. (Lei et al., 2011). In the last few years, the Web-based GIS have become largely widespread, with an increasing use of the related applications in natural hazards assessment (Nappi et al., 2008; Gitis et al., 2012). A Web-based GIS combines Internet and Geographic Information System environments; GIS provides the capability for storing and managing large amounts of spatial data, while Internet technology allows easy access to the geospatial information (Nappi et al., 2008).

GIS and landslide hazard

The distribution of landslides and the resulting hazards has been estimated following both statistical and physically-based or process-based approaches. Landslide mapping through GIS is an important part of landslide research because maps showing observed landslides are necessary to calibrate and validate the landslide susceptibility models (Guzzetti et al., 2006; Chang et al., 2007; Rossi et al., 2010). Different techniques are used to compile landslide event-inventory maps where GIS plays an important role (Guzzetti et al., 2012): interpretation of stereoscopic aerial photographs taken shortly after an event (Guzzetti et al., 2004), using single or multi-temporal aerial photographs (Brardinoni et al., 2003; Prokesova et al., 2010); satellite images (e.g., Nichol et al., 2006; Hong et al., 2007; Mondini et al., 2011); synthetic aperture radar (SAR) (Czuchlewski et al., 2003; Hilley et al., 2004; Bulmer et al., 2006; Roering et al., 2009); and analysis of high-resolution DTMs obtained from airborne Lidar (McKean and Roering, 2004; Van Den Eeckhaut et al., 2007; Kasai et al., 2009; Tarolli et al., 2012). All these methodologies are based on the detection of landslides, through digital quantification of the DTM, or statistical interpretation of images. In addition to these, the physically-based or process-based approaches (Hammond et al., 1992; Montgomery and Dietrich, 1994; Crosta and Frattini, 2003) were largely used for landsliding hazard mapping in the last few decades. They consist in integrating hydrologic and geotechnical models for evaluating landsliding susceptibility maps. These maps usually comprised a stability index spatially distributed and expressed as Factor of Safety *FS* and Stability Index *SI* in the case of Pack et al. (1998), and Tarolli and Tarboton (2006) respectively, or as critical rainfall (Montgomery and Dietrich, 1994; Borga et al., 2002; Tarolli et al., 2011) needed to cause instability for each topographic element. Susceptibility maps need to be evaluated and validated (Dietrich et al., 2001; Tarolli et al., 2011). The evaluation of the effectiveness of susceptibility maps can be carried out by mapping all observed landslides, and comparing them with the map of predicted stability index. Figure 1 shows an example of such approach where Most Likely Landslide Initiation Points (MLIPs) (Tarolli and Tarboton, 2006), landslide locations, and high-resolution aerial photographs are superimposed in a GIS environment. Similar landslide susceptibility maps can be of immense support to decision-makers and environmental planners.

Several studies have demonstrated the potential of GIS for hazard assessments in the particular case of debris flow (Huggel et al., 2003; Medina et al., 2007; Cavalli and Marchi, 2008; Carrara et al., 2008; Stolz and Huggel, 2008; Scheidl and Rickenmann, 2010). Many different runout prediction methods can be applied to estimate the mobility of future debris flows during hazard assessment (Hürlimann et al., 2008). Using a statistical approach, He et al. (2003) developed a quantitative model of hazards assessment and zonation through synthesis analysis of basin areas, gradients, and the relative reliefs of these debris flow sites. The location of each debris flow site and its physical and activity characteristics were entered into the GIS-based database. Cavalli and Marchi (2008) used LiDAR data in GIS environment to examine the morphology and to characterize surface complexity of the alluvial fan of an alpine debris-flow stream.

Geographic Information Systems (GIS) and Natural Hazards, Figure 1 Most likely landslide intiation points and landslide locations (Tarolli and Tarboton, 2006).

Carrara et al. (2008) in order to predict location of the debris-flow source areas proposed two multivariate procedures (discriminant and logistic regression) and a physically-based approach. Berti and Simoni (2007) and Scheidl and Rickenmann (2010) proposed two empirical approaches for prediction of debris flow inundation areas and prediction of debris-flow mobility and deposition on fans respectively. Medina et al. (2007) and Stolz and Huggel (2008) proposed 2D model analysis of debris-flow hazard zones which can be easily implemented in GIS software.

GIS and flood hazard

Floods are one of the major natural hazards. Predicting an inundation in an urban area is a crucial tool for the mitigation of flood risk, in order to be prepared for the flood, and to minimize its impact and for providing the basis for management decision, flood protection system, and a suitable urban planning. Flood hazard mapping can be performed using different methods that can be grouped into two main categories: geological-geomorphological and hydrological-hydraulic methods (Lastra et al., 2008). Geomorphological analysis has been carried out for flood-risk prevention plans in the Mediterranean regions (Guzzetti and Tonelli, 2004; Guzzetti et al., 2005). For regional planning purposes, the prediction of flood processes can be carried out by means of GIS analysis of topographic and remote sensing data. Simple morphometric properties (i.e., Melton ratio) can help in identifying watersheds prone to flooding (Wilford et al., 2004), and the analysis of remote sensing images taken during a flood and in a dry season allows to estimate flooded area and therefore, to create accurate flood hazard map (Islam and Sado, 2000). Conventional image processing techniques for extracting flooded areas from SAR imagery have been used with varying accuracy (depending on spatial resolution) (Kiage et al., 2005; Schumann et al., 2009), since SAR imagery presents advantages over optical instruments, especially in flood management applications (Matgen et al., 2007). Combining supervised land cover classifications from LANDSAT and Shuttle Radar Topographic Mission Digital Elevation Model (SRTM DEM) seemed an efficient method for mapping coastal flood risk (Wang et al., 2002; Demirkesen et al., 2006). Umitsu et al. (2006) demonstrated the utility of SRTM incorporated with GIS data for studies on flooding and micro-landforms. Ho and Umitsu (2011) developed an integrated method for classifying micro-landforms and flood hazard zones based on a geomorphological approach utilizing in GIS environment SRTM and LANDSAT ETM (Enhanced Thematic Mapper Plus) data combined with field investigation. Lastra et al. (2008) combined geomorphological and hydrological methods for flood hazard delineation. Several other approaches included also the hydrological-hydraulic approach for flood hazard mapping (Horritt et al., 2001; Horritt and Bates, 2001; Xia et al., 2011; Stephens et al., 2012). The results are flood inundation maps visualized in GIS environments, wherein it is possible to recognize and locate, in detail, the places with different water depth and extension. A good risk analysis of such phenomena is given by combining flood risk maps with other data such as streets, buildings, land use, etc. Such maps play an important role in flood management (Plate, 2002). GIS flood applications depend on resolution of topographic data used in flood simulations. New remote sensing technologies such as LiDAR measure high-resolution terrain (elevation) data that help in measuring

surface morphology and roughness (Cavalli et al., 2008). This is advantageous when small-scale processes have a significant effect on model, for example, where the extent of inundation is controlled by predictions of small topographic features (Horritt and Bates, 2001). Fernandéz and Lutz (2012) proposed a GIS-aided urban flood hazard zoning, applying multicriteria decision analysis and to evaluate it by means of uncertainty and sensitivity analysis.

