While the concepts of modularity and integration are ubiquitous in the field of evolution, there is no general consensus on either the meaning or the measurement of morphological integration. All the techniques aim for a similar goal – assessing covariation. Many different approaches have been used, but a general strategy to discover modules comes from comparisons among different subsets of the total set of traits under scrutiny. Trait subsets that show stronger covariation can be considered part of the same module. Integration and module detection is thus a matter of degree, not absolute linkage or independence.

Variational modules have been detected using a number of statistical methods, primarily involving comparing magnitude of correlations and covariance in identified traits (Klingenberg *et al.*, 2003; Leamy *et al.*, 1999; Marquez, 2008; Mitteroecker and Bookstein, 2007; Polly *et al.*, 2001; Klingenberg 2009; Hallgrimsson *et al.*, 2009). Differences among methods are partly due to choice of clustering and filtering methods by the researcher seeking to emphasize particular processes (Klingenberg, 2008).

Important model systems that have been used in the development of theory and technique for detecting modularity and integration include the mouse lower jaw (Zelditch *et al.*, 2008; Cheverud, 1982), mammal skulls (Goswami *et al.*, 2009, 2014), appendages/limbs (Minelli, 2000; Shubin *et al.*, 2009; Kavanagh *et al.*, 2013), butterfly wingspots (Brakefield, 2003), and vertebral regions (Polly *et al.*, 2001; Burke *et al.*, 1995; Buchholtz, 2014).

Because many of these measures require a priori division of the organism into potential modules, there is often some level of investigator bias in these methods of estimating modularity. In any measure, modularity is a sum measure of the degree of integration across the selected structures in these techniques.

The direct causative mechanism or regulatory network is most often unknown in these comparative morphological studies and indeed may differ among structures. However, in a few cases, *in situ* experimental measurement of integration has been attempted.

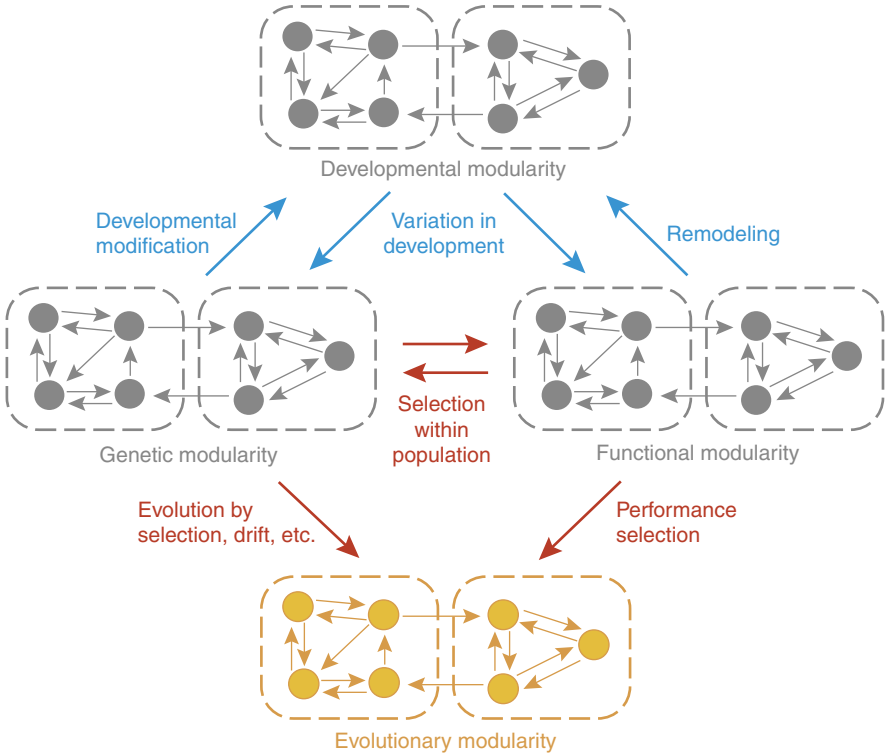

Figure 1 Types of modularity that concern morphological variation and the connections between them. Developmental, genetic, and functional modularity are based on processes taking place within extant individuals or populations (gray diagrams), whereas evolutionary modularity results from the history of divergence among evolutionary lineages in an entire clade (orange diagram). These types of modules are mutually influencing each other through various processes within individuals (blue arrows) or within populations (red arrows). Developmental modularity has an effect on both genetic and functional modularity by modulating the available morphological variation. Genetic modularity feeds back to developmental modularity through the genetic control of development, whereas processes of tissue remodeling (e.g., bone remodeling under mechanical load) provide a feedback from function to developmental processes. At the population level, the process of natural selection establishes a two-way interaction between genetic and functional modularity. These effects of selection, jointly with the additional effect of genetic modularity on changes by drift, accumulate through time to constitute the evolutionary modularity of an evolving lineage or clade (from Klingenberg, 2008).

Experimental Analysis and Direct Measurement of Integration

More direct measurements of integration have been attempted through developmental experimental manipulations that perturb one part of a system and observe the consequent effects on downstream elements or structures. If the perturbation is genetic, as in a genetically modified mouse, for example, the effect could indicate pleiotropy (Cheverud, 1996). Another method used is direct embryonic manipulation at particular stages or times. Protein bead or foil barrier interference experiments within modules may show coordinated effects. For example, foil barriers that perturb proximal joint-positioning fields within the phalanges were shown to affect positions of later-developing distal joints downstream, indicating a system-wide or modular effect (Kavanagh *et al.*, 2013).

Selection experiments are another type of experimental method to detect modular structure. If selection for one trait causes coincident evolution of another trait, then it may be interpreted as evidence of modularity in regulatory structure. To get a sense of the level of integration, experimental selection to break apart modules can be measured as more or less difficult. For example, butterfly wingspot sizes in fore and hindwings evolve in coordination in nature, modularly, and it was only possible after many generations of disruptive selection in the laboratory for the wingspot sizes on the forewing and hindwing to be independently selected (Beldade and Brakefield, 2003).

Interpretation is similar in all of these cases, where alteration of an element within the module (by evolution or developmental perturbation) has greater effects on the rest of the elements in the module than on elements of other modules. Furthermore, organisms can show a nested hierarchical modularity, such that there can be modules within modules with varying degrees of integration, for example, digits within limbs (Young *et al.*, 2015).

Evolution May Favor Modularity; Modularity May Bias Evolution

Modularity itself may be a consequence of biological evolution; it is observed that other types of networks such as electrical or computational networks do not necessarily evolve modularity, while biological systems inevitably do (Kashton and Alon, 2005). Evolution proceeds primarily by tinkering with the same conserved genes, genomic regions, protein interactions, developmental networks, dynamic patterning

modules (Newman and Bhat, 2008), and tissue mechanics from generation to generation. Because it is the 'path of least resistance,' biological evolution appears to be biased toward conserving these functional integrated connections. Therefore, modular differential regulation of body parts may be an inevitable result of organisms under selection.

Viewed from another perspective, such modular construction may have consequences on how selection shapes adaptations to changing environments. Because individual modules can be selected semi-independently, the entire organism can remain functional while selection acts on particular networks, organs or structures. For example in birds, forelimbs have been modified independently of hindlimbs to evolve wings while still maintaining walking legs. Since modularity and integration occurs at many organizational levels, adaptations can be many and varied, yet still biased along lines of least developmental resistance. As such, it is no wonder that the concepts and consequences of modularity and integration pervade all aspects of evolutionary biology (**Figure 1**).

Glossary

Adaptive landscape The relationships between genotype, phenotype, and fitness.
Ancestral sequence reconstruction The inference of ancestral gene sequences at the nodes in a phylogenetic tree from the gene sequences at the tips.
Clinal polymorphisms Allele frequencies change over geographic space.
Comparative method The inference of process based on observational data collected from different taxa across space and time.
Directed evolution Process of goal-oriented laboratory adaptation through repeated rounds of mutagenesis and selection.
Dykhuizen–Hartl effect The phenomenon whereby mutations that are selectively neutral in one environment, or in one genetic background, are subject to selection in others.
Ecological genetics The study of adaptation in natural populations.
Epistasis Nonadditive interactions among mutations.
Functionalism The experimental study of mechanistic proximate causes.
Maximum parsimony A method for constructing phylogenetic trees using characters that are both shared (two or more species/genes have it) and derived (have arisen by mutation within the phylogenetic tree).
Subfunctionalization The process by which specialist genes arise following duplication of a generalist ancestor through the complementary degenerate loss of ancestral functions.

Background

There exists a deep rift within biology, evident even in Darwin's time, between functional biology (which studies the 'how?') and evolutionary biology (which studies the 'why?') (Mayr, 1961). Functionalists are interested in proximate causes (how does a bird's wing generate lift?), whereas evolutionists are interested in ultimate causes within a historical context (what is the origin and adaptive significance of a bird's wing?).

The rift is deepened further by the very different approaches taken to resolving scientific questions. Functionalists consider the relationship between cause and effect to have been established only when all other variables in an experiment have been held constant. Necessarily, their studies are conducted in controlled laboratory settings to eliminate extraneous noise. Though causality can be established in these unnatural circumstances, its biological relevance is often unclear to evolutionists.

Evolutionists forgo the rigors of functional biology and embrace nature's noise – variability within and between individuals, species, and habitats – as the stuff that needs to be explained. Their approach is comparative, identifying patterns and associations in data gathered from field surveys. Unfortunately, statistical associations alone cannot establish causality and predictions from divergent hypotheses often cannot be distinguished. This ambiguity leads many functionalists to regard evolutionary biology as unscientific.

The first half of the twentieth century saw the rise of a general mathematical theory of evolution, one consistent with known facts and data, yet one necessarily detached from the then unknown relationships between gene structure and function, between genotype and phenotype. By midcentury, many evolutionists had concluded that functional biology could only add detail to the big picture already painted by evolutionary biology (Morange, 2011).

That soon happened – spectacularly – as new molecular approaches swept through biology to reveal the structure of the gene, the genetic code, protein structure–function relationships, metabolic and intracellular architecture, etc. Ignored in the stampede for proximate mechanisms were larger questions of evolutionary causation. Dobzhansky (1973), in particular, recoiled at the rampant reductionist thinking and declared, "Nothing in biology makes sense except in the light of evolution ..."

Evolutionary biology was not untouched by these developments. Molecular biology provided first protein and then gene sequences to revolutionize phylogenetics and population genetics (Zuckerkandl and Pauling, 1965). Yet even as they adopted the techniques of molecular biology, evolutionists rejected functionalism in favor of their comparative approach (Graur and Li, 1999). From the 1980s onwards, statistical analyses of sequence data, and today of entire genomes, would come to dominate studies of molecular evolution.

Setting the Stage

Functionalism was not entirely absent from evolutionary biology. In the 1950s, Kettlewell provided direct experimental evidence that differential predation by birds was responsible for maintaining the melanic (dark) and peppered forms of the moth *Biston betularia* (Kettlewell, 1973). During the 1970s, a small band of ecological geneticists pursued functional studies on clinal enzyme polymorphisms, attempting to establish relationships between kinetic activity, physiology, and fitness components (reviewed in Hedrick *et al.*, 1976,

 doi:10.1016/B978-0-12-800049-6.00233-X

1986). Their results were tantalizing, but technical limitations severely hampered progress. Laboratory experiments with *Drosophila* faced similar difficulties.

The ability to construct strains of *Escherichia coli* that differ only at specific loci enabled Dykhuizen and Hartl to demonstrate that enzyme polymorphisms might be selectively neutral in some genetic backgrounds and environments and yet selected in others (Dykhuizen and Hartl, 1980; Hartl and Dykhuizen, 1981). When combined with metabolic control theory (Kacser and Burns, 1981; Hartl *et al.*, 1985), their approach culminated in an exact mechanistic model of fitness, one that could be used to predict the direction and intensity of selection solely from knowledge of enzyme kinetics (Dean, 1989). The old criticism that 'the survival of the fittest' is a mere tautology could be laid to rest. Darwinian fitness can be predicted from biochemistry alone (**Figure 1**).

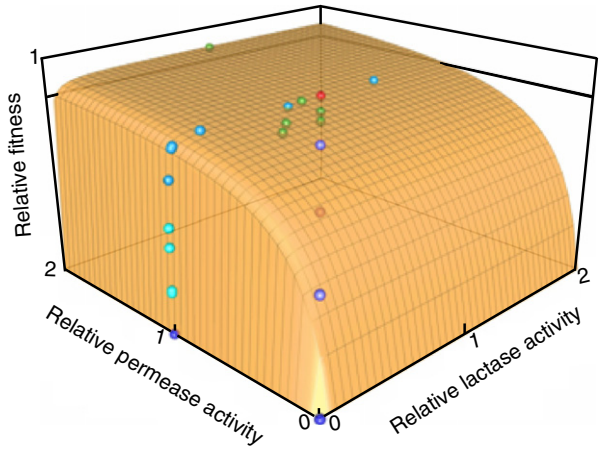

Figure 1 The adaptive landscape of *lac* operon. The surface is not fitted to the fitness data, but is instead the prediction based solely on knowledge of biochemical kinetics. Wildtype K12 *lac* operon (red), laboratory mutants of β-galactosidase (blue), and evolved β-galactosidase (light blue), varied expression of wildtype in competition with a constitutive *lacI*$^-$ *lac* operon (purple) and six operons from natural isolates (green).

However, the precise connection between gene sequence and biological function was still tenuous. In the early 1980s, Hall (1984) showed that either of two single amino acid replacements conferred sufficient activity on evolved β-galactosidase, a secondary β-galactosidase in *E. coli*, to allow growth on lactose. In another study, a comparison of protein structures led Holbrook and coworkers to identify a single amino acid replacement that, when introduced into the active site of *Bacillus stearothermophilus* lactate dehydrogenase (using the then new technique of site-directed mutagenesis), produced a malate dehydrogenase as active and as specific as any natural homologue (Wilks *et al.*, 1988). That such massive functional changes could be wrought by single amino acid replacements suggested that functional changes during molecular evolution might proceed in similar fashion. The classical evolutionary idea of gradualism, enunciated by Darwin himself, that adaptation proceeds slowly, was dead.

Rise of the Functional Synthesis

The 1980s had seen the tools of phylogenetics and molecular biology develop to the point that hypotheses generated by comparative sequence analyses could be tested decisively using functionalist experiments. Work during this period had undermined much conventional wisdom and, with the straightjacket of NeoDarwinian dogma ripped apart, the Functional Synthesis was free to emerge in the 1990s as a means to explore the mechanistic foundations of molecular evolution.

Benner and coworkers (Stackhouse *et al.*, 1990) were the first to resurrect ancestral proteins (**Figure 2**). They chose to study RNase A, a digestive enzyme abundant in certain artiodactyls. Using parsimony, they inferred the ancestral sequences of *Pachyporrux lutidem*, the extinct ancestor of modern ox and buffalo, and several other ancestors. The ancient genes were synthesized by cassette mutagenesis, expressed in *E. coli*, and purified. Consistent with neutral evolution, the kinetic properties and thermostabilities of these ancient enzymes were indistinguishable from their modern counterparts.

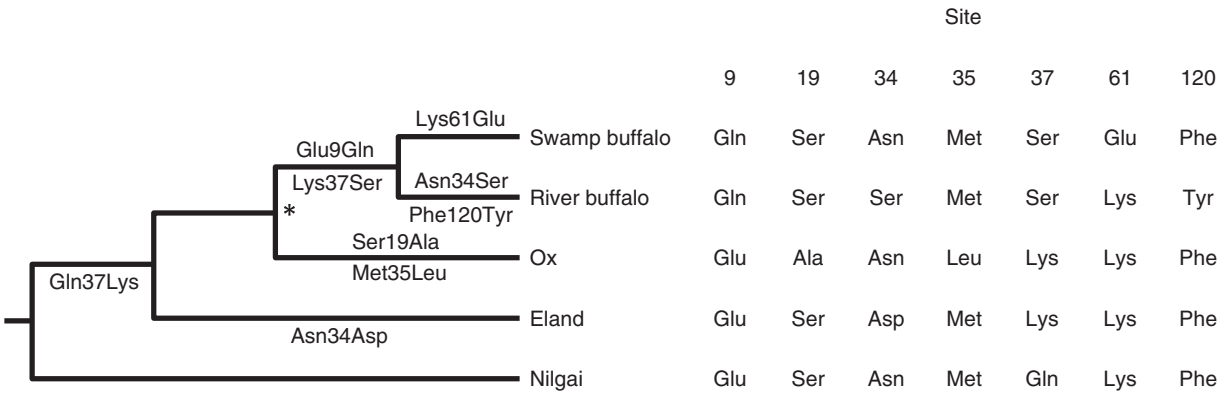

Figure 2 Maximum parsimony phylogeny and amino acids at variable sites in artiodactyl RNAses studied by Stackhouse *et al.* (1990). The marked node (*) was the first ancestral gene ever to be resurrected: Gln9, Ser19, Asn34, Met35, Lys37, Lys61, Phe120.

This article brought to fruition the dream of Zuckerkandl and Pauling (1965) that,

> By, furnishing probable structures of ancestral proteins, chemical paleogenetics will in the future lead to deductions concerning molecular functions as they were presumably carried out in the distant evolutionary past.

The Functional Synthesis was born.

Later, Jermann *et al.* (1995) would resurrect and express 13 ancestral genes using a broader artiodactyl phylogeny. Results showed a modest increase in thermostability and a fivefold decrease in activity toward double stranded RNA associated with the Gly38Asp replacement that appeared approximately 40 million years ago when ruminant digestion first arose.

At about the same time Yokoyama and Yokoyama (1990) used phylogenetic analysis to show that red visual pigments had evolved independently in both humans and Mexican cavefish, following duplications of their respective ancestral green visual pigments. Three amino acid replacements, Ala180Ser, Phe227Tyr, and Ala285Thr, were identical in both lineages (**Figure 3**). The probability of such a parallelism occurring by chance is so remote that the replacements were almost certainly adaptive. Yokoyama and Yokoyama (1990) wrote:

> Molecular characteristics of the visual pigment genes in different species provide valuable information as to which residues are important for specific wavelength absorption. Fortunately, it will be possible to test such hypotheses of adaptive evolution by using site-directed mutagenesis at specific residues (such as 180, 277, and 285), expressing them in cultured cells and measuring their absorbance …

A year later, Neitz *et al.* (1991) determined the gene sequences and spectral properties of several closely related primate visual pigments and concluded that replacements Ala180Ser, Phe227Tyr, and Ala285Thr accounted fully, and additively, for the spectral shift. The following year Chan *et al.* (1992) used site-directed mutagenesis to show that a similar spectral shift could be engineered into rhodopsin and confirmed that the contributions were additive. Asenjo *et al.* (1994) constructed chimeric proteins and additional site-directed mutants to show that four additional replacements, each of small functional effect and not found in the evolution of cavefish visual pigments, were needed to fully interconvert the human red and green visual pigments. A strictly additive model accounted for 98% of the variation in maximum absorbance. The genetic basis of an adaptive shift in function had been established.

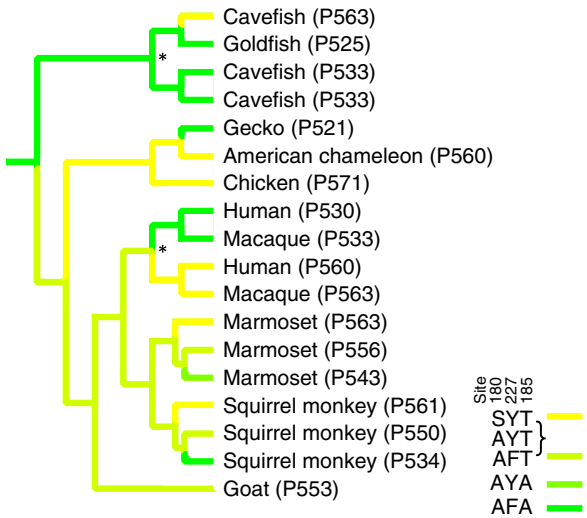

Figure 3 Spectral tuning in vertebrate medium wavelength visual pigments. Amino acid replacements occur in parallel and in reverse at sites 180, 227, and 185 are associated with specific shifts in the maximum absorption (in parentheses) of cone opsins. Such repeated changes, highly improbable due to chance alone, indicate that adaptive responses can be highly constrained. Asterisk denotes gene duplications.

The accuracy with which ancient gene sequences can be inferred declines with every inference made, with every site that changed and with every insertion and deletion incorporated. The nicotinamide adenine dinucleotide phosphate (NADP)-dependent isocitrate dehydrogenase of *E. coli* (EcIDH) differs from its NAD-dependent ancestor at 341 of 429 sites (Dean and Golding, 1997). Resurrecting this ancestor would be a dubious exercise.

X-ray crystallography identified the modes of coenzyme binding in EcIDH and in the distantly related, though structurally similar, *Thermus thermophilus* isopropylmalate dehydrogenase (TtIMDH) (Hurley *et al.*, 1991; Hurley and Dean, 1994). Six conserved amino acids bind the 2'-phosphate of NADP in EcIDH. At the same sites in TtIMDH three conserved amino acids bind the adenosine ribose hydroxyls of NAD, while three others play no role in binding NAD and vary freely in related NAD-dependent enzymes (**Figure 4**). Site-directed mutatgenesis was used to engineer EcIDH into an NAD-dependent enzyme (Chen *et al.*, 1995), one as active and as specific as any known NAD-dependent family member. TtIMDH was then engineered to use NADP (Chen *et al.*, 1996). Engineering in both directions eliminated 246 amino acid replacements at the 334 sites in common, and 91 sites comprising 13 insertions and deletions, as making any net contribution to coenzyme use. Identifying sites critical to a 3.5 billion year old functional change in isocitrate dehydrogenase (IDH) opened up the entire history of life to experimental investigations of biochemical evolution.

Epistasis and Ancestral Sequence Reconstruction

Epistasis was evident in early experiments in the Functional Synthesis. If introducing the active site Gln102Arg replacement converted *B. stearothermophilus* lactate dehydrogenase into a malate dehydrogenase, the reciprocal replacement in *E. coli* lactate dehydrogenase failed to produce an active enzyme (Nicholls *et al.*, 1992). Epistatic interactions with the genetic background can thwart identifying functionally important residues.

Epistatic interactions are common (Lunzer *et al.*, 2010) and arise within the complex web of physical interactions underlying protein architecture, solubility, conformational fluidity, specificity, and activity. Most amino acid replacements compromise protein stability and those causing functional changes are no exception (Tokuriki *et al.*, 2008; Soskine and Tawfik, 2010).

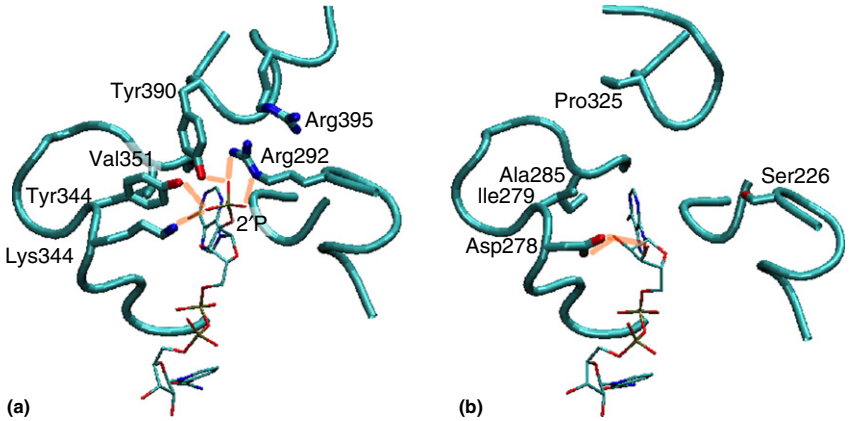

Figure 4 Coenzyme binding sites of (a) isocitrate dehydrogenase with bound NADP and (b) isopropylmalate dehydrogenase with bound NAD. Amino acids hydrogen bonding (transparent orange) to the coenzyme 2′-phosphate (2′P) in IDH are replaced in IMDH where Asp278 instead hydrogen bonds to the 2′ and 3′ hydroxyls of the adenosine ribose. Repulsion between the negatively charged Asp278 and the 2′-phosphate serves to further reduce specificity toward NADP in IMDH. Color code: carbon (cyan), oxygen (red), nitrogen (blue), and sulfur (yellow).

Indeed, replacements necessary for a functional change can be so destabilizing that no folded protein is produced. Using directed evolution, Bloom *et al.* (2006) showed that prior selection for increased stability of cytochrome P450 BM3 was essential to the subsequent acquisition of novel activities.

Ancestral sequence reconstruction provides a powerful approach to identify causal mutations when background epistasis confounds our engineering modern proteins. The idea is to recapitulate the evolutionary course that nature itself took. First, the branch in the phylogenetic tree on which the functional change occurred is identified. Then the ancestral gene at the base of the branch is synthesized. Mutations on that branch are then introduced singly, and in combination, into the ancestral gene. Finally, the proteins are expressed, assayed, and the mutations causing the functional change identified.

Using this approach Thornton and coworkers (Bridgham *et al.*, 2006) explored how subfunctionalization in an ancient steroid receptor led to the modern glucocorticoid receptors. They identified two replacements, Ser106Pro and Leu111Gln, that together restricted activation of the ancestral receptor to cortisol alone (**Figure 5**). Introducing the same pair of replacements into a modern paralogous receptor abolished function. Functionally important replacements are best identified in the genetic background on which they first arose and for this very reason ancestral gene reconstruction has become *de rigueur* when reconstructing the history of functional changes.

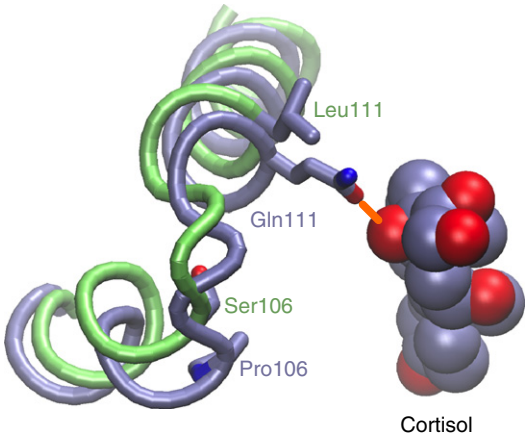

Figure 5 Snapshots of molecular dynamics simulations of cortisol bound to homology models of ancestral (green) and descendent (gray) glucocorticoid receptors showing the hydrogen bond between Gln111 and cortisol which is retained despite Pro106 occupying a variety of positions. Color code for side chains and cortisol: carbon (gray), oxygen (red), nitrogen (blue), and sulfur (yellow).

Some Consequences of Epistasis

Sign epistasis, in which the same mutation has opposite effects in different genetic backgrounds, limits the number of mutational pathways to high fitness (Weinreich *et al.*, 2006). Resistance by *E. coli* to high levels of the antibiotic cefotaxime is conferred by five replacements in TEM-1 β-lactamase, many of which interact in nonadditive fashion. For example, the Met182Thr replacement reduces resistance in wildtype TEM-1, but increases it when the Gly238Ser replacement is present. Weinreich *et al.* (2006) constructed all $2^5 = 32$ combinations of residues and showed that epistasis limited the number of pathways where resistance was increased at each step to just 18 out of the possible $5! = 120$.

Structural studies revealed the mechanism generating epistasis among mutations leading to the glucocorticoid receptors (Ortlund *et al.*, 2007; **Figure 5**). Alone, replacement Leu111Gln has little effect on structure and function and the mutated ancestor remains sensitive to both aldosterone and cortisol. Alone, replacement Ser106Pro severely impairs sensitivity toward both steroids, repositioning a helix in the binding cleft to impede steroid binding. In the double mutant, the repositioned helix enables the amide of the Leu111Gln replacement to hydrogen bond to the hydroxyl unique to cortisol, restoring sensitivity to this steroid alone.

Sign epistasis can delay an adaptive response. The neutral Leu111Gln replacement must have occurred first and drifted for some time before the Ser106Pro replacement produced the

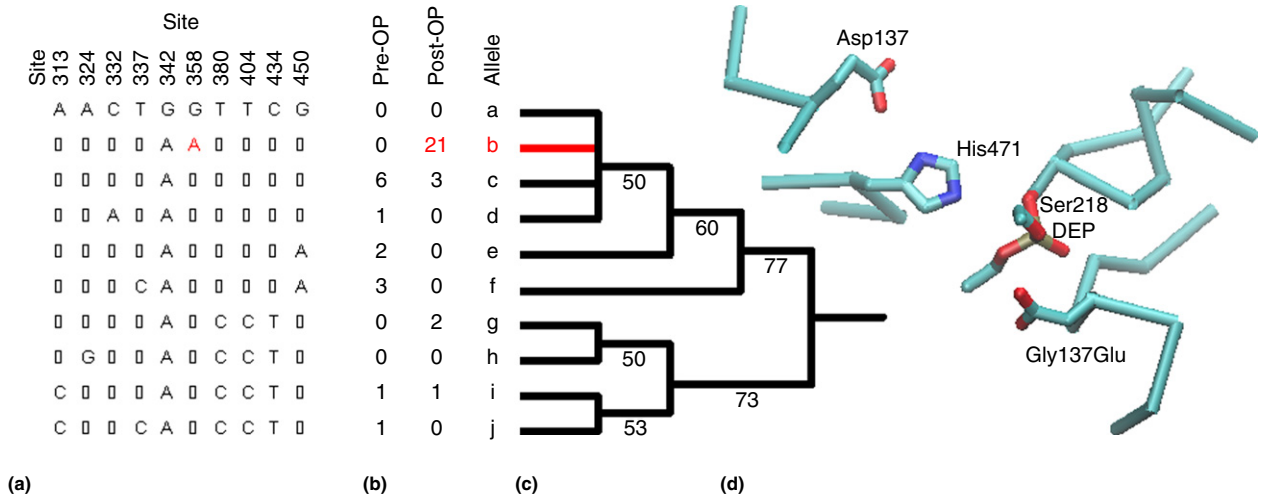

Figure 6 Evolution of blowfly insecticide resistance. (a) Variable sites in the gene sequences of *Lucilia cuprina* α-esterase 7. The diazinon resistance conferred by amino acid replacement Gly137Asp is caused by base substitution G358A (red). Amino acid replacements caused by base substitutions at sites 313, 324, 337, and 450 have no effect on the ability to hydrolyze organophosphates. (b) Allele frequencies before and after diazinon was introduced to Australasia. (c) Genealogy of alleles shows that diazinon resistance (red) arose recently. (d) The active site of organophosphate inhibited blowfly α-esterase 7 showing the catalytic triad (Asp137, His471, and Ser218) with diethylphosphate covalently attached to the catalytic Ser218 (Jackson *et al.* 2013). Modeled is the Gly137Asp replacement that converts fatty acid methyl esterase activity into an organophosphate hydrolase activity to confer resistance to the organophosphate pesticide diazinon, perhaps by activating a water (not shown). Color code: carbon (cyan), oxygen (red), nitrogen (blue), and phosphorous (yellow).

first glucocorticoid receptor. In the conger eel visual pigment RH1 each of three amino acid replacements barely affects maximum absorbance, yet together they cause a shift from green to blue (Yokoyama *et al.*, 2008). Here, epistasis need not have affected the order in which the replacements accumulated but, as in the steroid receptor example, the selective pressure for functional change probably arose long before an adaptive response was made possible.

Zuckerkandl and Pauling (1965) first suggested that selectively neutral mutations might be needed to bring a gene to the point where a functional change is possible. Dykhuizen and Hartl (1980, 1981) demonstrated that many selectively neutral alleles possess a latent potential for selection that is expressed in certain genetic backgrounds and/or in certain environments. Known as the Dykhuizen–Hartl effect (Kimura, 1983), this phenomenon is key to several models of functional adaptation. The innovation period of the innovation–amplification–divergence model of gene duplication (Bergthorsson *et al.*, 2007) assumes weak promiscuous enzyme activities drift in a neutral fashion until a mutant arises with sufficient activity that selection can act. The same idea of a neutral walk applies when replacements that stabilize protein structures beyond current needs are required for future functional changes, as demonstrated with P450 BM3 (Bloom *et al.*, 2006) and TEM-1 β-lactamase (Bershtein *et al.*, 2006).

Causes of Selection

The Functional Synthesis identifies mutations causing functional changes. Most often the functional changes are assumed to be adaptive. However, *demonstrating* that a functional change is adaptive is rather more involved.

Ecological geneticists have the advantage of being able to observe selection in action, and hence the possibility of decisively assigning a selective cause. For example, Oakshott and coworkers (Newcomb *et al.*, 1997) showed that the Gly137Asp replacement converts the E3 esterase of the blowfly *Lucilia cuprina* into an organophosphate hydrolase that confers resistance to diazinon (**Figure 6**). In the absence of diazinon, the Gly137Asp replacement is costly owing to pleiotropic developmental instability (Batterham *et al.*, 1996). Indeed, the Gly137Asp replacement only reaches high frequencies in the presence of a modifier locus that alleviates the developmental instability. PCR analysis of museum specimens of *L. cuprina* collected in Australia before 1958, when diazinon was first introduced, found no evidence of the Gly137Asp replacement (Hartley *et al.*, 2006). The first cases of resistance were detected in 1965 (Shanahan and Hart, 1966). By the early 1970s resistance had reached 95%. Consistent with the rapid sweep of diazinon resistance is the low genetic diversity and strong linkage disequilibrium evident at the E3 locus in modern populations (Rose *et al.*, 2011). These and other studies (Linnen *et al.*, 2013; Barrett *et al.*, 2008; Schluter *et al.*, 2010; Zera, 2011) provide coherent pictures of selection in action, having established chains of causality between mutations, molecular phenotypes, organismal fitness, and the resulting impact on the genetic architectures of extant populations.

Assigning a selective cause to an ancient functional change is challenging. We cannot observe the selection as it happened. The organisms in which the change arose are extinct and the habitats and ecosystems in which they lived no longer exist.

Studies with IDH push the limits of the Functional Synthesis in their attempt to assign an ancient selective cause (Zhu *et al.*, 2005). The engineered NAD-dependent IDH is selectively inferior to the wildtype NADP-dependent IDH

during competition for acetate, an oxidized carbon source where additional reducing power, in the form of reduced NADPH, is needed for biosynthesis. As expected, selection at IDH intensifies as other sources of NADPH are deleted from the genetic background. Genome surveys show that all species capable of growing on acetate have an NADP-dependent IDH. Those that have only an NAD-dependent IDH cannot grow on acetate.

Was the shift in coenzyme use from NAD to NADP in an ancient eubacterial IDH an adaptation to growth on acetate? Short of a means to travel back 3.5 billion years in time we can never know for certain. What we can say is that results from phylogenetics, genomics, structural biology, microbial metabolism, protein engineering, enzyme kinetics, and experimental evolution are consistent with the hypothesis.

Adaptive Constraints

The engineered TtIMDH is as active and specific toward NADP as the wildtype enzyme is toward NAD. Why then has no natural isopropylmalate dehydrogenase (IMDH) ever used NADP? The question is made all the more intriguing by the fact that the related IDHs evolved NADP use on at least two occasions (Dean and Golding, 1997).

Characterization of the adaptive landscape controlling coenzyme use by EcIMDH (**Figure 7(a)**) indicated that the reduced fitness of the engineered NADP-dependent EcIMDH might be attributable to product inhibition by abundant cellular NADPH (Lunzer *et al.*, 2006). Directed evolution experiments recovered mutations that weakened NADPH binding, with NADP binding weakened as a correlated response (Miller *et al.*, 2006). Changes in NAD and NADH binding were small and random. Increased growth rates always corresponded to decreased product inhibition by NADPH even at the expense of activity. Inhibition by NADPH alone reduced the fitness of the engineered NADP-dependent enzyme.

The close proximity of the reduced nicotinamide rings of the coenzymes to the γ-isopropyl of the substrate/product (**Figure 7(b)**) renders NADH and NADPH potent inhibitors of IMDH (Dean and Dvorak, 1995). Cellular NADH is sufficiently scarce that wildtype IMDH retains high activity *in vivo*. Cellular NADPH is so abundant that virtually all the engineered NADP-dependent EcIMDH is inhibited (Lunzer *et al.*, 2006; Miller *et al.*, 2006). This inhibition explains why no IMDH has ever evolved the capacity to use NADP. In contrast, NADPH is a weak inhibitor of IDH because there is no attractive force between the uncharged ring and the adjacent negatively charged γ-carboxylate of the substrate/product (Dean and Koshland, 1993). Hence, IDH has always been free to evolve NADP use. The pattern of functional constraint and evolution across 3.5 billion years of life finds its explanation in terms of just two physiochemical interactions (the one hydrophobic and the other electrostatic) and a metabolic demand for additional reducing power during growth on acetate.

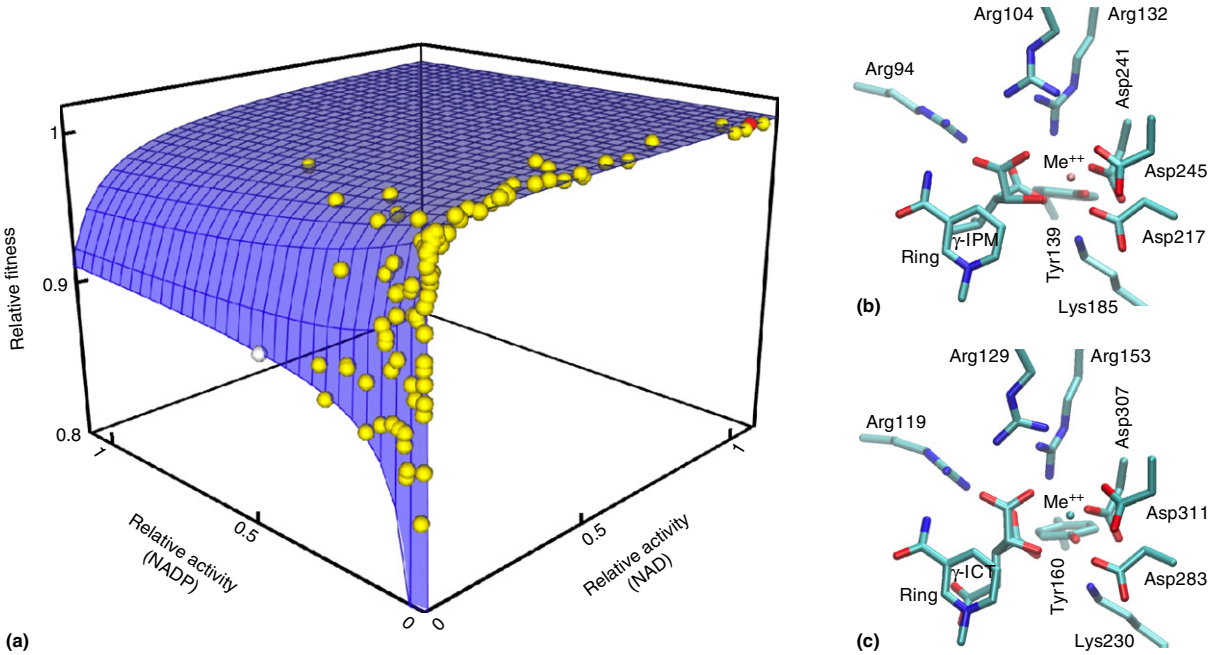

Figure 7 Constraint in the IMDH adaptive landscape. (a) The adaptive landscape controlling coenzyme use in IMDH shows that NADP use (white) confers lower fitness than NAD use (red) with genetic intermediates (yellow). The active sites of (b) *Thermus thermophilus* isopropylmalate dehydrogenase and (c) *Escherichia coli* isocitrate dehydrogenase with bound substrates and coenzymes (Pallo *et al.*, 2014; Gonçalves *et al.*, 2012). In both views the coenzyme nicotinamide rings are poised 'above' the γ-groups of the substrates. Catalytic reduction to NAD(P)H eliminates the charge on the ring. The resulting hydrophobic interaction with the γ-isopropyl renders the reduced coenzymes potent inhibitors of IMDH. In IDH, ring reduction eliminates the salt bridge to the γ-carboxylate. The reduced coenzymes now act as weak inhibitors (Dean and Koshland, 1993).

Mechanisms of Gene Duplication and Functional Divergence

How enzyme families arise through gene duplication and functional divergence is a classic problem in molecular evolution. Ohno (1970) popularized the 'mutation during nonfunctionality' model (Hughes, 1994). A new gene copy, freed from the constraints imposed by purifying selection, would accumulate 'forbidden mutations' during a period of 'nonfunctionality' until it fortuitously acquired a new beneficial function (**Figure 8(a)**). The problem is that during the period of 'nonfunctionality' a new copy would most likely be lost to drift or else inactivated by mutation.

In the subfunctionalization model (**Figure 8(b)**), specialist descendants are produced by the neutral loss of one or more functions following amplification of a multifunctional ancestor (Stoltzfus, 1999; Force *et al.*, 1999). In the escape from adaptive conflict model (**Figure 8(c)**; Hughes, 1994) selection maintains multiple copies of an ancestral gene that encodes an inefficient enzyme of broad specificity. In the innovation–amplification–divergence model (Bergthorsson *et al.*, 2007), selection for weak promiscuous functions in a highly active specialized enzyme stabilizes any gene duplications that arise (**Figure 8(d)**; gene amplification is far more frequent than a beneficial point mutation). In both models, trade-offs ensure selection for improved activities produces specialized enzymes, while selection against excess protein expression eliminates unneeded copies. In each case the outcome is the same; a family of specialized genes.

Näsvall *et al.* (2012) explored the role of transient gene duplication during the evolution of efficient specialists from an inefficient generalist ancestor. Homologous enzymes HisA and TrpF catalyze the same isomerization in their respective substrates during the syntheses of histidine and tryptophan. The two enzymes are so closely allied that to this day Mycobacteria and Streptomyces use a single efficient generalist enzyme, PriA, to catalyze both reactions. A *Salmonella enterica* strain lacking *hisA* and *trpF*, and expressing an inefficient bifunctional *hisA* mutant cotranscribed with a reporter protein from a constitutive promotor, was propagated in serial transfer on minimal medium (no histidine, no tryptophan). Within a few hundred generations faster growing strains had evolved. Consistent with gene amplification, expression of the reporter protein had increased twofold. Both copies encoded an improved version of the bifunctional *hisA* mutant. Continued selection produced an isolate at 1000 generations with one of the copies having evolved into a specialist HisA. Lineages carrying single copies each of a specialist HisA and a specialist TrpF were isolated at 2000 generations. Another lineage carried a single copy of a highly efficient PriA-like generalist (**Figure 8(f)**). Still other lineages carried multiple copies (up to 20) of the original bifunctional *hisA* mutant, with or without a derived specialist *hisA*. This work demonstrates that the same selective force that stabilizes gene duplications of an inefficient generalist can also drive the functional divergence of efficient specialists. Moreover, the recovery of efficient generalists shows that evolution of specialists does not arise from a fundamental trade-off between competing functionalities, but rather from a trade-off between the properties of the particular amino acid replacements concerned.

On the Use and Abuse of Statistics

A number of statistical methods (reviewed in Yang and Bielawski, 2000; Nielsen, 2005; Vitti *et al.*, 2013) have been developed to detect signatures of selection in the patterns of substitution among homologous sequences. For example, an elevated ratio of nonsynonymous (dn) to synonymous (ds) substitution rates is often interpreted as evidence for positive selection. These methods are so popular that "Thousands of papers have been published every year claiming evidence of adaptive evolution on the basis of computational analyses alone" (Hughes, 2008). In truth, rejecting a naïve neutral model is no guarantee that selection shaped the patterns of substitution, only that it might have shaped them. Given the complexity of large data sets, the subtlety of the statistical issues involved, and the ready availability of alternative biological explanations (Hughes, 2007; Friedman and Hughes, 2007; Hughes and Friedman, 2008; Nozawa *et al.*, 2009a,b; Yang *et al.*, 2009; Yang and dos Reis, 2011; Zhai *et al.*, 2012), one should consider statistical evidence for selection as a hypothesis in need of empirical verification.

In a number of studies elevated dn/ds ratios are associated with functional changes (Long and Langley, 1993; Ivarsson *et al.*, 2003; Zhang *et al.*, 2004; Levasseur *et al.*, 2006; Georgelis *et al.*, 2009; Briscoe *et al.*, 2010; Moury and Simon, 2011; Huang *et al.*, 2012; Loughran *et al.*, 2008). On the other hand, functional changes are no guarantor of the action of positive selection (Hartl *et al.*, 1985; Nozawa *et al.*, 2010). This criticism is especially pertinent where functional changes lack any direct connection to fitness.

Several studies have gone further and reconstructed ancestral sequences in combination with site-directed mutagenesis to test experimentally if elevated dn/ds ratios are reliable indicators of functionally important sites. Bielawski *et al.* (2004) identified five sites with elevated dn/ds ratios associated with a shift in maximum absorbance from green to blue in an ancestral bacterial light driven proton pump. Site-directed mutagenesis showed replacements at three of these sites explained the shift (Man-Aharonovich *et al.*, 2004; **Figure 9(a)**). In contrast, dn/ds ratio tests failed to identify sites controlling maximum absorbance in ancestral fish rhodopsins. Of those sites identified as selected, none were involved in spectral tuning (Yokoyama *et al.*, 2008; **Figure 9(b)**). Nor were sites modulating sensitivity to volatile sex-steroid-derived odors in ancestral primate odorant receptors identified by analyses for positive selection (Zhuang *et al.*, 2009). The failure of statistical tests to reliably identify sites where functional changes were likely selected (sight and sex have obvious adaptive significance) serves to emphasize that experimental verification of statistically derived hypotheses is essential to secure firm biological conclusions.

Epilogue

From initial hesitant steps, the Functional Synthesis has grown to become vibrant field of inquiry in its own right, focused on mechanisms of adaptation, both ancient and modern. Today, it finds applications in phlyogenetics (Bloom, 2014), ecological genetics (Barrett and Hoekstra, 2011), evolution of

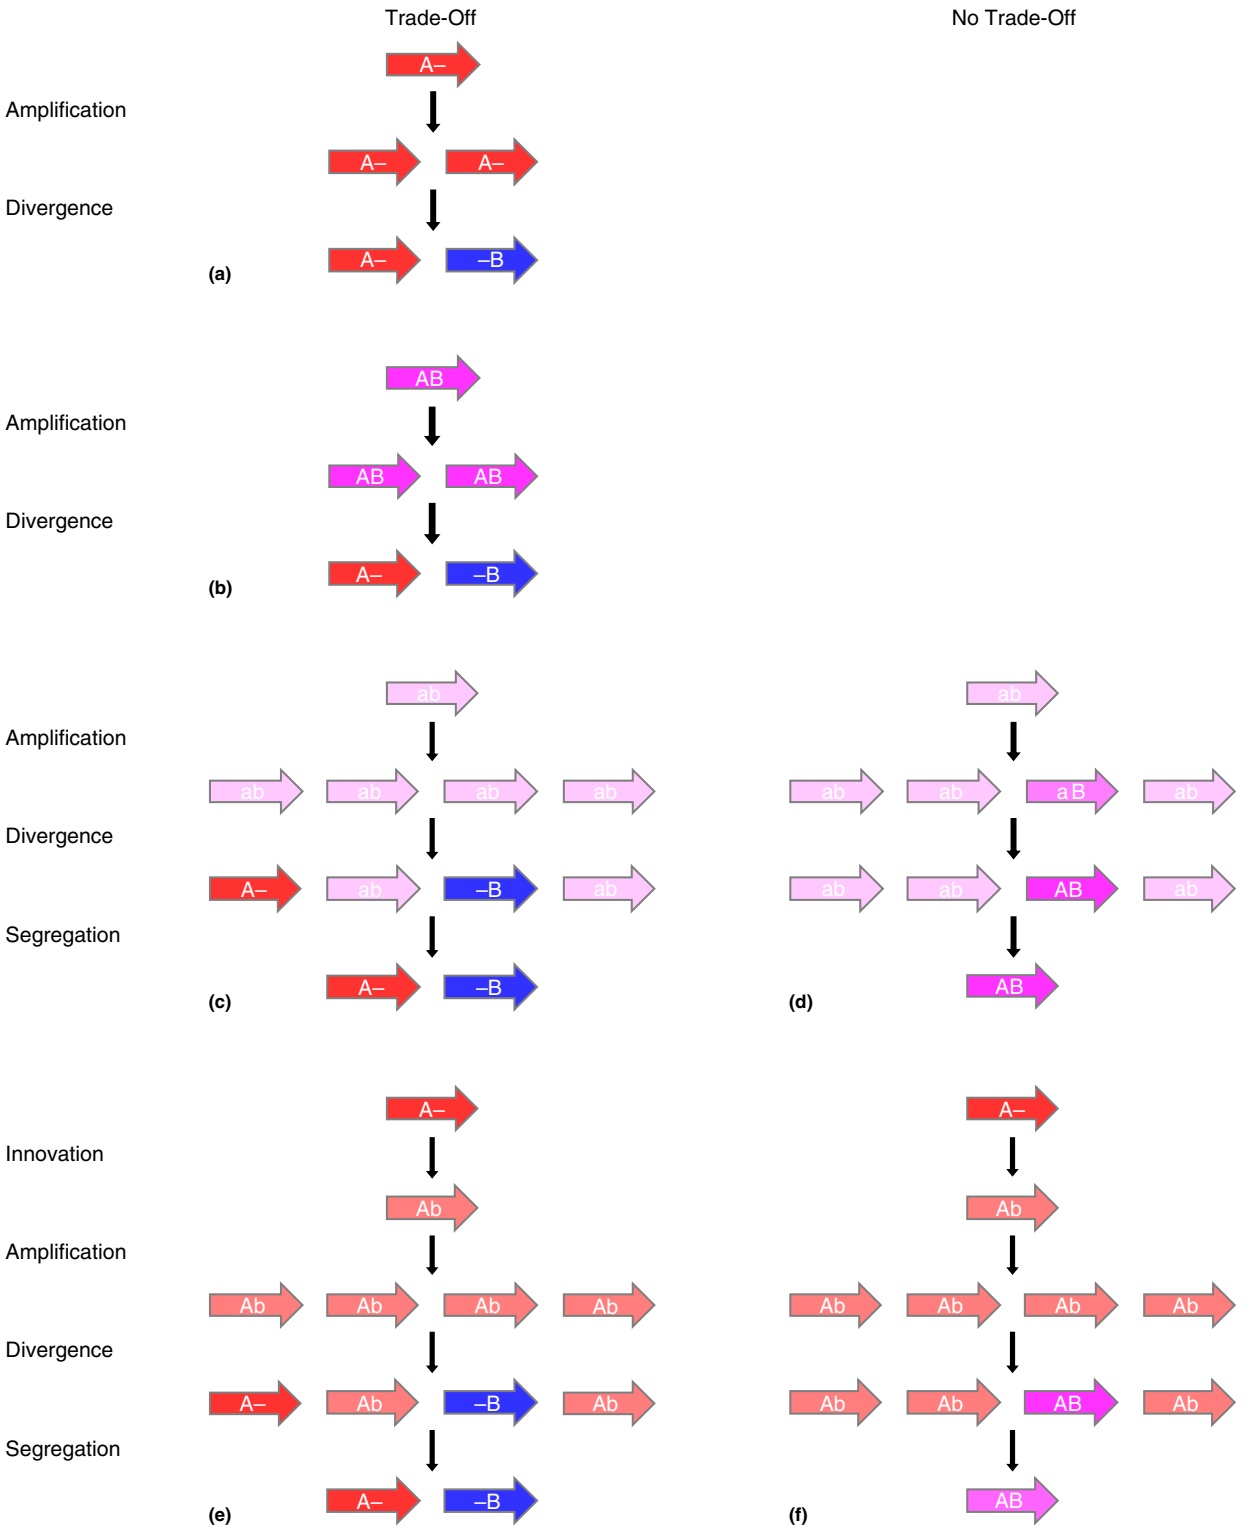

Figure 8 Models of gene duplication and divergence. (a) Ohno's original proposal. (b) Subfunctionalization of ancestral functions into separate genes. (c) Escape from adaptive conflict engendered by a trade-off between functions. (d) Evolution of an efficient generalist from an inefficient ancestor. (e) Evolution of specialists engendered by a trade-off between functions in the innovation, amplification, divergence, and segregation model. (f) Evolution of an efficient generalist in the innovation, amplification, divergence, and segregation model.

disease (Russell *et al.*, 2014; Chou *et al.*, 2014; Lynch *et al.* 2014), development (Lynch *et al.*, 2011), and design of industrial catalysts (Humble and Berglund, 2011; Wang *et al.*, 2015). In fusing functionalism and comparative biology, the Functional Synthesis provides a rigorous means to explore phenotypic evolution at the molecular level.