The use of GIS for decision makers to limit or analyze the impact of natural coastal hazards, such as sea level rise, storm surges, and coastal erosion given by tsunamis, and thus, protect the exposed assets (population, property, settlements, communications networks, etc.) (Desprats et al., 2010) is worth to be mentioned. By the analysis of the coastal risk scenarios within GIS environment, it is possible to identify "weak points" in human settlements and test the exposure of their future development (Desprats et al., 2010). This is indeed a critical issue if we consider the recent devastating 2004 Indian Ocean and 2011 Japan tsunamis. The analysis of tsunami hazards and mapping, and thus, the evaluation of population exposure can greatly benefit from the use of GIS which helps to improve the tsunami hazards assessment and mitigation (Løvholt et al., 2012).

GIS and seismic hazard

Managing seismic hazard requires different and independent observations and techniques (Salvi et al., 1999): epicenter distribution of recent and historical seismicity, geological and geomorphologic data, geophysical analysis, analysis and monitoring of deformation by geodetic data, photo interpretation of aerial and satellite images, and fluid geochemistry monitoring (e.g., Quattrocchi et al., 2000). The approach to seismic hazard evaluation is a multidisciplinary approach, wherein a GIS is strongly required for managing multi-scaled datasets in the same geographically referenced view (Salvi et al., 1999). The geologic and seismologic maps can be easily combined, and integrated in a GIS environment (Nath, 2005). This allows to overlay and analyze different thematic layers, and merge raster and vectorial data (Cubellis et al., 2004; Pal et al., 2008). With the overlay procedure of different thematic fields it is possible to derive new integrated maps of potential damage that may then be used in hazard assessment for a suitable planning in an urbanized area (Cubellis et al., 2004). Nath (2005) proposed a seismic microzonation model through thematic mapping and GIS integration of geological and motion features through GIS. The microzonation maps may be useful for land use planning or for making hazard mitigation decisions. Selcuk and Yucemen (2000) and Selcuk-Kestel et al. (2012) proposed a GIS-based software for lifeline reliability analysis under seismic hazard. The developed GIS-based software imports seismic hazard and lifeline network layers. It adopts a network reliability algorithm to calculate the upper and lower bounds for system reliability of the lifeline under seismic hazard. Zolfaghari (2009) proposed an approach to provide practical facility for better capture of spatial variations of seismological and tectonic characteristics, which allows better treatment of their uncertainties. In the proposed approach, GIS raster-based data models are used in order to model geographical features in a cell-based system. The cell-based source model provides a framework for implementing many geographically referenced seismotectonic factors into seismic hazard modeling.

As with the greater part of geographical data, even seismic information is currently shared with a large target of end-users (Pessina and Meroni, 2009). Due to this reason Web-GIS should be a strategic tool for sharing information on seismic hazard and to develop real-time warning systems. Martinelli and Meletti (2008) proposed a WebGIS application for rendering seismic hazard data in Italy, whereas Pessina and Meroni (2009) proposed a WebGIS tool for seismic hazard scenarios which consists in ground shaking scenarios associated with the repetition of the earthquake that struck an area.

GIS and volcanic hazard

Volcanic hazards have important scientific, economic, and political implications, especially for densely populated areas close to volcanoes (a clear example is Naples in Italy). Volcanic hazards require accurate assessment and mitigation plans, the development of suitable tools for prediction and management of critical situations, and the promotion of sustainable development within volcanic hazard areas (Felpeto et al., 2007). The use of GIS is crucial in this aspect. Mapping and studying of lava flows have been the subject in the last few years of recent advances where the combination of GIS and remote sensing techniques played a key role (Tarquini and Favalli, 2011). Digital elevation models, satellite images, hazards maps, vector data on natural and artificial features, and population density are the main input information that can be used in GIS for volcanic risk management and mitigation (Pareschi et al., 2000). Volcanic hazard maps and eruption scenarios can be developed from past eruptions and the geologic records (Felpeto et al., 2007). Several authors proposed GIS modeling and spatial analysis in order to produce maps for prevention and emergency management (Iverson et al., 1998; Gomez-Fernandez, 2000; Gaspar et al., 2004). Iverson et al. (1998) express the importance of defining lahar (i.e., a landslide of volcanic fragments mixed with water flowing on the flanks of a volcano) inundation zones from past events. They developed a model for lahar inundation based on the assumption that past inundation zones provide a basis for predicting future inundation areas. Renschler (2005) emphasizes the importance of considering spatial and temporal variability in volcanic processes and representing it in GIS-based volcano hazard simulations. Toyos et al. (2007) presented a methodology implemented within a GIS for hazard mapping of small volume pyroclastic density currents.

The results achieved highlight the applicability of this approach for hazard mitigation and real-time emergency management. Tarquini and Favalli (2011) introduced a GIS to obtain high-resolution boundaries of lava flow fields. This technique is mainly based on the processing of LIDAR-derived maps and DEMs.

GIS and drought hazard

Droughts are among the most important natural disasters, particularly in the arid and semiarid regions of the world (Núñez et al., 2011), especially in recent years due to climate change (Hao et al., 2012). Drought hazards maps combined with other layers in the GIS environment, especially those related to irrigated and food production areas, represent a useful tool for drought risk management and plan. Detailed analyses of spatial and temporal drought dynamics during monsoon and non-monsoon seasons have been carried out through drought index maps generated in GIS environment (Bhuiyan et al., 2006). Vicente-Serrano (2007) analyzed, in a semi-arid region, monthly and spatial differences in the effects of drought on the natural vegetation and agricultural crops by means of the joint use of vegetation indexes, a drought index (standardized precipitation index), and GIS. Shahid and Behrawan (2008) developed a standardized precipitation index method in a GIS environment for mapping the spatial extents of drought hazards in different time steps.

Summary

Understanding the natural hazards is one of the most important issues in the earth science field. This is useful not only for analyzing a natural process from the scientific point of view, but also for understanding the link between the human system and natural and potentially dangerous phenomena. In the last two decades, the GIS technology (commercial, open source, and also web-based) offered to the scientific and technical community a powerful tool to analyze natural processes. Natural hazards, such as landslides, debris flows, floods, volcanic and seismic activity, hurricanes, coastal erosion, and wildfires, but also droughts and human diseases (e.g., malaria and cholera), are now more easier to manage and understand, thanks to the introduction of GIS. In the field of natural hazards, the increasing availability of GIS coupled models and decision-support tools offers even more efficient support for governmental agencies and decision makers to help in risk management and protection activities.