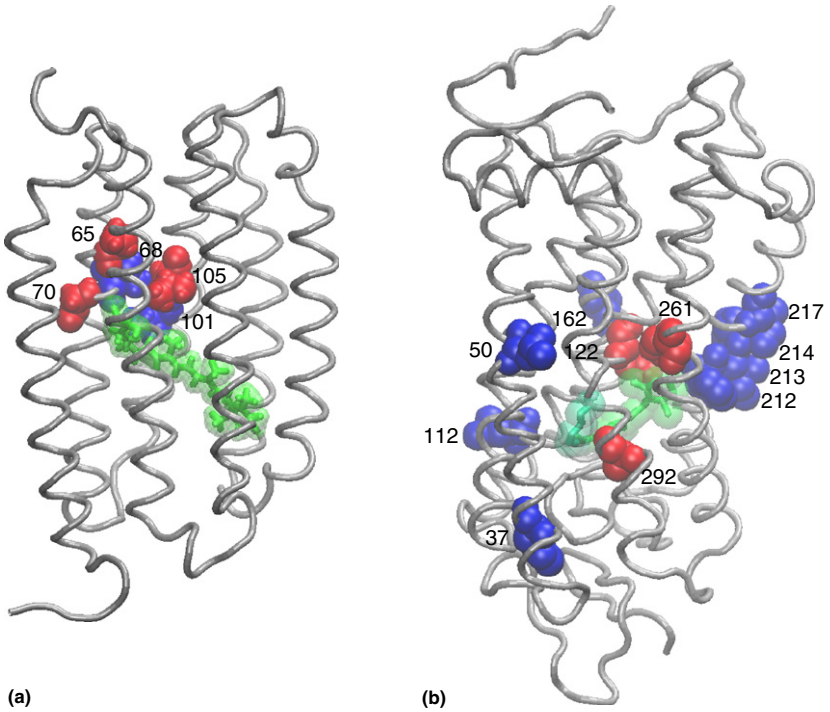

Figure 9 Success and failure of statistical 'tests for selection.' (a) Three (red) of five sites identified as subject to positive selection by statistical methods affect maximum absorbance in marine proteorhodopsin. (b) Statistical methods identified eight sites in squirrelfish rhodopsins as subject to positive selection but missed the three sites demonstrated to control maximum absorbance. The chromophores are shown in green.

Molecular Evolution, History of

MR Dietrich, Dartmouth College, Hanover, NH, USA
E Suarez-Diaz, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico

Introduction

Before molecular biologists had even cracked the genetic code and articulated the 'Central Dogma,' biochemists, anthropologists, geneticists, and evolutionary biologists were gathering to discuss how macromolecules at the heart of heredity and metabolism could have evolved (Dietrich, 1994, 2008). In the 1960s, as comparative and variability analysis of proteins developed, the idea that molecular evolution took place at a different pace with different mechanisms from those of organismic evolution gradually emerged. Heated controversies soon enveloped molecular evolution as it struggled to become widely recognized as a biological discipline (Smocovitis, 1996; Dietrich, 1998; Hagen, 1999). The interplay between molecular biology and evolutionary biology that shaped the history of molecular evolution is complex. New methods of experimentation in biochemistry and molecular biology produced new kinds of data regarding molecular phenomena (Suarez and Barahona, 1996). This spurred new reasoning about evolutionary processes at the molecular level. New concepts such as the molecular clock and new theories such as the neutral theory allowed biologists to argue for the distinctiveness of the processes of molecular evolution from organismal evolution (Dietrich, 1994; Morgan, 1998). While these new concepts and theories were controversial, by the 1980s and 1990s the increased availability of DNA sequence data allowed biologists to devise new statistical tests that would help depolarize earlier controversies, and bring the techniques and theories of molecular biology into the organismally oriented evolutionary biology.

Experimenting with Molecular Evolution

The history of systematic research of evolution at the molecular level began in 1904, when bacteriologist George H. F. Nuttall working at University of Cambridge used the precipitin reaction to measure affinities between the blood sera of different animal species. The strength of the reaction was taken as an indication of the genetic relation between species (blood groups had been recently shown to behave according to Mendelian laws, by Karl Landsteiner). Others followed suit, in particular the zoologist Alan A. Boyden, who for almost four decades aimed at improving the serology tests in order to make a more 'objective' systematics (Strasser, 2010a). Well into the 1970s, serology and immunology had a number of followers in systematic anthropology, including John Buettner-Janusch and Morris Goodman (Marks, 1996; Hagen, 2010).

A different, early approach was that of comparative biochemistry, which compared products of secondary metabolism (in plants) and metabolic pathways along biological groups. In 1937, Ernest Baldwin published *An Introduction to Comparative Biochemistry*, and in 1944 the Belgian biochemist (also a historian of the field) Marcel Florkin published his work *L´evolution biochemie*. Florkin´s book (English translation of 1949) included chapters devoted to biochemical adaptations in different physiological domains like respiration, digestion, photoreception, and osmoregulation; he also considered the systematic value of biochemical characters in different animal groups like vertebrates, tunicates, or insects.

The comparison of crystallization patterns, and the analysis of the tertiary (three-dimensional) structure of proteins were part of the biochemical study of proteins since the interwar period. After World War II, the idea that proteins had a stable structure (and were not aggregates of amino acids) practically dominated biochemistry, leading to an increased interest in tertiary structure analysis, which combined X-ray diffraction experiments with early computer calculations, particularly in the work of Max Perutz and Andrew Kendrew at the Medical Research Council laboratory in Cambridge, UK (de Chadarevian, 2002). Meanwhile, biochemist Alfred Sanger, at the Dunn Institute of Biochemistry at Cambridge, had published the first primary sequence of a protein, insulin. The Dunn Institute was directed by Charles Chibnall, who applied the methods of organic chemistry to break the proteins in its constituents, and then analyze the amino acid composition (Garcia-Sancho, 2010). Chibnall invited Sanger to his insulin analysis project, who in the following years developed a method using dinitrofluorobenzene, which reacted with the last amino acid of the insulin chain. Patiently, Sanger identified the amino acid peptides, which he called 'sequences,' and determined the complete sequence of both insulin chains between 1951 and 1955 (Garcia-Sancho, 2010). Soon, Sanger´s method was taken up by other biochemists, and modified by Pehr Edman, a Swedish biochemist who invented the so-called degradation technique, later on taken as the basis for sequencing automation in proteins by William Stein and Stanford Moore. Between the 1950s and 1960s, these methods allowed the determination of sequences of biologically relevant molecules (such as hemoglobin and cytochrome *c*). By the mid-1960s there were enough sequences available for Margaret Dayhoff to publish her first *Atlas of Protein Structure* (Strasser, 2010b).

Using these new protein sequences, in 1962 Emile Zuckerkandl and Linus Pauling articulated what was later referred to as 'the most significant result of research in molecular evolution' (Zuckerkandl and Pauling, 1962; Wilson *et al.*, 1977). After comparing the amino acids sequences of hemoglobin from different lineages, Zuckerkandl and Pauling discovered that the differences in amino acid sequence were 'approximately proportional in number to evolutionary time' (Zuckerkandl and Pauling, 1965, p. 148). In other words, the rate of amino acid substitution was approximately constant. Zuckerkandl and Pauling christened this constancy the molecular clock (Zuckerkandl and Pauling, 1965; Morgan, 1998).

Other experimental contemporary approaches also sought new ways to measure molecular similarity and difference. After the publication of Francis Crick and James Watson´s double-helix model of deoxyribonucleic acid (DNA), and their suggestion that the structure suggested a possible replication model, doubts arose concerning how the double helix could be disentangled (Holmes, 2001). Biophysicist Julius Murmur and biochemist Paul Dotty, at Harvard University, realized that DNA could be dissociated ('denatured') into its two constitutive chains, and regain its double structure ('renatured'), if the solution was heated and then slowly cooled. In 1958, Ellis T. Bolton and Roy Britten (at the Carnegie Institution at Washington) used this phenomenon as a tool to measure the degree of reassociation between two single DNA chains, each coming from different species. The amount of DNA reassociation was taken as a measure of the genetic distance between the two species and used to reconstruct evolutionary relationships. More importantly, hundreds of hybridization tests eventually led Britten to the discovery of a fraction of highly repetitive sequences in eukaryotic genomes ('satellite-DNA'), a non-expected phenomenon within the Darwinian prevailing framework. Together with the molecular clock, and the conviction that molecules provided a new type of evolutionary evidence, the field was set for controversy.

A Troubled Beginning

Indeed, the molecular clock immediately attracted interest and controversy. Some biologists, such as Richard Dickerson, realized that the clock was a powerful tool that could be used to date the evolutionary divergence of different species. Moreover, since molecules like cytochrome *c* were widely shared, for the first time evolutionary trees dating divergences from sponges to human could be constructed based on a set of shared molecular traits. While many evolutionary biologists appreciated the power of molecular clock as a tool for systematics, when Allen Wilson, Vincent Sarich, and Morris Goodman began using immunological comparisons to reconfigure the evolutionary history of primates controversy soon followed. More organismally focused biologists, such as the paleontologist George G. Simpson, thought that the idea of a constant rate of evolution at the molecular level was nonsense. Morphological features evolved in response to the environment and the resulting effects of natural selection. This process was irregular and thought to be irreconcilable with rate constancy at the molecular level. Even among those using molecular techniques, there was controversy as Wilson and Goodman worked to explain why the hemoglobin of higher primates seemed to evolve at a slower rate than they did in other mammals (Wilson *et al.*, 1977; Hagen, 1999; Aronson, 2002).

The rate estimates for protein evolution provided by Zuckerkandl and others fueled a second division between molecular and organismal evolution when in 1968 Motoo Kimura used them to argue that most observed changes at the molecular level were selectively neutral (Kimura, 1968; Provine, 1990; Smocovitis, 1996). Evolutionary biology in the late 1960s was gripped by panselectionism: natural selection was the dominant factor invoked in evolutionary explanations (Gould, 1983). Kimura used the high rate of protein evolution to argue that such a high rate would create too high a selective cost. In effect, all mammals should be extinct if evolution was occurring so quickly because too many deleterious mutants would have accumulated. Kimura's solution was to claim that many of those accumulating mutations were neutral, which rendered the observed rate innocuous. The next year, Jack King and Thomas Jukes extended Kimura's case for neutral evolution at the molecular level under the deliberately controversial name, 'Non-Darwinian Evolution' (King and Jukes, 1969). The controversy that followed between neutralists and selectionists persisted for at least 30 years (Dietrich, 2006).

Only 2 years before Kimura made his argument for neutrality, Jack Hubby and Richard Lewontin and Harry Harris had brought classical evolutionary genetics to molecular biology through the technique of electrophoresis (Hubby and Lewontin, 1966; Lewontin and Hubby, 1966; Harris, 1966). Gel electrophoresis is a technique that separates molecules by charge and size. This analytical separation method was developed during the interwar period by Arne Tiselius (Kay, 1988). Tellingly, the technique was originally developed to separate blood serum proteins, thus it intersected with contemporary immunochemical studies. The rise of electrophoresis was part of important biomedical advances, such as the study of anomalous hemoglobin (falciform anemia) and other serum components. By the early 1950s, the technique evolved from 'boundary' to 'zone' gel electrophoresis, which finally allowed complete molecular segregation (Chiang, 2009); by the 1960s, researchers adopted polyacrylamide gel as the stabilizing medium, thus transforming electrophoretic separation in one of the most successful, cheaper, and movable experimental tools available in biomedical research. By the mid-1960s, different research teams adopted gel-zone electrophoresis in order to measure the amount of genetic variation available in natural populations. In Great Britain, anthropologist Harry Harris used it to measure enzyme polymorphisms in human populations; while in the United States, Hubby and Lewontin at the University of Chicago, and Wilson Stone and his collaborators in Texas did the same for *Drosophila* populations (Lewontin, 1974; Suarez and Barahona, 1996). Such research was framed by debates regarding the number and kind of mutations caused by atomic radiation (see Beatty, 1987a), and seemed to support the view that argued for high levels of variation and a significant role for balanced polymorphisms. The rise of the neutral theory fundamentally changed the terms of the debate within evolutionary genetics by introducing neutral variation and genetic drift into the picture as real alternatives. That is not to say that the neutral theory was not controversial.

Initial responses to the neutral theory by evolutionary biologists were largely negative. Steeped as they were in selectionist explanations, evolutionary biologists were not convinced by Kimura's cost of selection argument and were skeptical that the theory could be easily tested. Biochemists, in contrast, were much more open to the neutral theory in part because they were less invested in natural selection and more easily moved by the prevalence of synonymous mutations. Because of redundancy in the third position of many codons, changes in the nucleotide at that site produced no corresponding change in which amino acid was coded for. This

meant that many third position substitutions would be synonymous and so not subject to selection. This biochemical argument was much more compelling, and meant that nucleotides in third positions were more likely to be governed by a process of genetic drift (Dietrich, 1994).

The prevalence of drift at the molecular level meant that the constancy of the molecular clock could be explained in terms of neutral rates of molecular evolution. According to the neutral theory, at neutral sites the rate of substitution was equivalent to the rate of mutation. Since the rate of mutation was more or less constant over long periods of time, the constant tick of the molecular clock could be explained as a result of the presence of neutral sites in the DNA coding for the molecule. Molecules had different rates of change depending on how many sites were constrained by selection (and so do not change) and how many were neutral (and free to change). Mary-Claire King and Allan Wilson invoked the prevalence of drift at the molecular level, but not at the organismic level in 1975, to explain how constancy at the molecular level could be reconciled with fluctuating rates at the organismic level (King and Wilson, 1975; Dietrich, 1998). Moreover, it implied a rupture of the 'extrapolationism' of the evolutionary synthesis: instead of one single mechanism (natural selection) explaining evolutionary processes at all levels of biological organization, the neutralists pushed for a differentiated explanation of evolution at the molecular and organismal level.

Making Molecular Evolution

Intellectually, molecular evolution was established as a separate field of study by biologists, such as Allan Wilson and Motoo Kimura, who argued that there were significant differences between evolution at the molecular level and at the organismic level. Tellingly, some evolutionary biologists, such as Ernst Mayr, Theodosius Dobzhansky, G. G. Simpson, and many others, noted a growing opposition between molecular and evolutionary biology. The 'molecular wars,' as E. O. Wilson called them, pitted molecular and organismal evolutionary biologists in a struggle for authority and resources that drew on wider tensions regarding the unity of science, the cultural standing of evolution, and the autonomy of biology as a discipline (Smocovitis, 1996; Wilson, 1994; Hagen, 1999; Dietrich, 1998). Molecular evolution was caught in this complex dispute as it tried to establish a disciplinary identity that drew from both evolutionary and molecular biology (Dietrich, 1998). Institutionally, Emile Zuckerkandl helped the new field come together through a new journal, the *Journal of Molecular Evolution*. Begun in 1974, Zuckerkandl's journal provided a venue for publication for this newly emerging field. Given the hostility of some organismic evolutionary biologists, the *Journal of Molecular Evolution* was an important outlet for early work in this field, especially since some of the first molecular evolutionists, such as Allan Wilson, were biochemists with little training in evolution. However, not everybody felt connected to Zuckerkandl´s journal. In 1982, Masatoshi Nei and Walter Fitch, in the context of a symposium on 'Evolution of Genes and Proteins' held at State University of New York in Stony Brook, launched a second journal for the field, *Molecular Biology and Evolution*. A certain amount of debate was clearly running through the nascent community concerning the best ways to foster communication and transmission of knowledge within the field. In 1992, Fitch and Nei ignited the creation of the Society for Molecular Biology and Evolution. In 1992, a third journal was created, *Molecular Phylogenetics and Evolution*, focused on problems of systematics, and whose editor-in-chief then was Morris Goodman (Suárez-Díaz, 2009).

Moreover, the 1970s and 1980s were challenging times for the study of molecular evolution. At the level of theory, the neutral theory, as applied to proteins, remained controversial. Initial tests of the neutral theory were either statistically problematic, or did not support the neutral theory (Ewens, 1972; Lewontin, 1991). For instance, Francisco Ayala's group used data about electrophoretic variability in populations of the fruit fly, *Drosophila*, to test a range of neutralist predictions. Ayala and his coworkers noted that the frequency distribution of heterozygous loci was significantly different from that predicted for neutral alleles in the infinite alleles model. Instead of the predicted distribution clustering, Ayala's distribution of heterozygous loci was fairly even, but tellingly had an excess of loci with very little heterozygosity. This high number of rare alleles was held against the neutral theory (Ayala *et al.*, 1974, p. 378). Neutralists, such as Jack King, located the problem, not in the neutral theory, but in assumptions made in the infinite alleles model. King suggested that infinite alleles model was not appropriate for electrophoretic data, since electrophoretic classes probably encompassed many allelic differences (King, 1974). Ayala and others were sensitive to these criticisms and introduced mutation models for electromorphs that better fit the data sources (Ewens, 1979). Neutralists, such as Tomoko Ohta and Masatoshi Nei, began to articulate alternatives to Kimura's strictly neutral theory. Ohta suggested a broader class of nearly neutral alleles that would still be largely subject to processes of drift, and could explain the observed numbers of rare alleles (Ohta, 1992; Ohta and Gillespie, 1996; Steen, 2008). Nei proposed that population dynamics, such as bottlenecks, could explain phenomena that confounded the strictly neutral theory (Nei, 1987).

As statistical testing of neutralist and selectionist hypothesis proved more difficult than anticipated in the 1970s, the molecular clock became a proxy for the neutralist–selectionist dispute. From its inception, Zuckerkandl and Pauling had insisted that the molecular clock was stochastic, and so exhibited both constancy and variability. The question was how much variability is reasonable in a clock. In 1971, Ohta and Kimura measured significantly higher variation in the molecular clocks associated with beta hemoglobin and cytochrome *c*. However, they did not interpret this variability as a problem for the neutral mechanism that produced the overall constancy of the rate of substitution. Rather, they held that the overall constancy had been thrown off by a small number of advantageous mutations: it was the balance of selected and neutral sites that was understood to give each molecule its characteristic rate of change. Others, like Morris Goodman, were less convinced, and argued that the slowdown in rates of evolution in hemoglobin in primates was evidence against a hemoglobin-based molecular clock. For clock advocates, like Kimura and Allan Wilson, there were going to be exceptions to the rule of the molecular clock, but what was important was seeing them as exceptions to an intrinsic rate rather than as

evidence that the clock did not exist (Wilson, *et al.*, 1987; Aronson, 2002; Hagen, 2010).

The Coming of the DNA Era

In 1962, Sanger was invited to the newly created Laboratory of Molecular Biology by Sydney Brenner and Francis Crick to develop a method for nucleic acid sequencing. By the late 1960s and early 1970s, Sanger had sequences small transfer and ribosomal RNA molecules, but the degradation method was not suitable for DNA sequencing. It was until the late 1970s that Sanger, using DNA polymerase, developed the plus, minus, and dideoxy methods. Allan Maxam and Walter Gilbert, almost simultaneously, developed their DNA sequencing method between 1976 and 1977 (Garcia-Sancho, 2010). The growing availability of DNA data in the late 1980s and 1990s sparked an important cascade of changes for molecular evolution. These changes were accompanied and made possible by the readily access to computer technologies and the creation of the first databases (Garcia-Sancho, 2010, 2012). They had an impact both on the development of comparative or phylogenetic analysis, a field that has been completely transformed by the advent of the molecular approach (Suárez-Díaz and Anaya-Munoz, 2008; Suárez-Díaz, 2014), and on the testing of the neutral hypothesis as evolutionary mechanism.

In the latter case, DNA sequence data promised direct quantitative comparisons. The idea was not new (Zuckerkandl and Pauling, 1965), and it was built up from previous developments in protein sequence comparison that took place during the 1960s. As the accumulation of hemoglobin and cytochrome data sequences progressed (see above), it opened the door to comparisons of amino acid sequences from different species and gives an estimate of their similarity. Algorithmic tools and the introduction of personal computers in biological research allowed for the construction of the first evolutionary trees from molecular–protein-data (Hagen, 2001; Eck and Dayhoff, 1966; Fitch and Margoliash, 1967; Dayhoff, 1969). The shared idea among these early practitioners was that molecular data provided a quantitative and non-idiosyncratic approach to systematics (Hagen, 2003; Strasser, 2010b; Suárez-Díaz, 2014). Thus, Fitch, for instance, defined similarity as 'minimum (mutational) distance.' Using an IBM of the 360 series he performed a pairwise comparison of pairs of sequences using Margoliash´s set of cytochrome *c* sequences to build a tree upon measures of minimum distance.

Starting in the 1980s, as DNA sequences accumulated in new databases, their use revolutionized the field of systematics. More powerful algorithms to explore similarities between sequences had been put to work and improved (Needleman and Wunsch, 1970; Sellers, 1974). However, as DNA datasets flooded, the number of problems and debates arose. Besides debates on aspects of systematics, including homology, phonetics, and parsimony (Sober, 1988), many methodological decisions need to be taken before a molecular tree is built. These include various approaches to sequence alignment, the multiple hit problem and the different methods for constructing trees (including distance-based methods, maximum parsimony, and maximum-likelihood methods), just to name the most important ones (Suárez-Díaz and Anaya-Munoz, 2008). More recently, Bayesian methods of statistical inference have been incorporated in the construction and election of phylogenetic trees; this movement has led to development of new software packages, like the very popular MRBAYES (Huelsenbeck and Ronquist, 2001). Moreover, the discovery of large amounts of horizontal genetic transfer, not only in bacteria, questioned the idea itself of the evolutionary tree (Doolittle, 1999; Sapp, 2007). As complete genome sequences have been produced in the last decade, new methods for genome comparison aim to surpass some of the limitations rising from one-to-one gene comparisons. Still, the contribution of molecular phylogenetics to our knowledge of the history of life has been enormous.

DNA sequencing was introduced into the study of mechanisms of evolutionary genetics by Kreitman (1983). As a Richard Lewontin's graduate student at Harvard, Kreitman used the sequencing techniques he learned in Walter Gilbert's laboratory to analyze the sequences of alcohol dehydrogenase (ADH) genes in *Drosophila melanogaster*. ADH had known a well-known polymorphism for fast and slow moving electrophoretic variants. Kreitman's investigation of the DNA sequences of the fast/slow ADH polymorphism revealed many differences between the DNA sequences of eleven different alleles, but only one DNA difference that corresponded to an amino acid difference. This nonsynonymous DNA substitution was at the site of the fast–slow protein polymorphism.

The striking difference between synonymous changes (which cause no change in amino acid sequence) and nonsynonymous changes (which cause a change in amino acid sequence) led Kreitman and his collaborators to devise new statistical tests for selection. Kreitman extended Kimura's 1983 idea of comparing synonymous and nonsynonymous substitutions by contrasting changes within and between species. The resulting McDonald–Kreitman test compares the ratio of nonsynonymous to synonymous changes within a species and between two species. If the sequences are neutral, the ratios should remain the same. If there is positive selection, then nonsynonymous changes should have accumulated over time, so there would be more nonsynonymous changes between species than within a species. The McDonald–Kreitman test and many other statistical tests that followed allowed evolutionary biologists to detect balancing selection, adaptive protein evolution, and population subdivision (McDonald and Kreitman, 1991; Kreitman, 2000). Where earlier statistical tests using electrophoretic data had been stalled by low power, these comparisons using DNA sequence data proved more effective in distinguishing the effects of drift and selection.

The success of tests of selection did not tip the balance of the neutralist–selectionist controversy in favor of the selectionists. On the one hand, tests of selection allowed the controversy between neutralists and selectionists to move beyond earlier either/or dynamics toward an acknowledgment that both selection and drift acted at the molecular level and were worthy of investigation. On the other hand, test of selection allowed biologists to recast the neutral theory that cast it as a null model, as the methodological starting place for molecular evolutionary analysis (Crow, 1987). When Kimura first championed the neutral theory in 1968, most evolutionary biologists understood natural selection to be the most important factor in biological evolution and as a result assumed

that searching for selection and its effects was the method of choice – they were panselectionists (Kimura, 1983; Gould and Lewontin, 1979). Indeed, in 1983, Ernst Mayr argued that biologists should continue to give selectionist explanations priority because random drift could not be demonstrated (Mayr, 1983). Mayr's confidence in selection was the result of earlier efforts that reinterpreted supposed cases of random drift governing the fate of morphological traits as actually the result of natural selection. As a result, for Mayr and many others drift became equated with an admission of ignorance of how selection was in fact operating (Beatty, 1987b). Mayr would have been hard pressed to hold such a stringent denial of drift only a few years later when statistical tests based on newly available DNA sequences became accepted tools in molecular evolution. By the late 1980s, both proponents and critics of the neutral theory recognized that neutrality, not selection, was a useful starting hypothesis when analyzing DNA sequences (Hudson *et al.*, 1987; Kreitman, 2000; Beatty, 1987b). In his review of methods to detect selection, Kreitman argues that "Kimura's theory of neutrally evolving mutations is the backbone for evolutionary analysis of DNA sequence variation and change" because a "substantial fraction" of the genome is best modeled as selectively neutral, because selective neutrality is a "useful null hypothesis," and because "statistical analysis of (potentially) neutral variation in a gene (or other region of the genome) can be informative about selection acting at linked sites" (Kreitman, 2000, pp. 541–542). Kreitman's view accepts both that there is a substantial amount of neutral variation and that the neutral theory is essential for detecting selection at the DNA level.

The acceptance of neutrality as a starting point for molecular evolutionary research demonstrates an important shift away from panselectionism in evolutionary biology. Over time, molecular techniques introduced information about a new level of biological organization: the molecular level, where drift plays a significant role. Molecular evolutionists helped create the divide between the molecular and morphological levels as a way of carving out space where their research could develop independently of the selectionist agenda of the architects of the Neo-Darwinian synthesis (Dietrich, 1998; Aronson, 2002; Hagen, 1999).

Molecular Evolution, Models of

JP Bielawski, Dalhousie University, Halifax, NS, Canada

Glossary

Covarion model A model proposed by Fitch and Markowitz in 1971 hypothesizing that the evolutionary process at a given site in a molecule is dependent on the state at other sites.

DNA transition A change between biochemically similar DNA states. Changes from one purine to another (A and G) or from one pyrimidine to another (C and T) are considered transitions.

DNA transversion A change between biochemically dissimilar DNA states. Any change from a purine to a pyrimidine, or from a pyrimidine to a purine, is considered a transversion.

Equilibrium distribution A steady-state probability distribution of possible states that does not depend on the initial states. The distribution represents a stable condition, and implies stable statistical behavior.

Instantaneous rate The rate of a change in state over an infinitesimally small unit of time.

Markov model A model for a stochastic process of change between states where the probability of an event depends only on the current state, and not on any of the events that may have preceded it.

Model bias The difference between the average performance of a model, often referred to as the expected value of the model, and the true value.

Model variance The difference between the individual results of a model and the long run average of the results when the modeling process is repeated many times.

Stationarity Pertains to a Markov process that has attained its equilibrium distribution and has no tendency to move away from that distribution.

Steady-state distribution An alternative term for the equilibrium distribution, which is defined above.

Stochastic Pertains to a process having a randomly determined sequence of events. A stochastic, or random, process can change over time according to any one of many different series of events.

Substitution rate matrix The matrix of instantaneous rates of character state change required to completely specify the evolutionary dynamics of a molecular sequence.

Time-homogeneity The property of a stochastic process where the transition probabilities for all changes among states are constant over time.

Time-reversibility The property of a stochastic process at equilibrium where the amount of change from state i to state j is exactly equal to the amount of change from state j to state i.

Introduction

Modern methods of phylogenetic analysis require a mathematical model to describe the process of sequence change over time. Often, the scientific goal will be to learn the evolutionary relationships from the sample of sequences. Although a model of the evolutionary process is an essential part of phylogenetic inference, it is sometimes referred to as a nuisance variable because it is not the objective of the study. Other times, the scientific purpose of the study will be to learn how molecules change over evolutionary time. Then, the phylogeny becomes the nuisance variable. In both settings, the evolution of the sequences underpins the endeavor, and success will depend on building an adequate representation of how the sequence changes over evolutionary time.

Sequence evolution is modeled by explicitly describing the probability of change between character states. Taking DNA sequence as an example, the model specifies the probability that a nucleotide will change from a given state (A, C, G, or T) to another given state (again A, C, G, or T) after some amount of time has passed. Because evolution of DNA proceeds by mutation of an existing nucleotide in a population, and its ultimate fixation in that population is by drift or by natural selection, it is reasonable to assume that the probability of a change depends only on the current nucleotide in the population. This assumption coincides with a special class of stochastic models that have very useful properties, called Markov models, where the probability of change does not depend on the history of past changes. Further restrictions are typically placed on Markov models because they provide computational benefits. The most common restrictions include the assumption that sites in an alignment evolve independently, the process does not change over time (time-homogeneity), the character states are at their equilibrium frequencies (stationarity), and the process is the same whether evolution was run forward or backward through time (reversibility). All these assumptions minimize the complexity of the model, which can aid the interpretability of the results.

Markovian models can be used to compute distances between pairs of sequences. These are the basis for the distance-based phylogenetic methods. The probability calculations of the model are critical to this approach because the amount of dissimilarity observed between a pair of sequences is not a linear function of evolutionary time; the observed difference between sequences progressively underestimate the actual evolutionary distance as time increases. A Markovian model is employed to estimate the actual evolutionary difference between sequences. Note that these models also provide the

probability calculations that underpin both the likelihood and Bayesian methods of phylogenetic analysis.

Parameters are used to define how different biological aspects of evolution determine the probabilities of a state change. Again, taking DNA as an example, it is well known that DNA transitions (A↔G and T↔C) occur more frequently during evolution than DNA transversions (all the other types of DNA changes). Thus, a parameter that permits the probabilities to differ between these two types of changes is often considered important to include in a DNA model. Model realism is considered improved only when parameters are subsequently found to provide a benefit to real data analysis. Model development has generally followed one of two tracks. Mechanistic models employ parameters to describe how a specific biological process impacts probabilities of change. The actual values for these parameters are not specified, but rather they are estimated by fitting the model to a sample of data (e.g., by using maximum likelihood). Through these estimated values, the model can serve as a tool for learning about the process of sequence evolution. Alternatively, the empirical models employ parameter values that have been previously estimated from a large reference dataset that is presumed to be broadly representative of sequence evolution. By leveraging the information in a large dataset, an empirical model can apply information about very complex biological processes to a relatively small dataset with little computational burden. The limitation is that any parameters that are fixed to database-derived values cannot be used to gain additional insight about the process of sequence evolution. For this reason, empirical models are more often used when the primary objective is phylogeny reconstruction, and a relatively complex model is warranted.

Mathematical Modeling of Substitution Dynamics

The task of constructing a model for sequence evolution begins with the assumption that the process is Markovian. Although this is a reasonable assumption, some conditions will be imposed on the process to facilitate otherwise difficult computation. In this section, changes among the states of a DNA sequence are used to illustrate the basis of model construction. As the purpose is to introduce the major properties of Markov models, readers can skip ahead to the different types of sequence models presented in Section 'Modeling the Evolution of Molecular Sequences' without loss of continuity.

Continuous Time Substitution Rates

The evolutionary dynamics implied by a Markov model are fully determined by the current states of the system, and the substitution probabilities from each state to all other states. Taking just adenine (A) as an example, let the current state of the system be the frequency of A at time t, $f_A(t)$. The frequency of A after some amount of evolutionary time has elapsed $(t+\mathrm{d}t)$ is determined by taking the current frequency of A, and subtracting the frequency of A lost by substitution of an alternative nucleotide (C, G, or T) and adding the frequency of new A's fixed by substitution

$$f_A(t+\mathrm{d}t) = f_A(t) - \sum_{x \neq A} f_A(t)\mu_{Ax}\mathrm{d}t + \sum_{x \neq A} f_x(t)\mu_{xA}\mathrm{d}t$$

where μ_{Ax} is the rate of substitution from A to any alternative state (C, G, or T), and μ_{xA} is the rate of substitution from an alternative state x to A. The substitution rate indicated by μ is called an 'instantaneous rate' because it gives the rate of a nucleotide substitution over an infinitesimally small interval of time, i.e., as $\mathrm{d}t$ tends to zero. A full description of the system requires three more equations:

$$f_C(t+\mathrm{d}t) = f_C(t) - \sum_{x \neq C} f_C(t)\mu_{Cx}\mathrm{d}t + \sum_{x \neq C} f_x(t)\mu_{xC}\mathrm{d}t$$

$$f_G(t+\mathrm{d}t) = f_G(t) - \sum_{x \neq G} f_G(t)\mu_{Gx}\mathrm{d}t + \sum_{x \neq G} f_x(t)\mu_{xG}\mathrm{d}t$$

$$f_T(t+\mathrm{d}t) = f_T(t) - \sum_{x \neq T} f_T(t)\mu_{Tx}\mathrm{d}t + \sum_{x \neq T} f_x(t)\mu_{xT}\mathrm{d}t$$

The total process (for all the nucleotide states) can be summarized by using a single equation, and a 4×4 substitution rate matrix, Q, that specifies the full set of substitution probabilities

$$F(t+\mathrm{d}t) = F(t) + QF(t)\mathrm{d}t$$

where

$$Q = \begin{bmatrix} -\mu_A & \mu_{AC} & \mu_{AG} & \mu_{AT} \\ \mu_{CA} & -\mu_C & \mu_{CG} & \mu_{CT} \\ \mu_{GA} & \mu_{GC} & -\mu_G & \mu_{GT} \\ \mu_{TA} & \mu_{TC} & \mu_{TG} & -\mu_T \end{bmatrix}$$

Because the values of Q fully determine the dynamics of the substitution process, the different DNA models are defined according to their unique 'substitution rate matrix,' Q. The off-diagonal elements of Q are used to determine the probability that a given state will change to another state over some fixed amount of time. The diagonal values of Q are set so that each row of the matrix sums to zero. Each diagonal value gives the total substitution rate of the nucleotide, for example, $\mu_A = \mu_{AC} + \mu_{AG} + \mu_{AT}$.

To construct a Markov model to describe the substitution dynamics of amino acids, or sense codons, the substitution rate matrix is simply expanded to accommodate the larger number of states. As there are 20 amino acids, a model for protein sequences will have a 20×20 matrix of instantaneous rates. A model for evolution under the universal genetic code will be even bigger, having a matrix of 61×61 instantaneous rates. The use of Markov chain theory is the same in these cases, so the DNA model serves as a good example.

Calculating Substitution Probabilities

Whether the states are nucleotides, codons, or amino acids, the instantaneous rate from any initial state i to another state j is given by μ_{ij}. This is the rate of a substitution over an infinitesimally small amount of time, but we want the substitution probability for a finite amount of evolutionary time, $p_{ij}(t)$ where $t > 0$. This quantity is known as a 'substitution probability,' and the matrix that gives the full set of these, $P(t)$, is called the 'substitution probability matrix.' This matrix is

given as

$$P(t) = \begin{bmatrix} p_{AA}(t) & p_{AC}(t) & p_{AG}(t) & p_{AT}(t) \\ p_{CA}(t) & p_{CC}(t) & p_{CG}(t) & p_{CT}(t) \\ p_{GA}(t) & p_{GC}(t) & p_{GG}(t) & p_{GT}(t) \\ p_{TA}(t) & p_{TC}(t) & p_{TG}(t) & p_{TT}(t) \end{bmatrix}$$

The diagonal elements of this matrix are set, so the rows sum to 1. In addition to being necessary to correct for multiple substitutions between states at the same site, the resulting values of $P(t)$ can be used to provide insights into the process of molecular evolution.

Given the instantaneous dynamics determined by Q, the behavior over a fixed amount of time t can be obtained by solving the differential equation

$$\frac{dP(t)}{dt} = P(t)Q$$

The solution gives $P(t)$ as the exponential of Qt

$$P(t) = e^{Qt}$$

There are several ways to obtain the exponential of the Q matrix, but this task is most easily handled by diagonalizing Q. If an invertible matrix U exists such that $Q = U^{-1}DU$, where D is a diagonal matrix, then:

$$P(t) = e^{Qt} = e^{(U^{-1}DtU)}$$

$$P(t) = U^{-1}e^{Dt}U$$

The matrix U is comprised of the eigenvectors of Q, and U^{-1} is the matrix inverse of U. The diagonal matrix is comprised of the eigenvalues of Q. Taking a 4×4 DNA matrix as an example for Q, the matrix $D = \text{diag}(\lambda_1, \lambda_2, \lambda_3, \lambda_4)$. The exponential of D, required to compute $P(t)$, is simply

$$P(t) = U^{-1}\text{diag}\{e^{\lambda_1 t}, e^{\lambda_2 t}, e^{\lambda_3 t}, e^{\lambda_4 t}\}U$$

A very common assumption of models used for inferring a phylogeny is that the substitution dynamics specified by Q are valid over the entire interval of time under study (e.g., over the entire evolutionary tree). This assumption is called 'time-homogeneity.'

Steady-State Distribution

The above Markov process has an interesting property worth noting. When the process has been running for a very long time, i.e., when time (t) tends toward infinity, the state frequencies will approach a distinctive distribution. This distribution is called the 'equilibrium' or 'steady-state distribution,' because this distribution does not depend on the initial state of the process. As long as the process is run long enough it will attain the 'steady-state distribution' and remain there.

Continuing with the DNA model as an example, let π^0 be an initial distribution of nucleotide frequencies and π^t be their distribution after some time (t) has elapsed, where

$$\pi^0 = (\pi^0_A, \pi^0_C, \pi^0_G, \pi^0_T), \text{ and}$$

$$\pi^t = (\pi^t_A, \pi^t_C, \pi^t_G, \pi^t_T)$$

The nucleotide frequencies at a point in time (t) are given by

$$\pi^t = \pi^0 P(t)$$

When the current distribution is the steady-state distribution (i.e., $\pi^t = \pi^{t+1}$), the Markov process is said to be 'stationary.' In the DNA case, if the process is stationary, the empirical proportions of the nucleotides (A, C, G, and T) in the evolving sequence will correspond to the steady-state distribution. This means that the frequency of, say, nucleotide A in those sequences gives an estimate of the expected proportion of time the Markov process at a given site was in the A state (π_A).

Time-Reversibility

Under the assumption of stationarity, we can be even more precise about what we expect for this process: the amount of 'movement' of the process from some state i into another state j will be given by $\pi_i q_{ij}$, and the movement out of that state j will be given by $\pi_j q_{ji}$.

'Time-reversibility' is just the special case where the steady-state amount of change from state i into j is exactly equal to the amount of change from state j into i for all possible pairs (i, j) of states:

$$\pi_i \mu_{ij} = \pi_j \mu_{ji}$$

Note that reversibility can be imposed on a Markov process when it is thought to be correct, or simply for mathematical convenience. Mathematical convenience is usually the reason for specifying a time-reversible evolutionary model, as there are few biological conditions that justify such a restriction on the process. Indeed, time-reversibility imposes an asymmetry in the substitution process between the two strands of DNA. Strand asymmetry can be relaxed by specifying a certain type of 'nonreversible model' (see Section 'Models for DNA Sequences' for further details), and such nonreversible models can have a stationary steady-state distribution.

Another convenience of a time-reversible model is that the off-diagonal substitution rates of Q can be expressed as the product of an 'exchangeability parameter' (s_{ij}) and the steady-state frequencies

$$\mu_{ij} = s_{ij}\pi_j$$

with time-reversibility imposed by the restriction

$$\pi_i s_{ij} \pi_j = \pi_j s_{ji} \pi_i$$

Thus, states i and j need not be equally frequent to have time-reversibility, making it possible to specify a time-reversible DNA model that allows biased nucleotide frequencies when at equilibrium.

Modeling the Evolution of Molecular Sequences

Evolutionary processes differ among genes, genomes, and organisms. Coding sequences are constrained by the function of the encoded proteins, whereas noncoding sequences are not.

Mitochondrial genomes are subject to very different evolutionary dynamics than the nuclear genes of the same species. The genome of a virus experiences different rates and patterns of spontaneous mutation than those of its hosts. Given that these examples represent just a small fraction of the natural diversity in evolutionary processes, it is not surprising that many different types of models have been developed for sequence evolution.

Different models are defined by different parameterizations of the rate matrix. The three most popular types of models differ according to the number of character states (DNA, amino acid, and codon). DNA models, having just four states (A, C, G, and T), have a relatively small rate matrix with $4 \times 4 = 16$ elements. Amino acid models allow up to 20 distinct states, so they employ a much larger rate matrix having 400 elements. Codons are triplets of nucleotides that encode an amino acid, and the 61 sense codons of the universal genetic code yields an even larger rate matrix. A very large number of alternative evolutionary models have been derived from these three types of rate matrix. While it is not possible to review them all, descriptions of selected models are provided in the following sections.

Models for DNA Sequences

The first Markov model for sequence evolution, proposed by Jukes and Cantor (1969), is also the most simple. This model assumes that every nucleotide substitution has the same probability of occurring. If the rate parameter is denoted by α, then the substitution rate matrix for this model is

$$Q = \begin{bmatrix} \cdot & \alpha & \alpha & \alpha \\ \alpha & \cdot & \alpha & \alpha \\ \alpha & \alpha & \cdot & \alpha \\ \alpha & \alpha & \alpha & \cdot \end{bmatrix}$$

Recall that the diagonal elements of a rate matrix must be set so that each row will sum to zero. For this model, the diagonal elements would be -3α, and are excluded for simplicity. A consequence of this model is that if a sequence had evolved for a sufficiently long period of time (i.e., the substitution process is at equilibrium), the resulting gene sequences would exhibit nearly equal nucleotide frequencies regardless of their frequencies at the start. This is a strong expectation that is clearly violated in the majority of real sequences.

Recognizing that different genes have different nucleotide frequencies, Felsenstein (1981) proposed a model whereby the substitution rate depends on the equilibrium frequencies:

$$Q = \begin{bmatrix} \cdot & \alpha\pi_C & \alpha\pi_G & \alpha\pi_T \\ \alpha\pi_A & \cdot & \alpha\pi_G & \alpha\pi_T \\ \alpha\pi_A & \alpha\pi_C & \cdot & \alpha\pi_T \\ \alpha\pi_A & \alpha\pi_C & \alpha\pi_G & \cdot \end{bmatrix}$$

The frequencies (π_x) can be estimated by simply measuring the nucleotide composition of the sequences under study. This represents an increase in complexity, as this model has three more parameters than the Jukes and Cantor (1969) model. It is only an increase of three because given any three frequency parameters, the fourth can be obtained by subtraction.

Due to greater biochemical similarity between purines (A and G) and between pyrimidines (C and T), DNA sequences more frequently experience changes from purine to purine and from pyrimidine to pyrimidine. These are called DNA transitions. Changes from a purine to a pyrimidine, or vice versa, occur less frequently over evolutionary time and are referred to as DNA transversions. This difference is a clear example of a biologically relevant aspect of sequence evolution that can be easily built into a model. In fact, it is so critical that it has been built into DNA models on three different occasions (Kimura, 1980; Felsenstein, 2004; Hasegawa *et al.*, 1985). The model of Hasegawa *et al.* (1985) is

$$Q = \begin{bmatrix} \cdot & \beta\pi_C & \alpha\pi_G & \beta\pi_T \\ \beta\pi_A & \cdot & \beta\pi_G & \alpha\pi_T \\ \alpha\pi_A & \beta\pi_C & \cdot & \beta\pi_T \\ \beta\pi_A & \alpha\pi_C & \beta\pi_G & \cdot \end{bmatrix}$$

In this model, there are separate rates for the DNA transitions (α) and DNA transversions (β) in addition to the frequency parameters, π_x. Collectively, all these parameters determine the subsitution rates of this model. This is an increase in the complexity of the model (five parameters) relative to Felsentein's 1981 model (four parameters).

All the models presented so far make the time-reversibility assumption described in the previous section. For DNA, the substitution rate matrix of a reversible model can have at most eight free parameters, three frequency parameters, and five exchangeabilities:

$$Q = \begin{bmatrix} \cdot & a\pi_C & \beta\pi_G & \gamma\pi_T \\ \alpha\pi_A & \cdot & \delta\pi_G & \varepsilon\pi_T \\ \beta\pi_A & \delta\pi_C & \cdot & \varsigma\pi_T \\ \gamma\pi_A & \varepsilon\pi_C & \varsigma\pi_G & \cdot \end{bmatrix}$$

There are only five free exchangeabilities in the above matrix because one is set to a value of 1. This is called a general time-reversible (GTR) model, and several studies have explored this for DNA sequences (Lanave *et al.*, 1984; Tavaré, 1986; Yang, 1994a). Recall that reversible models are largely motivated by mathematical convenience. Although the parameterization of the GTR model offers considerable flexibility, it forces the evolutionary process to be strand-asymmetric; i.e., it requires that the evolutionary process differs between the two strands of DNA.

Strand-symmetry, or strand-asymmetry, are examples of biologically relevant aspects of the evolutionary process that impact the probability of a change in state. Several authors (Takahata and Kimura, 1981; Gojobori *et al.*, 1982; Yang, 1994a; Bielawski and Gold, 2002) have explored alternative parameterizations of DNA models that are not time-reversible; i.e., within the substitution matrix the rate of $i \rightarrow j$ differs from the rate of $j \rightarrow i$. Bielawski and Gold (2002) proposed a model with five free parameters that describes a fully symmetric process for both strands of DNA. Specifically, this model ensures that complimentary substitutions on the two DNA

strands have the same rate:

$$Q = \begin{bmatrix} \cdot & \alpha & \beta & \eta \\ \delta & \cdot & \varepsilon & \gamma \\ \gamma & \varepsilon & \cdot & \delta \\ \eta & \beta & \alpha & \cdot \end{bmatrix}$$

Because this model is not reversible, likelihood calculations are conducted on a rooted tree (note that reversible models can employ unrooted trees for likelihood calculations). This model was not intended for use in phylogeny reconstruction. Rather, given a tree topology, the model served as the basis for explicitly testing certain types of evolutionary strand asymmetry.

The model of Bielawski and Gold (2002) is a simplified case of the most general form of a DNA substitution model without the restriction of reversibility. This model has 11 free parameters in the substitution rate matrix, and was introduced by Yang (1994a). Yang (1994a) referred to this model simply as the unrestricted model:

$$Q = \begin{bmatrix} \cdot & \mu_{AC} & \mu_{AG} & \mu_{AT} \\ \mu_{CA} & \cdot & \mu_{CG} & \mu_{CT} \\ \mu_{GA} & \mu_{GC} & \cdot & \mu_{GT} \\ \mu_{TA} & \mu_{TC} & \mu_{TG} & \cdot \end{bmatrix}$$

As it is not reversible, likelihood calculations must be carried out on a rooted tree. This is because likelihood scores can be different for the different rooted trees that correspond to a single unrooted tree. The unrestricted model is itself a special case of the model of Barry and Hartigan (1987) that employs a general substitution rate matrix for every branch within a phylogenetic tree.

In the majority of cases, the parameter values for the above mechanistic models are derived from the sequence data under study. There has been some exploration of empirical DNA models, where values for parameters are derived from reference datasets (Lanave *et al.*, 1984; Zharkikh, 1994; Arvestad and Bruno, 1997). Such models are not widely used in phylogenetic analyses due to concerns about finding suitably informative reference datasets. Furthermore, for the purpose of estimating a phylogenetic tree, the biological reality that is sacrificed by the reversible forms of DNA models does not seem to have much of a negative impact. However, the nice mathematical properties of reversible models (Keilson, 1979) greatly aid the task of phylogeny reconstruction. For this reason, the vast majority of phylogenetic analyses employ mechanistic models for a reversible DNA process.

Models for Double-Strand RNA

There are many types of biologically active RNA molecules (e.g., mRNA, tRNA, and snRNA) which are transcribed according to a DNA sequence template. Phylogenetic trees can be inferred from these molecules for the purpose of inferring the evolution of the organisms that carry them, or the evolution of the different gene families that encode them. Although the DNA models described above could be applied to RNA-encoding genes, the results would be biased. The problem is that the RNA molecules are biologically active as a single-stranded molecule that folds into secondary and tertiary structures. Hydrogen bonding between complementary nucleotides stabilizes secondary structures known as stems, and the evolutionary process is biased in favor of substitutions that preserve this structure. Because DNA models treat character state changes independently, paired substitutions that preserve stability are inferred to occur much less frequently than they should for RNA-encoding DNA.

To avoid these biases, Markov models have been formulated for evolution between nucleotides at different sites that pair within stem structures. Rather than the four individual DNA nucleotides (A, C, G, and T), these models specify probabilities of change between Watson-Crick RNA pairs (A:U, U:A, C:G, and G:C) and the 'wobble' pairing G:U and U:G. Because pairing occurs between sites within an RNA molecule, uracil (U) is used instead of thymine (T). There are 16 unique pairwise configurations, but only the six shown above are stable enough to form secure interactions. For this reason, the models are often restricted to either six or seven states (Tillier, 1994; Tillier and Collins, 1995, 1998; Higgs, 2000). The seventh state, M:M, is introduced to accommodate the 10 remaining pairs of nucleotides that do not form stable interactions. The most general form of this seven-state model was introduced by Higgs (2000):

$$Q = \begin{bmatrix} & AU & GU & GC & UA & UG & CG & MM \\ AU & \cdot & \alpha_1\pi_{GU} & \alpha_2\pi_{GC} & \alpha_3\pi_{UA} & \alpha_4\pi_{UG} & \alpha_5\pi_{CG} & \alpha_6\pi_{MM} \\ GU & \alpha_1\pi_{AU} & \cdot & \alpha_7\pi_{GC} & \alpha_8\pi_{UA} & \alpha_9\pi_{UG} & \alpha_{10}\pi_{CG} & \alpha_{11}\pi_{MM} \\ GC & \alpha_2\pi_{AU} & \alpha_7\pi_{GU} & \cdot & \alpha_{12}\pi_{UA} & \alpha_{13}\pi_{UG} & \alpha_{14}\pi_{CG} & \alpha_{15}\pi_{MM} \\ UA & \alpha_3\pi_{AU} & \alpha_8\pi_{GU} & \alpha_{12}\pi_{GC} & \cdot & \alpha_{16}\pi_{UG} & \alpha_{17}\pi_{CG} & \alpha_{18}\pi_{MM} \\ UG & \alpha_4\pi_{AU} & \alpha_9\pi_{GU} & \alpha_{13}\pi_{GC} & \alpha_{16}\pi_{UA} & \cdot & \alpha_{19}\pi_{CG} & \alpha_{20}\pi_{MM} \\ GC & \alpha_5\pi_{AU} & \alpha_{10}\pi_{GU} & \alpha_{14}\pi_{GC} & \alpha_{17}\pi_{UA} & \alpha_{19}\pi_{UG} & \cdot & \alpha_{21}\pi_{MM} \\ MM & \alpha_6\pi_{AU} & \alpha_{11}\pi_{GU} & \alpha_{15}\pi_{GC} & \alpha_{18}\pi_{UA} & \alpha_{20}\pi_{UG} & \alpha_{21}\pi_{CG} & \cdot \end{bmatrix}$$

The above matrix has been simplified according to various restrictions, such as base-pair reversal symmetry (e.g., Tillier and Collins, 1998) or restricting the number of exchangeability parameters (e.g., Tillier, 1994).