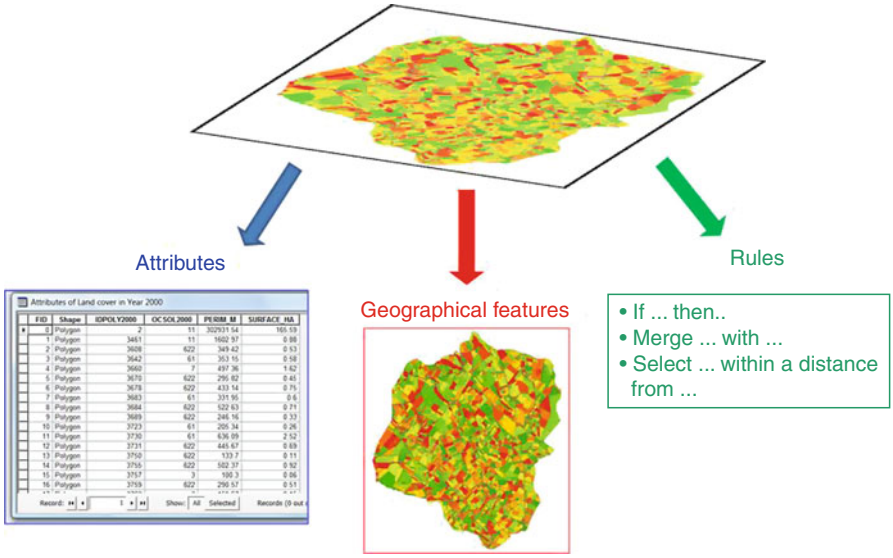
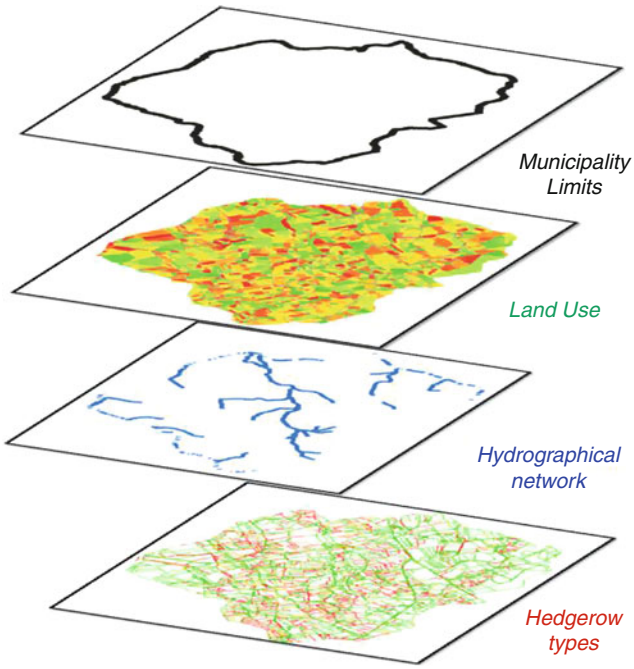
Definition

Geographic information technology uses computer-based tools to analyze spatial information into a geographic information system (GIS). In a GIS, data of the real world are stored into a georeferenced database, which can be displayed via maps. There is a dynamic link between the displayed maps and the stored georeferenced data, that is, a change on the maps leads to a change in the database and vice versa.



Use of geographic information technologies

There are a number of applications that use geographic information technologies in numerous economical sectors, such as transportation, medicine, agriculture, mineral exploration, forestry, and governance. Geographic information technologies are used in natural resource management, environmental assessment and planning, demographical studies, land use management and planning, emergency management, transportation management, logistics, and so on.



Geographic information system components

A GIS is mainly used for storing, accessing, manipulating, transforming, analyzing, and displaying spatial information (georeferenced data). It can create new spatial information from those stored in the database. GIS outputs are maps, tables, or charts. A GIS allows study of spatial relationships, patterns, and trends among data, for example, searching for the best soil type for a given crop. Real world objects, such as streets, streams, cities, forest stands, and others, are defined in a GIS using three main characteristics:

1. Geographic features, which define geometric shapes and geographic positions of world objects. This characteristic is used in the map display.
2. Attributes, which are variables or parameters describing each geographic feature. They are stored into an attribute table.

Geographic Information Technology, Figure 1 Three characteristics used in GIS to represent real world objects.

Geographic Information Technology, Figure 2 Thematic layers used to store specific spatial information in a GIS database.

3. Rules, which allow analyzing or displaying spatial data.

In the illustration example, agricultural plots are represented as polygons. Each plot is described by attributes, that is, municipality where it is located, crop type in the year 2000, and plot area. Rules such as "*locate the corn plots that are close to wheat plots*" can be defined (Figure 1).

How spatial information is stored in a GIS database?

In a GIS database, spatial information from the real world is stored as thematic layers that are geographically linked. Each layer has features with similar attributes. The following GIS database has as layers the municipality limits, the land use, the hydrographical network, and the hedgerow type.

Data in a GIS database can be of two main formats: vector and raster. Vector data are either point layers (made of punctual data), line layers (made of linear data like the above hydrographical network layer), and polygon layers (made of data having an area like the above land use layer). Raster (or matrix-type) data are either digital images or grid data (Figure 2).

Geological Hazards; Geomorphological Hazards

Definition

Geohazard is a relatively new scientific term related to *Natural Hazard* studies. It indicates geomorphological, geological, or environmental processes, phenomena, and conditions that are potentially dangerous or pose a level of threat to human life, health, and property, or to the environment.

Discussion

Geohazards include subaerial and submarine processes, such as *Earthquake*, volcanic eruptions, floods, erosion, debris flows, rockfalls, and other types of *Landslide* and *Tsunami*. Human-induced processes may also be considered as geohazards.

Since the term *Hazard* represents a particular state of the geomorphic system that may develop further into a situation leading to damage or uncontrolled risk, studies in this field treat the changes in nature that may affect society. Geohazards research may be considered a fully geographical topic, since it includes both natural and social dimensions and is related to the complex of activities related to assessment, prevention, and mitigation, including the adjustments of society to natural hazards.

From the geomorphological perspective, innumerable studies on natural systems, their processes, and phenomena have been elaborated until now. They have focused on the geomorphic processes, dynamics, space, and timescales with special regard to frequency and magnitude. Statistical analysis of the geomorphic processes and evolution of the geographic information systems make it possible to predict the occurrence of certain natural events. Geomorphologists have increasingly become aware of the societal dimensions of the problem by implementing vulnerability analyzes and hazard and risk assessment.

The majority of countries have evolved several complex physical, social, and normative responses to the most frequent natural processes, raising their resilience and thus enabling them to absorb the effects of potential geohazards. In many cases, the effects of geohazards are multiplied by the results of deforestation and unsuitable land-use practices, often related to human activities. This is one of the reasons why the European Commission has lately put more emphasis on social aspects of geohazards. In response to the increasing threat of geohazards to global society, several international organizations and initiatives have been struggling to cope with geohazards; among them are the United Nations International Strategy for Disaster Reduction (UN ISDR), the EUR-OPA Major Hazards Agreement, GeoHazards International, and several scientific organizations, such as the Japan Landslide Society, International Centre for Geohazards, and the Platform on Natural Hazards of the Alpine Convention – PLANALP.

Disaster

A disaster is an event that causes hardship, loss of life, or damage to infrastructure, the environment, the economic well-being, or other things that humans value. It is a cultural construct that refers to the relative impact of a hazard. It is important to recognize that a disaster would not exist without some direct impact on humans. A volcanic event, for instance, is an occurrence of a volcano. A volcanic hazard is the threat to humans from impacts of this event. A volcanic disaster is the negative impact of a volcanic hazard on things humans value. Disasters are therefore heavily influenced by a community's vulnerability to a particular hazard or group of hazards.

As a cultural construct, a disaster may be perceived differently by individual persons or groups of people, and there is no absolute disaster scale. The magnitude of a disaster may not be related to the magnitude of a hazard, highlighting, once again, the important role of vulnerability by humans and human communities.

A large magnitude earthquake in a remote region, for instance, may have no impact to humans and be considered an event, but a more moderate earthquake in a vulnerable and heavily populated city that results in widespread loss of life is very likely to be considered a disaster. A disaster typically implies that external assistance is required to facilitate recovery or that the effects of a hazard will be particularly persistent.

Disaster research is a relatively new but rapidly growing science with professionals publishing in several key scientific journals and research that spans almost all types of human endeavor. On December 11, 1987, the 42nd session of the General Assembly of the United Nations declared the International Decade for Natural Disaster Reduction (IDNDR) from 1990 to 1999 inclusive. In 1994, the Yokohama strategy was declared, and in the resolution, it was stated, "Natural disasters continue to strike and increase in magnitude, complexity, frequency and economic impact. While the natural phenomena causing disasters are in most cases beyond human control, vulnerability is generally a result of human activity. Therefore, society must recognize and strengthen traditional methods and explore new ways to live with such risk, and take urgent actions to prevent as well as to reduce the effects of such disasters. The capacities to do so are available" (ISDR, 2004, p. 9).

The IDNDR ended at the turn of the twenty-first century, however, buoyed by its success in engaging both scientists and policy makers toward reducing disasters and recognizing that the need for disaster reduction had arguably grown, the United Nations created the International Strategy for Disaster Reduction (ISDR), an institution that is still active today.

The IDSR definition of disaster states, "A serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources" (ISDR, 2004, p. 17).

In 1988, the World Health Organization (WHO) collaborated with the Belgian government to form the Centre for Research on the Epidemiology of Disasters (CRED). CRED collects and maintains EM-DAT (a database of worldwide disasters), which, in addition to the above criteria, includes any of the following situations:

- Ten or more people are killed.
- One hundred or more people are affected.
- A state of emergency is declared.
- A call for international assistance is made.

Geological/geophysical disasters

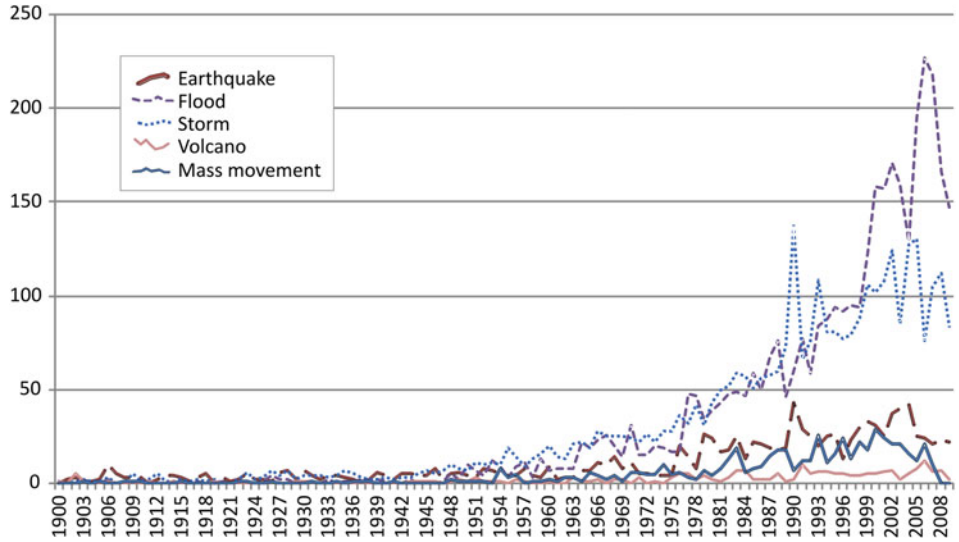
Geological disasters are those destructive events that originate within or are caused by the processes of the earth. Geological disasters include:

- Earthquakes
- Tsunamis
- Volcanoes
- Landslides and other mass movements
- Floods (including glacial lake outburst floods and landslide dam failures)
- Subsidence

Geophysical disasters include a slightly broader range of events that involve the physics of the earth that function principally in five areas:

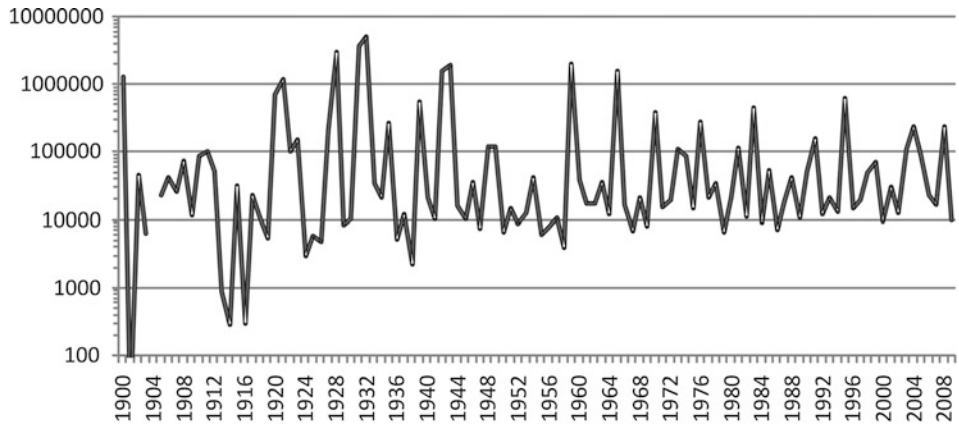
- Electricity
- Gravity
- Magnetic
- Seismic
- Thermal

Therefore, geophysical disasters include all the geological disasters as well as:



- Cyclones
- Lightning storms
- Drought
- Ice storms
- Fire
- Floods (due to high runoff)

The latter categories of geophysical disasters are typically considered climatological or hydrometeorological disasters. Climatological and hydrometeorological events are both subcategories of geophysical events; however, they are not always recognized as such and may instead be considered categories in their own right.



There is, in addition, a class of geological/geophysical hazards for which the potential for geological/geophysical disasters is sufficient that it bears mentioning. These hazards have not yet occurred in modern human history, but have occurred repeatedly in geological time and include the terrestrial collision of near-Earth objects (NEOs) such as asteroids, volcanoes of sufficient explosive capacity to be popularly called "supervolcanoes," and magnetic pole reversals.

The global occurrence of geological/geophysical disasters

Geological and geophysical disasters affect every continent substantially populated by humans. History contains a long record of geophysical disasters that both capture our imagination and give us pause: the 1556 Shaanxi earthquake in China that killed 830,000, the 1755 tsunami in Portugal that killed 60,000, the explosion of Vesuvius in 79 AD that buried Pompeii and Herculaneum, and the landslide in Tajikistan in 1949 that killed 12,000. Disaster reporting has increased dramatically in recent decades (Figure 1) as a result of increased awareness and technology, as well as increased populations, for some, increasing their vulnerability. In contrast, however, the trend for numbers of deaths reported in disasters has remained steady over the same time period (Figure 2), suggesting that major events were well recorded historically as they are now. Variability in the reporting of geophysical disasters appears to have diminished since the latter half of the

Geological/Geophysical Disasters, Figure 1 The number of geophysical disasters reported per year over the twentieth century (Data from EM-DAT, 2010).

Geological/Geophysical Disasters, Figure 2 The number of reported deaths due to geological and geophysical disasters worldwide 1900–2009 (Data from EM-DAT, 2010).

twentieth century, reflecting perhaps more accurate characterization of geophysical disasters and more consistent reporting of "smaller" events. Problems of reporting remain. If the cost of damage in terms of dollars is considered a benchmark, then developed industrialized countries tend to be the most heavily impacted by geological disasters (Table 1 and Figure 3). However, if one reports the cost in terms of displaced persons or number of people affected, geological disasters are most severe in densely populated developing countries. An argument could be made that the fundamental measure of quality of life begins with life itself. While it may overlook millions of affected individuals, loss of life is a relatively straightforward measure of disaster magnitude. Once again, the impacts are most severe in developing countries that have close proximity to abundant geophysical hazards (Table 1 and Figure 4). The countries located in an area, known as the Pacific or Asian "Ring of Fire," are particularly vulnerable to the full suite of geophysical hazards. These areas are affected by the tectonic and volcanic events occurring along active plate margins, landslides in steep terrain among the highest mountains in the world, as well as cyclone and high temperatures and humidity characteristic of the tropical location.