With 16 possible pairwise configurations, it is possible to construct a 16×16 rate matrix. In such a model, changes in state can proceed by all possible single- and double-nucleotide changes, regardless of stability. However, the most general form of this model would have 134 free parameters, making it impractical for maximum-likelihood-based inference. As with the six- and seven-state models, restrictions are used to simplify the rate matrix (Schöniger and Von Haeseler, 1994; Muse, 1995; Rzhetsky, 1995; Savill *et al.*, 2001).

Models for Protein Coding Sequences

Amino acid models are useful when phylogenetic signal is lost due to saturation of nucleotide substitutions. This modeling task represents a straightforward extension of Markov chain techniques to describe substitutions between the 20 different amino acids. The most simple Markov model for amino acids is reminiscent of the Jukes and Cantor (1969) model, as it is a symmetrical model having a single rate for all changes among the 20 amino acids (i.e., $\mu_{ij} = \alpha$). This model was first applied to phylogenetics of three species by Neyman (1971), and extended by Adachi and Hasegawa (1996) such that the substitution rate was proportional to the frequency of the target

amino acid (i.e., $\mu_{ij}=\alpha\pi_j$, where π_j is the frequency of amino acid j). These models are not often used in modern phylogenetic analyses, as they are considered too simplistic.

There is wide agreement that modeling replacement rates between different amino acids is critical to phylogenetic inference from amino acid data. Recall that these rates are determined by the off-diagonal values of a Q matrix, and they can be expressed as the product of an exchangeability parameter and a steady-state frequency ($\mu_{ij}=s_{ij}\pi_j$). Thus a 20×20 amino acid Q matrix will have 189 exchangeabilities (s_{ij}), and these will be difficult to reliably estimate from a single gene dataset. For this reason, amino acid models in phylogenetics typically employ a matrix of 189 s_{ij} values previously estimated from a large database of proteins. Such a model can be thought of as an extension of the nucleotide GTR model to amino acid data, where each of the s_{ij} parameter values is estimated from the database via maximum likelihood.

Two empirical exchangeability matrices (WAG: Whelan and Goldman, 2001, and LG: Le and Gascuel, 2008) have been very widely used in phylogenetics because they are intended for use with 'generalized' globular proteins. However, these matrices might not be suitable for other types of proteins (e.g., transmembrane or mitochondrial proteins) or domains of life (e.g., viruses). As mitochondrial encoded proteins have long been used for phylogenetic inference, the greatest choice of substitution matrices is available for these types of proteins. In addition to a very generalized matrix (mtZoa: Rota-Stabelli *et al.*, 2009), there are matrices tailored to specific lineages (e.g., mtREV20: Adachi and Hasegawa, 1996; mtMam: Yang *et al.*, 1998; mtArt: Abascal *et al.*, 2007; mtPAN: Carapelli *et al.*, 2007). Substitution matrices are also specifically available for viral proteins (e.g., HIV-B and HIV-W: Nickle *et al.*, 2007; FLU: Dang *et al.*, 2010). **Figure 1** illustrates differences among selected matrices.

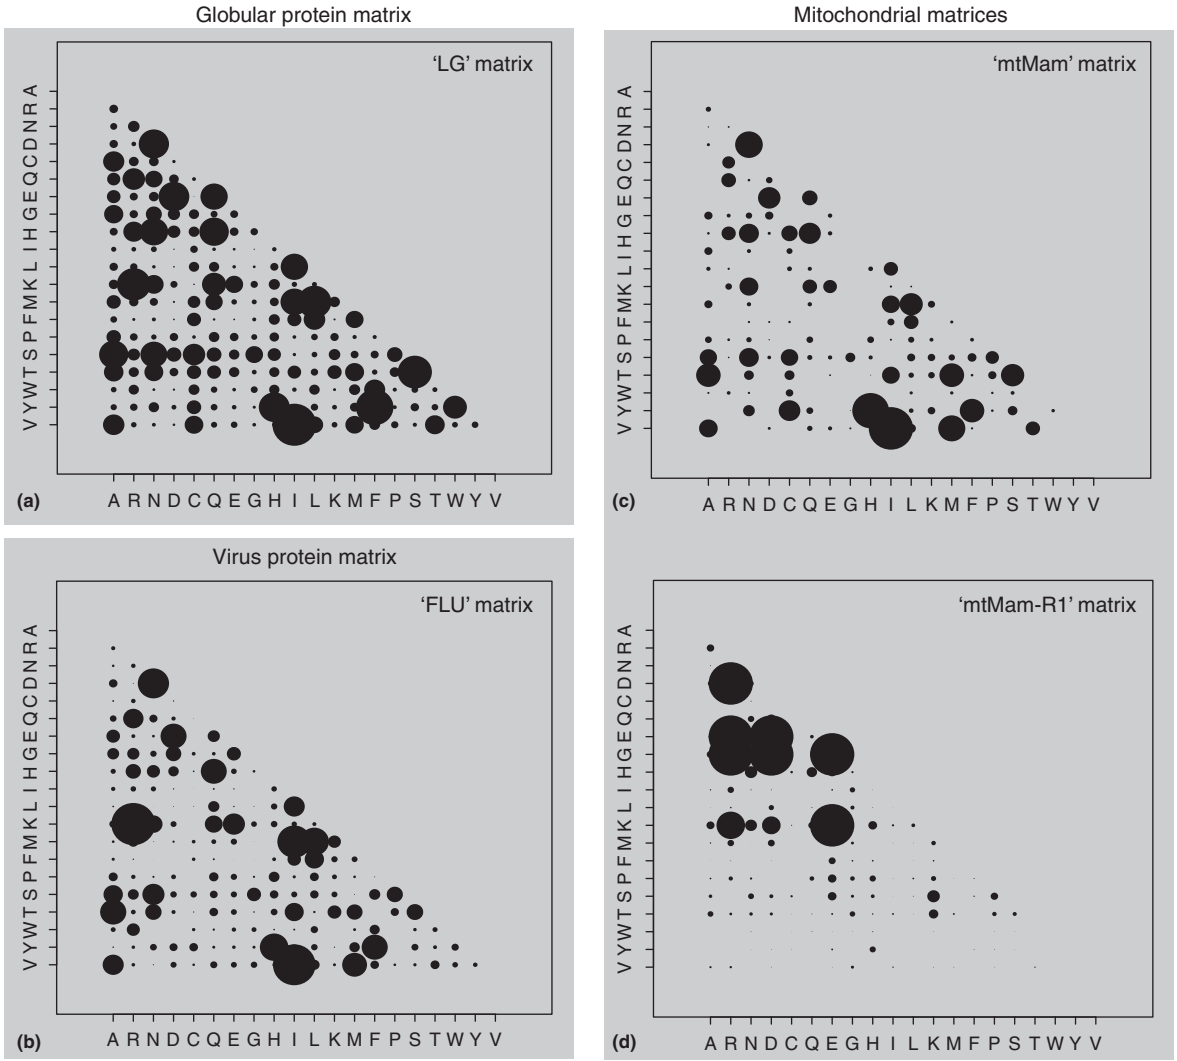

Figure 1 Examples of empirically estimated amino acid exchangeability matrices. The exchangeabilties are plotted as circles within a 20×20 matrix, where the diameter of the circle is proportional to parameter value. (a) The LG matrix for globular proteins. (b) The FLU matrix for viral proteins. (c) The generalized mtMam matrix for mitochondrially encoded proteins of mammals. (d) The mtMamR1 matrix for a specified subset of amino acid sites (1750 sites) with distinct physiochemical properties (bulky, hydrophobic, and amenable to alpha helices and beta structures).

In addition to exchangeability parameters, protein databases have been used to obtain a generalized set of steady-state amino acid frequencies (π_j). However, most researchers do not use them, preferring to set the π_j values in their model to the amino acid frequencies observed within their own data. This preference is likely because it is not computationally costly to obtain them from a single dataset.

It is possible to combine information about both the evolution of the DNA and the encoded protein in a model describing substitutions between triplets of nucleotides (codons). These codon models have the added benefit of accommodating the dependancies between adjacent DNA sites that are ignored by DNA models. The drawback is that the Q matrix grows to 61×61 (universal genetic code with stop codons removed), making these models much more computationally expensive to employ even though no new theory is required to carry out the probability calculations. The basic codon models were independently developed by Goldman and Yang (1994) and Muse and Gaut (1994). Although the rate matrix is very large (3721 elements), each substitution rate can be determined from the knowledge of just a few parameter values. For example, a simplified version of the Goldman and Yang (1994) codon model can be completely described by

$$q_{ij} = \begin{cases} \pi_j & \text{if synonymous transversion,} \\ \kappa\pi_j & \text{if synonymous transition,} \\ \omega\pi_j & \text{if nonsynonymous transversion,} \\ \omega\kappa\pi_j & \text{if nonsynonymous transition,} \\ 0 & \text{if codons differ by } >1 \text{ nucleotide,} \end{cases}$$

where κ is the DNA transition to transversion rate ratio, ω is the nonsynonymous to synonymous rate ratio and π_j is the steady-state frequency of the j^{th} codon. Many variants of the basic codon models have been proposed, and nearly all are used to study the process of codon evolution rather than infer a phylogenetic tree (reviewed in Anisimova and Kosiol, 2009). Because of the added benefits over amino acid models, they should also be desirable for phylogenetic analyses (e.g., Ren *et al.*, 2005; Miyazawa, 2013; Gil *et al.*, 2013). However, they have not yet been widely adopted because of their additional computational costs. Their use is likely to increase over time now that highly efficient implementations tailored for phylogenetic analyses are available in programs such as Garli (Zwickl, 2006) and CodonPhyML (Gil *et al.*, 2013).

Heterogeneous Evolutionary Dynamics and More Complex Models

The evolutionary models considered so far are defined in terms of a single substitution rate matrix. The problem is that real gene sequences typically evolve according to a process that differs among sites (e.g., membrane-bound versus non-membrane-bound sites of a transmembrane protein), and possibly over time (e.g., via lateral gene transfer events). Naive application of a constant rate matrix, no matter how sophisticated, to a heterogeneous substitution process can negatively impact biological inferences (Whelan, 2008). There are two broad approaches to modeling spatial and temporal heterogeneity. In the first approach, a priori biological knowledge is used to assign sites within a gene, or branches within a tree, to one of several discrete classes having different substitution parameter values. The heterogeneity among classes is referred to as a fixed effect because the relationship to the data (sites or branches) is fixed within the model. The second approach is used when suitable biological information is unavailable. Sequence heterogeneity is then modeled by using a statistical distribution, and this is referred to as a random effect within the model. Because biological knowledge is typically imperfect, the latter strategy is more common.

Site-wise heterogeneity in the substitution rate can be dramatic, and nearly all modern approaches to sequence analysis employ the gamma distribution to model rate variation. Although it is possible to use the continuous form of this distribution (Yang, 1993), it is computationally costly. A discretlized approximation of the gamma distribution works nearly as well, and is far more practical (Yang, 1994b; Waddell *et al.*, 1997). Note that the gamma distribution is used because it is convenient, and other strategies are possible. For example, Gu *et al.* (1995) proposed adding a simple parameter for the proportion of invariant sites, and Waddell *et al.* (1997) considered several alternative distributions. The underlying concept is that the rate at a site is modeled as a random draw from a statistical distribution so that rates do not have to be specified a priori on a site-by-site basis. Variation in other kinds of parameters can be modeled via this strategy (e.g., ω in codon models (Yang *et al.*, 2000)). Even the whole rate matrix, Q, can vary among sites as a random effect (e.g., Le *et al.*, 2008, 2012), or as a fixed effect (e.g., Dunn *et al.*, 2013), within a model.

The above models for spatial heterogeneity assume that the process is temporally homogeneous. Temporal heterogeneity can be accommodated by adding a second rate matrix to model the process of 'switching' between different evolutionary regimes over time (Wang *et al.*, 2007). The regime can represent binary states for the evolutionary process such as 'on' and 'off' (Tuffley and Steel, 1998), or alternative substitution rates (Galtier, 2001), or even alternative selective regimes modeled via the ω parameter of a codon model (Guindon *et al.*, 2004). These models are often referred to as 'covarion-like' because the Markovian 'switching' process is a computationally tractable approximation of Fitch and Markowitz's (1970) covarion model for coevolving sites. A very important difference is that the Markovian process of regime switching treats the evolution of the data at each site as independent of evolution at the other sites.

Model Selection

In phylogenetics it is often the case that some aspect of the results (topology, branch lengths, or measures of support) are sensitive to the assumed model. Thus, model selection is just as fundamental to modern phylogenetics as it is to other scientific disciplines (Posada and Crandall, 2001; Posada and Buckley, 2004). The task of model selection for phylogenetics is inherently statistical; the goal being to minimize different sources of statistical error by balancing the impact of using too complex a model against the impact of using too simple a model.

Bias and Variance

The process of model selection seeks to find a good balance between two different types of errors: bias and variance.

Variance is perhaps the more familiar type of error. In phylogenetics the goal is to predict the tree topology and branch lengths. Because there will be randomness in finite datasets, we expect a model to make somewhat different predictions for different samples of data. If we were to sample a gene, say, twice, and each time we sampled that gene from different species to represent the same lineages of interest (say, families), we would not be surprised to sometimes observe differences among tree topologies estimated under the same model. This is an example of variance, and it refers to the difference between results obtained under the same model when the modeling process is repeated multiple times.

Bias is less familiar because this type of error concerns how a model's mean result differs from the true values of the variables (which are typically unknown). When some aspect of the model is mis-specified, it will make some fundamental mistakes with the variability in the data. This leads to differences between the average of the predictions made by the model and the true value we want to predict; this is the error due to bias. Model bias is measured relative to the average prediction because model variance yields different predictions for different samples of data.

Figure 2 illustrates how both bias and variance contribute to the total error under a model. In this representation, the true value that we want to estimate is the center of the target, and each spot on the target is a result obtained under the same model when the modeling process is repeated multiple times. Minimizing model variance entails minimizing the spread of the results about the average result. If the model happens to be biased, this leads to estimates that consistently miss the target (Figure 2). Attempting to minimize bias, regardless of variance, might seem appealing because such a model could be thought of as being 'on average' correct. But this is also undesirable because the individual results can be as far, or farther, from the true value as they are under the biased model (Figure 2). Furthermore, in phylogenetics you need the model to be as good as it can be for the data in hand; you do not typically have data suitable for measuring a long run average. Thus both bias and variance must be managed when choosing a model for phylogenetics.

In general, increasing model complexity increases variance and decreases bias. Statistical methods of model selection attempt to manage both sources of error by trading off the negative effects of overly complex models (too high variance) against the negative effects of overly simple models (too high bias). Figure 2 illustrates how the contribution of variance and bias to the total error changes according to the complexity of the model. From Figure 2 we see that there is a level of model complexity that minimizes the total model error through a particular balance of variance and bias. A more complex model than this one is said to be 'over-fit' and a less complex model is said to be 'under-fit.'

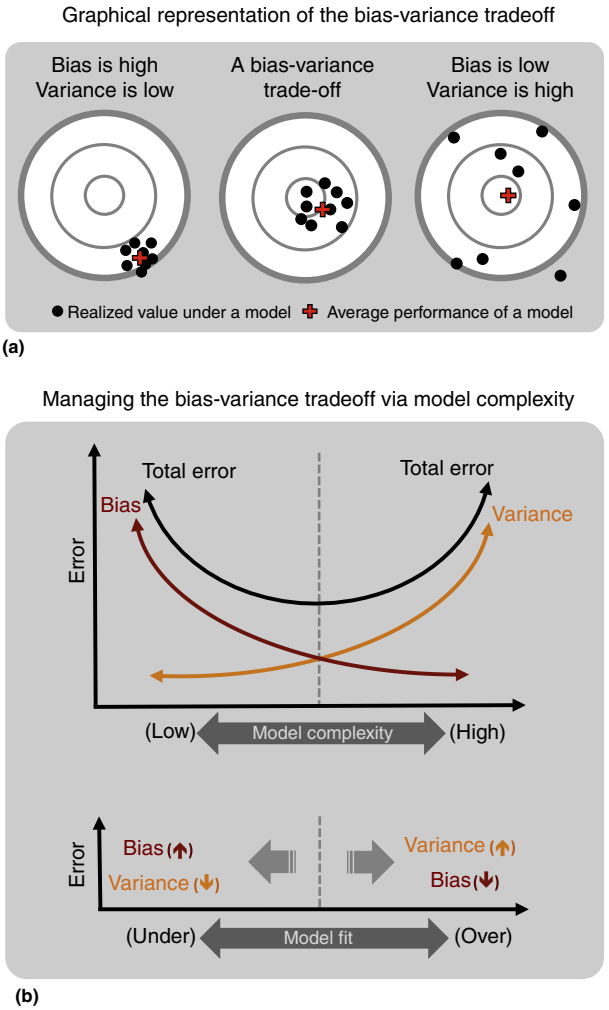

Figure 2 Model fitting as a means to manage the error due to bias and the error due to variance. (a) A graphical representation of the bias-variance trade-off. Here there are three 'targets,' each representing the predictions of a different model. A perfect model would make predictions that 'hit' the center of its target. Assuming that the modeling process can be repeated, the black dots represent individual realizations of the model, and the red plus sign represents the average performance of the model. The further the black dots are from the bulls-eye, the worse the predictions. (b) Managing the bias-variance trade-off via model complexity. Total error can be decomposed into bias and variance. Bias is the difference between the average predictions of the model and the 'target' value. Variance is the difference among the model predictions when the modeling process is repeated multiple times. Bias and variance depends on the complexity of the model. By managing the relationship between bias and variance, the total error associated with the model can be minimized. Relative to the point of minimal error, models that increase the total error by increasing variance are said to be over-fit, and models that increase the total error by increasing bias are said to be under-fit.

Testing Model Fit

In practice, there is no analytical solution for the level of model complexity that minimizes total model error. Thus, decisions about model complexity must be made according to how competing models fit the data in hand. The challenge is to use this information to choose a model that neither over-fits nor under-fits the data. This section presents three of the more widely used approaches (LRT, AIC, and BIC). Each compares competing models to determine if additional complexity yields a significant improvement in model fit. Lacking such an improvement, the simpler model is preferred. In this way, a

model can be selected that provides the best explanation of the data without over-fitting it.

The likelihood ratio test (LRT) is used to compare the fit of two models where one model (the null model, H_0) is a parametric simplification of the other model (the alternative model, H_1). As the pair of models are nested, this test focuses on how adding complexity to the null model improves model fit. The alternative model will always fit at least as well as the null, so the ratio of likelihoods is used to measure how much more likely the data would be under the alternative model. When certain regularity conditions are satisfied, two times the likelihood ratio serves as the basis of a formal statistical test. The test is typically applied to the logarithm of the ratio, defined as

$$2\delta l = 2\ln\left(\frac{\text{likelihood for } H_1}{\text{likelihood for } H_0}\right)$$

This statistic is approximately χ^2 distributed when the null is true, with degrees of freedom equal to the difference in the number parameters between the two models. Thus the significance of the improvement can be assessed according to the p-value of the observed likelihood ratio.

Several information theoretic approaches can be used to assess model error via the estimated loss of information associated with a candidate model. The most popular of these is the Akaike information criterion (AIC). The AIC score is defined as a function of the likelihood of the fitted model and the number of parameters in the model (k):

$$\text{AIC} = -2\ln(\text{likelihood}) + 2k$$

The second part serves to penalize the model fit according to its complexity. A different information theoretic approach is the Bayesian information criterion (BIC). It works in a similar way to AIC, but employs a stronger penalization for model complexity that depends on the sample size n (sequence length):

$$\text{BIC} = -2\ln(\text{likelihood}) + k \cdot \ln(n)$$

Under both AIC and BIC, models with a small score are preferred. A general guideline for avoiding over-fitting the data is to prefer simple models unless the difference in scores between competing models is greater than 2. Unlike the LRT, this approach does not require that the candidate models are nested.

Bayesian methods are now widely used alongside more traditional methods for phylogenetic inference. In a fully Bayesian setting, the relative fit of competing models is measured by a statistic called the Bayes factor, which is the ratio of the posterior odds of the two models to their prior odds. The Bayes factor is attractive to Bayesians because it permits use of the preferred prior for each model. When the two models (denoted M_1 and M_2) are believed to be equally probable a priori, the Bayes factor is approximated as the ratio of the marginal likelihoods under the competing models:

$$B_{12} = \frac{pr(D|M_1)}{pr(D|M_2)}$$

There are several interpretations of Bayes factors for model selection, but a widely used approach is to accept model M_1 when the Bayes factor is >1. Note that BIC is often viewed as a conservative approximation of the Bayes factor, and is thought to be reasonable for cases where there is little prior information. Model selection according to Bayes factors has advantages over the LRT in that it can be used for non-nested model comparisons and it can account for model uncertainty. Bayes factors can be challenging to compute and are only defined when the marginal probabilities densities under both models are proper.

Robustness

By trading off the negative effects of overly complex and overly simple models, the one that is chosen will not match reality in every detail. The model is necessarily simplified, and the researcher hopes that it has captured the features of the data that are most relevant to the inferences to be made. Implicit in this activity is the desire for a robust model; i.e., a model that has good performance under the small, and inevitable, departures from the model's assumptions. Although the robustness of the commonly used models for phylogenetic inference has been widely explored in the literature (e.g., Ripplinger and Sullivan, 2008, 2010), there will be many situations where it is prudent, and informative, for the researcher to further explore model robustness.

Glossary

Additive genetic correlation (r_A) A standardized measure of the additive genetic covariance (Cov_A) between a pair of traits in the population. r_A is calculated as $Cov_A/\sqrt{V_{A(X)} \cdot V_{A(Y)}}$ and is constrained to range between -1 and 1.

Additive genetic covariance (Cov_A) A measures of the degree to which two traits are influenced by the same genes (i.e., pleiotropy) or pairs of genes (linkage disequilibrium).

Additive genetic variance (V_A) Trait variation that is due to the additive effects of genes.

Artificial selection The process of selective breeding used to produce organisms (typically domesticated animals) with more desirable traits. It is also used as a tool by evolutionary genetics to understand the dynamics of trait evolution, such as demonstrating that a trait has genetic variation and determining if it is genetically correlated to other traits.

Correlated response (to selection) The evolutionary change in a given phenotypic trait that is not due to direct selection acting on that trait but due to selection acting on other genetically correlated traits.

Diagonalization It refers to the process of extracting the eigenvalues and eigenvectors of a symmetric matrix. Principal Component analysis is one of the most common methods of matrix diagonalization.

Principal component analysis It is one of the most common methods of matrix diagonalization.

Direct response (to selection) The evolutionary change in a given phenotypic trait that is due to selection directly targeting that trait. The direct response to selection depends on the strength of selection targeting that trait and its additive genetic variance.

Genetic architecture It refers to the pattern of genetic effects that underlie variation in a given phenotypic trait.

Heritability It refers to the proportion of the total phenotypic variance (V_P) that is due to genetic causes. Heritability can be estimated in either the broad sense or narrow sense. Narrow-sense heritability (denoted h^2) refers to the proportion of total V_P that is specifically due to additive genetic variance (V_A) and broad-sense heritability (denoted H^2) refers to proportion of total V_P that is due to all forms of genetic effect (V_G). Narrow-sense heritability is therefore estimated as V_A/V_P, whereas broad-sense heritability is estimated as V_G/V_P.

Linear selection gradient (β) A measure of the direct linear selection acting on a trait after removing the effects of indirect selection acting on other correlated traits being examined. β for a given trait is typically derived from a multiple regression analysis of the standardized measures of the traits being examined (where the standardize trait values (z) are determined as $z=x-\mu/\sigma$) against relative fitness. Depending on the sign, a significant β is predicted to either increase or decrease mean trait size.

Phenotypic variance (V_P) A measure of the variation present in a population for a given phenotypic trait.

Relative fitness (w) The fitness of an individual relative to the mean fitness of the population. w is typically calculated by dividing absolute fitness of an individual by the mean absolute fitness of the population.

Selection differential (S) A measure of the total phenotypic selection (both direct and indirect) acting on a trait. Under a regime of truncation selection, S can be estimated as the difference in the mean trait size of the selected individuals and the mean trait size of the entire population before selection.

Truncation selection The most common form of artificial selection where individuals subject to selection are ordered by the trait being selected and a proportion (p or $1-p$) is selected to reproduce and derive the next generation.

Vector A quantity or phenomenon that has both a magnitude and direction. In the case of $\Delta\bar{z}$ and β used in the multivariate breeder's equation, these vectors represent a single column with the number of rows equaling the number of traits being examined.

Evolution Is a Multivariate Process

Most traits of interest to evolutionary biologists, including behavior, morphology, life history, and physiology, are targeted by natural and/or sexual selection and their expression is controlled by the action of many genes (i.e., polygenic) (Falconer and Mackay, 1996; Lynch and Walsh, 1998). In the simplest sense, the evolutionary change in a trait can be predicted by the breeder's equation (Lush, 1937):

$$R = h^2 S$$

where R is the per generation *response to selection* of the trait being examined, h^2 represents the narrow-sense *heritability* of the trait, which encompasses the pattern of polygenic inheritance, and S represents the *selection differential*, which represents the covariance between the trait and *relative fitness*. Consequently, the breeder's equation measures the *direct response* of a given trait to selection and clearly illustrates the crucial point that R increases as either h^2 or S (or both) increases (Lush, 1937). While this fundamental equation has a long and successful history in predicting short-term evolution in a variety of agricultural and laboratory systems (e.g., Roff, 1997), this same

level of success does not appear to extend to natural populations (Morrissey *et al.*, 2010). It is therefore important to consider the underlying assumptions of this equation.

The breeder's equation assumes (1) that the trait being studied is not correlated with other traits that have a causal effect on *relative fitness* and (2) that the genes controlling variation in this trait are not associated with the genes that control variation in other traits. However, decades of quantitative genetic research has shown that selection rarely targets single traits but rather combinations of traits (Lande and Arnold, 1983) and that few traits are likely to be genetically independent (Falconer and Mackay, 1996; Lynch and Walsh, 1998). In quantitative genetics, the degree to which the genes for two traits are associated can be quantified by the sign and strength of the *additive genetic correlation* (r_A) between these traits. Values of r_A vary between -1 and 1 and the strength of the genetic association between traits increases (and therefore the degree of genetic independence decreases) with the absolute magnitude of r_A. Whenever traits are genetically correlated, the evolutionary response of a given trait will not only depend on the direct selection targeting this trait but also on the selection that targets any correlated traits. Therefore, just as the h^2 determines the magnitude of the direct response of a trait to a given strength of selection, r_A determines the magnitude and direction of an evolutionary response to a given level of selection on a correlated trait; a process referred to as a *correlated response to selection*. Genetic correlations between traits can therefore have dramatic effects on trait evolution, including altering the rate (e.g., Marchini *et al.*, 2014) and direction (e.g., Norry *et al.*, 2000) of evolution of a given trait and can even facilitate the evolution of this trait when it is not the direct target of selection (e.g., Hall *et al.*, 2004). Moreover, countless breeding experiments and analyses of natural pedigrees have shown that genetic correlations between traits appear commonplace (Roff, 1996) and *artificial selection* has also been used to demonstrate that these genetic correlations do indeed generate correlated responses to selection (Falconer and Mackay, 1996; Roff, 1997; Lynch and Walsh, 1998).

When selection operates on multiple, genetically correlated traits, a multivariate extension to the simple breeder's equation is needed to incorporate how these genetic associations between traits influences the response of a given trait to selection. This extension is known as the multivariate breeder's equation (Lande, 1979):

$$\Delta\bar{\mathbf{z}} = \boldsymbol{\beta}\mathbf{G}$$

where $\Delta\bar{\mathbf{z}}$ is the *vector* of mean trait responses over a single generation and $\boldsymbol{\beta}$ is vector of standardized *linear selection gradients* that directly targets each trait. **G** represents the additive genetic variance–covariance matrix that describes the *genetic architecture* of the traits being examined:

$$\mathbf{G} = \begin{bmatrix} Var_{1,1} & Cov_{1,2} & Cov_{1,3} \\ Cov_{1,2} & Var_{2,2} & Cov_{2,3} \\ Cov_{1,3} & Cov_{2,3} & Var_{3,3} \end{bmatrix}$$

G is described as a square matrix because it has an equal number of columns and rows, with one row and column for each trait being examined: the above example provides an illustration of **G** for three traits, represented by the numbers in subscript. The diagonal elements of **G**, in which both subscripts are the same, represent the *additive genetic variances* (V_A) of the traits (e.g., $Var_{1,1}$ equals the additive genetic variance in trait 1). The off-diagonal elements of **G**, with different subscripts, represent the *additive genetic covariances* (Cov_A) between pairs of traits (e.g., $Cov_{1,2}$ equals the additive genetic covariance between trait 1 and 2). **G** is also referred to as a symmetrical matrix because each genetic covariance occurs twice in the matrix: once above and once below the diagonal (since $Cov_{1,2} = Cov_{2,1}$, and therefore the same subscripts are used for both entries in the matrix). It is important to note that V_A and Cov_A are used in **G** and not estimates of h^2 and r_A. The reason for this is because scale matters when considering units of evolutionary change and estimates of h^2 and r_A are scaled in different units: h^2 is scaled by the phenotypic variance of the trait, whereas r_A is scaled by the square root of the sum of the additive genetic variances for the two traits (Falconer and Mackay, 1996; Lynch and Walsh, 1998).

The easiest way to understand how **G** influences both the direct and correlated responses to selection is to write out the individual equations for evolutionary change for the set of traits derived from the multivariate breeder's equation (i.e., the $\Delta\bar{z}$):

$$\begin{bmatrix} \Delta\bar{z}_1 \\ \Delta\bar{z}_2 \\ \Delta\bar{z}_3 \end{bmatrix} = \begin{bmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix} \begin{bmatrix} Var_{1,1} & Cov_{1,2} & Cov_{1,3} \\ Cov_{1,2} & Var_{2,2} & Cov_{2,3} \\ Cov_{1,3} & Cov_{2,3} & Var_{3,3} \end{bmatrix}$$

$$\Delta\bar{z}_1 = \beta_1 Var_{1,1} + \beta_2 Cov_{1,2} + \beta_3 Cov_{1,3}$$
$$\Delta\bar{z}_2 = \beta_1 Cov_{1,2} + \beta_2 Var_{2,2} + \beta_3 Cov_{2,3}$$
$$\Delta\bar{z}_3 = \beta_1 Cov_{1,3} + \beta_2 Cov_{2,3} + \beta_3 Var_{3,3}$$

where the terms in red capture the direct response to selection for each trait, whereas the terms in black capture the correlated response to selection. For example, the evolutionary response of trait 1 ($\Delta\bar{z}$) is the sum of direct selection (β_1) acting on the acting on the additive genetic variance in the trait ($Var_{1,1}$), noting that $\beta_1 Var_{1,1}$ (or $\beta_1 V_A$) is just an alternate form of the 'univariate' breeder's equation outlined above ($R = h^2 S$), and the correlated response to selection caused by the fact that trait 1 is genetically correlated with traits 2 and 3 (i.e., $Cov_{1,2}$ and $Cov_{1,3}$) that are also targeted by linear selection (β_2 and β_3).

Here we provide an overview of multivariate concepts in quantitative genetics, paying specific attention to the importance of **G** in directing phenotypic evolution. Although we appreciate the fundamental contribution of multivariate selection to the evolutionary process, we direct the reader to other articles in this encyclopedia for information on the topic and how linear and nonlinear selection gradients can be quantified in natural populations.

What Does G Tell Us about Evolution?

As **G** contains the raw ingredients for evolution (V_A and Cov_A), this matrix can be used to describe the potential of a population to evolve (i.e., evolvability) and the extent to which

genetic architecture restricts or limits the course of phenotypic evolution (i.e., genetic constraint, Arnold, 1992). However, as the number of phenotypic traits contained in **G** increases it becomes progressively more difficult to understand these processes by interpreting the individual elements of **G**: for n traits, there will be $n(n+1)/2$ individual elements contained in **G** to interpret. Consequently, matrix algebra and trigonometry is often useful in describing the geometry of **G** (Blows, 2007) and therefore in determining how **G** influences evolvability and genetic constraint in a population. A useful mathematical property of all symmetrical matrices is that they can be *diagonalized* to find a set of real eigenvalues and orthonormal eigenvectors. Each eigenvector of **G** represents a linear combination of the original traits (known as a dimension) and the set of eigenvectors collectively describes the genetic space encompassed by the original traits. Each eigenvalue represents the scale factor that describes the length of the associated eigenvector and in the case of **G** this represents the genetic variance in the original traits. These two properties of **G** form the basis of a diverse array of metrics that have been used to characterize evolvability and genetic constraint in a population (Blows and Hoffman, 2005; McGuigan, 2006; Hansen and Houle, 2008; Agrawal and Stinchcombe, 2009; Kirkpatrick, 2009; Walsh and Blows, 2009). Here we provide a brief overview of some of these commonly used metrics and use an empirical data set on three important life-history traits in male Indian meal moths to help illustrate the utility of these metrics. Our list is not exhaustive and we classify these metrics in two broad categories: metrics of evolvability and genetic constraint that are derived exclusively from **G** and those that incorporate information on both selection and **G**.

An Empirical Example

The Indian meal moth (*Plodia interpunctella*) is a cosmopolitan pest of stored food products. In a study examining the evolution of sexual dimorphism in life-history traits in *P. interpunctella*, Lewis *et al.* (2011) quantified multivariate selection acting on three important life-history traits (development time, lifespan, and body size) in the sexes, as well as **G** for these traits within and between the sexes using a half-sib breeding design. Here, we use the quantitative genetic data on males as an example and the vector of standardized linear selection gradients, $\boldsymbol{\beta}$ and $\Delta\bar{z}$ for these traits is presented in Table 1. Table 2 presents the eigenvectors and eigenvalues of **G** derived by matrix diagonalization. The dominant eigenvector (referred to as $\boldsymbol{g}_{\max}$, Schluter, 1996) explains 95% of the genetic variation in **G** and is positively loaded to development time and to a lesser degree body size. $\boldsymbol{g}_2$ explains the remaining 5% of the genetic variance in **G** and is negatively weighted to lifespan and body size and positively weighted to development time. The final eigenvector ($\boldsymbol{g}_3$) is positively loaded to body size and negatively loaded to lifespan and development time but does not explain any of the genetic variance in **G**.

Table 1 The standardized linear selection gradients ($\boldsymbol{\beta}$), the additive genetic variance–covariance matrix (**G**), and the predicted response to selection ($\Delta\bar{z}$) for development time (DT), lifespan (LS), and body size (BS) in male *Plodia interpunctella*

Traits	β	**G**			$\Delta\bar{z}$
		DT	*LS*	*BS*	
DT	−0.07	4.74	0.03	1.52	−0.27
LS	0.11	0.03	0.12	0.16	0.02
BS	0.05	1.52	0.16	0.66	−0.06

Evolvability and Genetic Constraint Based on Estimates of G

G will always contain as many dimensions as original traits and if each of these dimensions contains additive genetic variance, phenotypic traits will in theory be able to evolve in all regions of genetic space. However, if one or more of these dimensions have zero eigenvalues (as occurs if **G** is singular), then certain trait combinations will not contain additive genetic variance and therefore will not be evolutionary accessible in the population. Consequently, the rank of **G** (i.e., the number of nonzero eigenvalues) provides a useful measure of absolute genetic constraint (c) in the population (Table 3). The difficulty with this metric, however, lies in determining exactly how many dimensions of **G** have eigenvalues that differ significantly from zero, although bootstrapping (Mezey and Houle, 2005) or factor analytic modeling approaches (Kirkpatrick and Meyer, 2004) exist to test this directly. This latter approach provides statistical support for $\boldsymbol{g}_{\max}$ having an eigenvalue that is significantly greater than zero but not $\boldsymbol{g}_2$ or $\boldsymbol{g}_3$ for *P. interpunctella* (Table 2). This suggests that these lower two dimensions of **G** are unlikely to support evolution and therefore pose an absolute constraint.

The size of **G** can be quantified as the sum of the eigenvalues (known as the trace of **G**) and this value must equal the sum of the additive genetic variances of the original traits. Consequently, the trace of **G** provides a measure of the total amount of additive genetic variance (v_T) present in **G** and therefore an useful overall measure of the evolvability of a population: in theory, higher v_T will provide greater potential for the population to evolve (Table 3). The high V_A for development time and body size in male *P. interpunctella* (Table 1), which is substantially larger than in females due to sex linkage (Lewis *et al.*, 2011), results in a large v_T of 5.52

Table 2 Eigendecomposition (diagonalization) to extract the eigenvectors ($\boldsymbol{g}_{\max}$, $\boldsymbol{g}_2$, and $\boldsymbol{g}_3$) and eigenvalues of **G** provided in Table 1. The percentage of genetic variance explained by each eigenvector is also provided, as well as how each life-history trait contributes to these eigenvectors

Dimension	g_{max}	g_2	g_3
Eigenvalues	5.24	0.28	0.00
Variance explained (%)	95.00	5.00	0.00
Eigenvectors			
DT	0.95	0.25	−0.20
LS	0.02	−0.66	−0.75
BS	0.32	−0.71	0.63

Table 3 Some simple metrics measuring the evolvability and genetic constraint operating in a population that are based (A) exclusively on estimates of **G** and (B) on estimates of **G** and selection. We also provide values for each of these metrics based on the Plodia *interpunctella* data set provided in **Tables 1** and **2**

Metric	*Symbol*	*Formula*	*References*	*Value*
A. Based on G				
Absolute genetic constraint	c	$c=\lambda_i>0$	McGuigan (2006)	1
Total genetic variance	v_T	$v_T=\sum_{i=1}^{n}\lambda_i$	Kirkpatrick (2009)	5.52
Maximum evolvability	e_{max}	$e_{max}=\sqrt{\lambda_1}$	Kirkpatrick (2009)	2.29
Average evolvability	$\bar{e}$	$\bar{e}=\sum_{i=1}^{n}\lambda_i/n$	Hansen and Houle (2008)	1.84
Effective number of dimensions	n_D	$n_D=\sum_{i=1}^{n}\lambda_i/\lambda_1$	Kirkpatrick (2009)	1.05
B. Based on G and $\boldsymbol{\beta}$				
Angle between $\boldsymbol{\beta}$ and $\boldsymbol{g}_{max}$[a]	θ	$\theta=\cos^{-1}\left(\frac{\boldsymbol{\beta}\cdot\boldsymbol{g}_{max}}{\|\boldsymbol{\beta}\|\cdot\|\boldsymbol{g}_{max}\|}\right)$	Schluter (2009)	110.99°
Angle between $\boldsymbol{\beta}$ and $\Delta\bar{z}$[a]	θ	$\theta=\cos^{-1}\left(\frac{\boldsymbol{\beta}\cdot\Delta\bar{z}}{\|\boldsymbol{\beta}\|\cdot\|\Delta\bar{z}\|}\right)$	Walsh and Blows (2009)	61.54°
Rate of adaptation[b]	$\boldsymbol{R}$	$\boldsymbol{R}=\frac{\Delta W_c(\bar{z})}{\Delta W_i(\bar{z})}$	Agrawal and Stinchcombe (2009)	DT = 0.77 LS = 1.38 BS = −1.86
Respondability[b]	$r(\beta)$	$r(\boldsymbol{\beta})=\frac{\|\Delta\bar{z}\|}{\|\boldsymbol{\beta}\|}$	Hansen and Houle (2008)	DT = 3.86 LS = 0.18 BS = 1.20

[a] $\boldsymbol{\theta}$ is calculated in radians using the equations provided but can be converted to degrees by multiplying by $180/\Pi$.
[b] $\boldsymbol{R}$ and $r(\beta)$ are both measured on the specific life-history traits being examined: development time (DT), lifespan (LS), and body size (BS).
Note: In all formulas, λ refer to eigenvalues and n to the number of traits (or dimensions) in **G**.

(Table 3) and suggests that there is ample additive genetic variance for these life-history traits to evolve.

There are also a number of alternate ways of expressing evolvability and genetic constraint in a population that are based on how the additive genetic variation is distributed across the eigenvectors of **G**: the maximum evolvability (e_{max}), average evolvability ($\bar{e}$), and the effective number of dimensions (n_D) of **G**. In short, all three of these metrics describe how additive genetic variation is distributed across the eigenvectors of **G**. e_{max} is the square root of the eigenvalue of $\boldsymbol{g}_{max}$ and therefore describes the combination of traits in genetic space in which there is the maximum additive genetic variation for proportional change (Table 3). A value of 2.29 in *P. interpunctella* indicates substantial genetic variance is available in $\boldsymbol{g}_{max}$ to support phenotypic evolution (Table 3). $\bar{e}$ is the trace of **G** divided by the number of traits being examined and is therefore equivalent to the average trait additive genetic variance (Table 3). A value of 1.84 in *P. interpunctella* suggests a high average evolvability across dimensions of **G** but this finding should be interpreted with caution because $\bar{e}$ provides a weaker approximation of the average evolvability of the population when the number of dimensions is small and the eigenvalues are not of similar magnitude (Hansen and Houle, 2008). n_D is the sum of the eigenvalues divided by $\boldsymbol{g}_{max}$ and therefore a value close to one suggest that all genetic variation lies in a single dimension, whereas a value close to the total number of eigevectors suggests that genetic variation is distributed equally across dimensions (Table 3). A value of 1.05 indicates that most of the variation in **G** for male *P. interpunctella* is contained in $\boldsymbol{g}_{max}$: a pattern that is confirmed in Table 2.

Interestingly, a recent meta-analysis across plant and animal species found evidence that sexually selected traits evolved faster than life-history and morphological traits (Pitchers *et al.*, 2014). This pattern, however, was not related to differences in the strength of selection across these trait types or any of the above metrics evolvability and genetic constraint derived from published estimates of **G**. One interpretation of this finding is that these metrics of evolvability and genetic constraint do not, on average, limit phenotypic evolution. This should be viewed with caution; however, as few individual studies have information on the rate of evolution, selection, and **G** and therefore the ability to examine the interplay between parameters is limited.

Evolvability and Genetic Constraint Based on Estimates of G and Selection

As evolutionary change is the product of both selection and the genetic architecture of the traits subject to selection, arguably more information about evolvability and genetic constraint acting in a population will come from metrics that combine **G** with selection. This can be illustrated with a simple example. Consider the case in male *P. interpunctella* where only $\boldsymbol{g}_{max}$ has statistical support for an eigenvalue greater than zero. As we argue above, this provides evidence for an absolute genetic constraint on phenotypic evolution as there are regions in genetic space that cannot support evolution. But will this actually reduce evolvability and impose a genetic constraint on phenotypic evolution if selection is not targeting these particular trait combinations? This raises the more general issue of how well the direction of selection is aligned with the additive genetic (co)variance contained in **G** and whether this constrains phenotypic evolution. In theory, if the direction of selection and additive genetic (co)variance in **G** is poorly aligned, this could limit evolvability and represent a significant directional genetic constraint in the population (McGuigan, 2006). This issue was first raised by Schluter (1996) who showed that across a range of vertebrate species, the major

direction of divergence in phenotype was aligned with $\boldsymbol{g}_{\max}$ over an evolutionary timescale of at least 4 million years. Although this approach does not distinguish the observed phenotypic divergence to different evolutionary processes (i.e., drift and selection), it has stimulated the development of numerous methods to understand the importance of the alignment of **G** and selection to phenotypic evolution.

The simpler of these approaches, and the one used by Schluter (1996) to examine the alignment between the dominant eigenvector of the divergence matrix and $\boldsymbol{g}_{\max}$, is to use trigonometry to calculate the angle ($\boldsymbol{\theta}$) between two eigenvectors. Two different angles are useful when examining the interplay between **G** and selection: the angles between $\boldsymbol{\beta}$ and $\boldsymbol{g}_{\max}$ and between $\boldsymbol{\beta}$ and $\Delta\bar{z}$ (Table 3). The angle between $\boldsymbol{g}_{\max}$ and $\boldsymbol{\beta}$ measures the degree to which linear selection is aligned with the greatest amount of additive genetic variance in **G**. Therefore, an $\boldsymbol{\theta}$ approaching 0° indicates a strong alignment between these eigenvectors meaning that genetic constraint should be minimal, whereas an $\boldsymbol{\theta}$ approaching 180° indicates that these eigenvectors are poorly aligned and genetic constraint should be maximal. In the case of *P. interpunctella*, the large $\boldsymbol{\theta}$ of 110.99° suggests genetic constraint is likely to be important (Table 3). One limitation of this approach, however, is that it ignores the genetic variation present in the lower dimensions of **G** (Blows and Hoffman, 2005). While this is unlikely to be an issue in *P. interpunctella* because 95% of the additive genetic variance in **G** exists in $\boldsymbol{g}_{\max}$, this may not be the case in all species. In this regard, the angle between selection ($\boldsymbol{\beta}$) and the predicted evolutionary response to selection ($\Delta\bar{z}$) may provide a better estimate of genetic constraint in a population. While the interpretation of the magnitude of $\boldsymbol{\theta}$ between these eigenvectors is identical, the meaning is slightly different. As the estimation of $\Delta\bar{z}$ has been filtered through **G**, this angle measures the extent to which **G** biases predicted phenotypic evolution away from the direction favored by $\boldsymbol{\beta}$. Thus, a large $\boldsymbol{\theta}$ approaching 90° means that **G** is biasing the direction of phenotypic evolution, whereas as value of $\boldsymbol{\theta}$ that approaches 0° means that **G** is having little influence on the direction of phenotypic evolution. In *P. interpunctella*, $\boldsymbol{\theta}$ is 61.54° indicating that **G** is biasing the predicted evolution of life-history traits in this species (Table 3).

Another useful approach for examining the potential biasing effects of **G** on $\Delta\bar{z}$ is a metric known as the – rate of adaptation (***R***) (Table 3). ***R*** essentially compares $\Delta\bar{z}$ for a suite of traits when the genetic covariances in **G** have been set to zero ($\Delta W_l(\bar{z})$) versus when they are unaltered ($\Delta W_c(\bar{z})$). ***R*** is expressed as a ratio of these two parameters (Table 3), whereby if $\boldsymbol{R}=0.5$ for a given trait then the additive genetic covariance structure causes the fitness of the mean trait to increase by only 50% as quickly as expected if the trait was genetically independent. Alternatively if $\boldsymbol{R}=2$, then the additive genetic covariance structure accelerates evolution, such that the rate of adaptation occurs twice as fast as expected under genetic independence of traits. In *P. interpunctella*, the additive genetic covariance structure constrains the predicted evolution of development time. In the case of body size, the negative value of ***R*** occurs because of the difference in sign of $\Delta W_c(\bar{z})$ and $\Delta W_l(\bar{z})$ which is -0.062 and 0.033, respectively.

A final metric, known as the respondability ($r(\boldsymbol{\beta})$), measures the predicted evolutionary response of the population per unit of selection (Table 3). While $r(\beta)$ does not specifically measure evolvability along a given selection gradient, it does examine the potential for **G** to bias how rapidly a trait will respond when subject to directional selection (Hansen and Houle, 2008). Thus, large values of $r(\boldsymbol{\beta})$ indicates that the structure of **G** promotes evolutionary change, whereas small values indicates that **G** constrains such evolution. In the case of *P. interpunctella*, both development time and body size (largely owing to the larger V_A in these traits and reduced linear selection gradients, Table 1), whereas the reverse pattern in seen for lifespan (Table 3).

The Limitations Associated with Using G to Understand Multivariate Evolution

While the above examples provide a clear overview of why **G** is important in predicting phenotypic evolution, it is important to consider the limitations associated with using **G** in this manner. First, as is the case when examining multivariate selection operating on a suite of correlated traits, the utility of **G** in predicting phenotypic evolution is sensitive to the original traits contained in this matrix. Given the ubiquity of genetic covariance between traits and the large effects this can have on biasing evolution, it is tempting to include as many traits as possible in **G** and use matrix diagonalization to define 'new' composite traits (expressed as eigenvectors). It is important, however, to consider the biology of the traits being examined as there is the potential for this to obscure biological interpretation (Hunt *et al.*, 2007). That is, the 'new' traits described by the eigenvectors of **G** may not always have biological meaning. Thus, biological interpretation should always take precedence over statistical inference when determining which traits to include in **G** (Hunt *et al.*, 2007).

Second, the ability to predict phenotypic evolution using the multivariate breeder's equation is based on the assumption that **G** remains constant over evolutionary time. While this may be the case over one or a few generations, it is now widely accepted that **G** is unlikely to be stable over longer evolutionary timescales (Steppan *et al.*, 2002). The structure of **G** is ultimately determined by the frequency of alleles in the population and therefore any evolutionary process that alters allele frequency can also drive the evolution of **G**. While the effects of selection, drift, and mutation on the evolution of **G** have been examined mathematically (e.g., Jones *et al.*, 2003; Revell, 2007), we still know relatively little about the evolution of **G**. Until this is better understood, using **G** to predict evolutionary change will always face limitations.

Mutation and Genome Evolution

LY Yampolsky, East Tennessee State University, Johnson City, TN, USA

Glossary

Biased gene conversion Unequal rates of utilization of the two DNA strands as templates in heteroduplexes containing gaps or mismatches during homologous recombination and/or recombinational repair.
Copy number variation, CNV Variation reflecting chromosomal and segmental deletions and duplications.
CpG hotspot A 5′CG3′ dinucleotide often methylated (C→^{m}C) in many genomes. Because deamination, a common mechanism of transitions, results in a ^{m}C→T change, such mutations cannot, unlike deamination of Cs into Us, be repaired by base excision repair, resulting in an abnormally high rate of C→T transitions at CpG sites.
Ectopic or illegal crossing-over Crossing-over between short areas of homology located at nonhomologous chromosomal sites. A major source of chromosomal and segmental deletions, duplications, inversions, and translocations.
Indels Insertions and deletions collectively, in particular in situation when it is impossible to distinguish between a deletion in one lineage and insertion in the other.
Isochores More or less (often less) well defined regions of high or low CG content in vertebrate genomes.
Microsatellites or short tandem repeats Hypervariable sites in which a motif of 2–6 nucleotides is repeated 10–200 times.
Mutation A heritable change in genetic material.
Mutational bias Intrinsic systematic differences in frequencies of mutations of different types; cause by either chemistry of mutagenesis, or by biased gene conversion/asymmetries in DNA repair mechanisms.
Neutral mutations Mutations conveying no fitness differences to organisms that carry them. Invisible to selection; their frequencies change by genetic drift.
Segmental duplications Relatively long (1–100 kbp) tandem duplications observed in many genomes.
Transition Nucleotide substitution within a class of nucleotide (purin to purine/pyramidine to pyramidine); as opposed to transversion, nucleotide substitution across nucleotide classes (purin to pyramidine); typically transitions are more likely events than trnsversions.
Transposons or transposable elements Selfish genetic elements capable of copying themselves (and occasionally other genetic material) into new genomic locations. DNA transposons cut themselves from one location and paste into another; if such transposition occurs during DNA replication from an already replicated to a not yet replicated region it is accompanied by the increase in number of transposon's copies. RNA- or retrotransposons multiply by transcribing themselves into an RNA copy which is then reverse-transcribed and the resulting cDNA copy inserted into a new location.

Introduction

For much of the 100 years since the rediscovery of genetics and the introduction of the New Synthesis, the field developed under unique conditions of extreme shortage of data on chemical nature of heritable differences among organisms. It was clear from the theoretical standpoint that such heritable changes occur randomly, affect the germline, and are inherited in a discrete manner, but, perhaps with the exception of large-scale chromosomal rearrangements, no such changes could be directly observed. As the result, evolutionary genetics possessed a well-developed theory that predicted the fate of an individual heritable change in the population, but could not be made specific to describe particular types of changes or predict their abundance in the genomes. The amount of polymorphism present in the genomes of living organisms at any given moment of time was greatly underestimated and quantification of genomic differences among species was intractable. Everything changed with the discovery, largely in 1960s, of the mechanisms of spontaneous and induced mutagenesis and off, first, protein-level (allozyme) and, later, nucleotide sequence-level polymorphisms. DNA sequencing methodologies, developed in 1970s and perfected in 1990s, allowed a significant flow of sequence data to enter the field, greatly expanding our understanding of the nature of heritable variation in genes and genomes. These data were, in turn, dwarfed by the flood of sequences resulting from the next generation sequencing methods developed since the onset of the twenty-first century, with thousands of full genomes from hundreds of different species now available for the analysis. Today we can fully apply the classic population-genetics theory to explain genomes' nucleotide composition, variability, and architecture. This article reviews recent insights on how properties of mutagenesis shape the evolution of genomes.

Theoretical Considerations: Rate of Substitution and Stable Polymorphisms For Neutral and Harmful Mutations

A fundamental result of neutral theory of evolution (Kimura, 1983) is that mutations free of the effects of selection reach fixation at the same rate at which they are introduced into populations by mutagenesis. Indeed, if one compares a finite diploid population of size N at two sufficiently distant moments of time (sufficient for coalescence of all gene lineages), then any new allele created by a mutation at the earlier moment has the $1/(2N)$ probability to become fixed. There are

$2\mu N$ such alleles at this moment of time (where μ is the mutation rate per generation), thus that the rate at which new mutations become fixed is equal to μ. This is true for all mutations and for any mutation of a particular type, thus the rate at which neutral mutations of different molecular nature reach fixation reflects their mutational probabilities. For example, if deletions are more frequent than insertions of similar size and both are neutral, genomes will tend to become more compact; if substitutions to CG pairs are more frequent than substitutions from CG pairs, higher equilibrium CG content will be reached. While strictly speaking this is true only for neutral mutations, similar mutation biases exist also for mutations reaching fixation under positive selection, if selection is not too strong, and differences in mutation rates are large (Stoltzfus and Yampolsky, 2009). Therefore, properties of mutagenesis influence genome architecture in both neutrally evolving genomic regions and in regions under moderate positive selection. Conversely, any part of the genome in which either current state or inferred evolutionary dynamics of nucleotide composition or genome architecture drastically differ from what can be predicted from mutational pressures, can be hypothesized to experience strong positive selection.

The generation of new mutations affects not only rates of substitution but also the occurrence of polymorphic sites and allele frequency in them. There are at least two mechanisms through which mutagenesis can maintain stable polymorphisms: direct-reverse mutation balance and mutation-selection balance (Crow and Kimura, 1970). Direct-reverse mutation balance occurs between neutral mutations introduced by the mutagenesis process at roughly equal rates, with equilibrium allele frequency at a 2-allele locus being $q_{eq}=\mu/(\mu+\nu)$, where μ and ν are direct and reverse mutation rates (exactly equal rates resulting in the equilibrium frequency of 0.5). The rate approach to this equilibrium in large populations is equal to total mutation rate, i.e., is extremely slow. Mutation-selection balance occurs because stabilizing selection is inefficient in eliminating rare mutations, in particularly recessive ones. As the result deleterious alleles can persist in a population at a low frequency if constantly introduced by mutations. This equilibrium frequency of a harmful recessive allele is $q_{eq}=\sqrt{(\mu/s)}$, where μ is the mutation rate to a harmful allele and s is the selection coefficient against it. This frequency can be many orders of magnitude higher than mutation rate if selection is not too strong. For example, with $\mu=10^{-6}$ and $s=0.001$, the harmful allele will segregate at the easily detectable frequency of $q_{eq}=0.032$. For a harmful codominant allele with dominance coefficient h ($h=0.5$ corresponds to full codominance, $h=1$ to complete dominance) the equilibrium frequency at mutation-selection balance can be approximated as $q_{eq}\approx\mu/hs$. It is believed that many segregating sites in the human genome, both those with and without known clinical effects, are maintained in polymorphic state by mutation-selection balance (Olson, 2012). This is particularly true for sites with high mutation rates, such as microsatellite sites or CpG sites.

Genome Size Under Mutational Pressure

Genome size depends on differences in the rates at which deletions and insertions occur and on the efficiency of natural selection in promoting or eliminating such changes (Lynch, 2007). Small changes in genome size are probably of negligible significance in terms of energetic costs of replication, particularly in multicellular eukaryotes, in which genomes are large and metabolic costs of locomotion and development are many orders of magnitude higher than those of genome duplication. Similarly, while large genomes have higher mutational liability, even in noncoding areas, the disadvantage of a small further increase is likely to be insignificant. Thus, a large fraction of noncoding regions are likely to evolve neutrally with respect to insertions and deletions (**Figure 1**).

Three major types of mutations contribute to genome size: small indels (single nucleotides to few dozens of nucleotides), transposone activity, and segmental duplications. As these mechanisms can lead to opposing pressures on genome size, the size of the genome greatly depends on their relative occurrence rates. Small indels occur as the result of polymerase slippage during replication (in particular at short tandem repeat or microsatellite sites) and as the result of imprecise repair of double-strand breaks. It appears that in many genomes (*Drosophila melanogaster* and *Caenorhabditis elegans* genomes being well documented examples) deletions occur at a higher rate than insertions and are on average longer, resulting in compact genomes (**Table 1**; Petrov, 2002; Witherspoon and Robertson, 2003). Compact size of such genomes is often explained by the net losses of nucleotides in neutrally evolving genome segments. There are also documented cases of a significant mutational bias toward net gain of nucleotides, for example, in pseudogenes in rice (Noutsos *et al.*, 2005). Yet, it is difficult to imagine that mutational bias observed for small indels can overcome or significantly enhance much stronger bias toward insertions imposed on genomes by transposition and segmental duplications (see below).

Transposable elements, retrotransposons in particular, impose a significant mutational pressure toward potentially nonadaptive expansion of genome size (Cordaux and Batzer, 2009;

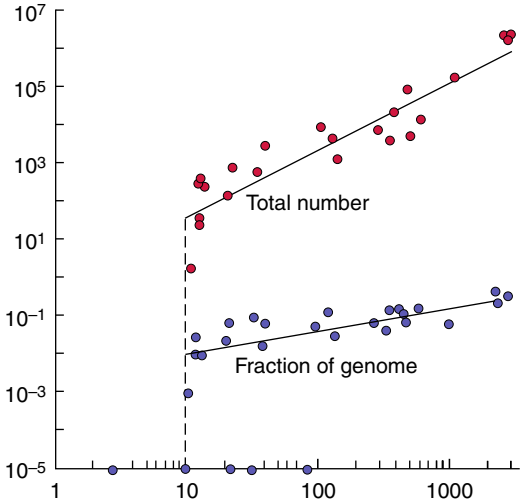

Figure 1 Number of transposons copies and fraction of genome made up by them vs. genome size (Mb) in a variety of organisms with fully sequenced genomes. Reproduced from Lynch, M., 2007. The Origins of Genome Architecture. Sunderland, MA: Sinauer Associates.

Table 1 Ratios between rates and average length of deletions and insertions in the worm, the fly, and mammalian (average of mouse, rat, and human) genomes

	Deletions: Insertions	
	Rates	*Average length*
Caenorhabditis	1.8	1.1
Drosophila	4.1	3.5
Mammals	1.9	0.8

Lee and Kim, 2014), often demonstrating a linear relationship between the number of transposon copies and genome size. In addition to potential energetic cost of replicating and, possibly, transcribing extra genetic material, proliferation of transposons increases mutational liability in at least three different ways. Firstly, extra genetic material, even fully neutral, implies higher risks of deleterious gain-of-function mutations. Secondly, higher copy number of functional transposons leads to a higher genome-wide transposition rate, resulting in a higher rate of loss-of-function mutations due to transposition into coding or regulatory regions. Finally, high transposon copy number increases the likelihood of ectopic crossing-over by providing numerous areas of homology at non-homological sites, resulting in higher rate of chromosomal aberrations, including segmental duplications (see below). Thus, the enormous mutational bias toward increased copy number (transposition rates can be as high as 10^{-5} per transposable element per generation) is likely to be counterbalanced by selection favoring curbing transposon activity and deletion of existing copies. It has been argued that enormous genomes of some fish and amphibians may be a result of inefficiency of such selection in small populations, resulting in a runaway growth of genome size (Sun *et al.*, 2012).

Finally, genome size and variability may be affected by the mutational pressure of chromosomal and segmental duplications and deletions. Because each ectopic crossing-over event occurring between repeated areas of homology within the same chromosome generates both a deletion and a duplication of the region between these homologous sites, one should expect that the dynamics of the resulting copy number variation will be governed by direct-reverse mutation and mutation-selection biases. Indeed, CNVs in the human genome are numerous, result from mutations that occur at a high genomic rate, and their frequencies are well described by the mutation-selection model (Itsara *et al.*, 2010). Although much duplication also has detrimental effects, generally speaking deletions should be under stronger stabilizing selection than duplications. This may lead to a run-away process of proliferation of segmental duplications, as each additional duplication increases the opportunities for ectopic crossing-over. It is not currently clear in what situations segmental duplications drastically increase size and number of genes in a genome, but such genomes are known. For example, the genome of *Daphnia*, a plankton crustacean, contains numerous segmental duplications with about half of the genes represented by multiple paralogous copies residing in such duplications (Colbourne *et al.*, 2011).

Variation at Microsatellite Sites

Microsatellite sites are defined as sites at which a short (206 pb) sequence of nucleotides is repeated a large and variable number of times, typically 10–200. (Compare to a different type of hypervariable tandem repeats site, minisatellites, in which repeats are longer, 10–150 bp, and which mutate largely though the ectopic crossing over mechanism described above). While not contributing significantly to genome size, microsatellites are ubiquitous and harbor a significant amount of variability in the number of repeats. This variability is expensively used for identification purposes and sometimes has medical significance.

Microsatellites' abnormally high rates of insertions and deletions are caused by the phenomenon of polymerase, or replication slippage. During DNA replication the template and the newly synthesized strands of DNA sometimes become separated. It probably can happen in any area of the genome, but in the regions of high sequence complexity this has no consequences, as there is only one way the two complementary strands can pair up again. However, in the areas of low complexity, such as runs of single nucleotides or at microsatellite sites, the two strands may pair up with a short loop formed on either one or the other (**Figure 2**). Looping on the new strand results in an insertion, while looping of the template strand results in a deletion of a whole number of repeats. Generally speaking both outcomes are approximately equally frequent, so one may expect to observe the direct-reverse mutation balance. Moreover, each newly created allele with a larger number of repeats is now capable of generating even longer alleles, so microsatellite sites often contain numerous alleles, and therefore extremely high heterozygosity (**Figure 3**).

The majority of microsatellite sites are located in noncoding regions of the genome, such as intergene spacers and introns. Such microsatellites are likely to be neutral unless they disrupt a regulatory site or a splicing signal. However, a number of microsatellite sites located within coding portions of genes are known to cause severe hereditary diseases in humans. Clearly a 3-mer microsatellite within a coding portion causes a run of a particular amino acid in the polypeptide chain encoded by the gene, while microsatellites with repeat length of n nucleotides, where n is not a multiple of 3 cause repeats of n amino acids in the polypeptide chain; copy number mutations at such sites cause frameshifts. Probably for this reason, the majority of microsatellite sites located within coding regions are 3-mers. Diseases caused by microsatellites in coding portions of genes have several features in common. Firstly, they are more likely than single nucleotide substitutions to be gain-of-function and therefore dominant mutations. For example, the normal allele of huntingtin gene in humans contains a microsatellite site with 25 or less repeats of CAG triplet (i.e., a run of glutamines in the polypeptide sequence that is 25 residuals or less). Mutant alleles with over 40 repeats result in an abnormal protein that is characterized by a gain of a toxic function: it has the ability to aggregate and accumulate in neurons where huntingtin is normally expressed, disrupting the neurons' functions, resulting in Huntington's disease, a dominant hereditary condition. This also probably explains why there are many neurodegenerative

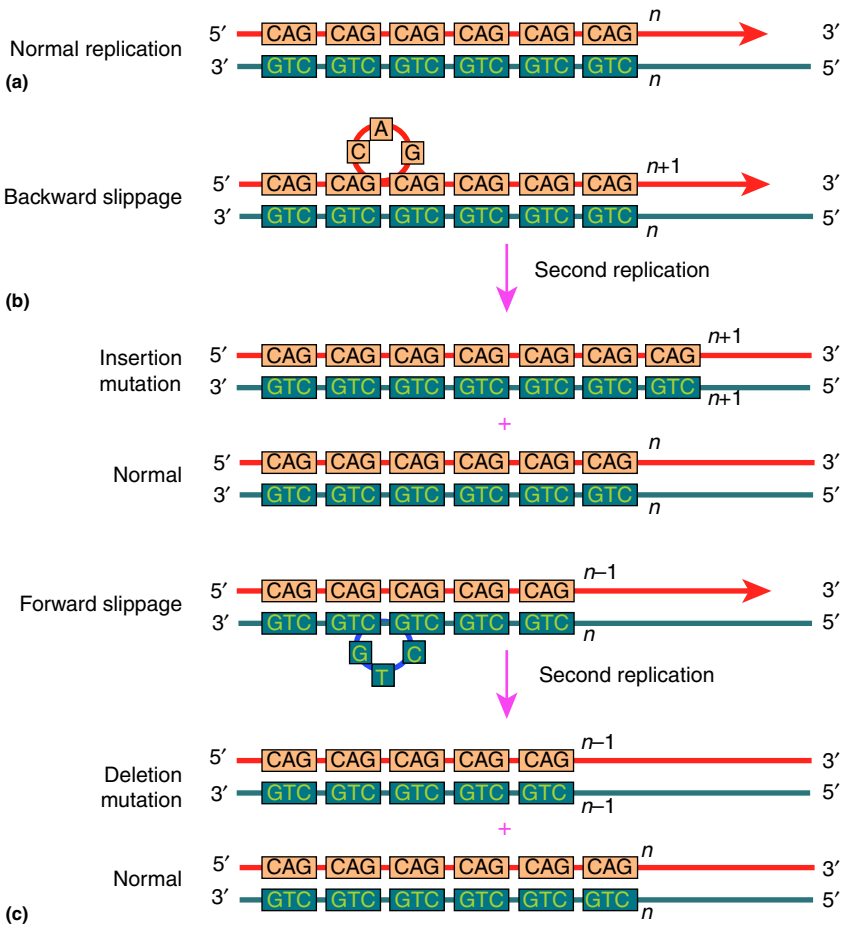

Figure 2 Polymerase slippage. Adapted from http://www.web-books.com/MoBio/.

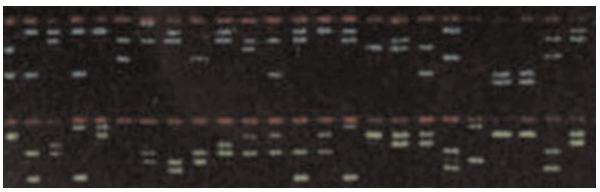

Figure 3 Multiplexed microsatellite gel showing variation at two microsatellite sites (amplified with different fluorescent dyes). Note that majority of individuals are heterozygotes for both loci. Adapted from http://125.218.212.107/fzswx/index.php?con=lesson&action=chapter&lcid=151.

conditions among microsatellite-caused diseases: neurons appear to be sensitive to gain-of-function mutations. Secondly, microsatellite-caused diseases often demonstrate different degrees of penetrance and the phenomenon of anticipation: the increase of penetrance and/or severity from one generation to the next. The reason for this is that (1) alleles with intermediate repeat number have a lower penetrance than alleles with high repeat number and (2) further mutations expanding already long alleles will generate alleles with increased severity or penetrance. This is typical for Huntington's disease as well as for fragile-X disease (a CGG repeat in gene responsible for normal functioning of synapses). Of course the bidirectional nature of microsatellite indel mutations will just as likely cause the decrease of the number of repeats from one generation to the next, but a decrease of penetrance and severity is much more difficult to detect (a mild allele becomes nearly normal and escapes clinical attention).

While the role of hypervariable microsatellite sites in shaping the spectrum of neurodegenerative hereditary diseases has been extensively studied, the degree to which they can serve as generators of adaptive variations is much less understood. Yet, some intriguing evidence exists that adaptive divergence among populations of grasses, behavioral changes in *Drosophila* and voles and skeletal changes in dogs during domestication are likely to have evolved by tapping into the endless pool of microsatellite mutations as the suppliers of raw material for adaptation (Kashi and King, 2006).

CG Content Across and Within Genomes

If all nucleotide substitutions occurred at the same rate, the equilibrium frequency of the 4 nucleotides in either DNA strand would have been 0.25 each, implying equal number of CG and AT pairs. This is almost never the case; CG content of whole genomes and parts of genomes deviate from this expectation widely. Recent findings in nucleotide composition

analysis indicate that CG content is determined by the interplay of mutational pressure, biased gene conversion, and, in some cases, selection. Mutational pressure typically favors CG→TA transitions over TA→CG ones (Hildebrand *et al.*, 2010; Hershberg and Petrov, 2010). This occurs because both C's and G's happen to be more liable to the two most common base-modifying mutagenesis processes than either A's or T's – deamination and oxidation. Deamination of cytosine results in a uracil, which will, in the next round of DNA replication, reliably pair up with an A instead of G. The product of oxidative conversion of guanines, 8-oxo-guanine (8oG) pairs up with T instead of a C. Thus, both processes lead to CG→AT transitions. Similar processes affecting A's and T's either are less likely to occur, or result in more promiscuous bases, meaning lower mutation probability per event, or result in bases that are easily removed by excision repair (such as hypoxanthine, the product of deamination of A's). Both U's and 8oG's present in DNA strands as the result of these processes can also be removed by base excision repair, eliminating the mutation. However, deamination of methylated cytosines results in a thymine base, which, as a base normally occurring in DNA, is invisible to excision repair mechanisms. As a result, methylation of cytosines in general, and in particular at CpG sites in animal genomes (see below), leads to even higher rate of CG→TA transitions (Krawczak *et al.*, 1998). The loss of CG pairs due to mutational pressure may also be a self-enhancing process. In particular, the deamination of C's is much more likely to occur in single-stranded DNA, and strand separation is more likely in AT-rich regions, because AT pairs are held together by two hydrogen bonds, not three, as CG pairs are (Fryxell and Zuckerkandl, 2000).

It is therefore not surprising that the rate of CG→TA transitions is universally 2–4 times higher than the rate of TA→CG transitions (Lynch, 2007, Table 6.1). Given these differences one could expect many genomes to be extremely CG-poor. This is not the case due to two other processes that oppose this mutational pressure: biased gene conversion and selection. Gene conversion occurs during crossing-over or double-strand break repair when a strand from one recombining homologous DNA is used as a template to build or repair the complementary strand from the other homologous DNA. If the choice of template strand in the recombinational heteroduplex was random, gene conversion would have been unbiased with respect to nucleotide composition. Yet, there is strong evidence that whenever G:T or C:A mismatches occur in a heteroduplex region, the strand containing G or C nucleotides is more frequently used as the template to repair the other strand, resulting in a bias favoring CG pairs over TA pairs. Relatively high CG content in animal and fungal genomes is almost certainly maintained by biased gene conversion opposing mutational pressure.

The role of selection in opposing the AT-favoring mutational pressure has been discussed in the context of CG-content differences among prokaryotes and CG-content heterogeneity within many eukaryotic genomes (isochores). In both cases selection in favor of DNA stability (i.e., higher CG content) in organisms inhabiting warmer environments or maintaining higher body temperature has been hypothesized. There is, however, little evidence for this effect either in prokaryotes (little if any correlation between temperature optimum and CG content) or for isochores in eukaryotic genomes (CG-heterogeneity is present in both homeotherm and poikiloterm vertebrates; it is difficult to see why some parts of genomes can be affected by thermostability more than others). Rather, it appears that the heterogeneity of CG content among prokaryotic genomes and within eukaryotic genomes is caused by the self-sustaining nature of mutational pressure: genomes or genomic regions with stochastically low CG content will tend to further lose CG pairs due to lower DNA stability.

Hypervariable CpG sites, which experience higher than average rate of transitions due to methylation of cytosines, are worse special attention. In animals, in particular in vertebrates CG→TA transitions are 10–20 times more likely at such sites than at non-CpG sites and constitute a disproportional share of variation within species (Krawczak *et al.*, 1998) and divergence among species (Nachman and Crowell, 2000). This results in a rapid loss of nonessential CpG dinucleotides in the genomes, suggesting that de-novo mutations at CpG sites are likely to be deleterious. Yet, recent evidence suggests that, at least in the context of adaptation to novel or extreme environments, CpG hypervariability may be a source of raw material for adaptive evolution (Galen *et al.*, 2015).

Replication and Mutation

We have already seen that transitions caused by base modification and mutations at hypervariable microsatellite sites occur during DNA replication. In fact, this is true about the majority of point mutations. Any mismatch of nucleotides caused by spontaneous or induced mutagenesis requires two rounds of DNA replication to become a permanent mutation affecting both DNA strands. Thus, non-replicating DNA (i.e., DNA in cells stalled in G1 or G2 phase of the cell cycle) will accumulate mismatches, which still retain the possibility of being repaired by DNA repair mechanisms, but few permanent mutations. There are several evolutionary consequences of this fact.

Firstly, because the two DNA strands spend different amount of time single-stranded during replication (lagging strand longer than the leading strand) and mutations frequently are initiated in the single-stranded state, the two strands should be expected to differ in the spectrum of mutations that occur in them, and thus in their nucleotide composition. Therefore, either strand on one side of the origin of replication should be expected to evolve the same nucleotide composition as the opposite strand on the other side of the origin. This phenomenon, known as strand asymmetry, is indeed observed, at least in prokaryotes (**Figure 2**). In contrast to CG-bias also mediated by single-strandedness (see above), strand asymmetry results, in most cases, not in excess of Cs and Gs over As and Ts, but in excess of Gs over Cs and Ts over As on the leading strand (Lobry and Sueoka, 2002; **Figure 4**).

Secondly, because most mutations occur during DNA replication, genomic mutation rate per generation strongly depends on the number of mitotic divisions from zygote to zygote. This has several consequences. Larger multicellular organisms have to deal with higher mutation rates, a problem exacerbated by the fact that larger organisms tend to have

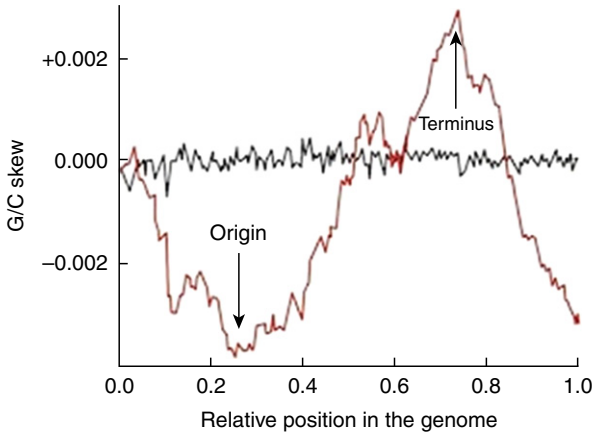

Figure 4 Local (black) and cumulative measure (red) of G/C skew on either side of the origin of replication in Mycoplasma pneumonia chromosome. Reproduced from Lynch, M., 2007. The Origins of Genome Architecture. Sunderland, MA: Sinauer Associates.

larger genomes (Lynch, 2006). Furthermore, in bisexual organisms with separate genders there is a universally higher number of mitotic divisions in males than in females, due to many orders of magnitude higher sperm production than egg production (Haldane, 1947; Miyata *et al.*, 1987). For example, in mammals there are about 15–30 mitoses in the female germ line, from an egg to an egg, but hundreds of mitoses in the male germ line. In a given species, this number is constant in the female germ line, but linearly increases with a male's age in the male germline, since spermatogenesis continues through a males' lifespan (Hurst and Ellegren, 1998). Thus, many more mutations initially occur in male than in female germ line and the number of new mutations increases with the paternal age (Kong *et al.* 2012; Campbell and Eichler, 2013).

Do Mutation Rates Evolve?

The entire above discussion assumes that mutation rates and biases are physical or chemical constraints that organisms have to deal with. However, much of the variation in these rates and biases is caused by details of complex enzymatic processes such as DNA polymerase fidelity, proofreading, and DNA repair rather than on extrinsic chemical constraints. Such processes can evolve and they do evolve. For example, one may hypothesize that the observed bias in rates of deletions versus insertions may be a result of selection favoring genotypes that are more efficient in streamlining genomes or that the degree of CG bias in gene conversion is the result of selection in favor of counterbalancing maladaptive effects of mutational pressure. Numerous theoretical and experimental studies show that mutator alleles that increase mutation rates (e.g., hypomorphs at genes responsible for DNA repair) are readily hitchhicked by positive selection in organisms with little or no recombination (Raynes and Sniegowski, 2014). However, it is difficult to demonstrate how hitchhiking of such mutator alleles with genome-wide effects can occur when recombination is frequent and when positive selection is moderate, because the cost of elevated mutation rates would be too high. Likewise, selection favoring extremely low mutation rate is both weak (and the lower the mutation rates are, the weaker this selection is) and limited by high costs of replication fidelity. On the other hand, gene-specific modulations of mutation rates and spectra have been described, at least in prokaryotes (Martincorena and Luscombe, 2012). Mechanisms of targeted hyper- and hypomutation include local changes in recombination rate and/or DNA repair activity, propensity of lagging strand to form secondary structures (thus reducing the mutation-prone singlestrandedness), and affinity of protective DNA-binding proteins. Targeted hypomutation can also be achieved by selection favoring removal of mutation-prone sequence elements such as microsatellites and CpG dinucleotides and of repeats facilitating ectopic crossing-over.

Mutation, Population Genetic Models of

JK Kelly, University of Kansas, Lawrence, KS, USA

Models of mutation long predate the discovery of DNA as the hereditary material. Still, the development of new models of mutation have often followed advances in molecular genetics. The field of genetics was initiated by Gregor Mendel and he focused on dichotomous traits. In the 1860s and 1870s, Mendel collected data on seven characteristics of the common garden pea. For each trait, he recognized two alternative forms and hypothesized a specific underlying 'factor' associated with each alternative (what we now call alleles). When variation is described in this way, a natural way to model mutation is given below, where A and a indicate alternative alleles, u is the mutation rate from A to a, and v is the reverse mutation rate (Hartl and Clark, 1989)

$$A \underset{v}{\overset{u}{\rightleftharpoons}} a$$

This very simple model was developed extensively by population geneticists to explore the balance of evolutionary forces. If p is the population frequency of the A allele and q is the frequency of a ($q=1-p$) and mutation is the only process at work, then the frequency of A in the next generation is given by

$$p' = (1-u)p + vq \qquad [1]$$

and the population approaches a stable equilibrium,

$$\hat{p} = \frac{v}{u+v} \qquad [2]$$

Equation [2] illustrates the simple idea that if mutation to one allele is most probable, that allele will be most common in the absence of other forces.

This very simple two-allele model remains in use today, despite knowing, at the molecular level, that more than two types are possible even in the simplest situations. For example, there are four alternatives at any location in a DNA sequence (nucleotides A, G, C, and T). The two-allele model remains useful, because it is routinely possible to group all the possible molecular variants into two functional classes, such as wild-type (A) and detrimental (a). The detrimental allele may actually be constituted of many distinct DNA-level alleles, but to a first approximation, we treat them as equivalent. The basic model of 'mutation-selection balance' posits mutation recurrently introduces the detrimental allele into the population. It reduces fitness of heterozygotes by hs and of homozygotes by s, where h gives the degree of dominance and s the selection coefficient. If a is wholly recessive ($h=0$), the equilibrium frequency of the deleterious allele q is:

$$\hat{q} \approx \sqrt{\frac{u}{s}} \qquad [3]$$

while if a is not completely recessive:

$$\hat{q} \approx \frac{u}{hs} \qquad [4]$$

The mutation rate for a to A (v) does not contribute to eqns [3]–[4], because the a allele remains rare (unless mutation rates are unrealistically large or selection is very weak). Equations [3]–[4] illustrate the important effect of recessivity in allowing deleterious alleles to persist. An important practical implication of eqn [3]: For rare, recessive genetic diseases, for every affected individual, there are likely to be thousands of unaffected 'carriers' of the deleterious allele.

Wright (1931) extended mutation-selection balance to consider the effect of genetic drift. Now, a single value for $\hat{q}$ is replaced by a distribution:

$$f[q] = Ce^{-4Ns}\, q^{4Nu-1}(1-q)^{4Nv-1} \qquad [5]$$

where C is a constant insuring that the integral $f[q]$ from 0 to 1 equals 1. Here, $f[q]$ is the density function for q at the statistical equilibrium between mutation, selection and drift. Equation [5] assumes additive gene action ($h=½$) and that the adult population consists of N diploid adults in each generation. Equation [5] yields a number of important insights (Crow and Kimura, 1970, Chapter 9) about the likely frequency of an allele depending on how strong selection is relative to drift and mutation. Most basically, it illustrates that the relative values of different evolutionary parameters, and not their absolute values, often determine predictions. Both the selection coefficient (s) and the mutation rates (u and v) only appear as a product with the population size (N). If $N=1000$ and $s=u=v=0.01$, we get the same distribution for q when $N=100\,000$ and $s=u=v=0.000\,1$. This feature is not specific to eqn [5]. In eqns [3]–[4], u always appears in a ratio of u/s.

The fact that parameters only occur in specific combinations (in compound parameters) has both positive and negative implications. On the positive side, it simplifies exploration of the parameters space of a model. The parameter space of eqn [5] is basically three dimensional despite that four constants appear in the formula, N, u, v, and s. The fact that the population size N invariably occurs in a product with mutation rates and selection coefficients is also practically important. It suggest that one might be able simulate evolution using a relatively small N, say 1000, and obtain results valid for much larger population sizes if one adjusts the other parameters so that Ns, $4Nu$, and $4Nv$ remain unchanged. This will not always work, but it has proven an effective approximations in many population genetic studies. A negative feature of having parameters occur only in combinations is statistical identifiability. If one measures a predicted statistic, say the number of polymorphic sites in a sample of gene sequences (see below), one cannot estimate a particular value for u. Many different values of u will fit the data equally well because many different values for u produce the same product for $4Nu$.

Despite the utility of the two allele model for studying evolutionary process, many situations require an explicit consideration that a genetic locus can have more than two

 doi:10.1016/B978-0-12-800049-6.00029-9

Figure 1 Motoo Kimura (1924–94) was a Japanese population geneticist who made many contributions to the theory of mutation.

alleles. From a modeling perspective, this is a straightforward generalization. We posit that there are K possible alleles at a locus and then specify the rate that each allele can mutate to every other allele. While simple in principle, this model can be cumbersome in that it is difficult to choose a reasonable value for K, and unless K is small, the number of mutation rates to be specified, $K(K-1)/2$, can be very large.

There are a large number of 'simplified' multi-allelic models of mutation in which the process can be specified with a tractable number of parameters. Perhaps the most elegant is the 'Infinite Alleles Model' of Kimura and Crow (1964). Motoo Kimura, pictured in **Figure 1**, made fundamental contributions to the theory of mutation throughout his career. The idea underpinning the Infinite Alleles Model is that mutation occurs at a constant rate u, but when it occurs, it invariably produces a novel allele. This is a sensible approach to many situations where the number of possible alleles is enormous (consider the number of unique permutations of A/G/C/T that are possible in a sequence of 100 nucleotides). The premise that all new alleles are different also makes some potentially difficult calculations quite simple. Consider heterozygosity in a population. For a selectively neutral locus in a closed population (no migration), heterozygosity is determined by a balance between mutation and genetic drift. Let F denote the probability that two randomly sampled alleles are the same in the current generation. In the next generation,

$$F' = (1-u)^2\left[\left(1-\frac{1}{2N}\right)F+\frac{1}{2N}\right] \qquad [6]$$

First term in brackets on the right hand side corresponds to event that distinct alleles are sampled from current generation (which were the same with probability F) while $1/2N$ is probability that same allele is sampled twice. Finally $(1-u)^2$ is the probability that neither allele mutates. After simplifying by assuming u and $1/2N$ are much less than 1, and noting that heterozygosity (H) is equal to $1-F$, we find the equilibrium heterozygosity:

$$\hat{H} = \frac{4Nu}{1+4Nu} \qquad [7]$$

The neutral theory of molecular evolution has been greatly elaborated over the last 45 years, but the Infinite Alleles Model provides a succinct route to one of its fundamental results. This is, the amount of genetic diversity within a population is determined by $4Nu$, a quantity often called θ in population genetics. This same product is also a primary ingredient in Wright's formula for the allele frequency distribution (eqn [5]), although the interpretation of u is a bit different between the two models.

Two basic difficulties emerge with the Infinite Alleles Model, at least when we are looking at DNA sequence data sampled from a population. The first is that we lose information by simply treating each sequence as a distinct allele. Some sequences are much more similar than others. In other words, we lose information about the haplotype or linkage disequilibrium structure among point mutations within a sequence. Also, if we treat the entire DNA sequence as the locus and each unique sequence as an allele, the process of recombination can generate new alleles. For a variety of reasons, we cannot easily absorb the recombination process into u.

The 'Infinite Sites Model' addresses these issues, while retaining simplicity. There is still a single mutation rate, but we are now thinking of this in terms of point mutations at a particular sequence location. The assumption (captured in the name) is that all new mutations occur at previously monomorphic sites. This model produces predictions for statistics more usually calculated for nucleotide sequence data, such as S (the number of polymorphic sites in a sample) and π (the average number of sites that differ between two sequences in the sample). At equilibrium of mutation/drift balance,

$$E[\pi] = 4Nu \qquad [8]$$

and

$$E[S] = 4Nu\sum_{i=1}^{n-1}\frac{1}{i} \qquad [9]$$

where n is the sample size (number of sequences), u is the overall mutation rate (product of per site mutation rate and the number of sites in the sequence), and E[*] is the expectation operator. Hudson (1993) reviews results employing the infinite sites model.

Equations [8]–[9] imply that different aspects of the data depend on the same quantity. This can be put to use. For example, if we take the observed average difference among sequence to estimate $4Nu$ from eqn [8], we can then predict how many sites should be polymorphic in the sample using eqn [9]. This prediction can be compared to the observed number of polymorphic sites as a way to evaluate the model, specifically the assumption that variation reflects mutation-drift balance. Of course, sampling variation must be properly accounted for (both evolutionary and experimental), but this is the basic idea behind the widely used neutrality test of Tajima (1989). Other neutrality tests share the same basic property: The mutation rate implies a relationship between different aspects of a dataset and the test asks whether the observed deviations from the predicted relationship are large enough to reject the model.

A number of other multi-allelic mutational models have been derived suitable to different data types. In some cases,

alternative alleles naturally form an ordered series. For example, microsatellite loci can vary in the number of times that a sequence motif (e.g., AAT) is repeated. Allozyme polymorphisms can be scored in sequential fashion based on how rapidly alleles migrate on a gel. The 'Stepwise Mutational Model' of Ohta and Kimura (1973) posits that mutations occur at a constant rate and involve the gain or loss of a single unit. This model has been extended in several ways, allowing gain and/or loss of multiple units in different ways. Regardless, analysis of the model reveals similarities with other mutational models, at least when variation reflects mutation/drift balance. In the Stepwise Mutation Model, the variance in allele length (number of repeats for a microsatellite locus) is proportional to the product of mutation rate and population size.

Multi-allelic mutational models are also used to study phenotypic evolution. The 'Continuum of Alleles Model' of Kimura (1965) is a good example. It shares features with the Infinite Alleles Model in that each new mutation is unique. However, the mutations are characterized by their effect on a quantitative trait. Quantitative traits are those where variation is due to both genetic and environmental effects, and the genetic component usually involves contributions from many loci. The Continuum of Alleles Model posits the effect of a new allele on the quantitative character is only slightly different from the parent allele from which it was derived. In this way, it is similar to the Stepwise Mutation Model. However, unlike the Stepwise Model, the amount by which new mutations differ from their progenitor is a continuous variable drawn from a probability distribution (or, more precisely, a density function). This revision owes to the fact that most quantitative traits exhibit a continuous distribution of values in the population.

The Continuum of Alleles Model has most usually been applied to a quantitative trait with a subsequent consideration of how that trait affects fitness. A final category of multi-allelic models makes this mapping more direct, attributing fitness effects directly to alleles. The Kondrashov (1985) 'mutational model' is a generalization of eqns [3]–[4], considering the mutation-selection dynamic distributed across the genome. At these many unlinked loci, deleterious mutations occur that reduce fitness by s in homozygotes and by hs in heterozygotes. The simplest version of the theory assumes that the population mates randomly and that the effects of different mutations combine multiplicatively to determine the fitness of an individual. However, the model has been extended to identify the important effects of non-multiplicative interactions between mutations ('epistasis') and of nonrandom mating ('inbreeding') on mutation-selection balance.

Mutualism, the Evolutionary Ecology of

DM Althoff and KA Segraves, Syracuse University, Syracuse, NY, USA

Glossary

By-product mutualism An association among species in which the resources exchanged are cost free to at least one partner and are produced as by-products of other organismal functions such as metabolism.
Cheater An exploiter species that evolved from a mutualistic one and no longer reciprocates with its partner.
Coevolution Reciprocal evolutionary change caused by an interaction among species.
Coevolutionary hotspot Populations where all interacting species are evolving in response to one another.
Connectedness In a community of interacting mutualists, connectedness is the proportion of the total possible interactions among species that are observed within an interaction network.
Cooperation The act of individuals working together for a common benefit. Mainly applied to interactions among individuals within the same species.
Defensive mutualism An interaction among partner species in which one partner defends the other in exchange for a place to live or for nutrients needed for growth and reproduction.
Dispersive mutualism An interaction among species in which one partner moves the gametes, offspring, or individuals of the other species and in return receives nutrients or resources needed for growth and reproduction.
Exploiter A species from outside a mutualistic interaction that takes the resources or services provided by mutualistic species without providing anything in return.
Geographic mosaic of coevolution The concept that most of the coevolution among species occurs at different rates in different populations with some populations being hotspots of coevolutionary change.
Host sanctions A mechanism by which a mutualist can reduce the trade of resources or services in response to a partner that is of inferior quality.
Nutritional mutualism An interaction among species in which partners exchange nutrients needed for growth and reproduction.
Partner choice A mechanism by which mutualistic partners preferentially interact with high-quality partners.
Partner fidelity feedback Mutualisms where the increase in fitness of one mutualistic partner causes an automatic increase in the other resulting in a positive feedback loop. This is usually only possible between individuals of different mutualist species that associate long enough to experience changes in fitness.

Introduction

Species interact with one another in myriad ways with the ultimate goal of obtaining resources or services needed for survival and reproduction. Many of these interactions are antagonistic in which one species gains a benefit but the other suffers a cost. Predators, herbivores, and parasites either kill their hosts for energy and nutrients or take some resources directly from their hosts. In contrast, there are interactions in which the species involved all gain reciprocal benefits. Van Beneden (1873) was the first to call these interactions mutualisms. For example, bees visiting a flower gain energy from nectar rewards while providing pollen exchange for the plant. Since the term was coined, we have come to realize that mutualisms are the foundation of most ecosystems (**Figure 1**). For instance, in terrestrial systems, plants interact with a variety of species that help in the procurement of nutrients, the dispersal of pollen and seeds, and defense against herbivores. In aquatic systems, coral and their symbiotic algae build the extensive reef ecosystems that harbor much of the ocean's biodiversity. Furthermore, mutualisms involve a taxonomically diverse set of species, occur in every environment, and occur among highly mobile free-living species as well as those that live on or within other species. For this reason, many additional terms have been synonymized with mutualism such as cooperation, facilitation, and symbiosis. Each of these terms can apply to mutualistic interactions, but not all mutualisms include cooperation or facilitation, and not all symbioses are mutualisms.

Mutualistic interactions are traditionally divided into three different types based on the resources or services that are traded between species. Nutritional mutualism involves interactions among species that are trading resources that are needed for growth and reproduction. A classic example is the trade of carbon and minerals between plants and mycorrhizal fungi. Plant roots form intimate associations with the hyphae of fungi that are very fine and can forage efficiently for phosphorus, nitrogen, and micronutrients in the soil (Courty *et al.*, 2010). The roots exude rich carbon compounds that are used as food by the fungi which in return provide the plant with scavenged water and minerals. Dispersive mutualism involves one partner species distributing gametes, offspring, or individuals of another species in return for a resource. The diversification of angiosperm plants is partly attributed to their mutualism with pollinating insects that act as directed pollen dispersal agents (Grimaldi, 1999). Likewise, plants also often trade food rewards with a diversity of mammals, birds, and insects that inadvertently disperse plant seeds. Lastly, defensive mutualism involves one species defending another in exchange for resources and/or a place to live. For example, ants protect acacia plants from herbivores such as elephants in exchange for nesting locations within the tree and packets of

Figure 1 Examples of mutualisms. (a) Eastern deciduous forest in central New York, USA highlighting young maple seedlings that will need to establish mutualistic interactions with ectomycorrhizal fungi. (d) A species of bombyliid fly nectaring on a flower in central Florida, USA.

proteins produced by specialized leaves (Goheen and Palmer, 2010).

Regardless of the type of mutualism, there are a variety of ecological and evolutionary factors that influence the formation and continued functioning of the interaction. As a consequence, research in mutualism is focused on answering at least four major questions (Bronstein *et al.*, 2006). The first is to understand how mutualism originates. Why do species in essence hitch their futures together by relying on one another for goods or services? The second major question is: How is mutualism maintained among species that are under constant selection to obtain resources from their partners while reducing the cost of reciprocating? Why don't the partners cheat and reduce their costs? The third major question is: Why are some mutualistic interactions very specialized and involve, in some cases, just a pair of species and in other cases involve several or even dozens of other species? Finally, given that mutualism is the foundation of many communities, how does the addition of other community members that interact with mutualist species influence the dynamics of mutualism?

The Origin of Mutualism

Many of the mutualisms we observe today are likely the product of a long-term process of adaptation among one or both mutualists (Frederickson, 2013). In considering the origin of mutualism, a poignant question to address is whether the interactions were mutualistic from the beginning or did they gradually transition into mutualism over time. If it is the former, what conditions favor this scenario? If it is the latter, how do some antagonistic interactions eventually change into mutualistic ones? Additionally, are traits important to mutualistic interactions co-opted from existing traits or must novel traits evolve *de novo*?

Determining the origin of mutualism is a difficult process, especially given that interaction outcomes can change depending on the environmental context. Addressing this question also requires combining information on the phylogenetic history of the species involved and the dynamics of the interaction and the traits important for the mutualism (Sachs *et al.*, 2014). Some of the best evidence for how mutualism originates comes from studies of yuccas (Asparagaceae: Agavoideae) and their pollinating moths. Moths in the family Prodoxidae are plant feeders in which the larvae feed internally on plant tissues, either in the leaves, flowering stalks, or within developing fruits (Davis, 1967). Phylogenetic analysis of the three closely related prodoxid genera that feed on yuccas, *Prodoxus*, *Parategeticula*, and *Tegeticula*, reveals an interesting progression of the overall interaction from antagonism to mutualism (**Figure 2**).

Prodoxus moths colonized yuccas as herbivores and diversified to feed within galls on the leaves, within the

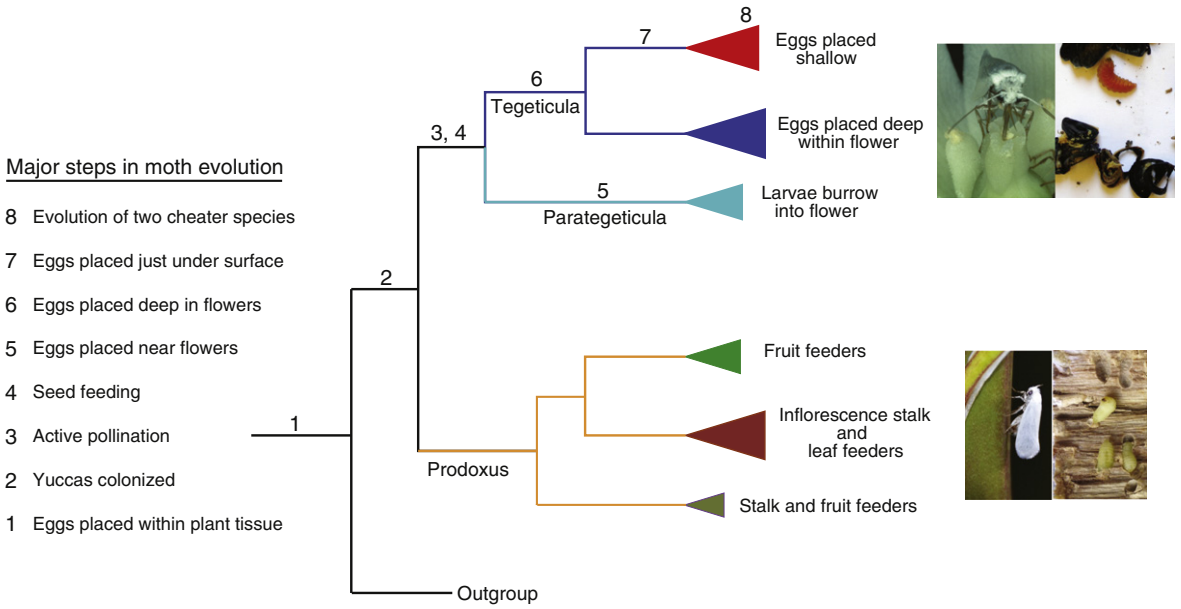

Figure 2 The evolutionary transitions between antagonism and mutualism in the yucca moth genera, *Prodoxus*, *Parategeticula*, and *Tegeticula*. Numbers along the branches correspond to major evolutionary changes in moth biology. Top right picture shows a female *Tegeticula* using the special 'tentacles' to actively deposit pollen into a yucca flower. Adjacent picture shows a larva and its feeding damage to the developing seeds. Bottom right picture shows a *Prodoxus* female laying eggs into a yucca flowering stalk. The larvae feed with the stalk and tunnel through the plant tissue.

flowering stalk, or within galls on developing fruit of yuccas (Pellmyr *et al.*, 2006). A female *Prodoxus* deposits her eggs into the plant tissue during the flowering season of her host plant species and the larvae develop internally, feeding on host plant tissue, but never on seeds. The interaction between *Prodoxus* and yuccas likely ranges from neutral to slightly antagonistic as larval feeding does not seem to impact plant reproductive success much (Althoff *et al.*, 2004). Like some *Prodoxus* species, *Parategeticula* moths also feed within galls on developing fruit, but unlike *Prodoxus*, the galls encompass a small portion of the developing yucca seeds that the larvae also consume (Powell, 1992). A *Parategeticula* female scrapes shallow pits into which she deposits her eggs in the flower pedicel or the small side branches holding the flowers. The larva then crawls to a flower and burrows into the base of the pistil to initiate a gall that replaces a few yucca seeds. Up to this point, the interaction would be considered antagonistic as moth larvae are killing potential plant offspring. However, the female *Parategeticula* also pollinates the flowers near where she deposits her eggs. This action increases the probability that the flowers will develop into fruit in which the larvae can feed and develop. To accomplish pollination, a female uses a completely novel trait – specialized mouthparts called tentacles – to collect yucca pollen into a ball that she carries beneath her head and to actively deposit some of the pollen into the stigmatic cavity of the yucca flower (Davis, 1967). Because a female moth transfers enough pollen to fertilize many more seeds than her offspring will eat, the net outcome for the plant is positive. The plant loses a small subset of its seeds to the moth larvae, but gains many more through active pollination by a highly specialized and efficient pollinator.

In *Parategeticula*, there has been a switch in the outcome of the interaction from antagonism, as in the case of *Prodoxus*, to mutualism in the case of *Parategeticula*. The only reason that the outcome of the interaction between yuccas and *Parategeticula* is considered a mutualism, however, is because the larvae only consume a small subset of the seeds in the yucca flower that their mother pollinated. The plant loses some seeds to the larvae, but experiences an overall positive fitness increase due to the pollination by the female moths. This overall interaction highlights a very important dynamic of mutualism – there is always some level of antagonism involved and it is the relative increases and decreases in fitness that determine whether we call an interaction an antagonism or a mutualism (Bronstein, 1994). If we just considered larval feeding, *Parategeticula* reduces yucca fitness much more than *Prodoxus* that do not feed on seeds. The evolution of active pollination, likely as a result of selection on female moths to increase their offsprings' survival, was the key event that shifted the outcome of the overall interaction. The effectiveness of active pollination by *Parategeticula* also likely selected for the loss of other pollinators of yuccas. Yucca flowers produce no nectar and there are no other known pollinators except for a single case of an introduced yucca in the United States, *Yucca aloifolia*, that is inadvertently pollinated by honeybees (Rentsch and Leebens-Mack, 2014). Thus, the interaction between moths and plants has become highly specialized and absolutely critical to the evolutionary success of both lineages.

Evolution within the moth genus *Tegeticula* further highlights the ongoing dynamic of antagonism within mutualism. This genus contains over 17 species of pollinator moths, but there has also been the evolution of at least two cheater species (Pellmyr, 1999). These cheater species no longer pollinate and accordingly have even lost the tentacles, yet the larvae still feed on yucca seeds. Like *Parategeticula* females, a female *Tegeticula* pollinates flowers but pierces through the locule wall and

deposits her eggs next to the developing plant ovules rather than in shallow pits outside of the flower. Egg and larval survivorship is likely increased because the eggs are protected inside of the flower. The tradeoff, however, is that the female's ovipositor damages some of the developing ovules. If there are many oviposition attempts on a single flower, the ovule damage triggers floral abscission and kills the eggs/larvae. Within *Tegeticula*, another lineage of moth species evolved probably in response to this floral abscission mechanism. In this second lineage, females lay their eggs superficially just under the style or pistil surface. This placement prevents ovule damage and potentially allows females to lay many eggs (Segraves, 2008). From within this superficially egg laying lineage arose the antagonistic cheater moths. There are two cheater species that lay eggs into early fruit or late fruit and do not pollinate. These species are capitalizing on the remaining seed resource that would not be eaten by the pollinator larvae. Thus, within the yucca moths, the interaction with yuccas has shifted from antagonism to mutualism and back to antagonism, even though all moths feed on yuccas.