Earthquakes

Earthquakes are caused by the quick release of stored potential energy into kinetic energy of motion in the form of seismic waves and the propagation of fractures in the

Geological/Geophysical Disasters, Table 1 Top 20 countries affected geophysical/geological disasters for the cumulative period 1900–2009 by cost (in thousands of US$) and by number of individuals killed or presumed dead (EM-DAT, 2010). Highlighted countries are on both lists

Country	Cost (millions of US$)	Country	Number killed (thousands of deaths)
United States	558,359	China	11,149
China	323,928	Soviet Union	6,368
Japan	214,259	India	4,570
Italy	67,036	Bangladesh	2,589
India	48,781	Korea	612

Bangladesh	18,171	Peru	84
Canada	17,218	Guatemala	83
Brazil	12,677	Chile	61

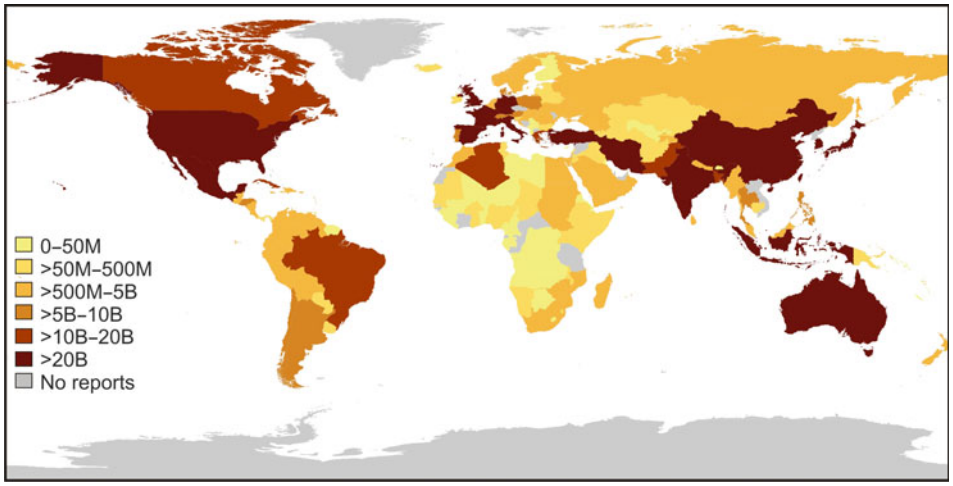
Earth's crust. Tectonic earthquakes (the usual case) are the release of elastic strain along plate boundaries, in turn caused by frictional resistance between plates as they slide against one another. The three main fault types associated with earthquakes are strike-slip (two plates slide horizontally against one another along the fault plane), thrust (crustal shortening that causes one plate to be pushed over another along the fault plane), and normal (crustal lengthening that causes one plate to slide against another as it drops down along the fault plane). These faults occur along transform, convergent, and divergent plate boundaries, respectively, and often, a combination of vertical (normal or thrust) and horizontal (strike-slip) movement results in oblique faults. Crustal deformations are ubiquitous around the globe, and small earthquakes are almost constant, though often go unnoticed.

Earthquakes may also be caused by man-made explosions, volcanic activity, landslides and outburst floods, and mining practices. Many of the natural hazards (and subsequent disasters) are themselves related to earthquake activity including landslides and tsunamis.

The magnitude of earthquakes is measured by the moment magnitude (M_W) scale (Hanks and Kanamori, 1979), a logarithmic scale that describes the amount of slip along a fault and the area of fault that slipped, which is a successor to the earlier Gutenberg-Richter scale (1954, 1956). In the moment magnitude scale, each increasing whole number represents an earthquake amplitude ten times greater than the previous number (M_W of 7 is 100 times greater than M_W of 5) and occurs ten times less frequently. The energy released during an earthquake, however, is about 32 times the earthquake amplitude, so an earthquake of M_W 7 releases about 1,000 times more energy than an earthquake of M_W 5. It is the energy release that ultimately causes damage and results in disasters.

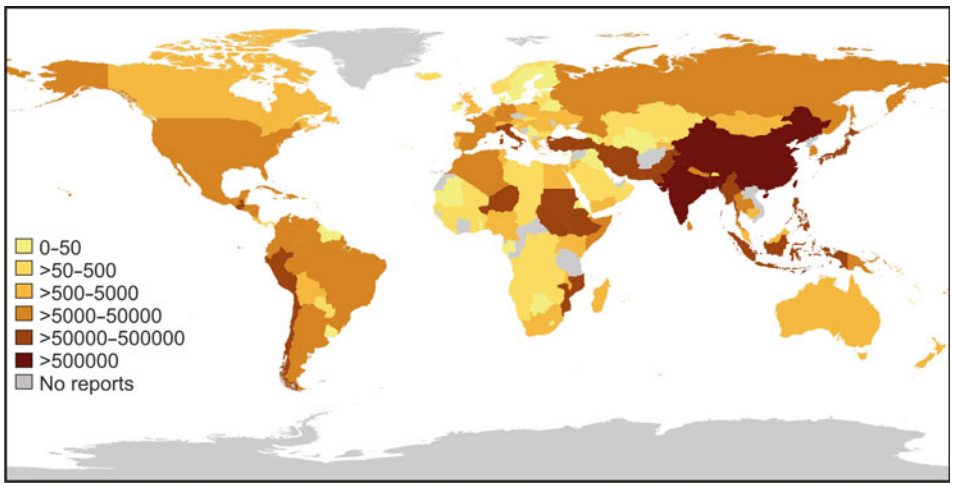
Globally, the most frequent earthquakes occur along convergent boundaries of the Pacific Plate in what is known as the Pacific "Ring of Fire" or the Asian "Ring of Fire" along convergent and transform boundaries of the Eurasian Plate and along the Nazca Plate as it collides with South America (Figure 5). Not surprisingly, the greatest losses of life from earthquake disasters have been in countries of Eastern Asia, followed closely by countries of South America (Table 2, Figure 6).

The deadliest earthquake on record occurred on January 23, 1556, in the Shaanxi province of China. An estimated 830,000 people died in one of the largest geophysical disasters ever recorded. The earthquake, an estimated M_W 8, was particularly devastating because a large percentage of the population lived in "yaodongs" or caves carved into cliffs composed of loess. Loess is wind-transported silt that is very unstable and may collapse when wetted or seismically shaken (e.g., Derbyshire, 2001). In this province, the loess cliffs collapsed or were buried in landslides, killing up to 60% of the population (cultural China website, 2010). In this same province of China, there have been at least four great earthquakes in the last 10,000 years, including one that occurred in 1,303 killing an estimated 270,000–470,000 people (Guogan et al., 1984).



Earthquakes remain a significant problem in China, and the country has experienced the greatest loss of life as compared to other countries in the twentieth century (Table 2). However, earthquake disasters occur elsewhere in the world, including the recent Haitian, New Zealand, and Japanese earthquakes.