The Maintenance of Mutualism

As evidenced by the evolution of cheater moth species in the yucca–yucca moth system, mutualism can be the target of exploitation, both from within mutualistic lineages and from without (Yu, 2001). Indeed, the prevention and mitigation of exploitation has played a significant role in directing empirical studies and in the development of mutualism theory. Two types of exploitation have been distinguished. The general term 'exploiter' refers to organisms that take the benefits of a mutualism without offering anything in return; thus, exploiters can be opportunists from the community or they can originate from the mutualism itself (Sachs and Simms, 2006). The term 'cheater' specifically refers to an exploiter that is evolutionarily derived from a mutualist lineage. Cheaters could be mutant mutualists that no longer provide a reward or, as in the case of yucca moths, they could be entirely different species that evolved from a mutualistic ancestor. The presence of exploitation in mutualism presents an evolutionary paradox. The reasoning is simple: because mutualisms generate resources that are often costly to make, individuals that can obtain these benefits without reciprocating will be favored by natural selection. Thus, exploiters of mutualism avoid the costs of participating in the interaction yet are able to obtain the benefits that enhance fitness. Natural selection, then, should favor exploitative individuals that maximize the benefits while reducing the costs, potentially leading to mutualism breakdown.

A long-standing question in the study of mutualism is to understand how mutualists prevent their partners or other organisms from overexploiting the benefits of the mutualism. Theoretical work has identified four general ways that mutualisms remain stable: by-product mutualisms, partner fidelity feedbacks, host sanctions, and partner choice. First, by-product mutualisms remain stable because one or both partners produce a cost-free by-product. The release of the by-product directly benefits the individual producing it, and as a consequence, there is no incentive for exploitation. For example, a bacterium might produce a waste product that is excreted into the environment. Once excreted, the by-product can be consumed by other bacterial species that require it. There are many examples of cross-feeding in microbes where partner species trade excreted products (Bull and Harcombe, 2009; Mee *et al.*, 2014).

Second, a similar mechanism that can stabilize mutualistic interactions is partner fidelity feedbacks. In this model, the resources being traded are costly; however, there is a direct link between the amount invested in the mutualism and the benefits received (Weyl *et al.*, 2010). That is, individuals that invest more in providing benefits to their partner will enhance the productivity of their partner and automatically receive more benefits in return. An example of a partner fidelity feedback is the interaction between plants and mycorrhizal fungi that live in plant roots. Plants that invest in carbon to roots infected with fungi increase growth of fungal hyphae that forage for nutrients in the soil. By doing so, the plants gain nutrients and can in turn grow and invest more carbon to fungi. The feedback continues with each partner receiving increased benefits as they trade resources.

A third regulatory mechanism that can prevent overexploitation by mutualist partners are host sanctions where one or both mutualist partners 'punish' partners that defect from the mutualism. A clear example of host sanctions is the mechanism by which yuccas use to regulate the number of pollinator moth eggs placed within flowers (Pellmyr and Huth, 1994). Some female yucca moths use their ovipositors to deposit eggs next to the developing seeds, and as they do so, they often damage the ovules and surrounding tissue. Yuccas selectively abscise flowers with large numbers of wounded ovules, killing all eggs/larvae within them (Marr and Pellmyr, 2003). As a result, yuccas can sanction female yucca moths that lay so many eggs that no seeds would survive.

Finally, partner choice mechanisms regulate mutualisms by allowing mutualists to choose among partners that vary in quality (Bull and Rice, 1991). Mutualists should associate more often with partners that provide the most benefits, thus reducing the costs of the interaction. The mutualism between cleaner wrasse and their ectoparasite-riddled fish hosts is an excellent example of partner choice. Host fish visit cleaning stations where cleaner wrasse feed on the ectoparasites; however, sometimes the cleaners also bite healthy host tissue. Repeated interactions between hosts and cleaners allow the hosts to selectively visit cleaners that remove ectoparasites without biting healthy tissue (Bshary and Schaffer, 2002).

Even with these mechanisms in place, exploitation is a common facet of mutualism. For example, cheater yucca moths do not pollinate, yet lay eggs into yucca fruit and their larvae feed on seeds. Many flowering plant species produce conspicuous flowers that contain a nectar reward that entices potential pollinators to visit the flower and inadvertently transfer and pick up pollen. Numerous pollinator species, however, will also sometimes cut through the base of the flower to rob the nectar (Irwin and Brody, 1998), or are not morphologically adapted to be good pollinators, so they feed on nectar without providing the pollen transfer service. Similarly, some frugivores (fruit feeders) are poor seed dispersers because the plant seeds are damaged or killed during passage through the digestive tract. Further empirical and theoretical

studies are needed to clarify whether the costs of exploitation are normally high or whether exploitation is more likely to have a minimal effect on a mutualistic interaction. The widespread prevalence of exploiters suggests that it might be the latter (Bronstein, 2001).

Mutualism, Specialization, and Coevolution

Another important facet of mutualism is that natural selection can favor the continued interaction of mutualists throughout time. Because of this, mutualists can end up being specialized through local adaptation to their partner(s). Hand in hand with this specialization, is the process of coevolution in which there is reciprocal evolutionary change among species. For example, the long nectar spurs of Madagascan orchids result in the extremely long proboscis of its hawkmoth pollinators (Arditti *et al.*, 2012). A similar pattern is observed among populations of the flowering scroph *Zaluzianskya microsiphon* (Scrophulariaceae) and its long-tongued fly pollinator *Prosoeca ganglbaueri* (Diptera: Nemestrinidae) in South Africa (Anderson and Johnson, 2007). In this example, the length of the floral tube for the plant is highly correlated with the length of proboscis of the fly across many different populations. Thus, specialization and coevolution can occur both within and among populations or across species in interacting lineages (Thompson, 1994). In particular, the geographic mosaic of coevolution championed by Thompson (2005) suggests much of the dynamics of specialization and coevolution occurs among populations within a species. *Greya politella*, another prodoxid moth, is a pollinating seed parasite of prairie stars, *Lithophragma parviflorum*, in the Inland Northwest of the western United States. Depending on the population, the interaction can be antagonistic or mutualistic, yet be a stable coevolutionary hotspot (Thompson and Cunningham, 2002).

Although specialization and coevolution are integral parts of mutualism, there are also many mutualisms in which mutualists are generalists and coevolutionary selection is likely weak (Waser *et al.*, 1996). Many pollination and fruit dispersal mutualisms involve plants that attract a wide variety of pollinators or dispersers. For example, saw palmetto populations that occur along the Lake Wales ridge in Florida attract hundreds of different species of floral visitors, many of which also carry pollen (Deyrup and Deyrup, 2012). A similar pattern has also been found in the mutualism between ectomycorrhizal fungi and trees in which fungal hyphal networks can involve many fungal species that connect to many different tree species (Courty *et al.*, 2010). A major approach to studying specialization and generalism in mutualism has been through examination of mutualistic species interaction networks. These studies describe the patterns of connectedness among mutualists within a community (Bascompte and Jordano, 2013). Interestingly, a repeated pattern of connectedness is found in many mutualistic communities – networks involving interactions of mutualists are nested and asymmetric in the sense that there are generalist mutualist species that interact with a subset of specialist mutualist species (Bascompte and Jordano, 2006). What remains to be tested is why such patterns of nestedness are prevalent, and why is it that some mutualists are specialists whereas others are generalists?

The Community Context of Mutualism

Irrespective of whether a particular mutualism is specialized or generalized, the biological reality is that all mutualisms are embedded in communities of interacting species. These species interact directly or indirectly with mutualists, and so may have the potential to influence the evolutionary ecology of the mutualism (Stanton, 2003). The study of mutualism is expanding to explore how not only other mutualist species but also how herbivores, natural enemies, and competitors of mutualists may shape both the dynamics and the evolution of mutualistic traits (Afkhami *et al.*, 2014). As mentioned earlier, the mutualism between yucca moth pollinators and yuccas is highly specialized, yet both moth and plant species have to contend with other visitors that feed on the flowers of yuccas. The inflorescences of *Yucca filamentosa* populations in the southeastern United States attract the pollinator moth *Tegeticula cassandra* as well as large numbers of the pollen-feeding beetle *Hymenorus densus* and the plant fluid feeding leaf-footed bug *Leptoglossus phyllopus* (Althoff *et al.*, 2013). Feeding by these two species can cause severe damage to yucca flowers and cause them to abscise from the plant. Thus, pollinator moths have to contend with additional egg and larval mortality that may influence the pattern of egg deposition both within a single plant and across many different plants. Furthermore, the effect of the beetle *H. densus* is even more pronounced on the pollinator moths because adult beetles inadvertently feed on pollinator moth eggs that are laid just below the style surface (Segraves, 2008). The beetles could potentially act as indirect mutualists of the plants by limiting the number of moth eggs and reducing the number of seeds eaten.

Mutualisms can also attract a large number of other species that can exploit the resources produced. This is particularly prominent in the mutualism between figs and their pollinating wasps. The fig is in essence an inflorescence that has been turned inside out and is pollinated by specialist agaonid wasps that must crawl through a narrow channel to reach the minute flowers within the fig inflorescence (Weiblen, 2002). As with yucca moths, the female wasp lays eggs into the flowers and then active pollinates each flower. The developing fig contains both mature seeds and pollinator larvae that can be used as resources by other species (Herre *et al.*, 2008). Indeed, in some localities in Australia, there are at least 12 other closely and distantly related wasp species that come to figs to attack the seeds, attack the wasp larvae, or a combination of both (Segar *et al.*, 2014). The presence of these additional community members might be one reason that female pollinator wasps only lay eggs in certain flowers within the fig (Al-Beidh *et al.*, 2012).

Addressing the role of additional community members on mutualism is a daunting task given that there are many different species that can potentially influence a mutualism. This work becomes further complicated by the fact that the effects of different species can be nonadditive and may prevent us from making predictions. In many cases, a single species can have both direct effects and indirect effects, and in other instances, the effect of one species might only be strong when in the presence of additional species. For example, in the defensive mutualism between ants and plants, ants can be very

beneficial by protecting plants from herbivores. Unintentionally, however, ants also deter pollinators from visiting the plants. Thus, when herbivores are rare, ant protection may shift from being very beneficial to less beneficial or even harmful to plants (Ohm and Miller, 2014). Many more studies are needed to examine the role of local community members on the dynamics of mutualism. Only then can we begin to understand and predict how different types of community members may change the ecology and evolution of a focal mutualism.

Synthesis

Mutualism has always attracted considerable attention because of the idea that species may help one another acquire resources or services. This is in part due to the fact that humans are highly cooperative in our day-to-day activities. Research on mutualism, however, is demonstrating that natural selection will always operate to increase the fitness of an organism. In terms of thinking about mutualism, this means that species will continue to interact with their partner species as long as there is a net fitness benefit. To achieve this, there will be evolution to decrease the costs of reciprocating and to increase exploitation. Because of this underlying tension, mutualism is a highly dynamic interaction in which there is likely to be continual evolution and coevolution among partner species. Sometimes this may lead to extreme specialization, but other times it might involve a suite of partner species. Adding to this dynamism is the fact that other community members may directly exploit resources or services provided by mutualists, thus adding to the costs of mutualism. What is perhaps most astonishing is that mutualism has persisted since life began and continues to be an important interaction for generating and maintaining biodiversity.

Mycorrhizal Fungi, Evolution and Diversification of

JD Lewis, Fordham University, Armonk, NY, USA

Glossary

Arbuscular mycorrhiza Mycorrhiza characterized by the formation of arbuscules, or tree-shaped structures, by the fungal hyphae after penetration of the cell wall of host plant root cells.

Arbutoid mycorrhiza Formed by members of the Arbutoideae, a subfamily within the Ericaceae, and representing one type of ectendomycorrhiza, as they exhibit morphological characteristics of both ecto- and endomycorrhiza.

Ascomycota Phylum of fungi characterized by the formation of the ascus, a reproductive structure in which haploid, nonmotile unicellular spores called ascospores are formed, and commonly called the sac fungi.

Basidiomycota Phylum of filamentous fungi that reproduce by the formation of basidia, reproductive structures that typically bear on their tips haploid, nonmotile unicellular spores called basidiospores.

Cavendishioid mycorrhiza Ectendomycorrhizal associations that include a mantle, Hartig net and intracellular growth of hyphae, originally described from *Cavendishia nobilis*, a species in the Ericaceae, and subsequently observed in other members of the Ericaceae.

Ectendomycorrhiza Mycorrhizal associations that exhibit morphological characteristics of both ecto- and endomycorrhiza, in that hyphae form a mantle around the root and may form a distinct Hartig net, while also growing intracellularly.

Ectomycorrhiza Mycorrhizal associations characterized by formation of a sheath of hyphae, called the mantle, on the exterior of the root, and formation of the Hartig net.

Endomycorrhiza Mycorrhizal associations characterized by hyphal penetration of the cell wall of root cells. Typically, the cytoplasms of the fungus and host are kept separate by the plasma membranes of each cell and the cell wall of the fungus.

Endophytic fungi Fungi that live symbiotically within plant cells and generally do not negatively affect plant growth, reproduction or fitness; most plants host endophytic fungi, and many endophytic fungi are beneficial to plants.

Ericaceae Plants in the heath family.

Ericoid mycorrhiza Formed by members of the Ericaceae and characterized by the formation of extensive hyphal coils in root cells.

Glomeromycota A phylum of fungi, the members of which typically form arbuscular mycorrhiza.

Hartig net A structure associated with ectomycorrhizal fungi, formed by a network of hyphae that grow around root cells but do not penetrate the cell wall of the host cells.

Mantle A sheath of hyphae formed by ectomycorrhizal fungi that may partially or completely cover the root surface.

Monotropoid mycorrhiza Mycorrhizal associations formed by members of the Monotropoideae, a subfamily within the Ericaceae. Morphologically similar to the arbutoid mycorrhiza in that they form mantles and Hartig net; however, rather than forming hyphal coils, they form fungal pegs, which cause indentations in the cell wall of host cells but do not penetrate the cell wall.

Mycoheterotrophic plants Plants that receive part or all of their carbohydrates from symbiotic fungi.

Orchid mycorrhiza Formed by members of the Orchidaceae, and characterized by the formation of pelotons.

Pelotons Distinct fungal coils formed by orchid mycorrhizal fungi in the space between root cell walls and plasma membranes of host orchids.

Pyroloid mycorrhiza Mycorrhiza formed by members of the Pyroloideae, a subfamily within the Ericaceae, and morphologically similar to, but distinct from, arbutoid mycorrhiza in the formation of a mantle, hyphal sheath, and intracellular hyphal growth.

Rhyniophytes Members of the class Rhyniopsida, a now-extinct class of plants that arose early in the evolution of plants, and have simple vascular tissue but lack leaves and true roots.

Overview

Mycorrhizal associations, symbiotic associations between fungi and plant roots, likely arose during the initial colonization of land by plants and are nearly ubiquitous in terrestrial habits, occurring in over 90% of plant families (Hibbett *et al.*, 2000; Malloch *et al.*, 1980). Mycorrhizal fungi are highly diverse and are a major contributor to fungal diversity (van der Heijden *et al.*, 2015). Although the mycorrhizal habit likely arose originally in the Glomeromycota, mycorrhizal symbioses arose independently many times within the Ascomycota and Basidiomycota (Hibbett *et al.*, 2014; James *et al.*, 2006; Kohler *et al.*, 2015; Schüßler *et al.*, 2001). Due to convergent evolution of symbioses that arose independently, most mycorrhiza are grouped into two broad types, endomycorrhizas and ectomycorrhizas (**Figure 1**), which reflect whether fungal hyphae penetrate the cell walls of host plant roots during formation of the association. Endomycorrhiza are further classified as arbuscular, ericoid, or orchid, based on the host plants and structural nature of the symbiosis found in each group. Additional types also have been described, including the arbutoid and monotropoid mycorrhiza (**Figure 1**), which form with plants of the Arbutoideae and Monotropoideae subfamilies, respectively, within the Ericaceae (heath family).

 doi:10.1016/B978-0-12-800049-6.00251-1

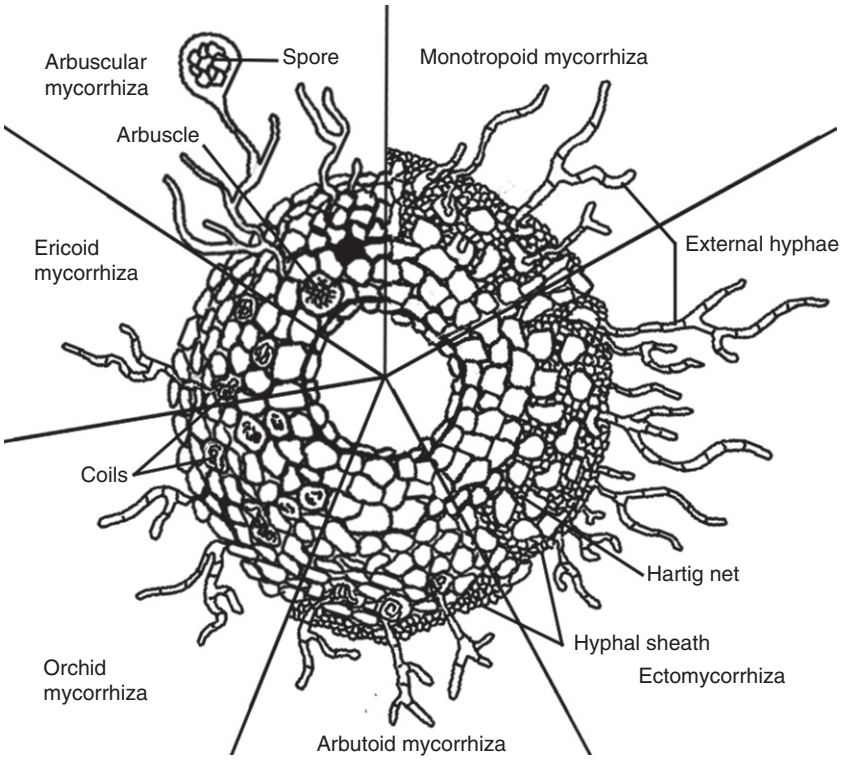

Figure 1 The primary structures of the arbuscular, arbutoid, ecto-, ericoid, monotropoid, and orchid mycorrhiza. Endomycorrhiza share similar structures and include arbuscular, ericoid, and orchid mycorrhiza. Ectendomycorrhiza share structural characteristics with both endo- and ectomycorrhiza, and include arbutoid and monotropoid mycorrhiza. Figure by Aidan Lewis.

As these categories suggest, host specialization is common in mycorrhizal fungi; yet, mycorrhizal fungal diversification patterns generally do not neatly follow plant diversification patterns (Allen *et al.*, 1995; Arnold *et al.*, 2010; Hibbett *et al.*, 2000). For example, although arbuscular mycorrhiza likely evolved first and are found on about 75% of plant species (Brundrett, 2009), only about 300 species of arbuscular mycorrhizal fungi are known (van der Heijden *et al.*, 2015), while there are an estimated 20 000 species of ectomycorrhizal fungal species, despite a limited range of plant host species (Rinaldi *et al.*, 2008; Tedersoo *et al.*, 2010; Allen *et al.*, 1995; van der Heijden *et al.*, 2015). Further, individual plants may simultaneously host many species of mycorrhizal fungi (Avolio *et al.*, 2009; Hibbett *et al.*, 2000; Lewis *et al.*, 2008; Wagg *et al.*, 2015), while individual fungi may form simultaneous associations with plants of different species (Hibbett *et al.*, 2000; Wagg *et al.*, 2015). And, even within a single fungal order, different fungal species may form ecto-, ericoid, and orchid mycorrhizal associations (Oberwinkler *et al.*, 2013). As a result, diversification of mycorrhizal fungi is thought to reflect evolution of the mycorrhizal form multiple times, generally from saprotrophic fungi, followed by convergent evolution both morphologically and physiologically (James *et al.*, 2006; Kohler *et al.*, 2015). Following is a more detailed discussion of the common patterns and key drivers of diversification across mycorrhizal fungi. Specific patterns within each of the major groups of mycorrhizal fungi are then described.

Common Patterns and Key Drivers of Diversification

Mycorrhizal associations generally provide the fungal symbionts with carbohydrates and certain biochemicals, while the plant host generally benefits from increased uptake of certain nutrients, and may receive other benefits, including increased water uptake and protection from pathogens. Fossil and molecular evidence suggest that mycorrhizal symbioses first arose about 460 million years ago between early plants and Glomeromycota, and played a critical role in the colonization of land by plants (Redecker *et al.*, 2013; Schüßler *et al.*, 2001; Selosse and Le Tacon, 1998; see also Desiro *et al.*, 2013). However, there is evidence the Glomeromycota arose earlier than this, and may have formed symbiotic associations with cyanobacteria (James *et al.*, 2006; Schüßler, 2002; Schüßler *et al.*, 2001). If so, the first mycorrhizal fungi may have arisen from fungi that formed mutualistic associations with cyanobacteria or algae, then subsequently formed associations with the earliest land plants (Schüßler *et al.*, 2001).

Although most extant land plants retain the ability to form mycorrhizal associations with Glomeromycota, many species have evolved the ability to form associations with Ascomycota or Basidiomycota. These associations, which most commonly form ectomycorrhiza, ericoid mycorrhiza, or orchid mycorrhiza, arose multiple times during the last 100 million years. Because mycorrhizal associations often fall on a mutualism–parasitism continuum, depending on the relative availabilities of soil nutrients and carbohydrate production, there has been

debate about whether mycorrhizal fungi arose from parasitic or saprotrophic fungi. Molecular evidence suggests ectomycorrhizal, ericoid mycorrhizal, and orchid mycorrhizal fungi typically evolved from saprotrophs (Hibbett *et al.*, 2000; James *et al.*, 2006; Kohler *et al.*, 2015), though there is some evidence that at least some of these fungi evolved from endophytic fungi (van der Heijden *et al.*, 2015).

A common pattern across these independent origins of the mycorrhizal habit is a suite of regulatory changes in the fungi in the form of reductions in decay mechanisms and induction of lineage-specific suites of genes associated with the formation of symbioses (Garcia *et al.*, 2015; Kohler *et al.*, 2015), coupled with the involvement of a set of genes in host plants that are associated with formation of mycorrhizal symbioses and that have been conserved since the early evolution of land plants (Wang *et al.*, 2010). Convergent evolution has also occurred morphologically, in that ectomycorrhizal, ericoid mycorrhizal, and orchid mycorrhizal fungi have distinguishing morphological characteristics that are shared across fungal species within each form, despite the multiple independent origins of fungal species that can form a given type of association.

Following initial evolution of the mycorrhizal habit within a particular lineage, coevolution with host plants is commonly seen. Coevolution between plants and mycorrhizal fungi is perhaps most obvious in mycoheterotrophic plants – plants that receive part or all of their carbohydrates from symbiotic fungi (Hynson *et al.*, 2015). While the general pattern is that mycorrhizal fungi receive carbohydrates from the host plant, most mycoheterotrophic plants have either partially or fully lost the ability to photosynthesize, and are either partially or fully reliant on fungal symbionts for carbohydrates, which, in turn, are obtained by the fungal symbionts from other plants or saprotrophically. Plants that are fully mycoheterotrophic typically are obligate hosts of mycorrhizal fungi, and many form species- or genotype-specific associations with mycorrhizal fungi.

The unique nature of this association and the close coevolutionary relationship between mycoheterotrophic plants and their mycorrhizal fungi has been long-recognized, and has been a model for examining plant–fungal coevolution in mycorrhizal associations. A key finding of this and related work is that although plants and fungal symbionts may coevolve closely, this pattern does not inherently lead to parallel cladograms (Arnold *et al.*, 2010). In fact, as with other mycorrhizal associations, mycoheterotrophic plants may simultaneously form associations with a suite of unrelated fungal species, and these fungi may simultaneously form associations with a suite of host plant species, including both mycoheterotrophic and autotrophic plants. More generally, the common pattern of individual plants hosting multiple fungi and individual fungi colonizing multiple plants often leads to a network of plants interconnected by mycorrhizal fungi, where carbohydrates from one plant may be indirectly transferred to other plants, including autotrophic plants, through the mycorrhizal network. This network may include different mycorrhizal forms, and may include plants that are normally autotrophic but that obtain carbohydrates from other plants via the mycorrhizal network during periods when the plants are heavily shaded or otherwise have carbohydrate demand exceeding supply.

In addition to the role of coevolution with plant hosts, diversification of mycorrhizal fungi also reflects the role of soil characteristics, as these are the key biotic and abiotic factors regulating resource availability for mycorrhizal fungi. As a result, diversification in the mycorrhizal fungi can be viewed as a result of niche partitioning following initial evolution of the mycorrhizal form. Diversification results from differences in the relative costs and benefits of the association among individual fungal species and genotypes within species driven by competition for carbohydrates from host plants and resources from the soil environment. However, although it is clear that both soil characteristics and host interactions play critical roles as drivers of fungal diversity, the relative roles of these factors, and other drivers of fungal diversity, including geographic isolation and drift, remain poorly understood. Ongoing research using molecular approaches to examine underlying evolutionary changes, coupled with research on ecological functions, promises to greatly enhance our understanding of the drivers of diversification in mycorrhizal fungi (Arnold *et al.*, 2010; Comas *et al.*, 2010; van der Heijden *et al.*, 2015). Recent research on specific patterns within each of the major groups of mycorrhizal fungi is described in the following sections.

Diversification of Arbuscular Mycorrhizal Fungi

Arbuscular mycorrhiza are characterized by the formation of arbuscules, or tree-shaped structures, by the fungal hyphae after penetration of the cell wall of host plant root cells. These arbuscules increase the surface area of the fungus–plant interface, increasing the efficiency of resource exchange. However, the fungus and plant cells typically do not exchange cytoplasm, which are kept separate by the plasma membranes and the fungal cell wall. As described above, phylogenetic analyses suggest the earliest arbuscular mycorrhizal fungi arose over 450 million years ago. Fossil evidence of arbuscular mycorrhizae extends back to the Rhyniophytes. Further, the rise of the arbuscular mycorrhizal form early in the evolution of land plants is reflected in the monophyletic evolution of arbuscular mycorrhizal fungi as a distinct phylum, the Glomeromycota (Schüßler *et al.*, 2001). The close association between the early evolution of arbuscular mycorrhizal fungi and plants, coupled with the radiation of plants to roughly 300 000 species, has led the arbuscular mycorrhizal association to be the most common mutualism formed by plants. However, despite the long evolutionary history of arbuscular mycorrhiza, and the concomitant diversification of plants, the diversity of arbuscular mycorrhizal fungal species is more than an order of magnitude lower compared with ectomycorrhizal and orchid mycorrhizal fungi.

Fossil evidence suggests that much of the extant diversity in arbuscular mycorrhizal fungi had already arisen over 400 million years ago, with limited speciation since then. The low species diversity of arbuscular mycorrhizal fungi despite their ancient origins and broad host range likely reflects at least in part a high degree of genetic diversity within fungal species coupled with low host specificity. Also, arbuscular mycorrhizal fungi host their own endosymbionts, mycoplasma-related endobacteria, which may play a critical role in the

maintenance of arbuscular mycorrhiza, and appear to have a high degree of genetic plasticity (Kuo, 2015; Naito *et al.*, 2015; Torres-Cortés *et al.*, 2015). Further, the Glomeromycota are asexual and have comparatively simple morphologies, making morphological distinctions difficult even among taxa identified as distinct based on molecular tools. As a result, molecular evidence is increasingly being used to assess the diversity and evolution of the Glomeromycota (Hart *et al.*, 2015; Krüger *et al.*, 2012; Redecker and Schüßler, 2014). Evidence from molecular analyses of field samples suggests that many species may not yet have been described, but careful assessment will be required in the further development of the classification of this phylum due to the unique challenges of identifying obligate symbionts (Redecker *et al.*, 2013).

Diversification of Orchid Mycorrhizal Fungi

In addition to the formation of pelotons, which are distinct fungal coils in the space between root cell walls and plasma membranes, orchid mycorrhizal associations differ from most other mycorrhizal associations in that orchids are mycoheterotrophic during germination and initial seedling growth, relying on mycorrhizal fungi as a carbohydrate source (Dearnaley *et al.*, 2012). Most orchids subsequently transition from mycoheterotrophy to autotrophy once the first leaves emerge and become photosynthetic, and, hence, they are mixotrophic. However, some orchids remain mycoheterotrophic throughout their life cycle. These parasitic plants typically acquire carbohydrates from fungi that are saprotrophic or form ectomycorrhizal associations with other plants. As a result, while many fungi only form associations with orchids, many ectomycorrhiza-forming fungi also form associations with orchids.

Orchid mycorrhizal fungi have been estimated to include about 25 000 species in the Ascomycota and Basidiomycota (Dearnaley *et al.*, 2012; van der Heijden *et al.*, 2015), forming associations with most orchid species, which represent about 10% of plant species (Brundrett, 2009). In contrast to the arbuscular mycorrhizal fungi, host specialization appears to have played a key role in the diversification of orchid mycorrhizal fungi. Closely related orchids often share specific combinations of mycorrhizal fungi, with some plant–fungal associations suggesting species- (Okayama *et al.*, 2012; Xing *et al.*, 2015), and even genotype-level (Taylor *et al.*, 2004; Okayama *et al.*, 2012), specificity. Despite this high degree of host specificity, recent phylogenetic analyses suggest orchid mycorrhizal fungi have independently arisen many times, typically from saprotrophic fungi and fungi that form ectomycorrhiza (Schüßler *et al.*, 2001), and there is evidence that some orchid mycorrhizal fungi may have evolved from arbutoid (Okayama *et al.*, 2012) and endophytic (Oberwinkler *et al.*, 2013) fungi. This pattern of high host specificity coupled with multiple independent origins suggests orchid mycorrhizal fungi may rapidly evolve host specificity, at least in some circumstances.

Diversification of Ericoid Mycorrhizal Fungi

Ericoid mycorrhizal fungi are characterized by the formation of distinctive hyphal coils within root cells during establishment of mycorrhizal associations with plants in the Ericaceae. Molecular evidence suggests ericoid mycorrhizae arose independently several times. In addition to arising from saprotrophic lineages, at least some ericoid mycorrhizal fungi apparently diversified from within clades of ectomycorrhizal fungi, and some may have arisen from endophytic fungi. As with orchid mycorrhizal fungi, host specialization appears to have played a key role in the evolution of ericoid mycorrhizal fungi, as these fungi are specific to this family. However, similar to ectomycorrhizal fungi, ericoid mycorrhizal fungi studied to date range greatly in host specialization, from narrow to very broad host ranges within the Ericaceae. In at least some cases, host specialization within the ericoid mycorrhizal fungi in the Ascomycota and Basidiomycota has led to the evolution of distinct mycorrhizal types, including the arbutoid and monotropoid, which are discussed below.

Diversification of Ectomycorrhizal Fungi

In contrast to the endomycorrhizal fungi, ectomycorrhizal fungi are characterized by lack of intracellular hyphae, coupled with the formation of a hyphal mantle on the root surface and a network of intercellular hyphae, referred to as the Hartig net, within the root. Highly diverse, ectomycorrhizal associations are estimated to have arisen independently at least 80 times in the Ascomycota and the Basidiomycota (Tedersoo and Smith, 2013). Molecular evidence suggests ectomycorrhizal fungi typically have arisen from saprotrophs, but there is some evidence suggesting that some ectomycorrhizal fungi have evolved from plant endophytes. Convergent evolution has led to morphological and physiological similarities among these lineages of ectomycorrhizal fungi, with some shared suites of gene changes related to decay function and mycorrhizal formation, but there also is evidence that independent origins of the symbiosis are associated with unique physiological changes in ectomycorrhizal fungi from a given lineage. The repeated independent origins of ectomycorrhizal fungi, coupled with these unique physiological adaptations and the combined effects of coevolution with host plants and evolution in response to environmental factors, likely play a key role in the high diversity of ectomycorrhizal fungal species.

Compared with arbuscular and orchid mycorrhizal fungi, ectomycorrhizal reflect a middle ground in the roles of environmental factors and host specialization in driving speciation. Host specialization in ectomycorrhizal fungi runs the gamut from cosmopolitan species that form associations with most, if not all, of the plants species that host ectomycorrhizal fungi, to fungal species that are only known to form associations with a narrow range of host species. Further, within the more generalist fungi, some genotypes may exhibit greater host specialization than others. While the typical ectomycorrhizal association is with autotrophic plants, some ectomycorrhizal fungi form associations with both mycoheterotrophic and autotrophic plants, though the effects of these interactions on fungal diversity and distributions are unclear. Ectomycorrhizal fungi typically have more restricted geographic distributions than arbuscular mycorrhizal fungi (Allen *et al.*, 1995). While this pattern

reflects in part effects of host specificity, a wide range of abiotic factors, including soil characteristics, such as nitrogen and phosphorus concentration, and successional dynamics, also affects ectomycorrhizal fungal distributions. Taken together, diversification in response to both host specialization and environmental factors has resulted in a high degree of niche differentiation and specialization among ectomycorrhizal fungal species.

Specialized Mycorrhizal Forms Within the Ericaceae

Given the long evolutionary history of mycorrhizal fungi, and the unique associations with certain plant families, it is perhaps not surprising that coevolution with host plants and further host specialization have occurred within at least some mycorrhizal fungal lineages. In particular, coevolution between certain fungi and certain subfamilies of plants within the Ericaceae has led to the development of mycorrhizal forms distinct from the common ericoid type, such as the arbutoid, monotropoid, cavendishioid, and pyroloid (Oberwinkler *et al.*, 2013). As more research is conducted, additional forms may be described; here, diversification in two of the most-studied forms is briefly discussed.

Diversification of Arbutoid Mycorrhizal Fungi

Arbutoid fungi fall somewhere between endo- and ectomycorrhizal associations, as they are characterized by the formation of a hyphal sheath while also growing intracellularly. As a result, this form often is referred to as ectendomycorrhiza. In addition to arbutoid fungi, other fungi that form ectendomycorrhizal associations include pyroloid fungi (Oberwinkler *et al.*, 2013). Arbutoid fungi have a very narrow host range, only forming associations with plants in the subfamily Arbutoideae. Nonetheless, the arbutoid mycorrhizal association arose multiple times within both the Ascomycota and the Basidiomycota, generally within taxa associated with ectomycorrhizal formation. Molecular evidence also suggests some arbutoid mycorrhizal fungi may have arisen from lineages of ericoid mycorrhizal fungi or endophytic fungi. As with ericoid and ectomycorrhizal fungi, arbutoid mycorrhizal fungi reflect convergent evolution both physiologically and morphologically across the disparate lineages.

Diversification of Monotropoid Mycorrhizal Fungi

Monotropoid mycorrhiza share some similarities to orchid mycorrhiza, in that plants are mixotrophic or heterotrophic, and monotropoid mycorrhizal fungi have a very narrow host range, only forming associations with plants in the subfamily Monotropoideae in the Ericaceae. However, monotropoid mycorrhiza are morphologically distinct from orchid mycorrhiza, in that they form a mantle and Hartig net, and evolved independently of orchid mycorrhizal fungi. Monotropoid mycorrhiza also are morphologically distinct from arbutoid mycorrhiza, in that they do not form the hyphal coils commonly observed in arbutoid mycorrhiza; rather than penetrating the cell wall, the hyphae form pegs that cause indentations in the cell wall without actual penetration. Molecular evidence suggests monotropoid mycorrhizal fungi arose multiple times within both the Ascomycota and the Basidiomycota, roughly paralleling evolution of arbutoid mycorrhizal fungi in that monotropoid mycorrhizal fungi appear to have arisen from ectomycorrhizal fungi, ericoid mycorrhizal fungi, and perhaps endophytic fungi, followed by convergent evolution.

Summary

Mycorrhizal fungi account for a significant fraction of fungal diversity. Coevolution with plants has played a significant role in diversification of mycorrhizal fungi, but fungal evolution does not parallel plant evolution. Although arbuscular mycorrhiza evolved first, during the initial invasion of land by plants, ectomycorrhizal and orchid mycorrhizal fungi are the most speciose groups of mycorrhizal fungi. Each of these groups, as well as the ericoid mycorrhiza, is the result of multiple independent evolutionary events, typically from saprotrophic fungi, followed by convergent evolution.

Natural Selection, Introduction to

SR Proulx and B Østman, University of California, Santa Barbara, CA, USA

Glossary

Absolute fitness A measure of fitness given by the number of offspring.
Density dependence Selection pressures in the population is affected by the population density.
Deterministic Not dependent of random events.
Fitness landscape A map of fitness given as a function of either the genotype or phenotype.
Genetic drift Random sampling of alleles within a population.
Geometric mean An average taken over the sample using the product rather than the sum of the values.
Heritability The degree to which offspring have the same traits as their parents.
Relative fitness The fitness advantage of an individual relative to that of others within a population.
Stochastic Influenced by random events.

One of Charles Darwin's most fundamental contributions to modern biology was his clear description of how 'natural selection' could result in changes in populations over time that would lead to the observed fit between the abilities of plants and animals to survive in the conditions that they are found in nature. We now understand that there is a range of forces that cause change in evolving populations over time (genetic drift, migration, mutation, gene conversion, demographic stochasticity, phenotypic plasticity), but selection is often considered the primary mechanism driving evolutionary change. Selection is a consistent, directional force that acts on the frequencies of alleles in populations and results in the change of the average phenotype within the population over successive generations.

Darwin presented an elegant argument that described when selection will act. He identified four factors, which, if present, imply that populations will change from generation to generation (Darwin, 1859; see the summary of chapter IV for a succinct passage). These assumptions are:

1. Individuals within populations vary in terms of their *traits*. For example, individual finches may have different bill sizes.
2. These traits are related to the ability to survive and reproduce. This ability if often called *fitness*. For example, finches with just the right bill size may have an advantage in finding insects to eat.
3. Offspring have traits that are similar to their parents. This is the notion of *heritability*. Finches with longer than average bills tend to have offspring that also have longer than average bills.
4. There are not enough resources for all offspring produced to survive. This can also be described as *density dependence*: when a population increases in size it will eventually exhaust resources, which will increase the rate of death in the population.

These simple assumptions lead to the conclusion that the population will change over the course of generations in terms of the traits that individuals bear and that the population will become more 'adapted' over time. Adaptation occurs when traits that increase fitness become more common. Darwin's elegant idea did not require an understanding of how traits are passed on to offspring, and in fact it would be almost a century before a detailed understanding of the molecular basis of genetic inheritance was developed.

While Darwin's simple set of assumptions lead to the conclusion that selection will lead to a change in populations over generations, a much more detailed theory of selection was developed to take into account the details of inheritance and population biology. A major advance was due to Fisher (1930) and is sometimes called the Fundamental Theorem of Natural Selection. This theorem states that populations will become more adapted (i.e., will increase in fitness) at a rate that depends on how much heritable variation is present in the population, how large the effect of differences in trait is on fitness, and whether fitness depends on the population or environment in a trait specific way. The main point is that adaptation will increase more quickly when there is a range of traits present in the population and there are large heritable differences in the reproductive output of individuals with different traits (Edwards, 2014).

 doi:10.1016/B978-0-12-800049-6.00026-3

Genotype versus Phenotype

To understand how selection works on biological organisms, it is important to distinguish between the genotype and the phenotype. The genotype is the genetic makeup of an organism, and it serves two purposes at the same time: it is both the code that gets copied and inherited between the generations and the code from which the phenotype is constructed as it interacts with the physical environment. The phenotype is the composition of the organism's traits or observable characteristics, and it is on the phenotype that selection acts, as it is the phenotype that interacts directly with the environment. Thus, what matters for selection in biological evolution are the changes that take place in the genotype and how those changes affect the phenotype. Changes to traits that are encoded in the genotype can be passed on to offspring, while traits acquired during the lifetime of the organism cannot.

Fitness and Strength of Selection

Fitness is a measure of an organism's long-term reproductive success and encompasses both its ability to survive and the rate at which it reproduces. The definition of fitness can be complicated and depends on the ecological context (Proulx and Adler, 2010). In the most general sense, the 'absolute fitness' of a phenotype or behavioral strategy can be measured by the number of offspring that a single individual with that phenotype produces over the course of their lifetime. The long-term measure of fitness for an allele is simply the increase in the number of individuals carrying the allele that are present in the population at a distant time in the future.

The strength of selection depends on this fitness, and is given by the 'selection coefficient,' s. The selective advantage of an allele or different phenotype is the new fitness, W', relative to the wild-type fitness, W, $s = W'/W - 1$. Beneficial mutations that cause an increase in fitness thus have a positive selection coefficient, while those of deleterious mutations are negative. This measure of fitness relative to other individuals is called 'relative fitness.'

The effect of relative fitness and the strength of selection also depend on the population size. Stochasticity in survival and reproduction has a smaller effect the larger the population is, while random events have a greater influence on the evolutionary dynamics in small populations leading to genetic drift becoming dominant. As the role of genetic drift increases, the greater the selection coefficient has to be for selection to be able to distinguish between organisms with different fitness. This dependence on population size means that small populations can better tolerate deleterious mutations than larger populations. This effect may enable smaller population to explore the space of possible genotypes and phenotypes it led Wright to propose his Shifting Balance Theory (Wright, 1932), in which a large population splits into smaller demes that are less affected by selection and can therefore explore phenotypic space and find other peaks in the 'fitness landscape' – the mapping from genotype or phenotype onto fitness. In larger populations, selection is stronger and smaller fitness differences can be detected. This increases the probability that advantageous alleles will become established in the population and eventually go to fixation.

Effects of Selection

Selection can be divided into natural and artificial selection, with the former being caused by nonhuman agents and the latter influenced by human interference. In principle, there is no difference in terms of the mechanism, as the population in question responds to any selection pressure in the same way, no matter what the origin is. However, while both types of agents can cause a wide range of changes in fitness, compared to natural selection, artificial selection can be persistently severe, and thereby faster than perhaps most instances of natural selection. For example, under the control of human breeders using artificial insemination, one stallion can potentially have thousands of offspring, which would not be possible under natural conditions. Breeding practices can thus severely affect fitness, and yet the mechanism of selection remains the same.

Natural selection is often further divided into ecological and sexual selection, distinguishing between changes in fitness due to both biotic and abiotic environmental agents leading to ecological selection, and competition for mating between conspecific individuals leading to sexual selection.

In terms of the phenotype, selection can have a number of effects. Stabilizing selection results from agents of selection that favors the current phenotype, with any changes leading to decreases in fitness, thereby stabilizing the population phenotype at its current value. Directional selection occurs when changes in the phenotype are favored, with individuals in the tail end of the phenotypic distribution having higher fitness. This drives the population away from the current phenotypic mean resulting in adaptive evolution. Disruptive selection is similar to directional selection in that the most abundant phenotype is not the most favored, but in this case there are more than one phenotypic direction that increases fitness. This can lead to the population splitting up into two or more subpopulations with different phenotypes. However, if there is no mechanism present to decrease competition between these subpopulations, this phase will be transient, and competition will cause the population to converge on just one of the new phenotypic values. On the other hand, if competition between segregating populations can be mitigated, then they may coexist in what is termed balancing selection. This can be caused by negative frequency-dependent selection, which results when rare phenotypes have a fitness advantage over abundant phenotypes (Ayala and Campbell, 1974). When one phenotype increases in abundance, the rarer type increases in fitness, which leads to an increase in the rare type and a decrease in the abundant type, thereby leading to balancing selection.

It is useful to illustrate these effects of selection in terms of the fitness landscape (Østman and Adami, 2014). The fitness landscape is a mapping of either genotype or phenotype onto fitness. For every unique type there is a corresponding fitness (this scalar value may change over time), and this multidimensional function constitutes the fitness landscape. In rugged fitness landscapes (a landscape with many distinct local maxima) populations located on a peak will experience

stabilizing selection, as every direction in phenotypic space away from the current position leads to a decrease in fitness. If the population is located on an incline in the fitness landscape, it will be under directional selection and will most likely evolve in the direction of the highest fitness increase. If the population is located in a valley with paths leading to different peaks, it will experience disruptive selection, and if the population is also under balancing selection, more than one peak can be climbed and populated for an indefinite amount of time. In a static fitness landscape where the fitness of every type is constant in time, disruptive selection can only be transient. Balancing selection through negative frequency-dependent selection implies that the fitness landscape fluctuates in response to the abundance of different phenotypes.

Stochasticity

It is important to appreciate the role stochasticity plays in evolutionary dynamics. Which organisms survive and which of those actually reproduce depends not only on the organism's phenotype, but also on random events. Random events may include predation, discovery of nest sites, and fluctuations in local weather. If every individual within a population has the same fitness, then obviously selection plays no role in the evolutionary outcome. On the other hand, a single fitter mutant has a higher chance to go to fixation than any other individual, with this probability being dependent on the selection coefficient (**Figure 1**). The specific details of the interplay between selection and random effects is complex, but in large populations competition between established alleles is largely deterministic: the allele with the higher average fitness almost certainly becomes more common (see Video 1).

However, when a mutation occurs the new allele will be represented by only one or a few copies. This means that a string of bad luck affecting all copies of a rare allele can remove it from the population, even when it has higher fitness on average than the common alleles in the population. This effect can be measured by considering the probability of fixation: the probability that a mutant allele present as a single copy eventually comes to be only allele present in the population. Without stochasticity, we might expect that alleles with higher fitness always come to dominate the population, meaning that their probability of fixation would be 1. A variety of mathematical models have been developed to study this process, but a simple result argues that the probability of fixation should be approximately $2 \times s$ in a large population (first derived by Haldane, reviewed in Patwa and Wahl, 2008). This is somewhat surprising since it means that even a mutation with a 5% advantage is lost from the population about 90% of the time. This approximation is valid only if the selection coefficient is small, in part because the fixation probability can never be greater than 1 (see **Figure 1**).

In smaller populations, particularly when there are small differences in fitness, random components tend to overwhelm the directional nature of selection. This means that alleles that have lower than average fitness may still spread in the population leading to a loss of adaptation over evolutionary time.

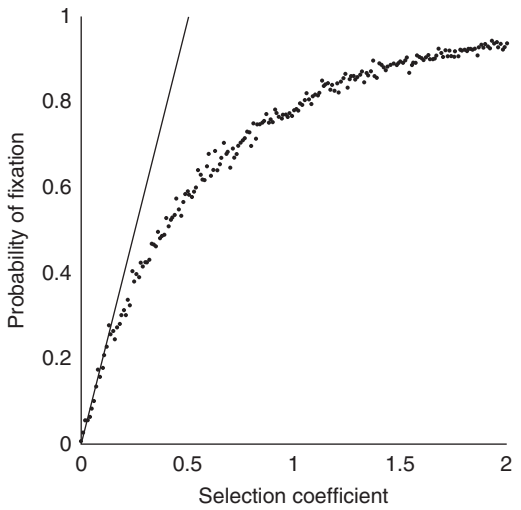

Figure 1 Probability of fixation as a function of selection coefficient. The dots are simulation results where a single mutant individual was introduced into an established population. Each simulation was run until only one allele was left, meaning that either the mutant was lost from the population or spread and became fixed. Each dot represents 1000 simulations with their results averaged. The straight line is the $2s$ prediction that is valid for small values of s. Note that the simulated results (dots) show some random variation around this prediction up until about $s=0.15$. For larger values of s, the approximate result is no longer valid. Data are from a simulation with a constant population size of $N=100$, nonoverlapping generations, asexual reproduction, chance of reproducing is equal to the normalized fitness, which is 1 for 99 individuals and $1+s$ for one individual.

Factors Affecting the Action of Selection

The strength of selection depends on fitness differences among phenotypes, but several factors can complicate the link between the long-term measure of fitness and the number of offspring carrying the parental genes.

1. Genetic relatedness: the offspring must bear the genes that were responsible for the phenotype that the parents developed. This is clearly not the case in situations where offspring are physically replaced, as is the case for brood parasites like the cuckoo. A similar effect can occur when genetic parasites are present that cause biased genetic transmission (see meiotic drive).
2. Offspring quality: while producing more genetic offspring does increase the number of individuals carrying the focal allele in the next generation, it will only lead to a long-term spread if those offspring also have the same ability. A strategy that results in increased offspring production but a decrease in offspring quality may therefore not have high fitness. This is an example of an intergenerational fitness effect (e.g., Hoyle and Ezard, 2012).
3. Sexual selection: offspring quality can vary because of parental investment, or because of genetic effects. Choosing a mating partner may influence the genetic quality of offspring without changing the total number of offspring.

This affects the genes present in the parent because genes that become associated with higher genetic quality will leave more offspring themselves, increasing the genetic representation of the parental allele in future generations.

4. Sex ratio: in many species, the sex of offspring is determined directly by the parent or by some combination of parental influence and environmental influences (genetic sex determination, as in humans and most other mammals, is rare across plants and animals as a whole).
5. Frequency dependence: the important measure of fitness is relative fitness, which relates the offspring production of one phenotype to the average offspring production in the population. When there is frequency dependence, the fitness of a phenotype depends on the phenotypes that it is competing against. For example, tree height is an important parameter to determine light competition and seed dispersal ability. The benefit of growing taller, however, depends on how tall the competitors are. This can lead to counterintuitive effects where total offspring production goes down over evolutionary time because more resources are devoted to competition (growing more wood) as compared with reproduction.
6. Population dynamics: the representation of an allele in future generations can depend on the timing of reproduction as well as the total amount of reproduction. In a growing population, it is generally better to reproduce earlier (for the same reason that investing in retirement early provides a higher return), whereas in a declining population it actually makes sense to reproduce later.
7. Environmental variability: because the performance of phenotypes depends on the environment that they experience, one allele may be favored in some environments but disfavored in others. Under environmental variability, the fitness of a phenotype depends on the type of variability in the environment. When variability affects each individual directly (e.g., variability in local resource density) then the appropriate measure of fitness is the arithmetic mean of fitness. However, when variability affects all individuals the same way (e.g., year-to-year variance in temperature) then the appropriate measure of fitness is the geometric mean of fitness. While the arithmetic mean is equally influenced by high and low values, the geometric mean is disproportionately affected by low values. Therefore, fitness can be greatly decreased when there is variability between generations.

Natural Selection, Measuring

CW Wood and ED Brodie III, University of Virginia, Charlottesville, VA, USA

Glossary

Fitness function The quantitative relationship between phenotype and fitness. Measuring selection requires estimating this function.

Opportunity for selection (I) Variance in relative fitness.

Relative fitness (ω) Individual fitness divided by population mean fitness.

Selection differential (S or C) Covariance between relative fitness and phenotype. S describes the strength of linear selection, and C, the strength of nonlinear selection.

Selection gradient (β or γ) Partial regression of relative fitness on phenotype independent of relationships with other (measured) phenotypes. β describes the strength of linear selection, and γ, the strength of nonlinear selection.

Natural selection (hereafter, 'selection') is the main driver of adaptive phenotypic evolution (Falconer and Mackay, 1996). Measuring selection is therefore foundational to our understanding of adaptation. Studying patterns of selection allows evolutionary biologists to identify the specific traits that drive variation in survival and reproductive success, provides the quantitative measurements used to predict evolutionary change, and pinpoints the ecological agents that shape evolution in natural populations. The measurement of selection has advanced the study of questions as diverse as the fitness consequences of trait integration (Brodie, 1992), the evolution of phenotypic plasticity (Baythavong and Stanton, 2010), and adaptation to changing environmental conditions (Etterson, 2004). Here we provide an overview of the most common statistical and analytical methods used to measure and interpret patterns of selection in natural populations.

What Is Selection?

Selection occurs when individuals with different characteristics ('phenotypes' or 'traits') differ in their survival or reproductive success ('fitness'). In other words, selection is a statistical association – the covariance – between phenotype and fitness (Robertson, 1966; Price, 1970; Lande and Arnold, 1983; Endler, 1986). Covariances (unscaled correlations) describe the degree to which two variables change together. This relationship is foundational in quantitative genetics because regardless of the complexity of the fitness function, larger covariance between phenotype and fitness indicates stronger selection (Lynch and Walsh, 1998). All of the methods of measuring selection described in this article are based on this fundamental relationship, though they may differ in the statistical approach used to estimate the function that relates fitness to phenotype.

The definition of selection as the covariance between phenotype and fitness highlights three crucial points. First, selection requires variation in both phenotype and fitness: two variables cannot covary unless both vary (Endler, 1986). Second, like correlation, covariance does not imply causation: covariance between a phenotype and fitness does not indicate why selection acts on that particular phenotype. For example, Fishman and Willis (2008) found that *Mimulus* plants with wide flowers produce more seeds, but pinpointing pollinators as the ecological agent of selection on floral width required a comparison of open-pollinated plants and plants that were caged to exclude pollinators. Finally, selection is a population-level process that affects characteristics of phenotype distributions – means, variances, and covariances (Endler, 1986; Brodie *et al.*, 1995).

The Data: Phenotypes and Fitness

To measure selection, phenotype and fitness data must be collected on the same set of individuals. Selection can be measured on any phenotype (measurable property) of an organism. In this article we focus on quantitative traits that vary continuously among individuals (Falconer and Mackay, 1996). Selection acts on phenotypes irrespective of their genetic basis, but selection results in evolution only when the phenotypic differences between individuals are heritable. This distinction between selection and evolutionary response allows biologists to study selection without knowing the genetic basis of a trait (Brodie *et al.*, 1995).

Fitness is estimated empirically as the number of offspring that an individual contributes to the next generation. However, total lifetime fitness is notoriously difficult to measure, especially for long-lived organisms, and few empirical studies are able to assess it (Kingsolver and Pfennig, 2007). Instead, most analyses use multiplicative fitness components – measurements that contribute to lifetime reproductive success – in lieu of total lifetime fitness (Conner and Hartl, 2004; Kingsolver and Pfennig, 2007). Commonly measured fitness components include survival, mating success, and fecundity. Different fitness components often drive very different patterns of selection. A single trait, for example, can be subject to opposing selection via survival ('viability selection') and via mating success ('sexual selection'). These episodes of selection can be combined to estimate lifetime selection, although care must be taken when dealing with complex fitness functions (Arnold and Wade, 1984; Wade and Kalisz, 1989; McGlothlin, 2010; Shaw and Geyer, 2010). Even when it is possible to measure total fitness, estimating the number of offspring an individual contributes to the next generation is complicated by the fact that populations are often age- or stage-structured, which blurs generation boundaries (Lande, 1982; Barfield

 doi:10.1016/B978-0-12-800049-6.00047-0

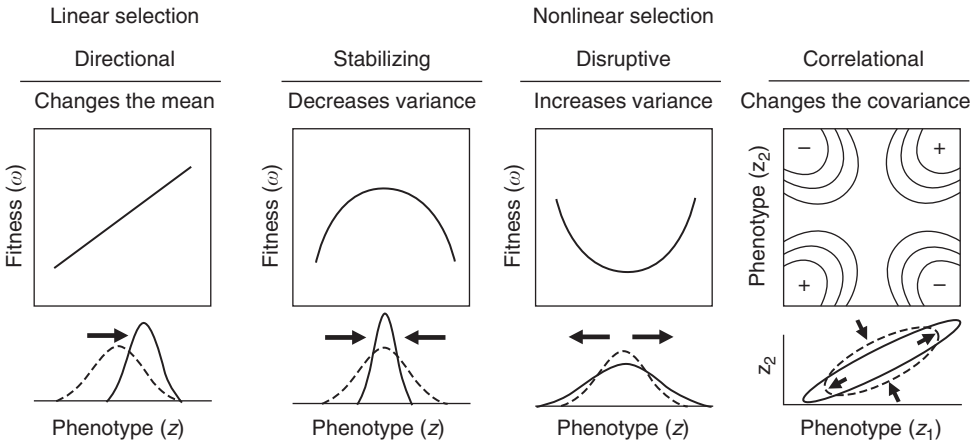

Figure 1 The modes of selection. They are characterized by the shape of the fitness function (top row) and their corresponding effect on the phenotypic distribution (bottom row). The fitness function for correlation selection is shown as a contour plot with isoclines of equal fitness.

et al., 2011; Moorad, 2014). Under these circumstances, an individual's reproductive value at birth (Moorad, 2014) or the 'sensitivities' of population growth to changes in age-specific fitness of individuals of different phenotypes (Lande, 1982) can be used to estimate fitness and selection on the relevant phenotypes.

Regardless of the fitness component, relative fitness rather than absolute fitness is always used to measure selection (Conner and Hartl, 2004). An individual's relative fitness is its absolute fitness divided by the population mean fitness. Relative fitness captures an individual's success compared to others in its population, and is used because selection operates on differences in fitness among individuals (Conner and Hartl, 2004). The variance in relative fitness sets a limit on the strength of selection on any phenotype, an upper bound known as the opportunity for selection, I (Arnold and Wade, 1984; Arnold, 1986). This limit exists because selection requires fitness differences among individuals that differ in phenotype, so the more variation there is in fitness, the greater the potential for strong selection. It is important to recognize that the opportunity for selection does not measure the actual strength of selection on any given phenotype, because selection requires a relationship between fitness and a specific phenotype.

Modes of Selection

Selection is described by a 'fitness function,' $\omega(z)$, that relates phenotype (z) to expected relative fitness ($\hat{\omega}$). Fitness functions can take many forms, or 'modes' (Phillips and Arnold, 1989; Brodie *et al.*, 1995). Selection can be conceptually decomposed into four modes: directional, stabilizing, disruptive, and correlational (**Figure 1**). The shape of the fitness function and its effect on the phenotype distribution distinguishes these modes. Directional selection occurs when individuals with phenotypes larger or smaller than the mean have higher expected relative fitness. Stabilizing or disruptive selection occurs when individuals with phenotypes closest to (stabilizing selection) or farthest from (disruptive selection) the mean have the highest expected relative fitness. Correlational selection describes selection on multiple traits simultaneously. It occurs when individuals with certain combinations of two or more phenotypes (e.g., large values of both) have the highest expected relative fitness (Brodie, 1992). Fitness functions observed in natural populations typically are complex mixtures of these four modes.

Because a selection function might include elements of multiple modes, it is often useful to classify selection as linear (directional) when the fitness function is not curved and nonlinear (stabilizing, disruptive, correlational) when the fitness function is curved (Phillips and Arnold, 1989). Linear and nonlinear selection affect different aspects of the phenotype distribution (**Figure 1**). Linear (directional) selection affects the mean, whereas nonlinear selection affects the variance (stabilizing or disruptive selection) or the covariance between two traits (correlational selection).

How to Measure Selection

A rigorous selection analysis involves three steps: collecting the data, estimating selection, and interpreting the results (Lande and Arnold, 1983; Brodie *et al.*, 1995). Details vary depending on the question and system, but selection analyses on two or more phenotypes generally include these fundamental elements:

Anatomy of a selection analysis on two (or more) phenotypes

Collect the data	Measure fitness and at least two phenotypes on each individual. Fitness is converted to relative fitness $\left(\frac{w}{\bar{w}}\right)$. Each phenotype is expressed as a deviation from the mean ($\tilde{z}=z-\bar{z}$) and standardized to unit variance $\left(\frac{\tilde{z}}{\sigma}\right)$. This standardization expresses traits in standard deviation units and allows comparison of selection between species or between traits measured on different scales (Hansen and Houle, 2008)
Estimate linear selection	Estimate selection using multiple regression of relative fitness on phenotypic values. The regression model to estimate linear selection includes fitness as the dependent variable (ω) and

	the two standardized phenotypes as independent variables ($\tilde{z}_1$ and $\tilde{z}_2$); ε is residual error: $\omega = \beta_1\tilde{z}_1 + \beta_2\tilde{z}_2 + \varepsilon$ β'_1 and β'_2 are estimates of linear selection on $\tilde{z}_1$ and $\tilde{z}_2$. They are known as linear selection gradients (primes are often used to note that they have been estimated on standardized traits). Positive βs indicate selection favoring larger values of phenotypes; negative βs indicate selection favoring smaller values of phenotypes
Estimate nonlinear selection	Estimate nonlinear selection by adding three quadratic forms of the original traits (expressed as deviations from the mean) to the regression: $\omega = \beta_1\tilde{z}_1 + \beta_2\tilde{z}_2 + \frac{1}{2}\gamma_{11}\tilde{z}_1^2 + \frac{1}{2}\gamma_{22}\tilde{z}_2^2 + \gamma_{12}\tilde{z}_1\tilde{z}_2 + \varepsilon$ γ'_{11}, γ'_{22}, and γ'_{12} are known as the nonlinear selection gradients. γ'_{11} and γ'_{22} measure the strength of stabilizing (negative γ) or disruptive (positive γ) selection on $\tilde{z}_1$ and $\tilde{z}_2$. γ'_{12} measures the strength of correlational selection on the simultaneous combination of $\tilde{z}_1$ and $\tilde{z}_2$. Positive γ_{12} reflects selection favoring similar combinations of the two traits, and negative γ_{12} reflect selection favoring opposite combinations. Linear terms from this quadratic regression model are ignored due to nonindependence with the nonlinear terms (Lande and Arnold, 1983; Brodie *et al.*, 1995)
Interpret the results	Test significance of the estimated selection gradients (i.e., whether βs and γs are statistically different from zero), accounting for statistical assumptions. Visualize, the relationship of phenotype and fitness to interpret selection estimates, and to identify peaks and valleys in the fitness function

The Details of a Selection Analysis

The approach outlined above is powerful because the parameters it produces – selection gradients and a related metric, the selection differential – are exactly what are required to quantitatively predict evolutionary change (**Table 1**). Both gradients and differentials can be plugged directly into the breeder's equation, which describes the change in a trait due to selection in a single generation (Lande and Arnold, 1983).

Selection gradients (β and γ): Direct selection on a trait

Total selection on a trait is composed of direct selection on that trait (i.e., its causal effect on fitness) and indirect selection on correlated traits. The selection gradients estimated using multiple regression (above) measure the strength of direct selection acting on a trait, independent of any correlated traits that are included in the model. Each partial regression coefficient measures the relationship between a single trait and relative fitness, controlling for the effects of all measured correlated traits on fitness (Lande and Arnold, 1983).

The linear selection gradients (β) are linear partial regression coefficients. These gradients measure the average slope of the fitness function around the population mean (directional selection) (**Figure 2**). The nonlinear selection gradients (γ) are quadratic partial regression coefficients that describe the average curvature of the fitness function around the population mean (stabilizing, disruptive, and correlational selection). The partial regression coefficients corresponding to stabilizing and disruptive selection (γ_{11} and γ_{22} above) estimated from the model must be doubled to estimate the stabilizing/disruptive gradients (Stinchcombe *et al.*, 2008).

Selection differentials (S and C): Total selection on a trait

The selection differential measures the strength of total selection on a trait (both direct and indirect) within a generation (Lande and Arnold, 1983; Brodie *et al.*, 1995), and is equivalent to the covariance of the trait with fitness, cov(ω, z). For viability selection, the linear selection differential (S) is the difference in the trait mean before and after selection (a weighted analog holds for other measures of fitness)

Table 1 Measures of selection, their interpretation, and method of estimation

Mode of selection		*Parameter*	*Interpretation*	*Method of estimation*
Selection gradients: direct selection on a phenotype				
Linear	Directional	β_i	Average slope of the fitness function	Partial regression coefficient from a regression of fitness on deviations from the mean phenotype
Nonlinear	Stabilizing/disruptive	γ_{ii}	Average curvature of the fitness function	Partial regression coefficient from a regression of fitness on squared deviations from the mean phenotype
	Correlational	γ_{ij}	Average curvature of the fitness function	Partial regression coefficient from a multiple regression of fitness on the cross-product of deviations from the mean phenotype
Selection differentials: total selection on a phenotype				
Linear	Directional	S_i	Change in the phenotypic mean due to selection	Covariance between deviations from the mean phenotype and relative fitness
Nonlinear	Stabilizing/disruptive	C_{ii}	Change in the phenotypic variance due to selection	Covariance between squared deviations from the mean phenotype and relative fitness
	Correlational	C_{ij}	Change in the phenotypic covariance due to selection	Covariance between the cross-product of deviations from the mean phenotype and relative fitness

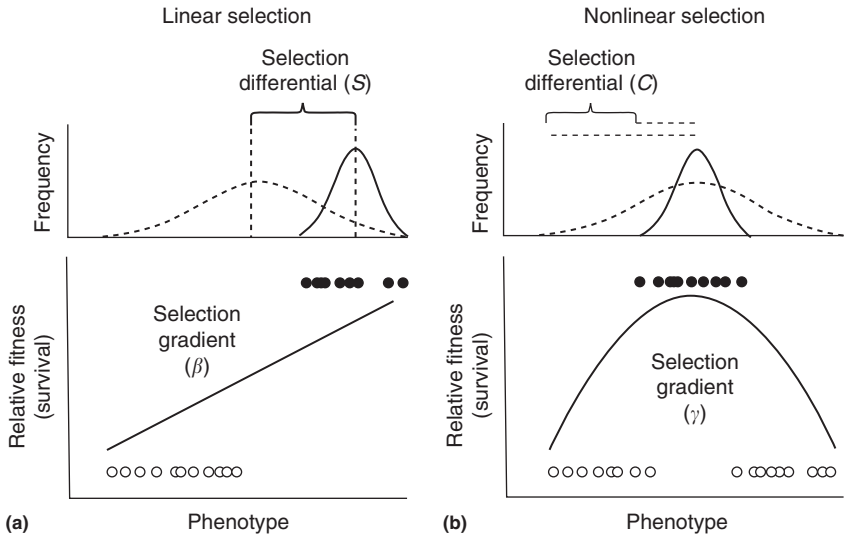

Figure 2 Illustration of selection gradients and differentials, in the case of survival selection on a hypothetical phenotype. The relationship between phenotype and fitness is shown in the panels below. The frequency distributions of the phenotype before and after selection are shown in the panels above. (a) Linear selection. The selection differential (S) is the difference in the phenotype means before and after selection. The selection gradient (β) is the regression coefficient from the regression of fitness on phenotype. (b) Nonlinear selection. The selection differential (C) is the difference in the phenotypic variance before and after selection. The selection gradient (γ) is the regression coefficient from the regression of fitness on squared deviations from the phenotype mean.

(Figure 2). Linear selection differentials can be compared across phenotypes or species if they are estimated on standardized traits (above), or by dividing the unstandardized differential by the phenotypic standard deviation. Such standardized linear differentials are known as selection intensities, i (Falconer and Mackay, 1996).

The nonlinear selection differential (C) is the difference in the trait variance or covariance before and after selection, after removing the effect of linear selection (Figure 2). As with linear selection differentials, nonlinear selection differentials can be estimated as covariances and standardized for comparison (Brodie *et al.*, 1995). The univariate nonlinear differential, which measures stabilizing and disruptive selection, is the covariance between relative fitness and squared deviations from the phenotype mean, $\mathrm{cov}(\omega, z^2)$. The bivariate nonlinear differential, which measures correlational selection, is the covariance between relative fitness and the cross-product of deviations from the phenotype means, $\mathrm{cov}(\omega, z_1 z_2)$.

Limitations and Underlying Assumptions

The application of multiple regression to the measurement of selection is powerful, but it is important to recognize that it is subject to the limitations and underlying assumptions of parametric statistics (Mitchell-Olds and Shaw, 1987). First, sample size limits the statistical power of a selection analysis. Robust quantitative estimates of selection require at least 200 individuals, so most selection gradients are associated with large standard errors (Kingsolver *et al.*, 2001, 2012). Second, the interpretation of a selection gradient as independent selection directly on a trait is strictly true only when all traits that affect fitness were included in the analysis (Lande and Arnold, 1983). Third, it is difficult to statistically disentangle the effects of extremely tightly correlated traits on fitness (a problem known as 'multicollinearity'; Mitchell-Olds and Shaw, 1987). Finally, fitness data frequently violate statistical assumptions, so significance testing of selection analyses often employs statistical techniques that account for non-normal data (e.g., generalized linear models; Bolker *et al.*, 2009).

Exploring the Complexity of Fitness Functions

The relationship between phenotype and fitness can be substantially more complex than the two-trait example outlined above. The strength, direction, and mode of selection depend on the biotic and abiotic environmental conditions that underlie the relationship between phenotype and fitness (MacColl, 2011). As a result, selection may vary substantially in space and time, which is easily missed in selection analyses conducted in a single year or in a single population (Kingsolver *et al.*, 2001, 2012; Siepielski *et al.*, 2009).

Even in a single selection analysis, the true fitness function may contain peaks and valleys that cannot be captured by quadratic selection gradients and differentials. Moreover, fitness is often determined by complex interactions between multiple phenotypes, making it challenging to disentangle their separate effects. The following approaches are useful ways to uncover and interpret complex fitness functions.

Rugged Fitness Functions

Perhaps the most fundamental assumption of the multiple regression approach is that a smooth linear or quadratic function is a good approximation of the true fitness function. Selection gradients are powerful evolutionary predictors because they measure the average slope and curvature of the fitness function, but this 'average' characterization does not

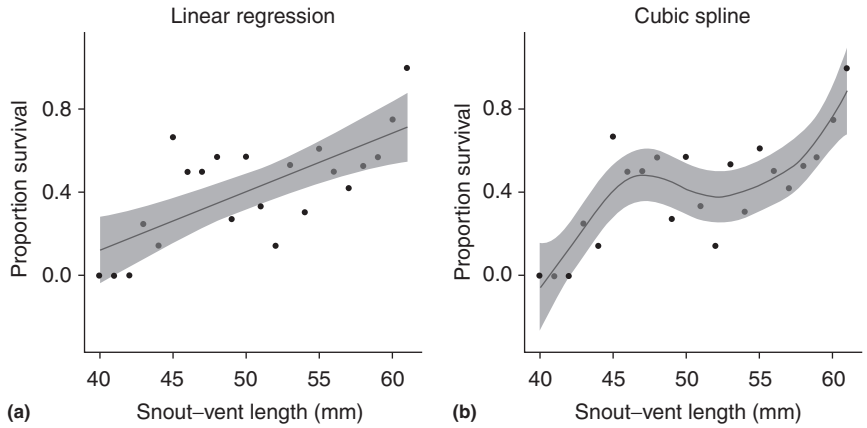

Figure 3 Alternative visualizations of the same data. Cubic splines identify peaks and valleys in rugged fitness functions that are undetected by linear regression. (a) Linear regression of survival on body size in male *Anolis* lizards suggests purely directional selection. (b) The use of a cubic spline to estimate selection reveals an intermediate local peak of high fitness not detected by linear regression. Data from Figure 4 in Cox, R.M., Calsbeek, R., 2010. Sex-specific selection and intraspecific variation in sexual size dimorphism. Evolution 64, 798–809.

reflect the idiosyncracies of rugged functions that contain many peaks and valleys (Schluter, 1988).

Cubic splines provide a nonparametric visualization of the fitness function that accurately reflects its rugosity (**Figure 3**). Splines derive their name from the flexible curves used in architectural drafting and engineering to interpolate between fixed points (Schluter and Nychka, 1994). Fitting a spline is similar to fitting a line using a moving average: the slope of the spline at any point reflects the local relationship between phenotype and fitness (Schluter, 1988). As a result, splines reveal fitness peaks and valleys that go undetected by quadratic regression.

Visualizing the spline is a powerful way to assess whether a linear or quadratic approximation of the average fitness function sufficiently captures the nuances of the relationships between traits and fitness. Spline interpolation is best employed as a complement of, rather than a replacement for, parametric estimates of the fitness function, because the equations used to predict adaptive evolutionary change rely on the coefficients obtained from parametric regression (i.e., linear and quadratic gradients and differentials; Brodie *et al.*, 1995).

Selection on Many Traits at Once

The multiple regression approach used to estimate selection gradients allows biologists to measure selection acting on many traits simultaneously. This property is essential because selection acts on organisms composed of integrated suites of traits, rather than on individual traits in isolation. In other words, each individual has many traits but only one fitness, so it is necessary to capture how all of its traits interact to determine its fitness. However, interpreting estimates of selection becomes difficult with large numbers of traits because each trait introduces a new dimension to the analysis. It is challenging to visualize the complete fitness function with more than two traits in the analysis, a critical step in interpreting the pattern of selection described by the shape of the fitness function. This problem is especially pronounced with nonlinear selection gradients. The addition of a trait to an analysis of n traits adds one linear selection gradient and $n+1$ nonlinear selection gradients: the stabilizing/disruptive gradient on the trait itself, plus correlational selection gradients with all other traits in the analysis. Moreover, the precise shape of the nonlinear fitness function depends on the relative strength of stabilizing, disruptive, and correlational selection gradients (Phillips and Arnold, 1989).

Dimensionality of the selection analysis is generally reduced in one of two ways: focusing on the trait combinations that contain the most variation or focusing on the trait combinations that experience the strongest selection.

Identifying the trait combinations containing the most variance

Principal components analysis identifies new variables ('principal components') comprising the trait combinations that contain the most variation. Principal components analysis produces the same number of principal components as original traits, but in most biological datasets, the first few principal components contain the majority of variation found in the original traits. Therefore, the selection analysis can be performed using only the first few principal components, decreasing the number of variables included in the analysis. The disadvantage of this approach is that the trait combinations that contain the most variation may not necessarily correspond to the traits that experience the strongest selection (Brodie *et al.*, 1995). It can also be challenging to interpret selection on principal components, because they are abstracted away from the original measured traits, the choice of which was usually motivated by a biological hypothesis about their effects on fitness (Brodie and McGlothlin, 2007).

Identifying the trait combinations under the strongest selection

One alternative is to focus on the trait combinations experiencing the strongest selection, which is accomplished with a procedure known as canonical analysis (**Figure 4**). Canonical

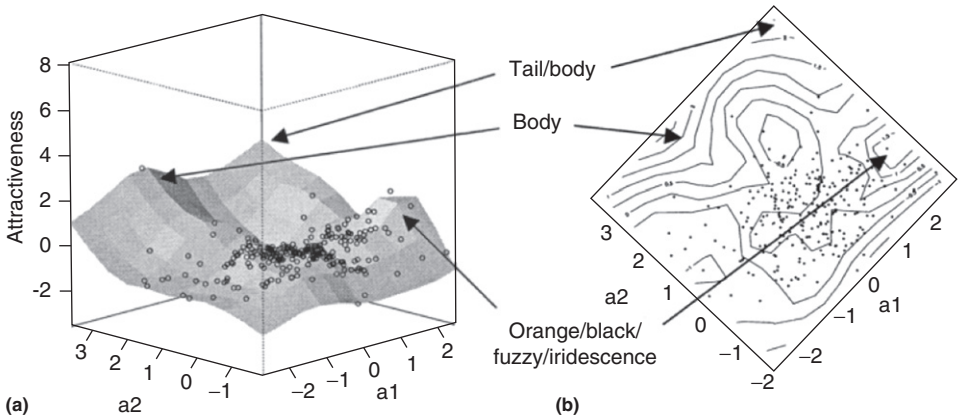

Figure 4 Selection on a suite of morphological and color traits in guppies. (a) Three-dimensional surface visualization of the fitness function, fitted with a thin-plate spline. (b) A top-down view of the same fitness function, where the lines are isoclines of equal fitness. The a1 and a2 axes represent combinations of traits under the strongest selection identified by projection pursuit regression. Peaks in the surface indicate combinations of traits that confer high fitness ('attractiveness'). Reproduced from Blows, M.W., Brooks, R., Kraft, P.G., 2003. Exploring complex fitness surfaces: Multiple ornamentation and polymorphism in male guppies. Evolution 57, 1622–1630, with permission from John Wiley and Sons.

analysis is most often used to identify the trait combinations that experience the strongest nonlinear selection, in order to reduce the number of nonlinear gradients in a selection analysis (Phillips and Arnold, 1989; Blows and Brooks, 2003). Canonical analysis is similar to principal components analysis (described above), but instead of identifying new variables composed of the trait combinations containing the most phenotypic variation, canonical analysis finds the trait combinations that explain the most variation in the relationship between phenotypes and fitness. Selection gradients are then calculated on these new composite traits (Phillips and Arnold, 1989). These composite traits tend to be under stronger nonlinear selection than the original traits, and the resulting gradients are more tractable to interpret because canonical analysis nearly always produces fewer nonlinear coefficients than the original selection analysis (Phillips and Arnold, 1989; Blows, 2007).

Canonical analysis still relies on parametric statistics to estimate nonlinear selection on the new trait combinations that it identifies. There are nonparametric analogs that can be used to distill rugged fitness functions that are insufficiently described by quadratic selection gradients. The nonparametric alternative to canonical analysis is projection pursuit regression, which estimates a function composed of univariate cubic splines (Schluter and Nychka, 1994). Projection pursuit regression identifies the trait combinations that experience the strongest overall selection, both linear and nonlinear. The multivariate extension of cubic splines – thin-plate splines – can be used to visualize the multivariate fitness surface (Blows *et al.*, 2003).

Complex Causal Relationships between Phenotypes and Fitness

Not all traits influence fitness directly. The effect of a trait on fitness is often mediated by other traits. Path analysis is used to estimate selection gradients on groups of phenotypes with

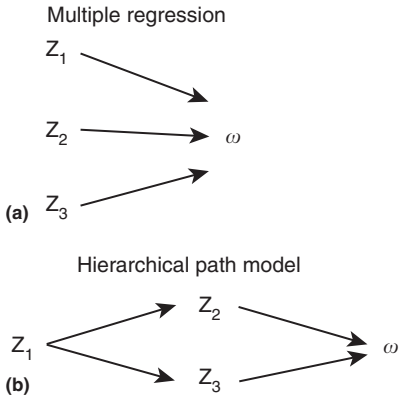

Figure 5 Path models capture complex relationships between phenotype and fitness. (a) A typical multiple regression model assumes all three phenotypes (z_1, z_2, and z_3) causally affect fitness directly. (b) Path models allow hierarchical relationships between traits and fitness. In this example, one phenotype (z_1) does not directly affect fitness. Instead, it affects two other phenotypes (z_2 and z_3) that in turn influence fitness.

complex effects on each other and on fitness (Lynch and Walsh, 1998; Morrissey, 2014). Path analysis is an extension of multiple regression that allows some phenotypes to mediate the effect of others on fitness (**Figure 5**). The coefficients estimated in path analysis are partial regression coefficients, just like the selection gradients from a multiple regression (Scheiner *et al.*, 2000).

Path analysis is a powerful tool to measure selection on suites of morphological and performance traits because the effect of morphological traits on fitness is mediated through their effect on overall performance (Arnold, 1983). Arnold (1983) applied path analysis to investigate the effect of skull morphology on fitness in snakes, a gape-limited predator. He used it to partition selection into two gradients: the effect of skull morphology on swallowing performance (the

'performance gradient'), and the effect of swallowing on fitness (the 'fitness gradient').

Targets and Agents of Selection

Selection gradients obtained from regression analysis identify traits that are the likely targets of direct selection, but purely statistical approaches are unable to demonstrate a causal relationship between a phenotype and fitness (Wade and Kalisz, 1990). These approaches give us quantitative descriptions of a pattern, but cannot tell us how or why selection acts on a particular trait. To these ends, measuring selection on naturally occurring phenotypic variation in unmanipulated populations must be coupled with experimental manipulation in order to conclusively identify the agents and targets of selection. A holistic understanding of adaptive evolution ultimately requires linking the environmental factors causing selection (selective 'agents') to the phenotypes on which they directly act (selective 'targets') (Conner and Hartl, 2004).

Targets of Selection

Phenotypic engineering – the manipulation of phenotypes – is a common technique used to confirm targets of selection identified by selection analyses (Conner and Hartl, 2004). Phenotypic engineering can be used to decouple correlated traits, facilitating the measurement of their independent effects on fitness. Such manipulation is especially important when two traits are so tightly correlated that their independent effects on fitness are impossible to disentangle statistically (e.g., Veiga and Polo, 2008; Sekii *et al.*, 2013). Second, phenotypic engineering is useful for expanding natural phenotypic distributions by creating more extreme phenotypes (Hotzy *et al.*, 2012). A perennial limitation on detecting selection on quantitative traits is that they tend to be normally distributed and occupy a relatively small region of phenotypic space. Most individuals exhibit phenotypes close to the mean, resulting in few samples and low statistical power at the extremes of the phenotype distribution. The current distribution is likely a by-product of past selection that eliminated phenotypes far from the optimum, confining the phenotypic distribution to a small flat region of the adaptive landscape. As a result, it is often necessary to artificially create phenotypes beyond the natural limits of the distribution to estimate the slope and curvature of the true fitness function. Sinervo *et al.* (1992) employed phenotypic engineering to circumvent these challenges and assess selection on offspring size in side-blotched lizards. They manipulated yolk investment to increase the frequency of extremely small and extremely large hatchlings, and demonstrated that selection favoring large offspring was not universal, but varied among years and between sexes.

Environmentally induced covariance between phenotype and fitness is a pervasive impediment to pinpointing the target of selection. It occurs when an underlying environmental factor influences both the expression of a trait and fitness, generating a spurious relationship between the two (Mauricio and Mojonnier, 1997; Pemberton, 2010). This problem can be solved experimentally by phenotypic engineering or by measuring selection under controlled environmental conditions. Alternatively, selection can be estimated by regressing fitness on genotypic (breeding) values rather than phenotypic values (Rausher, 1992). However, the latter is not always a practical solution, because it can be prohibitively difficult to estimate breeding values in natural populations.

Agents of Selection

Ultimately, questions about natural selection revolve around the functional relationship between organisms and their social, biotic, and abiotic environments (Wade and Kalisz, 1990; Boughman, 2001). Selection for larger bills in Galápagos finches, for example, is due to the fact that birds with larger bills are more successful foragers because they are able to crack larger seeds (Grant and Grant, 1995, 2011). However, this connection between an ecological agent and selection remains difficult to draw in the wild for many reasons (MacColl, 2011). A single trait can have many putative selective agents that are difficult to distinguish experimentally, and are challenging to manipulate without perturbing other aspects of a species' ecology. These experiments are logistically difficult to execute because identifying the agents of selection requires multiple estimates of selection under different ecological conditions.

Correlational, observational, and experimental approaches can be used to fill this gap (MacColl, 2011). Correlational studies exploit naturally occurring environmental differences between populations to ask whether the environment is associated with predictable differences in the fitness function (Wade and Kalisz, 1990). In some cases, field observation and attention to natural history can reveal the agents of selection. Young *et al.* (2004) identified loggerhead shrikes as the agent of selection on horn length in *Phrynosoma* lizards by comparing the length of the horns on live lizards to those on dead lizards that shrikes had impaled on trees. Alternatively, the putative environmental agents of selection can be manipulated. For example, although body size and performance traits are consistently targets of selection in lizards in the *Anolis* radiation, the mechanism responsible for the relationship between phenotypes and fitness is usually disregarded. Calsbeek and Cox (2010) addressed this question by manipulating both predation and intraspecific competition in *Anolis sagrei* and demonstrated that competition generates stronger selection on these phenotypes than predation.

Conclusion

The best selection analyses employ a holistic approach to characterize patterns of selection in natural populations. Measurements of selection from rigorous analyses have allowed us to identify general patterns in the causes and consequences of selection from studies performed in different sexes and species, or different habitats and years. Knowledge of the patterns and process of selection in natural populations is the foundation of our understanding of microevolutionary change.

Neutral Evolution, Population Genetic Tests of

CD Huber and KE Lohmueller, University of California, Los Angeles, CA, USA

Glossary

Background selection The effect of negative selection on diversity at linked neutral sites.
Balancing selection A type of selection that results in the maintenance of two or more alleles at a locus over some long period of time.
Divergence The genetic differences between two sequences sampled from two species.
Haplotype A particular combination of alleles found on the same chromosome.
Infinite island model A conceptual model for population structure and gene flow under which an infinite number of identical subpopulations (demes) exchange migrants with each other. Each subpopulation experiences an equal amount of gene flow from all other subpopulations.
Negative/purifying selection Selection against a mutation that reduces fitness.
Neutral theory The theory that segregating genetic variation is predominantly neutral and shaped by mutation and random genetic drift.
Nonsynonymous mutation A point mutation in the coding region of a gene that leads to a change of an amino acid in the corresponding protein.
Nucleotide diversity (θ_π) The average number of nucleotide differences per site between any two sequences chosen randomly from the population. Under the SNM, it is an unbiased estimator of θ.
Population mutation rate (θ) The per-generation mutation rate multiplied by four times the population size.
Positive/directional selection Selection favoring a mutation that increases fitness.
Segregating sites Sites where multiple alleles can be found in a sample of sequences. Its is equivalent to polymorphic sites.
Selective sweep The process by which positive selection eliminates neutral variation at linked sites.
Site frequency spectrum (SFS) A histogram describing the number (or proportion) of segregating sites that have different frequencies in the sample.
Standard neutral model (SNM) A simple model of the neutral theory, where mutation and drift act in a randomly mating population of constant size.
Stepping stone model A class of models that restricts gene flow to subpopulations that are adjacent or nearby in one or two dimensions. It is used to model isolation by distance, the increase in genetic differentiation with physical distance.
Synonymous mutation A point mutation in the coding region of a gene that does not alter the amino acid sequence of the corresponding protein.
Tajima's D A test statistic computed as the difference between two estimates of genetic diversity, θ_W and θ_π, divided by the standard deviation of the difference. Under the SNM, its average value is zero.
Watterson's θ (θ_W) An unbiased estimator of θ under the SNM. It is based on the number of segregating sites and is not influenced by the frequencies of the polymorphisms.

Introduction

Since the advent of DNA sequencing in the early 1980s, a major focus in empirical population genetics has been determining whether a particular DNA sequence has been neutrally evolving, or has been affected by natural selection (Hudson *et al.*, 1987; Kreitman, 1983; McDonald and Kreitman, 1991; Tajima, 1989). One way to do this is to assess whether patterns in the sequence of interest are compatible with predictions from standard neutral models (SNMs) of evolution (Kimura, 1983). This is typically done using a test of neutrality. Originally, these tests had been applied to a small number of candidate genes, but in more recent times, they have been applied to whole genomes (Akey *et al.*, 2002; Carlson *et al.*, 2005; Chávez-Galarza *et al.*, 2013; Huber *et al.*, 2014; Kelley *et al.*, 2006; Kimura *et al.*, 2007; Long *et al.*, 2013; Moon *et al.*, 2015; Qanbari *et al.*, 2014, 2012; Ramey *et al.*, 2013; Sabeti *et al.*, 2007; Tang *et al.*, 2007; Voight *et al.*, 2006; Wang *et al.*, 2006; Williamson *et al.*, 2007; Xia *et al.*, 2009). The advantage of scanning the genome for signatures of selection is that it provides an unbiased survey of genes that have been important throughout evolution, without external knowledge of what the genes do or the particular phenotype(s) involved. These selection scans are becoming an important part of evolutionary genetic studies across a wide array of model and non-model systems.

Here we will review basic tests of neutrality. These tests can be divided into several categories based on the information from the data that they use (**Table 1**). We will describe each type of test and highlight some strengths and weaknesses of the approach.

Site Frequency Spectrum-Based Methods

One class of tests for detecting deviations from neutrality is based on the site frequency spectrum (SFS). The SFS tabulates the number of mutations ξ_i that exist in a frequency of $x_i = i/n$ for $i = 1, 2, ..., n-1$, in a sample of size n (Nielsen, 2005), i.e., it summarizes the number of mutations segregating at particular frequencies in the sample. In a model of a single randomly mating population with constant population size N

 doi:10.1016/B978-0-12-800049-6.00032-9

Table 1 Comparison of tests of neutrality

Test	*Number of loci*	*Type of sites/regions*	*Number of species*	*Sensitivity to demography*	*Most power to detect*	*Direct or indirect selection*
Tajima's *D*	1	Any genomic region	1	Yes	Recent positive selection at a single site	Indirect
Fay and Wu's *H*	1	Any genomic region	2	Yes	Recent positive selection at a single site	Indirect
HKA test	2	Neutral and selected region	2	Yes	Recurrent positive selection at multiple sites	Indirect
MK test	1	Synonymous and nonsynonymous sites	2	No	Recurrent positive selection at multiple sites	Direct
Haplotype-based tests	Genome-wide	Any genomic region	1	Yes	Recent positive selection	Indirect
Population differentiation	Genome-wide	Any genomic region	1; but multiple populations	Yes	Population-specific positive selection	Direct & indirect

(SNM), the expected value of ξ_i equals θ/i (Fu, 1995), where θ is the population scaled mutation rate defined as $4N\mu$. The classic neutrality tests quantify deviations of the empirical SFS from this expectation.

One of the earliest tests of neutrality, Tajima's D (Tajima, 1989), contrasts the proportion of segregating sites at low and high frequency with the proportion of sites at intermediate frequency. It does this by calculating the standardized difference between two different estimators of θ, Watterson's θ (θ_W) and nucleotide diversity (θ_π). θ_W is based on the number of segregating sites in the sample, while θ_π is the average number of nucleotide differences between pairs of sequences in a region. Under the SNM, these two estimates of θ should be equal to each other, making the expectation of Tajima's D approximately zero. In the case of negative selection acting directly on sites within the region, or a close recent selective sweep, there is an excess of rare alleles compared to the SNM. Rare alleles contribute as much as common variants do to increase the value of θ_W, but contribute less than common variants to increase the value of θ_π. As such, Tajima's D becomes negative. Based on coalescent simulations under a neutral model, a p-value can be computed. Tajima's D was, for example, used to scan for selective sweeps in genome-wide human data (Carlson *et al.*, 2005; Kelley *et al.*, 2006). It is sensitive to demographic histories that also lead to an increase of rare variants, like a recent population expansion (Tajima, 1993). Such events might therefore lead to rejection of the SNM, but not because of a selective sweep, but because of the nonconstant population size. An excess of common variants relative to rare variants will lead to positive Tajima's D values. This may be seen for balancing selection, but also for population structure with equal sampling from different subpopulations.

If outgroup information is available (e.g., chimpanzee in an analysis of human genetic data) it can be used to polarize polymorphisms to test for an excess of alleles that are new (derived) and at high frequency in the population (Fay and Wu, 2000; Fu, 1996; Fu and Li, 1993). For example, Fay and Wu's H contrasts θ_π with θ_H, an estimate of θ that is sensitive to high frequency derived alleles (Fay and Wu, 2000). Negative values of H indicate an excess of high frequency derived alleles in the tested region. Tests based on the derived allele frequency seem to be less sensitive to population size changes when testing for the signatures of a recent selective sweep. However, this sweep signal is relatively short-lived and still suffers from false positives from population subdivision (Przeworski, 2002).

The classical neutrality tests discussed above can be expressed as a linear combination of ξ_i (Achaz, 2009), where the weights represent the sensitivity of the test to deviations from neutrality at different frequency classes of the SFS. They are not optimized to perform well under a specific alternative hypothesis. More recent methods, like SweepFinder, compare the SFS in a region of the genome with that predicted under a model of a recent selective sweep versus. the genome-wide background SFS (Nielsen *et al.*, 2005). By explicitly comparing to an alternative model including natural selection and using the genome-wide background SFS, this procedure is thought to be more powerful and robust to demography than the neutrality tests discussed above. Explicit models of selection in a similar framework were also developed to test for local selective sweeps (Chen *et al.*, 2010) and balancing selection (DeGiorgio *et al.*, 2014).

Faced with the problems of heterogeneous data and confounding demography, researchers have avoided specifying a model and instead take a pure outlier approach, assuming that most loci in the tails of the distribution are likely targets of selection (Teshima *et al.*, 2006). However, outlier selection scans do not provide an explicit test of a neutral model. Rather, they simply determine whether a particular region of the genome is unusual compared to the rest of the genome. Even with no selection, one region will always be the most extreme. The overall performance of these approaches will depend on

the demography and the proportion of the genome under positive selection (Kelley *et al.*, 2006; Teshima *et al.*, 2006; Thornton *et al.*, 2007).

HKA

The HKA test of Hudson *et al.* (1987) was the first test to utilize the positive association between polymorphism within a species and divergence between different species as a basis for a statistical test of neutrality. To apply the HKA test, one needs data from at least two different genomic regions in two (or more) species (Hudson *et al.*, 1987; Wright and Charlesworth, 2004). One of these regions needs to be neutrally evolving while the other may be subjected to natural selection. The HKA test compares the ratio of polymorphism to divergence of the neutral with the tested regions (**Figure 1**). Given an infinite sites model and assuming neutrality, it can be shown that the expected values for both polymorphism and divergence are a function of the time since the split, the effective population sizes of the two species, and the mutation rate for each region. As such, the ratio of polymorphism to divergence should, on average, be equal between all regions.

Although the mutation rate can vary between the regions, the ratio between diversity to divergence is unaffected by changes in the mutation rate. This is a consequence of the fact that both diversity and divergence scale linearly with mutation rate, and hence changes in mutation rate cancel out in both estimates. Any significant difference in the ratio between the tested and the neutral region indicates a violation of the assumption of neutrality in the tested region. Positive selection increases divergence relative to diversity (**Figure 1(b)**) while balancing selection (**Figure 1(c)**) and negative selection show the opposite pattern (Charlesworth and Charlesworth, 2010, p. 279).

	Neutral	Selective sweep	Balancing selection
Polymorphism	75	30	120
Divergence	105	105	105
χ^2		4.384	1.025
P-value		0.036	0.311

(d)

Figure 1 Example genealogies and data for the HKA test. χ^2 Statistic and *p*-value were calculated using HKAdirect (Esteve-Codina *et al.*, 2013).

The HKA test was shown to have high power for testing the null hypothesis of neutrality when multiple sites have been repeatedly targets of positive selection in the selected region. There is only little power for detecting weak purifying selection (Zhai *et al.*, 2009). Importantly, there is no power to detect strong purifying selection, because it affects both diversity and divergence proportionally, leading to a pattern equivalent to a lower mutation rate in the selected region. Inference about strong purifying selection can be made only when the neutral mutation rate for both regions is known.

Note that a significant HKA test only indicates a significantly larger or smaller diversity relative to divergence in one region compared to the other region. In the ideal case, one region is thought to be neutrally evolving, but often evidence of this is ambiguous. From the HKA test itself, there is no indication which of the two regions led to the deviation, and in fact, both regions might violate neutrality, but to a different degree or in different directions. For example, one region might be under the influence of balancing selection, leading to increased levels of diversity than expected, whereas the other region might be affected by a recent selective sweep, leading to a reduction of diversity. In such a case, there might be strong (and correct) support against the neutral model, but it is unclear if one or both regions are responsible for the deviation. Alternatively, it could be that both regions are affected by background selection to a similar degree, leading to a (misleading) non-significant HKA test. Note that a large portion of the genome can be under the influence of either direct or indirect selection. For example, about 40–70% of the noncoding DNA of *Drosophila melanogaster* are evolutionary constrained relative to synonymous sites (Andolfatto, 2005), and most, if not all, sites in the *Drosophila* genome are influenced by the indirect effects of deleterious mutations, i.e., background selection (Comeron, 2014). Finally, the HKA test has been extended to be applied to more than two genes (Wright and Charlesworth, 2004). In conclusion, although power of the HKA test is often superior to other methods (Zhai *et al.*, 2009), the necessity of defining a neutral region makes practical application of the HKA test challenging.

MK

The McDonald–Kreitman (MK) test (McDonald and Kreitman, 1991) is based on the same principle as the HKA test, except that instead of dividing the genome into neutral and nonneutral regions, it divides a region into interspersed neutral and selected sites, most commonly synonymous and nonsynonymous sites. Therefore, the MK test is often applied to protein-coding sequence (and we will discuss it in this context), but can also be used in situations where non-coding sites can be classified into interspersed neutral and putatively selected sites (Andolfatto, 2005). The basic premise is similar to that of the HKA test: Under neutrality, the synonymous ratio of diversity to divergence is expected to be the same as the nonsynonymous ratio (**Figure 2(a)**). Selection on nonsynonymous mutations generates a deviation from this proportionality that can be tested by any conventional test of independence (χ^2 test or Fisher's exact test, see Sokal and Rohlf, 2011). An excess of nonsynonymous divergence (i.e., a

	Neutral		Negative selection		Positive selection	
	S	NS	S	NS	S	NS
Polymorphism	75	45	75	30	75	45
Divergence	105	60	105	15	105	105
χ^2		0.0001		8.1		4.3
P-value		0.9936		0.0045		0.0376

(d)

Figure 2 Example genealogies and data for the MK test. χ^2 Statistic and *p*-value where calculated in *R* using 'chisq.test'. P_S = synonymous polymorphism, D_S = synonymous divergence, P_{NS} = nonsynonymous polymorphism, D_{NS} = nonsynonymous divergence. Red and blue squares represent nonsynonymous and synonymous sites of a gene, respectively.

too small diversity to divergence ratio at nonsynonymous sites compared to synonymous sites) is generally interpreted as evidence for positive directional selection (**Figure 2(c)**), whereas a deficit of nonsynonymous divergence is interpreted as evidence for weak purifying selection (**Figure 2(b)**). The MK test was found to be better at detecting negative selection than the HKA test (Zhai *et al.*, 2009). Again, very strong purifying selection does not lead to a significant MK test because it affects both diversity and divergence proportionally, leading to a pattern equivalent to a lower mutation rate at the nonsynonymous sites.

Comparison of the HKA and MK Tests

The crucial difference between the MK test and the HKA test is the spatial organization of neutral and selected sites. For the MK test, the two classes of sites are homogeneously interdigitated, whereas for the HKA test the two classes of sites are in separate regions with an arbitrary genetic distance in between. Although it seems like a trivial disparity, it has several important consequences. One has to do with the effect of negative selection at linked neutral sites. The classical model of the effect of negative selection on linked neutral sites, background selection, can be formulated as a local reduction in effective population size that is a function of the density of functional elements, selection coefficient, mutation rate, and recombination rate (Charlesworth *et al.*, 1993, 1995; Hudson and Kaplan, 1995, 1994; Nordborg *et al.*, 1996). Because background selection leads to a reduction in N_e at both synonymous and nonsynonymous sites, such indirect effects of selection do not affect the MK test. In contrast, the HKA test deviates from the nominal significance level when one of the regions is more strongly affected by background selection than the other regions (Williford and Comeron, 2010). A similar argument can be formulated for the effect of a recent selective sweep. Put differently, a significant MK test implies that the sites themselves are under selection, whereas a significant HKA test would also detect selection 'at a distance' (background selection, selective sweep), but does not necessarily provide information about the genes under selection (Nachman, 2006). Note that SFS-based methods discussed above fall into the same category as the HKA test by also being sensitive to indirect effects of selection.

A more subtle statistical issue relates to the theoretical distribution of the test statistic for sequences under recombination. The 2×2 test of independence of the MK test is based on the assumption of no recombination, so that the frequencies of different observations, i.e., the numbers in the contingency table, follow a multinomial distribution (Charlesworth and Charlesworth, 2010, p. 284). However, the MK test is relatively robust to recombination in the tested coding region, because synonymous and nonsynonymous sites share the same (local) genealogical history (Andolfatto, 2008). For the HKA test, on the other hand, neutral and selected sites do not share the same genealogy when the two regions are separated by recombination, or when there is recombination within the regions. This results in shorter or longer gene genealogies in one region over the other, and therefore more or less diversity due to chance. It adds another source of variance to the HKA test compared to the mutational variance accounted for in the MK test: the evolutionary variance of the gene genealogies. The MK test can be performed with any conventional test of independence (χ^2 test or Fisher's exact test, see Sokal and Rohlf, 2011), whereas the HKA test has to incorporate the evolutionary variance into the null distribution of its goodness-of-fit statistic. To do this, the HKA test assumes no recombination within the regions and no linkage between the regions, which are the most conservative assumptions one can make regarding linkage (Hudson *et al.*, 1987). However, to account for evolutionary variance, the HKA test makes three strong demographic assumptions: (1) constant population size, (2) random mating, and (3) ancestral population size equal to current population size (Hudson *et al.*, 1987).

In summary, the MK test is robust to any demographic assumption but cannot detect indirect effects of selection, like selective sweeps or background selection. The HKA test has power to detect indirect effects of selection and is more powerful to detect positive selection, but violation of the demographic assumptions, like population structure or bottlenecks, lead to an increased level of false positives (Andolfatto, 2008; Ford, 1998; Ingvarsson, 2004; Innan, 2006; Zhai *et al.*, 2009).

Other Tests of the Neutral Model

Haplotype-Based Tests

Another type of test uses information from haplotype patterns. The length of a haplotype is indicative about its age. Younger alleles tend to sit on longer haplotypes because they have not been disrupted by recombination. It is thought that positive

selection will bring young alleles to unusually high frequency (Hudson *et al.*, 1994). This idea of searching the genome for unusually long and common haplotypes as a test of selection has been implemented in the extended haplotype homozygosity (EHH; Sabeti *et al.*, 2002), cross population extended haplotype homozygosity (XP-EHH; Sabeti *et al.*, 2007), and integrated haplotype score (iHS; Voight *et al.*, 2006) tests and has been widely applied. Those methods are designed to discover incomplete (partial) sweeps, where the sweep haplotype is not fixed, but has reached a frequency $>10\%$. It has been argued that mutations that appeared after the human out-of-Africa migration are unlikely to have reached fixation today, even in case of a strong selective advantage (Coop *et al.*, 2009; Vitti *et al.*, 2013). In such a context, haplotype-based tests might provide useful information about adaptations to new environmental challenges. Recently, tests have been developed to detect soft sweeps, i.e., a pattern caused by multiple haplotypes increasing in frequency that can be the result of adaptation from standing genetic variation (Ferrer-Admetlla *et al.*, 2014; Garud *et al.*, 2015). Currently, rather little is known about performance of haplotype-based tests and their robustness to different demographic assumptions (but see Crisci *et al.*, 2013; Ferrer-Admetlla *et al.*, 2014).

Population Differentiation

A final category of test of the neutral model is based on population differentiation. It is predicted that population-specific positive selection will yield single nucleotide polymorphisms (SNPs) that show large differences in allele frequency across populations. A popular approach involves examining the distribution of F_{ST}, a summary of genetic variation, across the genome (Akey *et al.*, 2002; Oleksyk *et al.*, 2008). SNPs showing high values of F_{ST} may be candidates for positive selection (Beaumont and Balding, 2004; Foll and Gaggiotti, 2008; Guo *et al.*, 2009). A difficulty is that this outlier approach is not a formal test of neutrality, as there will always be outlier variants, even under neutrality. Thus, a more rigorous approach involves testing whether the differentiation at a candidate SNP is unusual under a null model of demography. The classical test is based on an infinite island model with symmetric migration and equal population sizes (Lewontin and Krakauer, 1973), and was shown to be quite robust against models of recent divergence and growth, or two-dimensional stepping stone models (Beaumont and Nichols, 1996). Importantly, the test is not robust against models with hierarchical population structure, i.e., when demes are grouped and exchange more migrants within groups than between groups (Excoffier *et al.*, 2009; Hermisson, 2009). These problems can arise due to historical population branching, or due to barriers to gene flow that isolate populations in different parts of a species range. Recent methods have extended the Lewontin–Krakauer test to account for hierarchical population structure (Bonhomme *et al.*, 2010; Excoffier *et al.*, 2009; Fariello *et al.*, 2013). Scanning the genome for sites with unusual population differentiation has yielded important candidate genes for adaptation in humans related to altitude (Bigham *et al.*, 2010; Simonson *et al.*, 2010), disease resistance (Barreiro *et al.*, 2008; Cagliani *et al.*, 2011; Fumagalli *et al.*, 2011, 2010), or climate (Lao *et al.*, 2007; Rees and Harding, 2012).