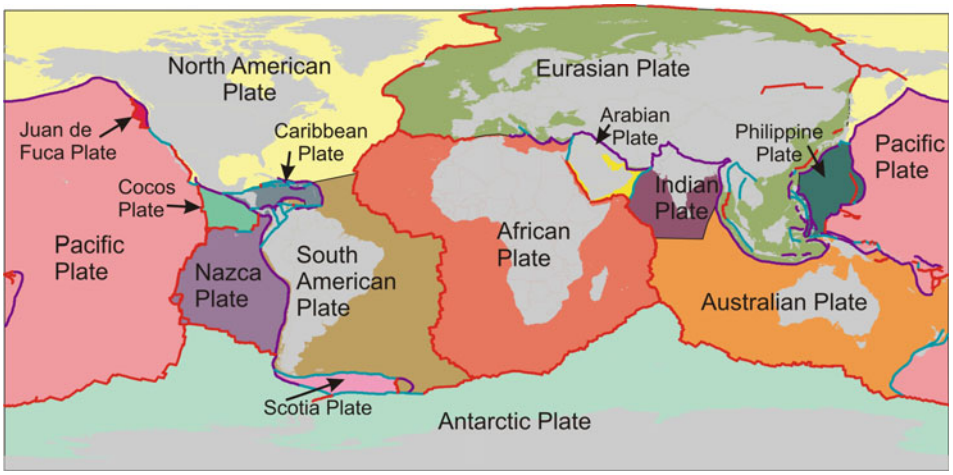
On January 12, 2010, an earthquake of M_W 7 occurred 25 km west of the capital of Haiti along a strike-slip fault and caused widespread building collapse (Figure 7), the deaths of approximately 230,000 people, and the displacement of over 1,000,000 residents (USGS, 2010a). The financial cost of the disaster may reach as much as 14 billion dollars (IDB, 2010).



The largest magnitude earthquake recorded globally was a Chilean earthquake of magnitude M_W 9.5 that occurred in Chile in 1960. This earthquake caused a transpacific tidal wave that eventually reached the island of Hilo, Hawaii (USGS, 2010b).

Tsunamis

A tsunami is a wave or a series of waves that form from the displacement of a large body of water. The term, literally meaning "harbor wave," originated in Japan where over 340 tsunamis have been recorded since 684 AD



Geological/Geophysical Disasters, Figure 3 The total cost of geophysical disasters reported over the period 1900–2009 by country (Data from EM-DAT, 2010).

Geological/Geophysical Disasters, Figure 4 The global distribution of geophysical disasters reported for the years 1900–2010. *Colors* represent the number of deaths by country for the entire period. The greatest numbers of deaths (over 11 million) last century were in China, due in a large part to flooding, earthquakes, and drought (Data from EM-DAT, 2010).

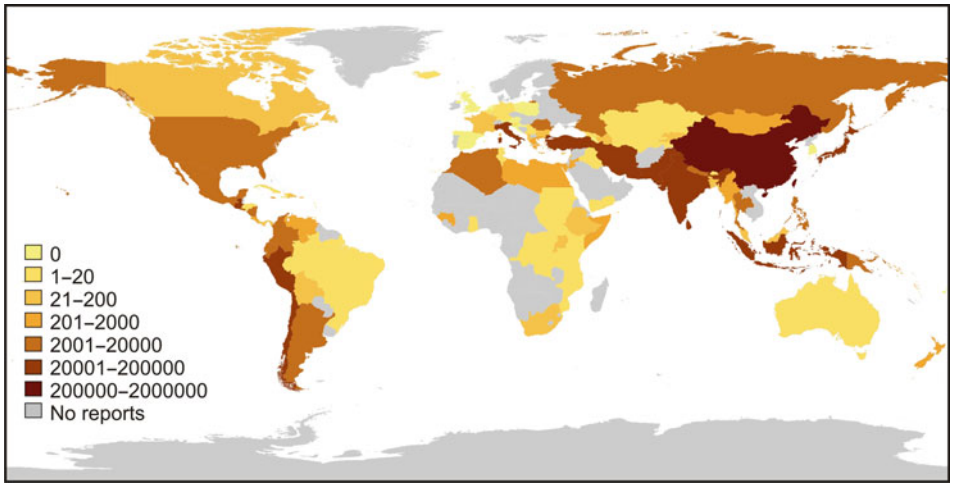
(NGDC, 2010). Other words to describe tsunamis have included tidal waves. However, this terminology is now discouraged as tides are predictable and driven by the gravitational attraction of the sun and the moon. While both tides and tsunamis can produce big waves, tsunamis have much greater potential for sudden and unexpected damage.

Tsunamis are caused by the displacement of a large body of water, which then travels outward from the center of the generating event like ripples in a pond. The most common source of a tsunami is sudden vertical movement in the Earth's crust along a convergent plate boundary, which, in turn, displaces a large part of the overlying water column in the ocean. Subduction zones, where oceanic plates are being pushed below an overriding continental plate, are the primary tectonic locations that generate tsunamis, and consequently, tsunamis are most common along plate boundaries rimming the Pacific Ocean. The displaced column of water may travel away from the source of seismic activity at speeds in excess of 1,000 km/h (NGDC, 2010). In the deep ocean, tsunami wavelengths may be hundreds of kilometers long, and their height may only be a few meters, making them hard to detect. However, as they approach land, shallower water slows the waves down, compressing them dramatically and causing a marked increase in amplitude

Geological/Geophysical Disasters, Figure 5 The global distribution of major plates. Convergent boundaries are indicated by *purple lines*, transform (strike-slip) boundaries by *blue*, and divergent boundaries by *red*. The mid-Atlantic ridge is a divergent boundary, and few earthquakes occur there as a result. In contrast, the convergent margins of the Pacific Plate as it collide with Asia produce significant earthquakes on a regular basis.

Geological/Geophysical Disasters, Table 2 The top 20 cumulative deaths from earthquakes reported by country for the period 1901–2009 (EM-DAT, 2010)

Country	Number killed
China	872,366
Indonesia	197,847
Japan	172,637
Former Soviet Union	155,400
Iran	147,106
Pakistan	142,978
Italy	115,621
Turkey	88,538
India	78,094
Peru	70,709
Chile	58,955
Sri Lanka	35,399
Guatemala	27,697
Taiwan	15,801
Morocco	12,728
Nicaragua	12,686
Ecuador	11,336
Mexico	10,677
Argentina	10,076
Nepal	9,929



(wave height). Tsunamis may also be generated by earthquakes, volcanoes, underwater explosions, and landslides.

Though approximately ten tsunamis occur each year, only one, on average, takes human lives (WHOI, 2010). The first recorded tsunami disaster was in Syria in 2000 BC and caused an estimated 100–1,000 deaths (the median number for this category of damage is 300 based on other events worldwide). Most of the early tsunami records have come from the Mediterranean countries. However, with better recording systems developed over the last several decades, more accurate information has been collected. The countries hardest hit by tsunami disasters are in the Asian Pacific region and countries along the west coast of South America, specifically Chile and Peru (Table 3 and Figure 8).

One of the worst geophysical disasters globally occurred on December 26, 2004, a result of the Sumatra-Andaman megathrust (Mw 9.2) earthquake between the subducting oceanic Indian Plate and the thicker Burma microplate. The earthquake released the energy equivalent of 100 gigatons of dynamite and created a sudden vertical displacement of 4–5 m, moving an estimated 30 km^3 of water and creating devastating waves up to almost 50 m high (Kawata et al., 2007). Nearly 230,000 lives were lost with the greatest devastation occurring along the shores of Indonesia, Sri Lanka, India, Thailand, and the Maldives (Figure 9).

The tallest tsunami wave ever recorded was in 1958 in Lituya Bay, Alaska, by a landslide-generated tsunami. The tsunami removed forest and soil from the bay to a height of 524 m above sea level (for comparison, the Eiffel Tower in Paris is 300.5 m high and the Petronas Twin Towers in Malaysia are 452 m high).

Other notable tsunamis include the wave that devastated Lisbon, Portugal, on All Saints Day in 1755, the 1960 Chilean tsunami that was generated by the greatest earthquake ever recorded (M_W 9.5) causing a transpacific wave of water that killed people as far away as the island of Hilo, Hawaii (USGS, 2010b), and the most recent 2011 Tohoku-Oki earthquake and tsunami events in Japan that displaced over 400,000 residents and reconstruction is estimated to be several hundred billions of dollars.