Neutral Models of Genetic Drift and Mutation

PW Messer, Cornell University, Ithaca, NY, USA

Glossary

Allele Specific molecular variant at a locus.
Demography History of population size changes over time.
Diffusion process Continuous-time stochastic process describing the random movements of particles.
Haplotype Combination of individual molecular markers that tend to be inherited together.
Locus Position in the genome where an allele resides.
Markov process Stochastic process in which the transition rates depend only on the previous state.
Null model Baseline model used to test whether additional processes need to be considered.
Ploidy Number of sets of chromosomes present in a cell (one set: haploid; two sets: diploid).
Poisson process Continuous-time stochastic process for modeling events that occur at a specified rate.
Segregating site Genomic position at which more than one allele is present in a population sample.
Substitution Mutation that has become fixed and is now present in every individual in the population.

Random Genetic Drift

In a finite population, the number of individuals that carry a specific allele may change over time merely due to stochastic variation in the reproductive success among individuals. This effect is termed random genetic drift. For studying genetic drift in statistically meaningful ways, we rely on idealized models that capture key biological aspects of the process while remaining mathematically tractable. The most commonly used model is named after two of the founders of population genetics, Ronald A. Fisher (Fisher, 1930) and Sewall Wright (Wright, 1931).

The Wright–Fisher Model

The Wright–Fisher (WF) model describes a population with discrete, nonoverlapping generations. In each generation the entire population is replaced by the offspring from the previous generation. Parents are chosen via random sampling with replacement. In a haploid population of constant size N, the probability that an allele present in i individuals will be present in j individuals in the next generation is then given by the binomial sampling probability

$$P_{ij} = \binom{N}{j} (i/N)^j (1 - i/N)^{N-j} \quad 0 \le i,j \le N \qquad [1]$$

The transition probabilities P_{ij} define a discrete-time Markov process on the state space of allele frequencies $x(t) = i(t)/N$. Expected allele frequencies remain constant across generations, whereas the variance per generation is $\mathrm{Var}[x] = x(1-x)/N$. The probability that an allele eventually becomes fixed is simply its initial frequency. In particular, the fixation probability of a new mutation present in a single copy is $1/N$. It is straightforward to extend the WF model to diploid systems by exchanging $N \to 2N$, as well as to nonconstant population sizes by taking larger or smaller samples in each generation.

Several alternatives to the WF model have been proposed for describing random genetic drift, notably the Moran and the Cannings models (Ewens, 2004). The Cannings model is a generalization of the WF model that can incorporate arbitrary variance in allele frequency between generations, which can span a wide range in biological populations. The Moran model is a continuous-time model with overlapping generations. Additional levels of biological complexity that one may wish to incorporate include different sexes, age structure, demography, and population substructure. The study of drift in such models is often facilitated by the concept of an effective population size, which specifies the population size of an idealized WF model that approximates evolutionary patterns in the real scenario (Charlesworth, 2009).

Loss of Diversity in the WF Model

We can easily quantify the rate at which genetic diversity is lost in the WF model. Consider an allele present at frequency $x(t)$ in generation t. When drawing two random individuals from the population, the probability that only one of the individuals carries the allele is $H(t) = x(t)[1 - x(t)]$. This probability is called heterozygosity and provides a useful measure for the level of diversity in a population. In generation $t+1$, two possibilities need to be distinguished: We might pick two individuals that have different parents in generation t, in which case the probability that only one will carry the allele, by definition, is $H(t)$. However, since parents are drawn with replacement, we can also pick two individuals that happen to have the same parent in generation t. In this case, the two individuals will either both have the allele or neither will have it. The probability of picking two individuals that originate from the same parent is $1/N$ in a haploid population of size N, and so the probability that they have different parents is $1 - 1/N$. This yields the recursion $H(t+1) = 1/N \times 0 + (1 - 1/N) \times H(t)$. Defining $H_0 = H(t=0)$, we obtain

$$H(t) = \left(1 - \frac{1}{N}\right)^t H_0 \approx \mathrm{e}^{-t/N} H_0 \qquad [2]$$

Genetic diversity is thus lost at an exponential rate in the WF model. For example, after approximately $N\log(2)$ generations, half of the initial variation will be lost.

The Diffusion Approximation

The WF model specifies the drift process by a discrete-time Markov process over a finite state space, defined by the transition probabilities $P[x(t+1)|x(t)]$ between generations. In principle, we can calculate transition probabilities over longer time intervals through iterative summation over all possible intermediate states. However, these calculations have proven extremely difficult in practice.

An elegant solution to this problem was provided by Motoo Kimura in the 1950s. Kimura showed that in large populations the discrete WF process can be closely approximated by a continuous time, continuous space diffusion process (Kimura, 1955). Specifically, the time evolution of the probability density $\phi(x,t)$ that an allele is at frequency x at time t can be modeled by the partial differential equation

$$\frac{\partial}{\partial t}\phi(x,t) = \frac{1}{2}\frac{\partial^2}{\partial x^2}[b(x)\phi(x,t)] \quad [3]$$

where $b(x) = \mathrm{Var}[dx]/dt$. In a haploid WF population of size N, we have $b(x) = x(1-x)/N$. Equation [3] is also known as the Kolmogorov forward equation and together with its close analogue, the Kolmogorov backward equation, it enabled the derivation of analytical expressions for various evolutionary quantities. For example, the expected time that an allele initially present at frequency x will remain polymorphic in the population until it either becomes fixed or lost is $-2N[x\log(x) + (1-x)\log(1-x)]$ generations, which is the same as the average time that an allele present at frequency x has already spent in the population if it originally arose in a single copy (Kimura and Ohta, 1973). For those alleles at frequency x that do eventually fix, the average time to fixation is $2N[(1-x)\log(1-x)]/x$; for those that become lost, the average time to loss is $2Nx\log(x)/(1-x)$ (Kimura and Ohta, 1973).

Kimura's solution to the diffusion approximation provides the full distribution of transition probabilities over arbitrary time intervals, which allows for the calculation of a wide range of summary statistics such as allele-frequency distributions, fixation probabilities, and sojourn times. The profound impact of the diffusion approximation on modern population genetics has been greatly facilitated by the fact that it also offers a straightforward approach for incorporating selection into its calculations (Kimura, 1964).

Mutation Models

In natural populations, mutational processes constantly generate new genetic variants upon which drift can act. As with drift, we again rely on idealized models to study the consequences of such mutational processes. Three basic models are widely used:

K-Alleles Model

The K-alleles model assumes that there exist only a finite number of possible alleles $\{A_1,\ldots,A_k\}$ at a locus – for instance the four different nucleotide states A,C,G,T. Mutations convert allele A_i into allele A_j at rate μ_{ij}. This defines a rate-matrix, $\mathbf{U} = \{\mu_{ij}\}$, with diagonal elements given by $\mu_{ii} = 1 - \sum_{i\neq j}\mu_{ij}$. We can incorporate this model into the WF framework by combining allele frequencies into a vector $x(t) = (x_1,\ldots,x_k)$. After each generation, allele frequencies then simply need to be adjusted according to $x'(t) = x(t)\mathbf{U}$. If we were to neglect drift, this process will converge toward an equilibrium distribution of allele frequencies specified by the condition $x(t) = x(t)\mathbf{U}$. For example, in a model with only two alleles, these equilibrium frequencies will be given by $\bar{x}_1 = \mu_{21}/(\mu_{12}+\mu_{21})$ and $\bar{x}_2 = \mu_{12}/(\mu_{12}+\mu_{21})$.

Infinite Alleles Model

In contrast to the K-alleles model, the infinite alleles model assumes that there is no limit to the number of possible alleles at a locus and that each mutation produces a new allele that has not previously existed in the population. We can describe this model in terms of a Markov process for allelic states with an infinite state space: $A_1 \rightarrow A_2 \rightarrow A_3 \rightarrow \ldots$. Mutations are assumed to occur at a uniform rate in this model. The infinite alleles model is commonly used for describing haplotypes in a sufficiently large genomic region, if one can assume that every mutation or recombination event creates a novel haplotype.

Infinite Sites Model

The infinite sites model is an extension of the infinite alleles model that preserves information on the mutational history of each allele. We can construct this model from the infinite alleles model by assuming that our locus contains an infinite number of individual sites. Each mutation event produces a point mutation at a new site. This allows for the definition of an evolutionary distance between two alleles in terms of the number of point mutations by which they differ. The infinite sites model is often used for describing genomic regions in which the rate of point mutation per site is very low, such that double hits and back mutations can be ignored.

Patterns of Neutral Genetic Variation Under Mutation and Drift

In a WF population, drift systematically removes diversity from the population. This loss is counterbalanced in natural populations by the continuous generation of new mutations. The study of the interplay between these two processes has led to important insights into how genetic diversity can be maintained within populations even in the absence of selective forces.

The Coalescent Process

When studying patterns of diversity in real systems it is typically unrealistic to obtain information for every individual in

the population. Instead, observations will often rely on samples taken from the population. One of the most fruitful insights in modern population genetics was the realization that for understanding evolutionary patterns it often suffices to focus on the genealogical history of such population samples, rather than the population as a whole.

The mathematical framework that captures this approach, coalescent theory, was developed in the 1980s by Kingman (1982) and others. It has since come to be the workhorse of population genetics, especially for scenarios in which selective forces can be ignored. Due to its focus on population samples, results from coalescent theory are often directly relatable to empirical observations and tend to provide a very intuitive understanding for the interplay between patterns and processes. In addition, the coalescent process offers a very efficient framework for numerical simulations (Hudson, 2002).

Before we address how mutations can be incorporated into the coalescent framework, let us quickly review some key properties of the standard coalescent in the absence of mutation. The coalescent is a continuous-time Markov process for modeling the genealogy of a population sample under random genetic drift. Note that the coalescent is not a framework for inferring the actual genealogy of a given population sample, which may be very difficult in practice. Rather, it provides a stochastic model that allows us to study the patterns we would expect to observe in such a sample under a given evolutionary scenario. The key event of the coalescent process is that two lineages in the sample can coalesce when going backward in time because they share a common ancestor, reducing the number of remaining lineages by one. Consider a haploid WF population of size N, composed of genetically identical individuals. In this population, two lineages coalesce in the previous generation with probability $1/N$. In the continuous-time coalescent framework, we describe this event by a Poisson process with instantaneous coalescence rate dt/N. The expected time until a given pair of lineages coalesces is then $E[t_c]=N$ generations, and the probability that two lineages have not yet coalesced after t generations is $P[t_c>t]=(1-1/N)^t\approx e^{-t/N}$.

In samples with more than two individuals, the coalescent process is slightly more complicated, as coalescence can occur between any possible pair of lineages in the genealogy. In a sample of size n, there are initially $n(n-1)/2$ possible pairs. The average time until the first two lineages coalesce is thus $2N/[n(n-1)]$ generations. Each coalescence event reduces the number of remaining lineages by one until all lineages in the sample have reached a single common ancestor. The expected time to reach this most recent common ancestor is $2N(1-1/n)$ generations and the expected total length of all individual branches in the coalescent tree is $E[L_n]=2N\sum_{i=1}^{n-1}(1/i)$ generations. For a more comprehensive review of coalescent theory, we encourage the reader to consult Wakeley (2008).

Adding Mutations to the Coalescent

Neutral mutations do not interfere with the genealogy of a population sample because they have no effect on the reproductive success of the individuals that carry them. In a neutral scenario, we can therefore treat coalescence and mutation by two independent Poisson processes. In particular, we can generate the genealogy first and then add mutations to the given genealogy afterwards ('mutation-dropping'). Mutations that occur in individuals outside of the genealogy can be ignored, as those mutations will not be observed in the sample. Along the branches of the coalescent tree, mutations are dropped at the same rate at which they occur in individuals and this can be done using any of the mutation models specified above. Figure 1 illustrates how this approach relates to a WF model with neutral mutations and how the resulting patterns will differ between the infinite sites and infinite alleles models.

We can immediately derive the expected level of heterozygosity in this framework. The probability that two individuals differ by at least one mutation is simply the probability that a mutation has occurred along their genealogy prior to coalescence. Mutation and coalescence are independent Poisson processes in the model, coalescence occurring at rate $1/N$ and mutation occurring at rate 2μ (the factor 2 arises

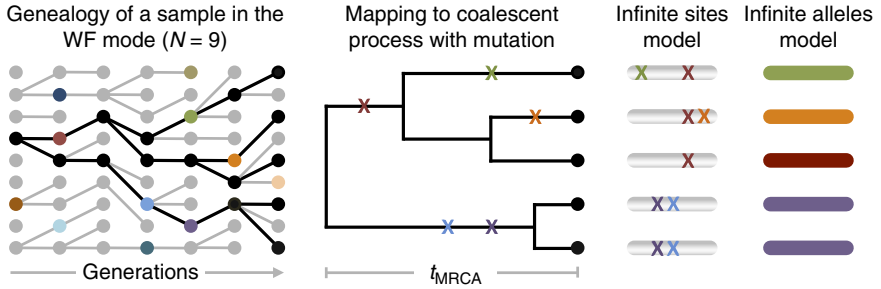

Figure 1 Correspondence between the WF model and the coalescence process. The left panel shows the genealogical relationships over six generations in a WF population with nine individuals. The black lines depict the genealogy of a sample of five individuals back to their most recent common ancestor. Colored circles indicate the occurrence of new mutations. The coalescent tree corresponding to this sample genealogy is shown in the middle panel. Note that in the coalescent we need to include only those mutations that occurred in individuals that are part of the sample genealogy. The right panel shows how patterns differ between the infinite sites and infinite alleles models. In the infinite sites model, every mutation occurs at a new site and each individual still carries all mutations that have occurred previously in its lineage. In the infinite alleles model, on the other hand, every mutation produces a new allele and the state of an individual is solely specified by the most recent mutation in its lineage.

because mutation can occur in either of the two lineages). The probability that a mutation occurs prior to coalescence is then

$$H = \frac{2\mu}{2\mu + 1/N} = \frac{\Theta}{1+\Theta} \quad [4]$$

with $\Theta = 2N\mu$. If $\Theta \ll 1$, we have $H \approx \Theta$, and the expected level of heterozygosity is thus simply twice the product of the population size and the mutation rate. Note that our derivation of eqn [4] applies to both the infinite sites and infinite alleles models. In contrast to a WF model without mutation, where heterozygosity decays exponentially, the addition of mutation therefore leads to the maintenance of an equilibrium level of heterozygosity that is proportional to the product of population size and mutation rate.

Site-Frequency Spectrum in an Infinite Sites Model

In the mutation-dropping approach we place mutations along all branches of the coalescent tree by a Poisson process with rate μ. The expected total number of mutations on the tree is then simply the product of the mutation rate and the expected total length of all tree branches (L_n). For a sample of size n, this yields

$$E[S] = \mu E[L_n] = \Theta \sum_{i=1}^{n-1} \frac{1}{i} \quad [5]$$

Under an infinite sites model, each of these mutations will have created a new polymorphic site in the sample. $E[S]$ therefore specifies the expected overall number of segregating sites in a sample of size n. Specifically, in a sample of size two, we expect to find $E[S] = \Theta$ segregating sites. For a derivation of the full probability distributions, $P[S = k]$, see Wakeley (2008).

In addition to the overall number of segregating sites in the sample, one might be specifically interested in the number of mutations, s_i, that are present in exactly i individuals in the sample. The vector $(s_1, s_2, \ldots, s_n)$ is called the site-frequency spectrum of the sample. In the infinite sites model, the expected value of s_i in a sample of size n is given by

$$E[s_i] = \frac{\Theta}{i}, \quad i = 1, \ldots, n \quad [6]$$

This famous equation has been derived in a number of ways, including the WF model, diffusion theory, and the coalescent framework, see, for example, Ewens (2004) for a collection of proofs.

Site-frequency spectra can be directly measured from population samples, making them a widely used statistic for evolutionary inferences. Importantly, we know that a number of processes, including demography and selection, are expected to produce characteristic deviations in the shapes of observed spectra from the theoretical prediction of eqn [6]. Comparison of empirical spectra with theoretical predictions has therefore become a popular approach for inferring the presence of such processes.

Ewen's Sampling Formula for the Infinite Alleles Model

Under the infinite alleles model every mutation event creates a new allele that maintains no information on its mutational history. In a sense, this makes the coalescent process simpler, as large parts of the genealogy will have no influence on the allele-patterns observed in a sample. Each lineage needs to be followed only until the most recent mutation, whereas mutations and coalescence events further back in time can be ignored. The mathematical process for describing this scenario is the so-called coalescent with 'killings,' in which coalescence and mutation are modeled simultaneously and each lineage is terminated once a mutation is encountered. The process stops when only a single lineage remains.

Since there is no information in the comparison of two alleles other than whether they are different or the same, the primary quantities of interest in this model are how many different alleles there are in the sample, and how many of those alleles are present in 1,2,… individuals, the counts of which we denote by a vector $(a_1, a_2, \ldots)$. The probability of observing a given set of counts $(a_1, a_2, \ldots, a_n)$ in a random sample of size n, drawn from a constant-sized population evolving under neutral mutation and drift, is (Ewens, 1972)

$$P[(a_1, a_2, \ldots a_n)] = \frac{n!}{\Theta_{(n)}} \prod_{j=1}^{n} \frac{(\Theta/j)^{a_j}}{a_j!} \quad [7]$$

where $\Theta_{(n)} = \Theta(\Theta+1)\ldots(\Theta+n-1)$. Note that the number of distinct alleles in the sample is simply $k = \sum_{i=1}^{n} a_i$. Equation [7] is known as Ewen's sampling formula. As already noted above, the infinite alleles model is frequently used for describing the expected haplotype frequencies at a neutral locus evolving under mutation, recombination, and drift.

The Neutral Theory of Molecular Evolution

Neutral alleles present in a single copy in a haploid WF population of size N eventually become fixed with probability $1/N$, assuming that mutational processes are not affecting allele frequencies. This important result holds true more generally for models in which all individuals in the population have equal, nonzero probability of ultimately becoming the common ancestor to all individuals present at a future point. In the infinite sites model with neutral mutations arising at rate μ per individual, the overall rate at which substitutions accumulate in the population is therefore

$$u = N\mu \times \frac{1}{N} = \mu \quad [8]$$

Hence, the substitution rate simply equals the mutation rate per individual and is independent of population size. Figure 2 provides an illustration for how neutral mutations in an infinite sites model can occasionally drift to fixation in the population.

There has been a long-standing debate about whether random genetic drift and neutral mutation suffice to describe the majority of patterns of molecular variation observed in real biological systems. While selectionists argue that natural selection plays an important role in driving molecular divergence between species, as well as maintaining genetic diversity within populations, the neutral theory of molecular evolution posits that the vast majority of observed genetic variation is in fact selectively neutral and that molecular divergence between species is primarily the result of drift (Kimura, 1983). One key prediction of neutral theory is that

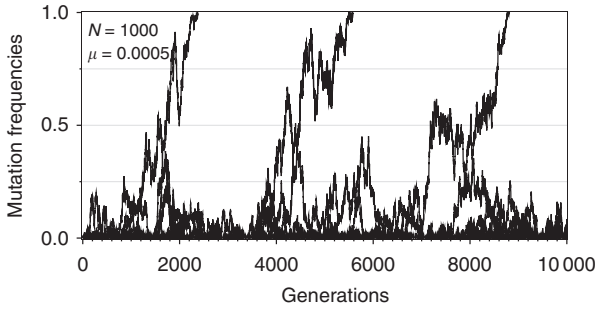

Figure 2 Trajectories of mutation frequencies in a simulated WF population of size $N=10^3$, evolving under an infinite sites model with mutation rate $\mu=0.0005$. A large number of mutations can be seen to arise over the course of the simulation, but the vast majority are quickly lost due to drift. Some mutations, however, succeed in drifting to higher frequencies and three of those mutations actually become fixed in the population, well within range of the $\mu \times 10^4=5$ substitutions we expect to observe over the duration of 10^4 generations.

substitution rates should then be approximately constant over time, and that we can therefore use the observed numbers of substitutions between species as a 'molecular clock' for dating phylogenetic events (Zuckerkandl, 1987).

The neutral theory of molecular evolution has been tremendously influential in helping us understand how stochastic processes can contribute to evolutionary dynamics. However, with the advent of population genomic data, it has become increasingly clear that natural selection does often play an important role in molecular evolution. Moreover, it is no longer clear whether the second pillar of neutral theory, random genetic drift, is always the dominant stochastic process, as it could be outrivaled by other stochastic processes such as genetic draft, which describes the fluctuations in allele frequency due to linkage with nearby selected mutations (Gillespie, 2000). Nevertheless, neutral theory has firmly established itself as the standard null model of population genetics and will likely continue to play an important role as the baseline scenario for the development of improved evolutionary theories (Kreitman, 1996).

Noncoding DNA Evolution: Junk DNA Revisited

MZ Ludwig, University of Chicago, Chicago, IL, USA

Nomenclature

bp base pair
CRE *cis*-regulatory element
eve S2E even-skipped stripe 2 enhancer
ncDNA noncoding DNA

Glossary

***Cis*-regulatory elements (CREs)** CREs are regions of noncoding DNA which regulate the transcription of nearby genes.
Enhancer The smallest fragment of DNA that, when linked to a reporter gene and transferred into an appropriate cell, executes a regulatory function in a fashion consistent with that of the native gene in its proper context.
Junk DNA Initial definition for nongenic DNA that had no known biological function.
Noncoding DNA (ncDNA) ncDNA sequences are components of an organism's DNA that do not encode protein sequences.
Position weight matrices (PWM) Quantitative representations of DNA-binding specificity for a transcription factor protein.
Transcription factor Sometimes called a sequence-specific DNA-binding factor, transcription factor is a protein that binds to specific DNA sequences, thereby controlling the rate of transcription.
Transcription factor binding sites Short DNA sequences (typically 4–30 base pairs long) that are the targets for binding by transcription factors.

Introduction

Numbers of proteins-coding genes do not change across the metazoan as a whole, and certainly not in relation to large differences in organismal complexity. The lack of correspondence between genome size (amount of DNA), morphological complexity, and coding proteins gene number is a prominent topic of discussion that started more then 40 years ago. Eukaryotic genomes mostly consist of DNA that is not translated into protein sequence (Alexander *et al.*, 2010). However, noncoding DNA (ncDNA) has been little studied relative to proteins. The lack of knowledge about its functional significance has led to hypotheses that much nongenic DNA is useless 'junk' (Ohno, 1972) or that it exists only to replicate itself (Doolittle and Sapienza, 1980; Orgel and Crick, 1980). A large fraction of many eukaryotic genomes consists of middle-repetitive DNAs and transposable elements that may constitute 'selfish' DNA. Variety and patterns of their interspersion with coding DNA make no phenotypically functional sense. Perhaps, this excess of DNA that does not affect the organismal fitness is carried passively from generation to generation, because of its physical linkage to functional genes. Indeed, there are indications that removal of certain ncDNA can be done without deleterious effects on phenotype.

The ncDNA, we now know, performs many essential functions, especially in the regulation of gene expression, but it is unclear yet how much of it is necessary. Functional components of ncDNA regulatory sequences are called *cis*-regulatory elements (CREs), including enhancers, core promoters, matrix or scaffold attachment regions, insulators, and silencers (Levine and Tjian, 2003). These regulatory sequences are distributed among selfish transposons and middle or short repetitive DNAs. The genome is an extremely complex machine; functionally as well as structurally it is generally not possible to disentangle the regulatory function from the junk selfish activity. The idea of junk DNA needs to be revised.

Mutations in ncDNA that affect regulation of gene expression can be a major source of evolutionary change (Carroll *et al.*, 2001). To understand the mechanisms by which CREs contribute to evolution, several fundamental questions need to be addressed, such as how conservative are the function and the sequence of CREs on an evolutionary time scale, and how CREs evolve a new function.

Regulation of gene expression involves an interaction between transcription factors and CREs. Eukaryotic genes contain highly structured regulatory DNAs that direct complex patterns of expression in many different cell types during development. Classes of regulatory elements to which the transcription factors bind include core promoters, enhancers, silencers, and insulators (**Figure 1**).

This article highlights evolutionary forces that can shape structure/function of CREs as a portion of ncDNA in eukaryotes. The major emphasis will be to characterize the evolution of enhancers.

CRE Structure/Function

Unfortunately, there is no general definition of a CRE. The best working definition follows one given by Arnone and

 doi:10.1016/B978-0-12-800049-6.00168-2

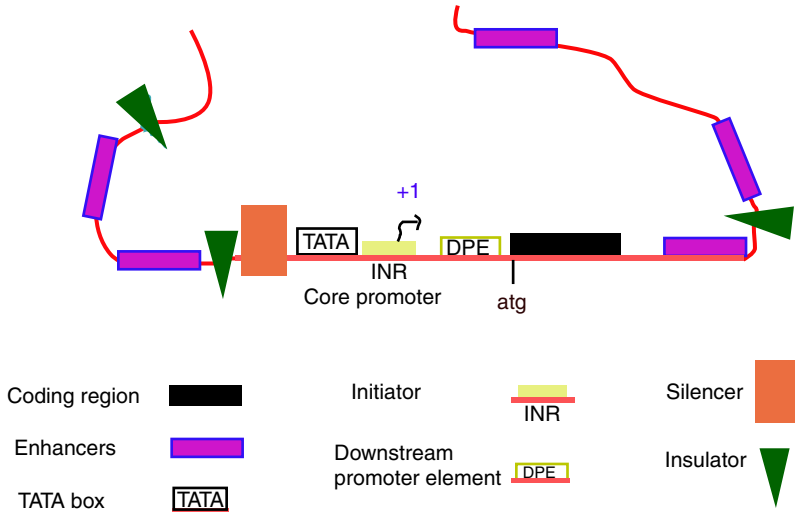

Figure 1 CREs in a eukaryotic transcription unit. TATA, TATA box; INR, initiator sequence; DPE, downstream core promoter element.

Davidson (1997) to enhancer: a *cis*-element such as an enhancer is defined as the smallest fragment of DNA that, when linked to a reporter gene and transferred into an appropriate cell, executes a regulatory function in a fashion consistent with that of the native gene in its proper context. This definition evidently simplifies natural relations between CRE structure and its function by paring down *cis*-neighboring sequences. It is not possible to define precise borders (up to one nucleotide) for any class of CREs. This fact evidently creates serious problems for evolutionary analyses.

Enhancers are perhaps the best understood type of CRE. The first eukaryotic enhancer was initially identified and characterized in mammalian virus called SV40 (Banerji *et al.*, 1981). A virus noncoding sequence of 72 bp could turn on expression in a manner relatively independent of its position and orientation with respect to a nearby rabbit β-globin reporter gene. Enhancers are typically 100–1000 bp long, and contain multiple short binding site sequences (6–12 bases in length) for targeting several different activators and repressors of transcription. Binding site motifs for a given transcription factor are often degenerate, and are better characterized as a probability (position weight matrix) than as a consensus sequence. Bound transcription factors can interact in many different contexts, and they can function as either activator or repressor of transcription. The spacing of binding sites modulates transcription factor interactions; mechanisms of interaction include direct competition for overlapping binding sites, quenching over short distances (<150 bp), and long-range (>150 bp) interactions (Ondek *et al.*, 1988; Arnosti *et al.*, 1996; Gray and Levine, 1996; Barolo and Levine, 1997).

A typical animal gene can have many enhancers as well as other CREs in order to ensure appropriate regulation in response to different temporal or spatial (surrounding cellular environment) cues (**Figure 2**).

A key property of enhancers is that they can act independently of each another. This independence is perhaps achieved by their physical separation along the ncDNA. Insulators are specific sequences that also contribute to specificity of gene regulation by restricting the action of one enhancer from activity of another enhancer. An enhancer can be located anywhere within a span of 100 kb upstream or downstream of a gene whose expression it regulates, including introns.

CREs and Length Variation of ncDNA

Insertions and deletions (collectively indels) obviously have impact on distance between interacting CREs as well on total length of ncDNA. There are several known mechanisms that generate indels: genome duplication, complete and partial chromosomal duplication, proliferation of transposable elements, replication errors, and unequal crossover. All of these diverse mutational mechanisms of indel production contribute to single locus as well as total ncDNA size variation in the genome.

It appears that the parameters of indel evolution such as mutation rate, insertions to deletions ratio, and mean indel size differ between species. Nevertheless, some general rules exist: deletion mutations are always more frequent than insertion mutations, the genomic prevalence of indels declines with length, and this decline is faster for insertions than for deletions (Lynch, 2007).

Small length changes, generally involving tandem repeats ranging in size from one to eight bases, are a common form of mutation in the noncoding regions. There is, for example, abundant length variation in the *Drosophila even-skipped* stripe 2 enhancer (S2E), both polymorphic and fixed differences between closely related species. The abundance of length differences in the S2E is surprising since spacing of transcription factors along the enhancer should be important for its function (Ludwig and Kreitman, 1995).

Analysis of short indel polymorphism and divergence in different compartments of the *D. melanogaster* genome (exons, introns of different lengths, and intergenic regions) in whole-genome dataset on 158 genotypes demonstrates the excess of short deletion over short insertion mutations. However, polymorphism and divergence data show that this deletion bias is almost completely compensated by selection: negative

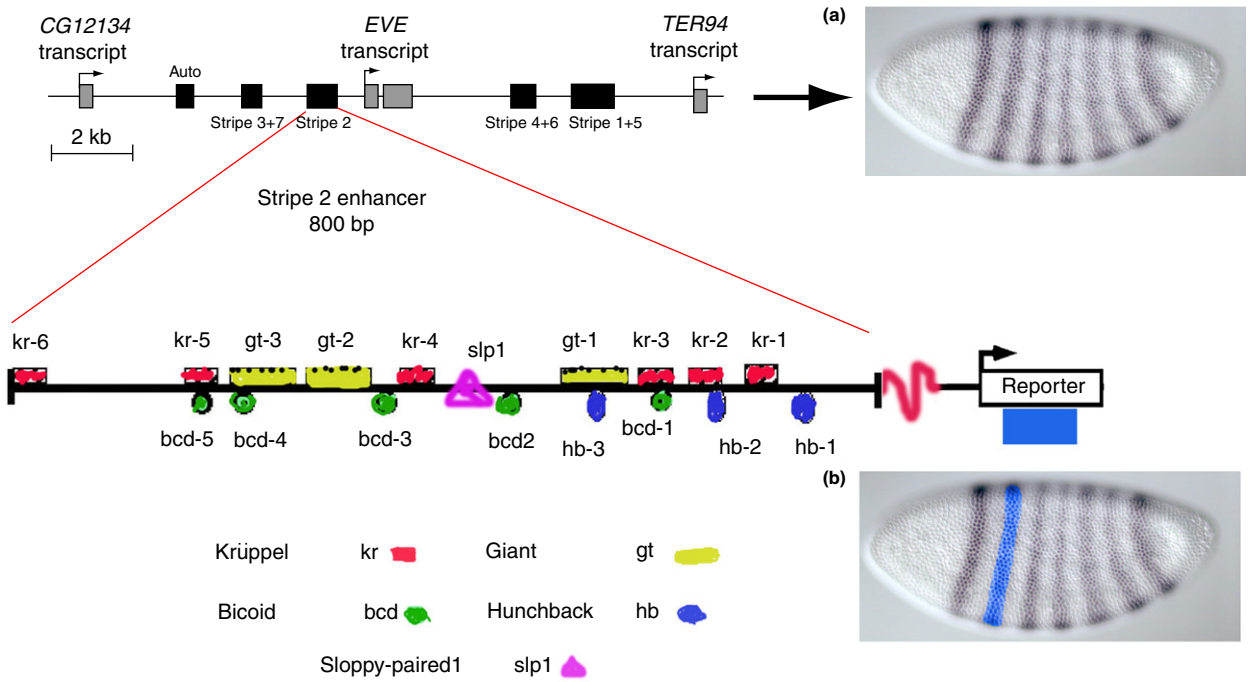

Figure 2 The *melanogaster even-skipped* locus of 16.4 kb is neighboring by two loci: *CG12134* and *TER94*. (a) The CREs-enhancers (black rectangles) regulate the *eve* seven stripes expression pattern at early embryogenesis stages. The *eve-skipped* protein; Stage 5. (b) Detailed view of the eve stripe 2 enhancer that contains many transcription factors binding sites (shown only experimentally validated binding sites for five transcription factors). This ~800 bp DNA fragment drives expression of reporter gene in stripe 2 (shown in blue).

selection is stronger against deletions, whereas insertions are more likely to be favored by positive selection. This implies a deletion bias, which needs to be compensated by opposing forces to prevent the genome from unrestrained contraction (Petrov, 2002; Leushkin *et al.*, 2013).

Preservation by Functional Constraint

Comparative genomics studies of ncDNA sequences show conserved regions interspersed among rapidly diverged segments, and conservation can be evident even after 300–450 million years of evolution (Muller *et al.*, 2002). Both the density and the block-lengths of highly conserved regions decrease as evolutionary distances increase. Interpretation of the punctate pattern of conservation in ncDNA has been guided by rules of molecular evolution first elucidated by Kimura (1983): "Functionally less important molecules or parts of molecules evolve (in terms of mutant substitutions) faster than more important ones." In other words, sequence-specific conservation of ncDNA implies functional constraint on these sequences and slower rates of molecular evolution.

Nearly 99% of the human genome does not encode proteins. A further 7% of the DNA has a functional regulatory gene expression role according to comparative genomics analysis of human genome with the pan-mammalian conserved sequence, ranging from dogs and rats to pandas and horses (Rands *et al.*, 2014). Thus, just to follow only comparative methods, there is no evidence for functional conservation of sequences for 92% of the human genome.

However, there are some serious caveats to the interpretation of quantitative comparative genomic data. First, conservative components of ncDNA in comparative genomics studies contain many different non-related classes of sequences, including *cis*-regulatory sequences, short and long functional noncoding RNAs, and cryptic genes. Additionally, comparative genomics has found noncoding elements that are conserved to varying degrees across mammalian or vertebrate genomes, which suggests some function conserved by natural selection. Lack of experimentally validated function for some ultra conserved elements, that can be >100 base pairs long and 100% identical across human, mouse, and rat genomes, shows that the extent of sequence conservation is not a good predictor of the functional importance of a sequence. Furthermore, the values obtained are also dependent on alignment methods and can vary substantially between different regions of a genome.

Crude comparative genomics analysis numbers alone provide little insight into evolutionary mechanisms acting in the noncoding portion of genome. Andolfatto (2005) has overcome the limitations described above by combining comparative genomic analysis with population-level variability data. To assess the mode of selection acting on ncDNA, he has analyzed polymorphism data for gene coding fragments and noncoding fragments scattered across the X chromosome of *D. melanogaster*. To estimate levels of between-species divergence, he compared *D. melanogaster* with its closely related sibling species, *D. simulans*. His analysis demonstrated that a large fraction of the non-translated genome is functionally important and subject to both purifying selection and

adaptive evolution. These results imply that, although positive selection is clearly an important facet of protein evolution, adaptive changes to ncDNA might have been considerably more common in the evolution of *D. melanogaster*.

Preservation of Function and Evolutionary Changes in CREs

Many functionally important noncoding sequences in genomes are not evolutionary conserved. Some of these have lineage-specific functions and others are simply missing by current comparative genomics methods. There are many examples of extensively diverged regulatory sequences that have retained expression specificity.

What can we say about the evolutionary processes governing the changes in these functionally conserved elements?

From experimental studies of evolutionary changes in functionally conserved regulatory elements in different species, the following observations can be gleaned: there is a lack of complete conservation of functional binding sites; there is rapid turnover of spacer sequences between binding sites; conservation is apparent; turnover of binding site architecture occurs; and there is co-evolution of sites within an enhancer.

The S2E from segmentation gene *even-skipped* in *Drosophila* illustrates these points. This *cis*-element drives expression of the gene in a transverse stripe approximately 3 to 5 cells in width in early blastula embryo in many different dipteran species (Stanojevic *et al.*, 1991; Small *et al.*, 1992). This enhancer has been extremely well characterized in the fruit fly, *D. melanogaster*. For this reason, this CRE has been intensively studied from an evolutionary perspective among other species, including sepsid fly, *Themira putris* (Hare *et al.*, 2008). Enhancer from these two species, which diverged about 100 millions years ago, are unalignable at the DNA sequence level. Predicted locations of the functionally important transcription binding sites are absolutely different (**Figure 3**). However, in transgenic experiments a sepsid S2E sequence can be identified that drives expression of reporter gene in an embryonic transverse stripe in nearly the same location as observed with the endogenous *melanogaster* S2E enhancer.

Models of Enhancer Evolution

A number of evolutionary models have been proposed to explain the observations concerning evolutionary changes in *cis*-elements such as enhancers. One proposal has been to model enhancer structure/function as a quantitative character. Many studies have shown that modular multibinding site architecture is required for eukaryotic enhancer function. The presence of multiple binding sites, each with many 'fuzzy'

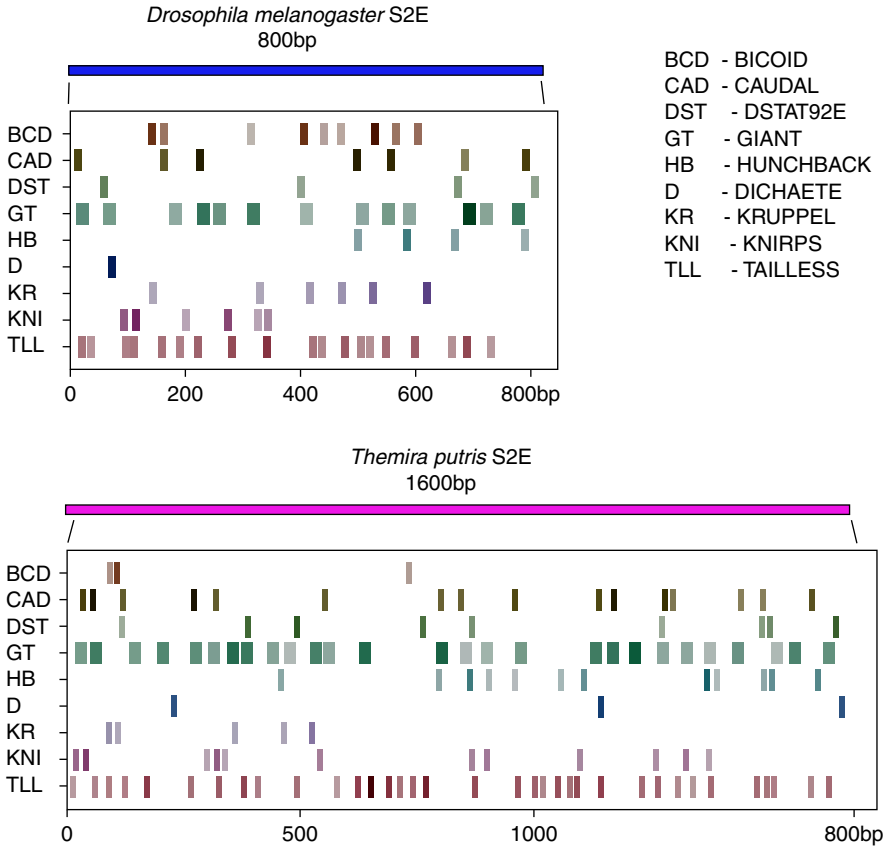

Figure 3 Strength and positions of predicted binding sites for transcription factors BCD (*bicoid*), CAD (*caudal*), DST (*Distat92E*), GT (giant), HB (*hunchback*), D (*Dichaete*), KR (*Kruppel*), KNI (*knirps*), and TLL (*tailless*) in the *even-skipped* stripe 2 enhancer of *Drosophila melanogaster* (~800 bp) and *Themira putris* (~1600 bp). Intensities of the color inside of the rectangles are proportional to the strength of binding site.

sites, and the possibility that subtle changes in spacing can also influence enhancer function, is compatible with the idea that many independent mutations will contribute to variation in gene expression. The spatio-temporal requirements for gene expression can then be viewed as a continuous character that can shift forwards and backwards subtly with mutations that affect transcription factor binding or interaction.

The above view naturally leads to the idea that the 'model of stabilizing selection' can be considered to be the major mode of enhancer evolution. Kimura (1981) investigated the rate of substitution assuming a quantitative character subject to stabilizing selection. If a large number of segregating sites (or loci) are involved, the average selection coefficient per mutant under stabilizing selection will be small. These weak mutations can then be controlled by genetic drift rather than selection, and the rate of substitution can be quite high. Applied to enhancer evolution, stabilizing selection can accommodate binding site turnover without disruption of primary enhancer function. The results of studies of the *eve* S2E evolution from *Drosophila* are consistent with the stabilizing selection model (Ludwig *et al.*, 1998; Ludwig *et al.*, 2000).

The evolution of some regulatory elements might also be consistent with a 'model of compensatory selection.' A pair of mutations at different sites (loci) that are singly deleterious but restore normal fitness in combination may be called compensatory neutral mutations. Kimura (1985) demonstrated that these mutations could easily become fixed in the population by genetic drift when the genes are tightly linked. Carter and Wagner (2002) modeled this process as it might apply to regulatory sequences. They found that large population size accelerates compensatory evolution, whereas small population sizes inhibit this form of drift from occurring.

Some theoretical and empirical studies have challenged the feasibility of compensatory evolution for transcription factor binding sites gain and loss (turnover) in CREs. A completely neutral model cannot achieve a high enough level of the turnover to explain observed rates for enhancer evolution in *Drosophila* (Durrett and Schmidt, 2008). The observed patterns of polymorphism and divergence in the transcription factor binding sites of well-characterized enhancers in two closely related *Drosophila* species are consistent with contributions of 'positive selection' to the transcription factor binding sites turnover as well as purifying selection in its maintenance (He *et al.*, 2011).

Origin of *Cis*-Elements with Novel Function

The major challenge for modeling the evolution of a novel regulatory element is to allow for the stepwise evolutionary progression of an element from one that initially contains by chance only a small number of functional transcription factor binding sites.

Moreover, the mechanisms of any CREs action always assume an interaction with their core promoter to achieve transcription of regulated gene. *Cis*-elements, including enhancers, cannot work alone without core promoters. Functional relatedness between the core promoter and enhancers, supporting the hypothesis that enhancers could have evolved from preexisting core promoter domains that bind essential transcription factors (Pikaard, 1994).

Three hypotheses have been proposed for how CREs evolve a new function through the modification and divergence of preexisting ones: first, duplication and DNA rearrangements involving either all or part of existing functional elements; second, modification of existing elements – for example, through gain and loss of binding sites, or acquisition of binding sites for additional transcription factors; and third, co-option of an existing element and expansion of its developmental function. These three scenarios adhere to generally accepted principles of developmental biology and population genetics; they involve the evolutionary modification of preexisting elements and they allow for a novel function to be gained without breaking the primary function of CREs.

Conclusion

Most of our current knowledge about evolution of ncDNA comes from direct experimental functional studies and/or indirect comparative genomics approaches.

Interspecific sequence comparisons of noncoding regions reveal conserved features, many of which are likely to be functional CREs. But despite obvious indications of selective constraint, the structure and sequences of *cis*-elements change over time, sometimes dramatically so – even in cases where expression patterns are conserved. Functional conservation of gene expression is not sufficient, therefore, to assure the evolutionary preservation of corresponding CREs.

It should be evident that a variety of evolutionary processes shape the structure of ncDNA. Functionally important regulatory sequences will tend to be conserved as a result of negative selection against deleterious mutations and positive selection for better-canalized performance. This need not be the case, however; some forms of stabilizing selection can maintain functional conservation of CREs for long periods of evolutionary time despite structural architecture turnover. In addition, compensatory evolution can even accelerate the substitution process in large populations to a level greater than the neutral rate of substitution. Finally, insertions and deletions have major impact on ncDNA evolution. This type mutation affects the transcription factor interactions that modulated by the spacing of binding sites in CREs. Negative selection is stronger against deletions, whereas insertions are favored by positive selection.

Eukaryotic CREs contain regulatory sequences that provide robustness of gene expression to genetic and environmental perturbation. Their function is not merely to turn genes 'on' or 'off' but to do so under a range of genetic and environmental (for example: gene dosage and temperature) conditions experienced by cells in a developing organism. Our work with *eve* S2E suggests that the architecture of enhancers (numbers and composition of the transcription binding sites) is adjusted by natural selection to ensure robust gene expression. Such adaptive fine-tuning may explain how CREs experience rapid sequence divergence between closely related species while exhibiting functional conservation (Ludwig *et al.*, 2011; Manu *et al.*, 2013).

Interactions between different CREs and multiple transcription factors could be seen as being parts of epistatic networks.

Under this view, all elements of this genetic system somehow should coevolve in both sequence-specific and location-specific ways to achieve the best possible functional performance. It will be difficult to elucidate how natural selection operates across such a complex system by examining either one gene at a time or the entire system of interacting genes, the two most common approaches employed in current research.

One of the main goals of fundamental biology is to identify CREs in ncDNA, understand their properties, and decipher how these elements regulate cell function by interacting with one another. The ultimate goal is to reveal the most basic laws of biology, which would allow us to understand functional aspects of evolutionary processes acting on ncDNA: preservation and variation of *cis*-elements structure/function and origin of *cis*-elements with novel function.

Acknowledgment

I thank Kenneth Barr for providing information on predicted binding sites for Transcription Factors in *even-skipped* gene.

Glossary

Co-option Reuse of preexisting genes, proteins, or systems with different functions from original ones, which sometimes enables organisms to establish new phenotypes without generating new genes, proteins, or systems from scratch.

Horizontal gene transfer Transfer of genes or any other genetic elements between different organisms.

Small RNA One of the major classes of noncoding RNAs, normally less than 50 nucleotides in length. Most of them are involved in regulation of genes and genomes.

General Introduction

Noncoding RNAs (ncRNAs) include all RNAs that do not encode any proteins but function as RNA molecules. Ribosomal RNAs and transfer RNAs, which play central roles in protein synthesis, have been recognized as representatives of ncRNAs for a long time. However, several different ncRNAs have recently been identified with the advancement of molecular biology and sequencing technologies (Table 1).

Discoveries of small RNAs including microRNAs (miRNAs), short-interfering RNAs (siRNAs), and Piwi-interacting RNAs (piRNAs) have attracted much attention in recent years. Many of these small RNAs associate with several common proteins to regulate genes, transposons, and even exogenous viruses. Because the regulation of genes and genomes is one of the key factors in organismal evolution, we should understand the origin and evolution of not only protein-coding genes but also ncRNA genes as well as other regulatory elements.

In this article, we review the origin and evolution of ncRNAs. We will mainly focus on eukaryotic small RNAs, i.e., miRNAs, siRNAs, and piRNAs, which have been relatively well characterized, and will illustrate the interconnection among them, particularly regarding their evolutionary processes. We will also briefly mention prokaryotic small RNAs to describe the commonality in the evolutionary processes of small RNA-based regulatory systems between eukaryotes and prokaryotes. Readers who are interested in other ncRNAs may refer to the following review articles: Shabalina and Koonin, 2008; Fox, 2010; Cech and Steitz, 2014.

microRNAs

Among eukaryotic small RNAs, miRNAs were first discovered in 1993 in *Caenorhabditis elegans* (Lee *et al.*, 1993). miRNAs are 21–24 nucleotides (nt) in length and regulate a variety of protein-coding genes at the posttranscriptional stage. Many eukaryotes, such as animals and plants, have hundreds to thousands of miRNA loci in their genomes. Many of these loci are independently located throughout genomes but some are clustered and function cooperatively through polycistronic transcription. When a miRNA gene is transcribed, the transcript immediately forms a hairpin (palindromic) structure. After several processing steps mediated by RNases such as Dicer (and Drosha in animals), a mature miRNA/miRNA* duplex is assembled into a RNA-induced silencing complex (RISC) including Argonaute. In general, only the antisense strand (or mature miRNA), which is complementary to the target RNA, is selected in this process, and the sense strand (or miRNA*) is degraded. Finally, the RISC binds to the target mRNA and prevents its translation (Carthew and Sontheimer, 2009).

These processes are largely shared in animals and plants but some key differences should be noted. For example, in plants a miRNA in RISC generally binds to a target mRNA with nearly perfect base complementarity and cleaves it with endonuclease activities, whereas an animal miRNA imperfectly binds to its target and typically represses translation without cleavage. The relationship between miRNAs and their targets is thus not one-to-one but many-to-many, particularly in animals (Grun *et al.*, 2005). This indicates that a considerable number of protein-coding genes can be regulated by miRNAs. Indeed, a bioinformatic prediction suggested that as many as ~30% of human genes are likely to be targets of miRNAs (Lewis *et al.*, 2005).

Origin of microRNAs

As mentioned above, miRNAs are present in eukaryotes including animals and plants (Figure 1). There are two possible explanations for the origin of miRNAs. One possibility is that miRNAs originated independently in animals and plants. This idea can be supported by the fact that biogenesis and target suppression differ between plant and animal miRNAs (Shabalina and Koonin, 2008). In addition, miRNAs have not been identified in some eukaryotes, such as fungi and choanoflagellates, whose phylogenetic positions are between animals and plants (Axtell and Bowman, 2008). Moreover, miRNAs have not been identified in ctenophores, the most basal animals (Maxwell *et al.*, 2012). Therefore, miRNAs may have originated independently in the lineage ancestral to plants and green algae and the other lineage ancestral to cnidarians and bilaterians. However, a recent study supports a common origin of the miRNA system in animals and plants. Moran *et al.* (2014) reported that several cnidarian species such as hydras, a sister group of bilaterians, have cleavage-type miRNAs in the genomes, which is analogous to plants. The cnidarian miRNA

Table 1 Characteristics of major noncoding RNAs (ncRNAs)

ncRNA	*Organism*	*Size (nt)*	*Source*	*Associated protein*	*Function*
Small RNA					
miRNA (microRNA)	Eukaryotes	21–24	Genomic loci (miRNA loci, introns)	Argonaute, Dicer, (Drosha[a])	Translational repression of mRNA, mRNA cleavage
siRNA (short-interfering RNA)					
Exo-siRNA (exogenous siRNA)	Eukaryotes	21–24	Viral or other exogenous RNAs	Argonaute, Dicer	Cleavage of exogenous RNA
Endo-siRNA (endogenous siRNA)	Eukaryotes	21–24	Genomic loci (mRNAs, Transposons, repeats), miRNA-cleaved RNAs, bidirectional transcripts	Argonaute, Dicer, RdRP	RNA cleavage
piRNA (Piwi-interacting RNA)	Animals	24–30	Genomic loci (transposons, repeats, piRNA loci)	Piwi, RdRP, Zucchini	Transcriptional repression, heterochromatin formation (DNA methylation), RNA cleavage
scnRNA (scan RNA)	Ciliates	25–32	Micronuclear	Dicer, Piwi	DNA elimination in developing macronuclei
crRNA (CRISPR RNA)	Prokaryotes	24–48	Genomic loci (CRISPR loci)	Cas	Cleavage of exogenous DNA/RNA
DsrA RNA	Eubacteria	~85	Genomic loci (DsrA loci)	Hfq	Translational repression and activation
Other ncRNA					
rRNA (ribosomal RNA)	Prokaryotes, Eukaryotes	100–5000	Genomic loci (rRNA loci in nuclei and mitochondria)	RNase III, RNase E, RNase G, ribosomal proteins	Protein translation
tRNA (transfer RNA)	Prokaryotes, Eukaryotes	73–93	Genomic loci (tRNA loci in nuclei and mitochondria)	RNase III, RNase P, RNase Z	Protein translation
snRNA (small nuclear RNA)	Eukaryotes	70–250	Genomic loci (snRNA loci)	RNase III, USB1	Modification, processing, and splicing of mRNA
snoRNA (small nucleolar RNA)	Eukaryotes	70–250	Genomic loci (introns of ribosomal RNAs)	RNase III, Rrp6p	rRNA processing, rRNA modification
lncRNA (long ncRNA)	Eukaryotes	>200	Genomic loci (*cis*-elements, introns, UTRs, pseudogenes)	Poly(A) Polymerase, Spliceosome	Transcriptional regulation

[a]Only in animals.

system may therefore be a mixture of the ancestral cleavage-type (plant-type) and the derived non-cleavage-type (animal-type). In other words, a transition from the cleavage-type to the non-cleavage-type may have occurred around the time of the cnidarian–bilaterian split. Future studies in different animal lineages will reveal more detailed aspects regarding the transitions.