Geological/Geophysical Disasters, Figure 6 The global distribution of earthquake-related disasters due to earthquakes reported for the period 1901–2009. *Colors* represent the number of deaths by country for the entire period (Data from EM-DAT, 2010).

Geological/Geophysical Disasters, Figure 7 Collapsed buildings in Port-au-Prince, the capital of Haiti, following the January 2010 earthquake (Public domain photograph by Marco Dormino).

Volcanoes

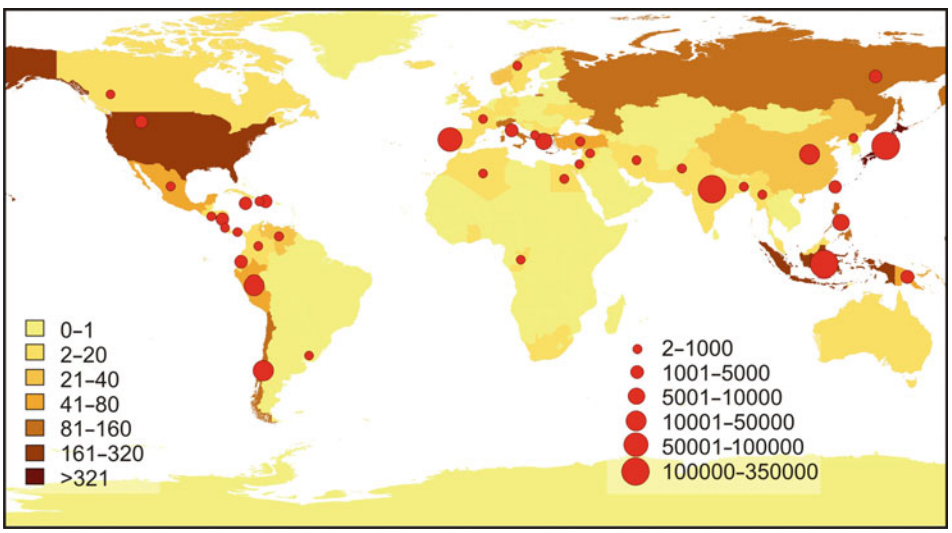
Volcanoes are the extrusion of molten rock, gas, and ash from within the Earth's crust onto the land surface. Volcanoes typically occur along plate margins at convergent and divergent boundaries (Figure 10). Consequently, volcanoes are particularly active along subducting portions of the plates and especially along the Pacific "Ring of Fire." Volcanoes may erupt explosively, effusively, as flows, or as clouds of superheated or poisonous gases; all the eruption styles can pose a threat to humans. Explosive volcanoes are particularly troublesome, and the volcanic explosivity index (VEI), a logarithmic index that describes the amount of material ejected into the atmosphere, the height of the explosion, and the qualitative size of the event, was developed to compare volcanoes to one another (Newhall and Self, 1982).

Volcanic disasters are associated with humans and human infrastructure that are in the path of extruded lava

and gases, particularly during explosive events from stratovolcanoes or with lahars, volcanic mudflows, which are generated by the volcanic activity. The top ten volcanic disasters that have occurred globally in the last century (1901–2009) are listed in Table 4. Only the Columbia disaster of 1985 is listed near the top of both lists (most expensive and most deadly). The reporting of cost from the last half of the twentieth century compared to lives lost over the first half of the century reveals that volcanoes are somewhat predictable and that loss of life is largely avoidable.

Geological/Geophysical Disasters, Table 3 The 20 most severe tsunami disasters by country and year recorded for the period between 2000 BC and 2010 (NGDC, 2010)

Country	Year	Number killed
India	1737	300,000
Indonesia	2004	227,898
Portugal	1755	60,000
Indonesia	1883	36,000
Japan	1498	31,000
Japan	1707	30,000
Japan	1896	27,122
Chile	1868	25,000
Japan	1771	13,486
China	1765	10,000
Japan	1586	8,000
Greece	365	5,700
Japan	1703	5,233
Japan	1605	5,000
Japan	1611	5,000
Peru	1687	5,000
Peru	1746	4,800
Philippines	1976	4,456
Japan	1792	4,300
Japan	1512	3,700

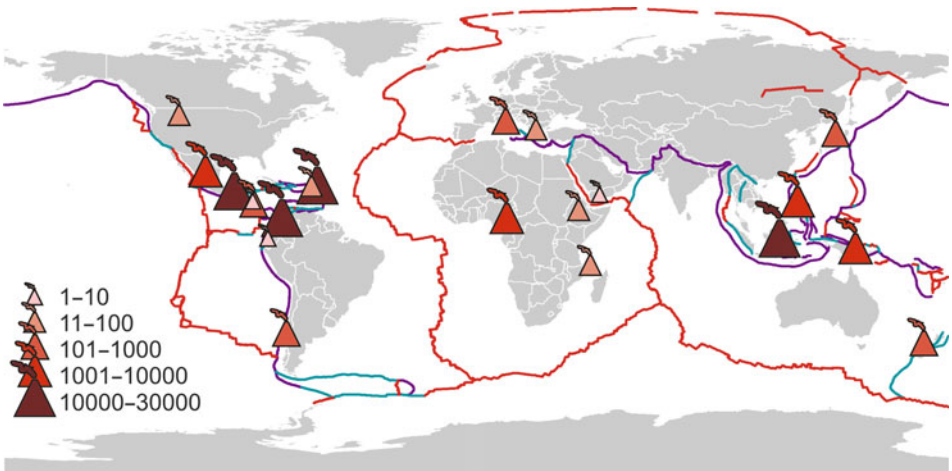


The deadliest and most expensive disaster in the United States (VEI 5) was the 1980 eruption of Mount St. Helens (Figure 11), a stratovolcano that lies along the eastern margin of the Pacific Ring of Fire along the Cascadia subduction zone. Mount St. Helens ejected about 1 km^3 of volcanic material into the atmosphere. While 57 people were killed, many more were evacuated safely from the area. Although the volcanic eruption was predicted, both the blast impact and subsequent debris flows from Mount St. Helens travelled farther than predicted.

History is replete with famous volcanic disasters, including the 79 AD eruption of Mount Vesuvius (VEI 5) in Italy; ash and pumice from the volcano buried the cities of Pompeii and Herculaneum killing more than 10,000. Today, about 3,000,000 people live in the shadow of Vesuvius, and it is considered to be one of the most dangerous volcanoes on the planet.

Krakatau was a stratovolcano that erupted in 1883 expelling 21 km^3 of volcanic material (VEI 6), killing approximately 36,417 people. The explosion was the most violent in recorded history and was heard about 3,500 km away.

Mount Pinatubo erupted in 1991 in the Philippines, ejecting 10 km^3 of magma and 20 million tons of sulfur dioxides into the atmosphere thus making it the second biggest eruption in the twentieth century (VEI 6). The eruption caused the deaths of more than 350 people (landslides and disease increased the death toll to 722) and was responsible for a maximum temporary cooling of global temperatures of about 1.5 °C (NOAA, 2010).



Another class of volcanoes exists that have the potential to cause a geological disaster of enormous magnitude. Supervolcanoes are those that eject over 1,000 km^3 of material (VEI 8) into the atmosphere with such enormous

Geological/Geophysical Disasters, Figure 8 The global distribution of tsunamis reported for the period 2000 BC to 2010. *Country colors* represent the number of reported tsunamis, while the *circles* represent lives lost by country (Data from NGDC, 2010).

Geological/Geophysical Disasters, Figure 9 Tsunami wave hitting Ao Nang, Thailand caused by the December 26 Sumatra-Andaman megathrust (M 9.2) earthquake (Public domain photograph by David Rydevik).

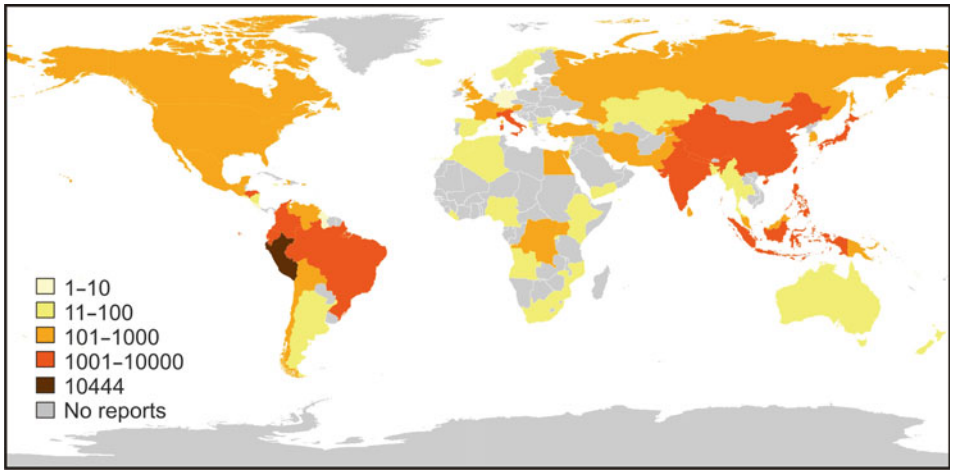
Geological/Geophysical Disasters, Figure 10 The global distribution of volcanic disasters from 1901 to 2009. Note that the volcanoes are largely concentrated along the convergent margins of the Pacific Plate (Data from EM-DAT, 2010).

impact that they change long-term weather patterns and cause extinctions of species. Examples of supervolcanoes include Lake Toba in Indonesia, Yellowstone in the United States, and Aira Caldera in Japan. Supervolcanoes often form as the result of rising magma beneath the crust that form hot spots, but initially are unable to reach the land surface. The underground pool of magma, therefore, continues to grow and increase pressure on the crust. Eruptions are infrequent; Yellowstone, for example, erupted 2.1 million, 1.3 million, and 640,000 years ago (Newhall and Dzurisin, 1988). However, the colossal size of such an event warrants recognition. Previous eruptions ejected between 1,000 and 2,500 km^3 of material into the air.

Landslides

Landslides are the downslope movement of rock, sediment, earth, and debris under the influence of gravity.

Geological/Geophysical Disasters, Table 4 The ten deadliest and ten most expensive volcanoes for the period between 1901 and 2009. Note that the most expensive volcanoes have all occurred since 1980 except for Japan (1945), whereas the deadliest volcanoes are mostly in the first half of the century. Only the Columbia disaster (1985) is on both lists. This suggests improvements in hazard zoning, awareness, and prediction, but at a substantial economic cost. Serious hazards remain, however, for dense settlements that are currently threatened by volcanic hazards



Country	Year	Deaths	Country	Year	Cost (000's of USD)
Martinique	1902	30,000	Colombia	1985	1,000,000
Colombia	1985	21,800	United States	1980	860,000
Guatemala	1902	6,000	Philippines	1991	211,000
Indonesia	1909	5,500	Indonesia	1982	160,000
Indonesia	1919	5,000	Ecuador	2006	150,000
Guatemala	1929	5,000	Indonesia	1983	149,690
Papua New Guinea	1951	3,000	Mexico	1982	117,000
Cameroon	1986	1,746	Papua New Guinea	1994	110,000
Indonesia	1963	1,584	Japan	1945	80,000
St. Vincent	1902	1,565	Indonesia	1983	25,500

Geological/Geophysical Disasters, Figure 11 The 1980 eruption of Mount St. Helens, the deadliest and most expensive volcano in the US history (Public domain photograph by Austin Post and the USGS).

They include a range of events including rock falls, debris flows, slumps, earth flows, and rock avalanches. Landslides may travel great distances at incredible speeds or more slowly along predictable paths. Landslide disasters have taken lives, caused untold injuries, and resulted in massive economic losses. Some records of landslide disasters date as far back as 373 BC (Seed, 1968) with the total loss of the Greek town of Helice. However, landslide disasters are notoriously underreported because such events frequently occur in conjunction with other natural hazards such as earthquakes, volcanoes, and floods. The deadly 1556 earthquake in Shaanxi province of China, for instance, had a massive death toll (~830,000 people), many a direct result from landslides. Similarly, volcanic debris flows may extend many kilometers beyond the eruption center of a volcano and threaten lives and property. The deaths in the Colombia volcanic disaster of 1985 (totally 21,800) were largely attributable to the volcanic debris flow associated with the event (Evans, 2006). Floods are especially linked to and often confused with landslides. High rainfall produces both floods and landslides, and they may grade into one another as part of a continuum depending on the concentration of sediment in the flow. In addition, many floods have been caused by the failure of a landslide-dammed lake, often to devastating effect. For example, in 1786, a landslide dam was breached on the Dadu River in the Sichuan province of China, causing flooding for 1,400 km downstream and the deaths of about 100,000 people (Schuster and Wieczorek, 2002).

Despite the problem of landslide reporting, global reports of landslide disasters do provide a sense of the distribution of landslide disasters in countries around the world (Figure 12). The distribution of landslide disasters relates to both the proximity of hazards, but also to the concentrations of people. The Canadian Cordillera, for example, has relatively high landslide hazards, but a low population density (~4 persons/km^2) and consequently

Geological/Geophysical Disasters, Figure 12 The cumulative global distribution of deaths by country for landslide disasters not otherwise recorded as another disaster type (flood, volcano, earthquake).

few disasters. In contrast, Peru has a much higher population density of 23 persons/km^2. Many people live at the base of the Andes Mountains, part of the South American Cordillera, and the populations are situated between the mountains and the ocean. Disasters are consequently more frequent and of considerably higher magnitude.

Landslide hazards may be substantially reduced or exacerbated by the activities of humans. Many landslides are readily monitored, hazard zonation is particularly effective, and there are numerous mitigation techniques that reduce the likelihood of a hazard becoming a disaster. Nevertheless, landslide disasters continue to occur.

One of the most famous landslide disasters of all time began high on Huascarán Mountain in the Yungay province of Peru in 1962 and again in 1970. Both events began as rock/ice falls and transformed into high-velocity (up to 85 m/s in 1970) debris flows by incorporating sediment and ice from the glacier and moraines below. About 7,000 people died (Evans et al., 2009a); earlier estimates were substantially higher. The two events and associated debris floods triggered by the 1970 landslide continued downslope for an additional 180 km.

On February 17, 2006, 1,221 people were killed and 19,000 displaced by a rockslide-debris avalanche (landslide) that buried the village of Guinsaugon in the Philippines (Figure 13). A rock mass slid down an 800-m-high escarpment (the surface expression of the slip-strike Philippine fault zone), entraining millions of cubic meters of colluvial debris that spread rapidly across rice paddies in the fields below. The total volume of debris was 15 Mm^3, and it was the deadliest single landslide in a decade (Guthrie et al., 2009). Landslides remain an ongoing hazard in the Philippines.