Evolution of microRNAs

New miRNA genes have been generated by several mechanisms (Berezikov, 2011) that differ between animals and plants. In plants, transposons and duplicates of preexisting miRNA genes are major sources of new miRNA genes (Nozawa *et al.*, 2012). In animals or at least in flies, in contrast, many miRNA genes appear to have originated from introns (so-called 'mirtrons') or hairpin structures in intergenic regions (Nozawa *et al.*, 2010).

Many newly arisen miRNA genes, however, appear to have been inactivated and eliminated because of random mutations before acquiring solid functions. In other words, most of these new genes are not really authentic but seem just genomic regions having transcription activity without any solid roles. Indeed, young miRNA genes appear to evolve almost neutrally (Nozawa *et al.*, 2010), and the turn-over rate of these young miRNA genes is quite high (Lu *et al.*, 2008). Only a few young miRNA genes acquire solid functions and are integrated into a preexisting gene regulatory network. Then, these miRNA genes are maintained in genomes for a long time with very low substitution rates. It has been reported that mature sequences of these established miRNA genes show a very low nucleotide substitution rate that is comparable to those of *EF1α* and histone *H3* (Sempere *et al.*, 2006).

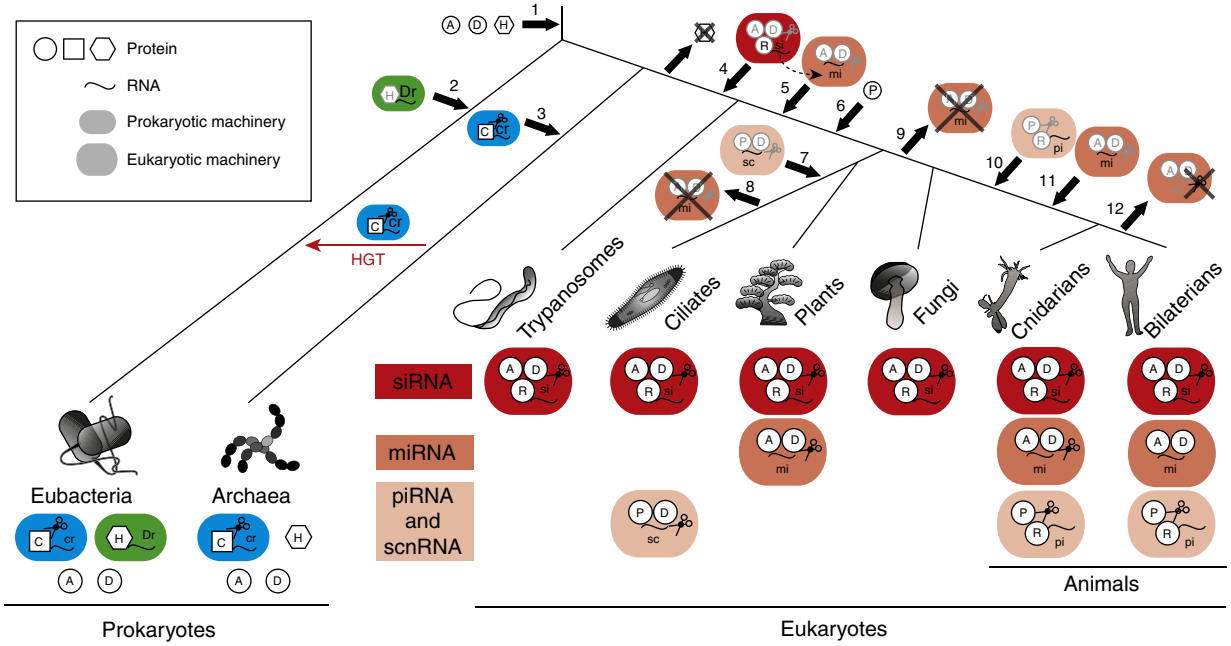

Figure 1 Phylogenetic distribution of small RNAs and their related proteins. Possible evolutionary events (gains and losses) regarding the small RNAs and related proteins are also given along the branches. Numbers along arrows correspond to the evolutionary events that are discussed in the main text. Gray objects are not involved in gains and losses. A red arrow represents horizontal gene transfer, whereas a broken arrow means a plausible origin of miRNAs from siRNAs. A, Argonaute; C, Cas; cr, crRNA; D, Dicer; Dr, DsrA RNA; H, Hfq; mi, miRNA; P, Piwi; pi, piRNA; R, RdRP; sc, scnRNA; and si, siRNA. Scissors indicate that the suppression of targets is generally accomplished by target cleavage. The phylogenetic relationship among species used is based on the timetree (Hedges *et al.*, 2006).

How is a new miRNA integrated into the gene regulatory network during evolution? Chen and Rajewsky (2007) proposed that a young miRNA is expressed only weakly in a specific tissue at a restricted developmental stage and that the effect of the miRNA on an individual would be weak or negligible. This model also predicts that natural selection continuously eliminates deleterious targets during evolution; therefore, the number of targets for a miRNA gradually decreases with time. This model has not been proven conclusively yet, and further studies are necessary to test this model.

Short-Interfering RNAs

siRNAs are also 21–24 nt long, like miRNAs, and generally work as guardians of genomes against viruses and other parasites. Unlike miRNAs, some siRNAs (exogenous siRNAs or exo-siRNAs) are directly generated from exogenous RNAs, whereas other siRNAs (endogenous siRNAs or endo-siRNAs) are derived from endogenous transcripts of genomic regions such as transposons, heterochromatic sequences, intergenic regions, and pseudogenes (Ghildiyal and Zamore, 2009).

Several sources of siRNAs such as viruses and bidirectional transcripts are double-stranded RNAs, but other precursors are single-stranded RNAs. These single-stranded RNAs are first converted into double-stranded RNAs by RNA-dependent RNA polymerases (RdRPs). All resultant precursors are double-stranded molecules with perfect complementarity. They are further processed by Dicer to mature duplex siRNAs which are then integrated into a RISC containing Argonaute. During this process, the sense (or passenger) strand of the duplex is degraded, and the RISC with the antisense (or guide) strand binds to its target RNA normally with perfect sequence complementarity and cleaves it (Carthew and Sontheimer, 2009).

Origin of Short-Interfering RNAs

Because siRNAs are the most widely distributed among the known eukaryotic small RNAs (**Figure 1**), a siRNA-like system may be the ancestral type of RNA-based regulation in eukaryotes (Shabalina and Koonin, 2008). This hypothesis is supported by shared features between siRNAs and miRNAs as well as between siRNAs and some other features with piRNAs. For example, both siRNAs and miRNAs associate with Dicer and Argonaute, whereas some siRNAs and piRNAs share functions to suppress transposons as mentioned in later sections.

To understand the diversification of siRNAs after origination, let us consider exo- and endo-siRNAs separately. Ancestral siRNAs are likely to have been exo-siRNAs derived from viruses and other parasitic RNAs, and that the first siRNA machinery in early eukaryotes was established to fight against these 'genomic predators.' Endo-siRNAs later came into existence as the functions of siRNAs began to diversify. Endo-siRNAs that are generated from transposons and heterochromatic sequences are apparently involved in the silencing of transposons and repetitive elements, whereas those from pseudogenes likely regulate their functional homologs. In some cases, endo-siRNAs are even produced from mRNAs. Because a subset of these endo-siRNAs can make long hairpins, they could be the ancestral state of miRNAs (broken arrow in **Figure 1**).

Evolution of Short-Interfering RNAs

Although siRNAs have a variety of functions, their major functions are defensive. The genes involved in siRNA pathways may have therefore evolved fast to trace the changes in exogenous RNAs. Indeed, the Argonaute (*Ago2*) and Dicer (*Dcr2*) genes, which are required for siRNAs, evolve much faster than their counterparts (*Ago1* and *Dcr1*, respectively) that are necessary for miRNAs (Obbard *et al.*, 2006). One possibility is that the proteins involved in siRNA pathways evolved under host–pathogen arms races similar to immune-related genes. Another possibility is that these proteins may have evolved faster due to under less functional constraints rather than the arms races. Because the molecules that directly interact with pathogenic RNAs are not these proteins but siRNAs, host–pathogen arms races on these proteins may not be necessary.

Piwi-Interacting RNAs

Compared with miRNAs and siRNAs, piRNAs are a bit longer in length, ranging from 24 nt to 30 nt, and they mainly function to suppress the activity of transposons. They are generated from long RNA transcripts that contain multiple piRNAs in tandem. There are hundreds of piRNA loci, each of which makes a large cluster (Ghildiyal and Zamore, 2009). During biogenesis, piRNAs, unlike miRNAs and siRNAs, do not require Dicer. Instead, long single-stranded primary piRNAs are cut into each unit of piRNAs by different nucleases (Kim *et al.*, 2009; Ipsaro *et al.*, 2012). The resultant piRNAs then associate with a specific member of the Argonaute family, Piwi, to form a RISC. The RISC binds to its target RNA based on a 10-nt complementarity with overhang between the piRNA and the target and cleaves the target RNA.

piRNAs are predominantly expressed in germline cells to suppress transposons at both transcriptional and post-transcriptional stages. It is interesting to note that piRNAs can also be generated by cleaved transcripts that are derived from transposons through the so-called 'ping-pong' cycle of piRNA amplification (Ghildiyal and Zamore, 2009). Through this process, a small amount of initial product can efficiently produce a large amount of piRNAs to suppress transposons.

Origin of Piwi-Interacting RNAs

piRNAs are confined to animals and presumably originated in the ancestor of animals (**Figure 1**). Piwi proteins, however, are found in ciliates, nonanimal eukaryotes. Indeed, a ciliate, *Tetrahymena thermophila*, has scan RNAs (scnRNAs) that are analogous to the animal piRNAs with respect to their length and their association with Piwi (Mochizuki and Gorovsky, 2004). Moreover, scnRNAs exist in another ciliate, *Paramecium tetraurelia*, where they function to determine mating types (Singh *et al.*, 2014). However, the biogenesis of scnRNAs resembles that of siRNAs but not that of piRNAs. In addition, they function mainly in DNA elimination during conjugation rather than binding to RNAs (Malone and Hannon, 2009). Therefore, the canonical piRNA machinery appears to have emerged in the ancestor of animals. In contrast, Piwi itself was generated before the divergence of ciliates and animals by duplication of genes that encode Argonaute and has functioned differently among lineages.

Evolution of Piwi-Interacting RNAs

As mentioned above, piRNAs are normally transcribed from piRNA gene clusters that predominantly consist of immobilized transposon remnants. Therefore, it is quite reasonable to hypothesize that piRNA clusters originated from transposons. piRNA clusters appear to have continuously increased at least in mammals (Assis and Kondrashov, 2009). Genomic locations of many clusters are conserved between species, but sequence contents in each piRNA cluster are quite different even between closely related species (Malone and Hannon, 2009). This expansion of clusters and rapid evolution of piRNA sequences could have been driven by positive selection to silence expanding and diverging repertoires of mammalian transposons, but the evidence is not convincing and further studies are necessary in a variety of organisms.

Small RNAs in Prokaryotes

miRNAs, siRNAs, and piRNAs have not been identified to date in prokaryotes. However, this does not mean that there is no RNA-based regulatory system in prokaryotes. Indeed, *Escherichia coli* has at least 60 small RNA genes in its genome (Majdalani *et al.*, 2005). Among them, the largest class of small RNAs, DsrA RNA, is analogous to miRNAs in eukaryotes with respect to its functions. This small RNA works cooperatively with a RNA chaperone protein, Hfq, and suppresses (or activates) the expression of target mRNAs via sequence complementarity (Aiba, 2007). Homologs of DsrA RNAs have been identified in many other eubacterial species. In addition, Hfq-like proteins have also been identified in archaea (Nielsen *et al.*, 2007).

A siRNA-like silencing system also exists in both eubacteria and archaea. In this system, small RNAs are transcribed from clustered regularly interspaced short palindromic repeats (CRISPRs) in genomes and bind to viral DNAs or RNAs for degradation in cooperation with Cas proteins. The RNAs derived from CRISPRs are called CRISPR RNAs (crRNAs). Because CRISPRs have been generated by repeated integrations of viral sequences (Barrangou *et al.*, 2007), the source of crRNAs is analogous to that of endo-siRNAs or piRNAs. In other words, this system is a type of 'memorization' of viral infections and can be regarded as a prokaryotic adaptive immune system. At present, 83% of archaeal and 45% of eubacterial species with sequenced genomes are known to have CRISPRs in their genomes (Grissa *et al.*, 2007). This machinery has recently been used to artificially modify the genomes of a variety of organisms including eukaryotes as one of the genome-editing technologies.

Interconnected Evolution of Small RNA Machinery

Based on the above information about small RNAs, we constructed a plausible scenario regarding the origins and

evolutionary processes of small RNA machinery (Figure 1). Here, small RNAs and related proteins are separately considered.

For prokaryotic machinery, Cas and CRISPRs are widely distributed in eubacteria and archaea. However, species with or without CRISPRs/Cas are highly intermingled, suggesting that none of them existed in the progenitor of all living organisms and that they were later generated and have spread into both eubacteria and archaea through horizontal gene transfers (HGTs) (Grissa *et al.*, 2007). Note that CRISPRs and Cas proteins are located adjacently in genomes; therefore simultaneous HGTs are quite possible. Regarding their origin, Makarova *et al.* (2011) compared the domains of Cas proteins among species and concluded that Cas as well as CRISPRs first originated in thermophilic archaea (evolutionary event 3 in Figure 1). This is consistent with the above statement that the proportion of species with CRISPRs is higher in archaea than in eubacteria. Therefore, the crRNA machinery as well as CRISPRs and Cas appear to have first originated in archaea and spread into many other species of archaea as well as eubacteria via HGTs (red arrow in Figure 1). Regarding the DsrA RNA machinery, the progenitor is likely to have possessed the Hfq protein (evolutionary event 1), because a wide range of eubacterial and archaeal species have the homologs. Yet, the functions of Hfq in the progenitor would have been different from the current ones, and the DsrA RNA machinery may have been established in the lineage of eubacteria by the generation of the DsrA RNA in combination with the co-option of Hfq (evolutionary event 2).

Regarding eukaryotic machinery, it is clear that several proteins such as Argonaute and Dicer already existed in the ancestor of all living organisms, because the homologs of these proteins are present even in prokaryotes (evolutionary event 1). The emergence of these proteins could be explained by aggregations of domains of preexisting proteins (Shabalina and Koonin, 2008). Yet, functions of Argonaute and Dicer in the ancestor appear to have been different from the current ones. Indeed, a function of Argonaute in eubacteria seems to acquire and maintain new plasmids (Wei *et al.*, 2012; Vogel, 2014). After the divergence from eubacteria and archaea, these proteins as well as novel proteins like RdRP started to function cooperatively with the small RNAs and established the first small RNA-based machinery in the early evolution of eukaryotes. Because siRNAs are most widely distributed in eukaryotes and defensive roles against predators are quite essential, the first machinery in eukaryotes may have been exo-siRNA-like machinery (evolutionary event 4).

After the divergence from trypanosomes, the miRNA-based regulatory system was established as the second machinery by generating miRNAs and co-opting the siRNA machinery (evolutionary event 5). Later, the system was independently lost in the lineages ancestral to fungi and animals (evolutionary event 9) as well as to ciliates (evolutionary event 8). miRNAs have not been identified in these 'in-between' lineages, but under this scenario, several proteins such as Argonaute and Dicer were maintained even in these species possibly for other functions, for example, siRNA machinery. Then, miRNAs were regenerated in the lineage ancestral to cnidarians and bilaterians (evolutionary event 11). Note that, at the time of this regeneration, the miRNA machinery in animals probably had a cleavage activity like the plant type. Yet, the machinery lost the cleavage activity in the bilaterian lineage after the split from cnidarians (evolutionary event 12).

Similar to the miRNA machinery, Piwi also came into existence in the lineage ancestral to ciliates and animals after splitting from trypanosomes (evolutionary event 6). However, the ancestral functions of Piwi appear to have been different from the current ones. Later, the piRNA machinery was established in the animal lineage by generating piRNAs in combination with the co-option of Piwi and RdRP (evolutionary event 10). Similarly, the scnRNA machinery was generated in ciliates by creating scnRNAs as well as the co-option of Piwi and Dicer (evolutionary event 7).

Conclusion

In conclusion, the RNA-based regulatory systems appear to have diversified mainly by repeated generations of ncRNAs in combination with recurrent co-options of preexisting proteins. A majority of ncRNAs share a basic aspect that they guide associated proteins to targets through sequence complementarity. This ncRNA–protein relationship has given rise to a variety of regulatory systems. Yet, the evolutionary processes of ncRNA-based regulatory systems largely remain mysterious. One of the challenges stems from the limited sizes of many ncRNAs. Because small RNAs are mostly less than 30 nt in their mature form, there may be insufficient information to distinguish evolutionary relationship (orthology) from independent origins. To understand the origins and evolutionary processes of the systems, we also need to consider both proteins that associate with ncRNAs and the targets of each of the ncRNAs. Given sufficient functional information, we will be able to take an integrative approach to understanding the evolutionary aspects of ncRNA-based regulation.

Novel Structures in Animals, Developmental Evolution of

AC Love, Minnesota Center for Philosophy of Science, University of Minnesota, Minneapolis, MN, USA
DJ Urban, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Glossary

Anlagen The cell or tissue primordia in an embryo that form the basis for a particular organ or other structure.
Co-option The acquisition of new roles or characters from ancestral ones, especially for genes.
Developmental capacitance The ability of developmental factors to buffer against potential changes due to genetic or environmental variation.
Developmental plasticity The ability of an organism to modify its phenotype in response to external cues.
Evolutionary novelty Derived body parts that usually lack homologous relations to structures in ancestral lineages and often possess the potential for new functionality.
Exaptation A trait either originally selected for another purpose or a by-product of a different trait's formation that now has a new function.
Extended Evolutionary Synthesis A broader theoretical framework for evolution that claims to incorporate recent empirical and theoretical advances (e.g., developmental plasticity or niche construction).
Gene regulatory network (GRN) A collection of hierarchically organized gene interactions that modulate gene expression.
Heterochrony Developmental changes in rate or timing.
Heterotopy Developmental changes in spatial location.
Homologous Biological structures that share common ancestry.
Hypertrophic zone Area of increasing cell size.
Imaginal discs Undifferentiated cells in insects that develop into specific adult structures.
Modern Synthesis The standard theoretical framework for evolution that developed in the twentieth century and emphasized natural selection as the explanation of organismal adaptation and species diversification.
Module Semiautonomous elements loosely connected to one another within a larger system.
Sexually dimorphic Phenotypic differences separating opposite sexes.

Overview

Historical Perspective

In an often misquoted passage from *On the Origin of Species*, Darwin claimed that, "How a nerve comes to be sensitive to light hardly concerns us more than how life itself first originated" (Darwin, 1859, p. 187). The origin of new structures was not a question on his research agenda: "Darwin explicitly disavowed theorizing … about the origins of the most primitive eyes" (Lustig, 2009, p. 113). It is not that he thought it an unanswerable question ("several facts make me suspect that any sensitive nerve may be rendered sensitive to light"). Instead, his aim was to show how natural selection increased complexity: "Natural selection has converted the simple apparatus of an optic nerve merely coated with pigment and invested by transparent membrane, into an optical instrument as perfect as is possessed by any member of the great Articulate class" (Darwin, 1859, p. 188). However, many evolutionary biologists have been concerned with explaining the origin of new structures, usually with special attention to how novel variation originates in and through developmental processes. For example, morphologists and paleontologists routinely attempted to account for the origins of higher taxa, which were characterized by distinct structures (e.g., chordates), with reference to developmental transformations, such as the dramatic morphological effects of precocious sexual maturation in a larval form (Love, 2007).

On the landscape of contemporary biology, the problem of explaining the origin of novelties emerged as a locus for criticizing the population genetic framework of evolutionary theory found in the Modern Synthesis: "It does not help much to say that there were one or two mutations that created eyespots and that these alleles were selected" (Wagner, 2000, p. 97). More positively, the problem represented a signature feature of research in evolutionary developmental biology (Evo-devo): "finding answers to what constitutes an evolutionary innovation … and how developmental mechanisms have changed in order to produce these innovations are major issues in contemporary [Evo-devo]" (Olsson and Hall, 1999, p. 612). This feature distinguished Evo-devo from other evolutionary research. "Evolutionary innovations are outside the scope of any current research program … we see in the problem of innovation and the evolution of body plans a unique opportunity for [Evo-devo] to develop its own independent identity as a research program" (Wagner *et al.*, 2000, p. 822). These themes are echoed in subsequent surveys of research on the origin of novelty (e.g., Moczek, 2008) and have constituted a hallmark in calls for an Extended Evolutionary Synthesis (Pigliucci and Müller, 2010). Apart from these broader questions about the disciplinary autonomy of Evo-devo and the adequacy of particular conceptions of evolutionary theory, when earlier discussions of the origins of higher taxa (e.g., Garstang, 1928) are set alongside recent Evo-devo studies (e.g., Lowe *et al.*, 2015), current investigations can be described aptly as tackling old evolutionary problems with new experimental and phylogenetic tools (Love and Raff, 2003).

Despite a consensus that explaining the origins of novelty requires understanding development ("it is essential to include

 doi:10.1016/B978-0-12-800049-6.00314-0

developmental mechanisms in the explanation of evolutionary innovations" (Wagner, 2000, p. 97)), there are ongoing debates about what counts as an evolutionary innovation or novelty and what causal factors, developmental or otherwise, best explain their origin. In addition to controversies surrounding the relative significance of gene regulatory network (GRN) changes in comparison to other factors (e.g., developmental plasticity), there remains a question about whether natural selection plays any explanatory role. After reviewing aspects of these debates, we outline three case studies that are representative of contemporary research into the developmental evolution of novel structures and conclude with reflections on prospects for future inquiry.

What Is an Evolutionary Novelty?

Ernst Mayr defined an evolutionary novelty as "any newly acquired structure or property which permits the assumption of a new function," which fit within the explanatory framework of the Modern Synthesis: "The problem of the emergence of evolutionary novelties then consists in having to explain how a sufficient number of small gene mutations can be accumulated until the new structure has become sufficiently large to have selective value" (Mayr, 1960, p. 357). In contrast, a different definition has been in view for most work in Evo-devo on the origin of novel structures. "A morphological novelty is a structure that is neither homologous to any structure in the ancestral species or [serially homologous] to any other structure in the same organism" (Müller and Wagner, 1991, p. 243). Instead of functional properties ('selective value'), morphology is accented in a phylogenetic context ('nonhomologous structures'); instead of mutations entering a gene pool, the developmental generation of qualitatively new variation is the focus. The growth of cladistic methods for phylogenetic reconstruction and emergence of molecular developmental genetics gave this structure-oriented definition operational traction in the context of Evo-devo. And yet the definition relies on the concept of homology, which has exhibited its own share of semantic disagreements across biological disciplines (Brigandt, 2003).

For some researchers, these difficulties suggest that defining evolutionary novelty is a fruitless endeavor. Although the emphasis has been on novelty as a qualitative departure from an ancestral condition ("quantitative change is only part of the story of evolution, for it does not address the question of the origin of discrete (qualitatively different) novelties" (West-Eberhard, 2003, p. 6)), the existence of a continuum between a qualitative difference and a mere quantitative variant makes it difficult to distinguish novelty from nonnovelty in absolute terms. Biologists draw the line on this continuum differently (Brigandt and Love, 2010; Palmer, 2012), and there are always precursors or homologous features at lower levels (e.g., gene expression, cells, or tissues) for those structures deemed qualitatively novel (Shubin *et al.*, 2009; Hall and Kerney, 2012). However, serious biologists never assumed that evolutionary novelties lacked precursors (Wagner, 2014). How then should we interpret this diversity of definitions?

Rather than trying to identify a single, correct definition of evolutionary novelty, one way forward is to shift attention from defining the concept – delineating the set of entities a term classifies ('categorization') – to characterizing the explanatory agenda associated with the concept (Brigandt and Love, 2012). The meaning of the term 'innovation' or 'novelty' serves to indicate explanatory expectations for the study of diverse morphological features (**Figure 1**). For example, the criterion of nonhomology makes a trait's novelty a matter of what was historically present in a lineage. Forward-looking definitions characterize novelty in terms of the developmental potential for future morphological variation and diversification (Wagner and Zhang, 2011) or the capacity to transform

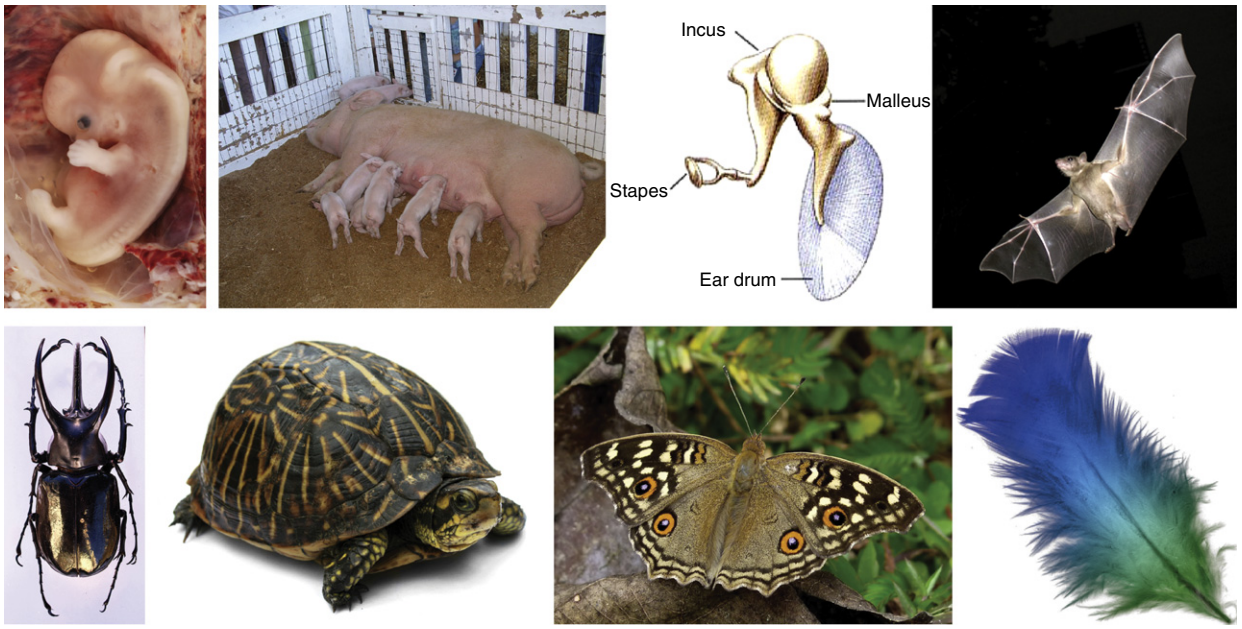

Figure 1 Examples of phenotypes commonly referred to as novel structures. Clockwise from the top-left: tetrapod autopod, mammary glands, mammalian middle ear, bat wings, feathers, butterfly eyespots, turtle shell, and beetle horns (open source images).

an ecosystem's carrying capacity (Erwin, 2012). The explanatory relevance of different causal factors can vary. Thus, focusing on characterizing the explanatory agenda highlights questions about adequate explanations for particular novelties, whether in terms of developmental mechanisms or adaptive advantages in ecological contexts.

On this construal, we can refer to evolutionary novelties as derived body parts that usually lack homologous relations to structures in ancestral lineages and often possess the potential for new functionality. However, to understand explanatory expectations in different disciplinary contexts, we should observe how the concept is structuring the problem space. This is often indicated by allied concepts used in conjunction with a specific definition of novelty. Discussions of novelty as nonhomology have stressed the importance of distinguishing character identity (e.g., the forewing of insects) from character states (e.g., wing blade vs. protective cover (elytra)), clarifying a particular sense of homology relevant to studying the developmental genetic origin of new structures (Wagner, 2014). Emphasizing the hierarchical level at which homology and novelty apply plays a key role in dissecting how mechanisms of gene regulation changed evolutionarily to produce novel anatomical structure (Shubin *et al.*, 2009). Linking novelty to evolvability accents the mapping relations between genotype and phenotype (Pavličev and Widder, 2015). Investigating the innovative ecological impact of a structural novelty makes natural selection germane to the explanation (Shirai *et al.*, 2012). (This strategy can be extended to include functional properties, such as behavior (Brown, 2014).) Additionally, typologies of evolutionary novelty help to carve out explanatory expectations. Müller's (2010) threefold typology of morphological novelty focuses attention on the epigenetic nature of developmental processes: type 1 – the primary anatomical architecture of a metazoan body plan; type 2 – discrete new elements added to an existing body plan; and type 3 – major changes to an existing body plan character. In alignment with this typology, Müller and colleagues have offered a physical explanation for types 1 and 2 novelties that is different from standard Evo-devo approaches (Newman *et al.*, 2006; Newman and Müller, 2005; see below).

How Do Novel Structures Arise?

Once the concept of evolutionary novelty is seen as an indicator of an explanatory agenda, it facilitates making explicit the expectations or criteria of adequacy related to the problem space. These include the need to specify the relevant level of structural organization, the degree of generality that can be derived from studying particular novelties, and the necessary disciplinary contributions for an adequate explanation (Brigandt and Love, 2012). The most prominent strategy of research in Evo-devo involves investigating how developmental genetic changes contribute to the construction of novel morphological structures, especially the formation of new GRNs. "Evolutionary change in animal form cannot be explained except in terms of change in [GRN] architecture" (Davidson, 2006, p. 29); "the evolution of development and form is due to changes within GRNs" (Carroll, 2008, p. 30); "Novelty requires the evolution of a new [GRN]" (Wagner and Lynch, 2010, p. R50). These changes can involve duplications followed by the differentiation of paralogous genes (Gompel and Prud'homme, 2009), modifications of regulatory interactions (Bloom *et al.*, 2013; Shirai *et al.*, 2012), and the cooption of gene expression from one time or context to another (Saenko *et al.*, 2008; True and Carroll, 2002). For example, a shift in the spatial location of gene expression (heterotopy), rather than a shift in the timing of gene expression (heterochrony), was responsible in part for the origin of the vertebrate jaw (Shigetani *et al.*, 2005). Thus, novel structures at one level of organization can arise from changes in homologous GRNs (Shubin *et al.*, 2009); they are explained by the recombination and redeployment of preexisting ancestral variation, rather than as a consequence of novel genes.

Although there is widespread agreement that evolutionary novelties arise from altered expression patterns due to GRN changes, some have argued for the importance of evolving protein–protein interactions based on overlooked functional divergence in conserved transcription factors (Lynch and Wagner, 2011). Günter Wagner has offered one of the most comprehensive theoretical perspectives on the origin of novelty with his genetic theory of homology (Wagner, 2014). Since there have been GRN changes without corresponding changes in animal form, a decoupling of developmental mechanisms and homologous characters (Abouheif *et al.*, 1997), Wagner isolates a subset of these network relations: character identity networks or ChINs (Wagner, 2007). These highly conserved GRNs can be activated by diverse inductive signals, but their activity determines which fate a cell adopts from among its intrinsic possibilities through specific regimes of gene expression. The developmental evolution of novel structures then consists in the origination of new ChINs.

Other Evo-devo practitioners do not focus exclusively on developmental genetics and view other mechanisms as pertinent to explaining novelty. For example, novel traits may begin as conditional structures that occur due to developmental plasticity (Moczek *et al.*, 2011; Palmer, 2012; West-Eberhard, 2003). Regulatory modules are often reused and recombined in response to different environmental conditions, potentially generating novel phenotypic responses. Subsequent mutations in GRNs can permanently establish these structures. A variation on this approach has stressed the significance of physical forces (e.g, fluid flow or differential adhesion) in generating basic morphological motifs (e.g., segmentation or tissue layering) under conditions of developmental plasticity early in metazoan evolution (Newman *et al.*, 2006; Newman, 2012). This explanation stresses the significance of epigenetic interactions at aggregate scales during development with evolutionary novelties arising from combinations of physical patterning processes (e.g., biochemical oscillation) and cell properties (e.g., polarity) under different environmental circumstances. Although this approach remains highly contested (Love and Lugar, 2013), work on the genomic complement available at the origins of multicellularity is clarifying to what degree this hypothesis is feasible (Suga *et al.*, 2013; Tweedt and Erwin, 2015).

From an ecological vantage point, it has been proposed that there are only two distinct possibilities for the origination of a structural novelty: exaptation or developmental capacitance (Moczek, 2008). Exaptation, a trait either originally

selected for another purpose or a by-product of a different trait's formation that is now exposed to a novel selective environment, presents the opportunity for a new adaptive function. Developmental capacitance refers to processes that buffer against genetic or environmental variation until a threshold for restraint is reached and breached. The potential was always there, but remained cryptic until exposed. For both possibilities, the emphasis is on what conditions make it possible for natural selection to act and thereby solidify the new trait via its functionality. But population genetic approaches relevant to explaining the origin of novel structures are available also, such as work on canalization and robustness (Hansen, 2006; Wagner, 2005). Although these do not replace or compete with explanations that invoke the rearrangement of ancestral variation through GRN changes, they concentrate on variational properties of phenotypes in order to ascertain their evolutionary potential, which can inform both why a trait is stable and how new structures become individuated evolutionarily (Pavličev and Widder, 2015).

Case Studies

Turtle Shells

The turtle shell represents the evolutionary addition of new parts to the standard vertebrate body plan: a dorsal carapace and ventral plastron connected by lateral bridges – more than 50 dermal bones not found in any other vertebrate (Gilbert *et al.*, 2001). Instead of the vertebrae and ribs encompassing the entirety of the neural and costal bones, they act as initiation centers for the ossifying dermal elements. The ribs grow in a lateral rather than ventral direction, and appear to become trapped within the ossifying dermis. A carapacial ridge, exclusive to turtles, appears on the flanks of embryos in early development and later extends anteriorly and posteriorly. This ridge may direct later development of the ribs, akin to the apical ectodermal ridge (AER) in the vertebrate limb bud, as its removal results in ribs growing ventrally in a manner more consistent with other amniotes (Burke, 1991).

Both ribs and plastron begin ossification prior to hatching; dermal bones of the carapace develop after hatching (Gilbert *et al.*, 2001). The ribs and neural arches undergo three successive stages of ossification to form the carapace: perichondral, endochondral, and membranous (Kuratani *et al.*, 2011). Recent paleontological finds have illuminated intermediate forms relevant to the origin of the shell. *Odontochelys* ($\sim$220 mya) exhibits a complete plastron but only a few neural plates for the carapace (Li *et al.*, 2008). This fossil appears to mirror the developmental origins of the plastron prior to the carapace. However, the evolutionary origin of the plastron remains enigmatic, not least because phylogenetic relationships among turtle species are contested (Lyson and Gilbert, 2009).

A peculiar feature of the skeletal arrangement in turtles is the ventral location of the pectoral girdle in relation to the ribcage, completely encapsulated within the shell, in contradistinction to all other vertebrates (**Figure 2**). Using *Sox9* to mark skeletal precursors, scapula 'anlagen' in turtles were observed to develop more anteriorly compared to mouse and chicken (Nagashima *et al.*, 2009). Given that turtle ribs are comparatively shorter initially, this in combination with the anterior positioning of the scapulae results in an overhang of the first rib (which does not participate in carapace formation) and eventual coverage of the scapulae by the remaining ribs as they grow laterally and anteriorly. Simultaneously, as the ribs fold the lateral body inward, the serratus anterior muscle rotates in a ventral medial direction and pulls the scapula to its final position underneath the developing carapace (Nagashima *et al.*, 2009). Here again, modern turtle development is suggestively consistent with the earliest known fossil (*Odontochelys*), which had its scapulae anterior to the ribs. Additionally, the latissimus dorsi and pectoralis muscles display connectivities that lack an equivalent outside of turtles (Kuratani *et al.*, 2011). The nuchal scute, at the anterior-most portion of the carapace, has been considered a novel structure, but it has been reported recently to derive from the cleithra: paired dorsal elements originally associated with the ancestral tetrapod pectoral girdle that have been lost in other tetrapods except frogs (Lyson *et al.*, 2013). Lyson *et al.* propose that these elements underwent a dorsomedial migration and eventually fused to form the nuchal scute.

Studies of the turtle shell illustrate that an indisputably novel structure might arise through developmental changes that may be less radical than originally thought. However, these minor tweaks along the evolutionary path have led to a profoundly different structure. Identifying the unique changes that resulted in the formation of the shell (e.g., rib outgrowth arrest followed by lateral infolding, serratus anterior muscle rotation, or dorsomedial cleithra migration) is necessary to account for its developmental evolutionary origination.

Bat Wings

Bats are the only mammals capable of powered flight. This advantage has led to an unprecedented adaptive radiation – bats account for over 20% of all mammalian species. The novel structure of bat wings results from a combination of components: greatly elongated digits, retention of interdigital tissues, and specialized wing membranes. In pterosaurs, the only other vertebrates to use a membranous wing for powered flight (Lingham-Soliar, 2015), the membrane was completely supported by the fourth digit; bats use all digits, excluding the thumb, to support the membrane. The distinctive morphology of the bat wing is a direct result of its development, beginning with a unique mechanism for interdigital membrane maintenance.

In bats, only hind limbs experience apoptosis of interdigital tissue (Weatherbee *et al.*, 2006). The retention of interdigital tissue in the forelimb is a result of increased *Fgf8* and *Gremlin* expression, which combine to inhibit cell death and decrease *Bmp* expression. Similar expression is presumed to be responsible for inhibiting cell death in the webbed feet of ducks (Merino *et al.*, 1999). *Fgf8* is normally expressed in the AER of other tetrapods, though in bats it is expressed at earlier stages, remains active later, is expressed in the forelimb interdigital area, and has an AER expression domain that is up to three times wider than mice (Cretekos *et al.*, 2007; Weatherbee *et al.*, 2006). These factors combine to preserve tissue in the bat's wing via a unique mechanism.

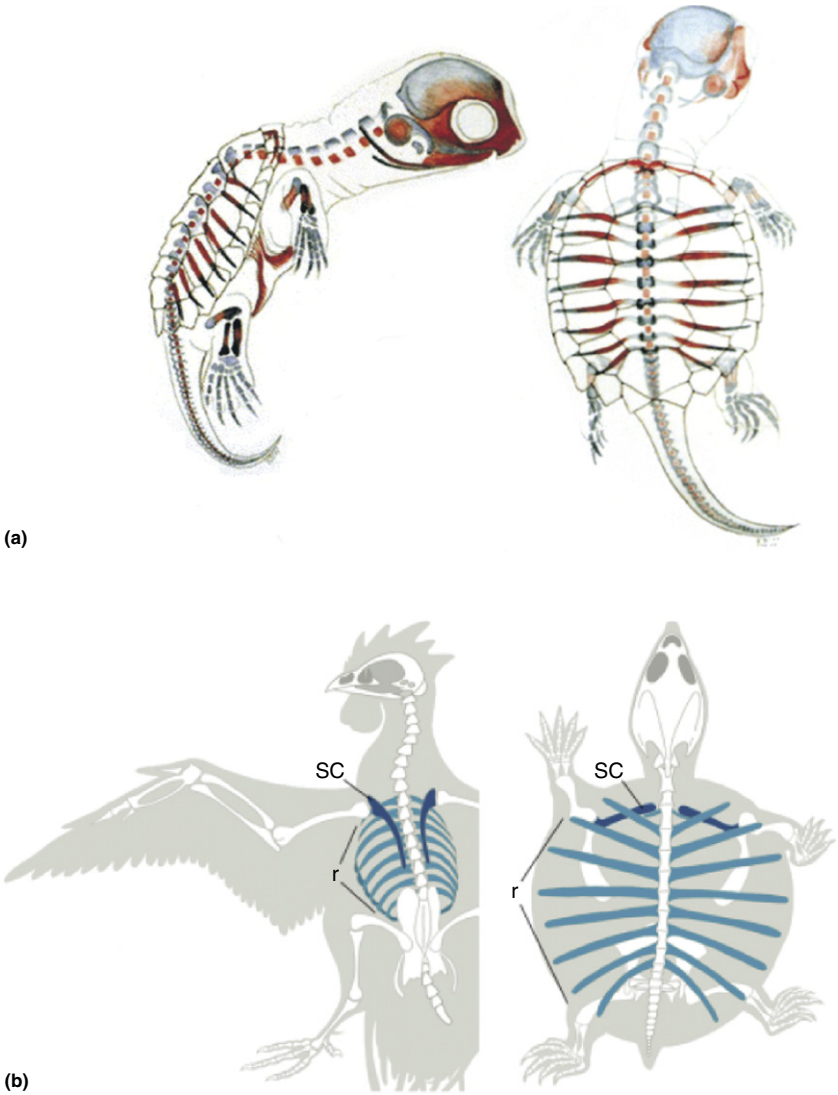

Figure 2 (a) Drawing of cleared and stained turtle embryo with cartilaginous (blue) and calcified (red) structures. Note the development of ribs prior to the formation of the carapace. (b) Drawing of avian scapulae (sc) external to the ribcage (r) compared to turtle scapulae inside of the ribcage. Modified from Gilbert, S.F., Loredo, G.A., Brukman, A., Burke, A.C., 2001. Morphogenesis of the turtle shell: The development of a novel structure in tetrapod evolution. Evolution & Development, 3, 47–58; Kuratani, S., Kuraku, S., Nagashima, H., 2011. Evolutionary developmental perspective for the origin of turtles: The folding theory for the shell based on the developmental nature of the carapacial ridge. Evolution & Development, 13, 1–14.

The earliest known fossil bat dates to ~50 mya. It already possesses the distinct morphology of modern bat wings and has proportionally similar lengths for metacarpals and phalanges (Sears *et al.*, 2006). A prominent hypothesis for the origin of bat flight is that it arose via gliding (Dudley *et al.*, 2007), facilitated by lateral wing membranes (plagiopatagium), similar to that seen in extant gliding animals (squirrels, lemurs, and some marsupials). Plagiopatagium outgrowth starts at stage 14 in bat development (Cretekos *et al.*, 2005) and by stage 17 it begins connecting to digit V of the forelimb. Early cartilage condensations of the limb are similar in size for both mice and bats, but bat limbs begin to drastically elongate later in development. Coincident with this elongation is a pronounced increase in the size of the hypertrophic zone of the metacarpals, accounting for over 30% of the growth plate (Sears *et al.*, 2006); hypertrophic zones in mice never exceed 12%. Bat and mice digits cultured in *Bmp2* show increased elongation, while those cultured in *Noggin* (a *Bmp* antagonist), exhibit stunted growth. *Bmp2* expression is more intense and continuous in bat forelimbs than in their own hind limbs or in mouse forelimbs (Sears *et al.*, 2006).

Shh is expressed in a wider domain within bat forelimbs than in other tetrapods, which produces a loss of symmetry across the anterior–posterior axis. Furthermore, unlike mice at comparable stages, a second round of *Shh* expression is initiated later in bat development and leads to expression of *Ptc1* (Hockman *et al.*, 2008). A novel patch of *Fgf8* expression in bat limbs immediately precedes the initiation of *Shh* and *Ptc1*. The

renewed *Shh* expression site corresponds to the location of *Bmp2* identified in earlier studies. *Bmp2* activates *Gremlin*, which in turn promotes *Fgf* expression. This suggests a *Shh–Fgf* feedback loop (*Fgf8* → *Shh* → *Bmp2* → *Gremlin* → repeat) that contributes to both forelimb elongation and survival of the interdigital membrane (Hockman *et al.*, 2008).

In addition to elongated digits and membrane retention, bats have unique wing musculature. The occipito-pollicalis muscle complex extends along the anterior edge of the wing and supports the anterior wing membrane (propatagium) and sheet-like muscles that run through the plagiopatagium, all of which influence the shape of the wing. The occipito-pollicalis originates from cranial mesoderm, as illustrated via its innervation by cranial nerve VII (facial nerve). Furthermore, *Fgf10* is expressed anterior and posterior to the forelimb and along the flanks, persisting after similar signaling in the limbs of other tetrapods has ceased (Tokita *et al.*, 2012; **Figure 3**).

Within the bat limb there are multiple examples of temporal and spatial gene regulatory changes (heterochrony and heterotopy) that contribute to its unique structure. This amalgam of changes in the expression of a few key genes has transformed the adult phenotype (e.g., *Bmp* reduction between digits and increased activity within digits). When combined with forelimb bones that have enlarged medullary cavities, providing uniquely low bone mass for a mammal (Cooper *et al.*, 2012), and highly compliant and elastic bones (Cooper and Sears, 2013), these results show that many of the developmental steps required in the origin of the bat's skeletal architecture have been elucidated.

Beetle Horns

Beetle horns are among the world's most dramatic sexually selected traits (Emlen, 2000). These rigid extensions

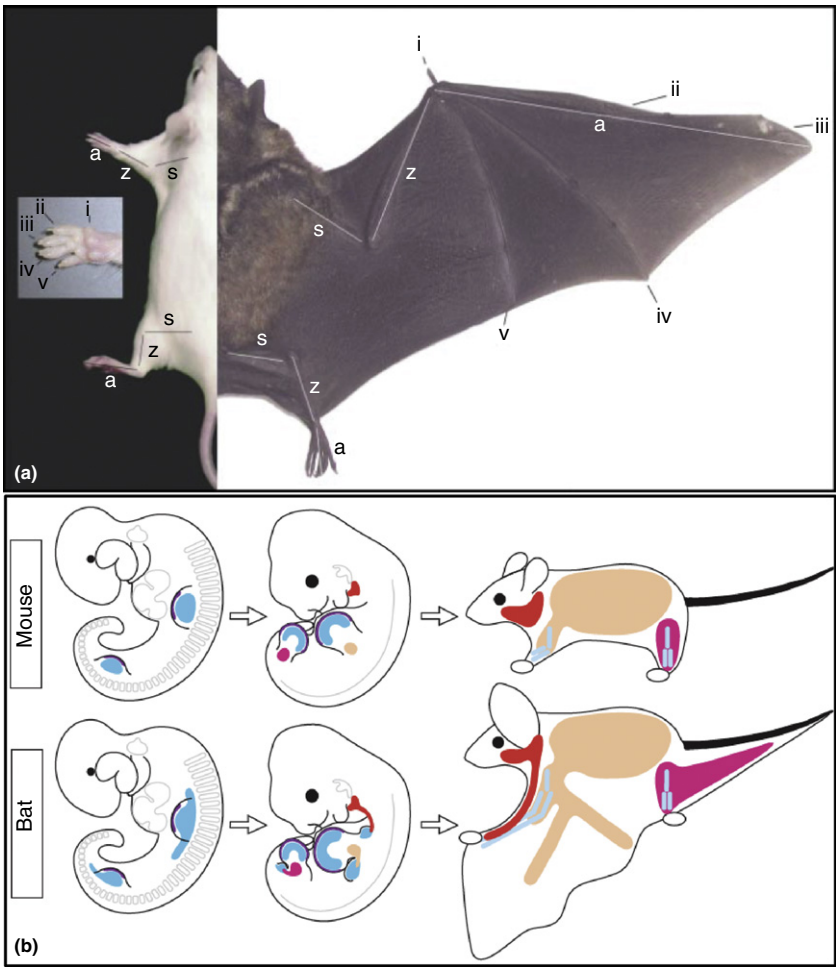

Figure 3 (a) Comparison of limb morphology between mouse (left) and bat (right), digits labeled i–v (anteriorly to posteriorly), lines drawn for stylopod (s), zeugopod (z), and autopod (a). Note that propatagium is anterior to zeugopod, and pluropatagium is connecting the forelimb and hind limb. (b) Illustration comparing muscle and membrane development in mouse and bat. Fgf10 expression (blue) is expanded in bats, where the future wing membrane will develop; Fgf8 expression (purple) in the AER; stylopod, zeugopod, and autopod (light blue); developing muscle (tan) expanding into the wing membrane in bats. Modified from Cretekos, C.J., Rasweiler IV, J.J., Behringer, R.R., 2001. Comparative studies on limb morphogenesis in mice and bats: A functional genetic approach towards a molecular understanding of diversity in organ formation. Reproduction, Fertility and Development 13(8), 691–695; Tokita, M., Abe, T., Suzuki, K., 2012. The developmental basis of bat wing muscle. Nature Communications 3, 1302.

of the exoskeleton have originated repeatedly in evolution and are present in thousands of species (Emlen *et al.*, 2007). Beetle horns display an astounding variation in shape, structure, and location, including the front of the head, base of the head, thorax, or some combination thereof (**Figure 4**). They range from tiny knobs to more than 10% of a beetle's body mass, and horn length scales with body size so that bigger males have longer horns (Moczek and Emlen, 1999). Horn expression is sexually dimorphic, predominantly found in males, where larger horns often equate to disproportionate access to females (Moczek and Emlen, 2000).

Nutritional conditions during larval stages determines both adult body size and horn length (Moczek, 1998). Horns develop at the same time and manner as many other paired appendages (eyes, legs, wings) via imaginal discs. These invaginations detach from the epidermis and undergo rapid cellular division, mediated by juvenile hormone (JH), to quickly increase in size (Emlen and Nijhout, 1999). A better nutritional environment leads to higher concentrations of JH, which in turn results in larger, horned adults. Any mutation that affects JH expression and signaling has the potential to impact horn evolution (Emlen, 2000). Horn development also affects nearby morphological traits. The size of cephalic horns can be negatively correlated with eye size, and thoracic horns can be negatively correlated with wing size (Nijhout and Emlen, 1998). These tradeoffs vary between species.

Beetle horns lack obvious homology to other insect traits, but share similar developmental aspects with .appendages (Moczek and Nagy, 2005). *Distal-less* (*Dll*) is expressed in the mediodistal portions of legs and horns, and *homothorax* (*hth*) is expressed in the proximal and medial portions of legs and horns (Moczek *et al.*, 2006). Both expression patterns have been co-opted and conserved. However, *dachshund* (*dac*) expression is found in the proximal and medial portions of legs, but is expressed throughout the entire horn (Moczek *et al.*, 2006). Although *dac* expression is not required for horn development, Moczek and Rose (2009) found that *Dll* affects head and thoracic horns, whereas *hth* affects thoracic horns only. The differential co-option of genes that function to pattern appendages plays a central role in the developmental evolution of horns.

Expression patterns co-opted for horn development not only diverge from what is observed for appendages but also differ within and across beetle species. *Doublesex* (*dsx*) is consistently elevated in male horns but not found in legs (Kijimoto *et al.*, 2009). In some species, *dsx* knockdown reduces the size of male head horns, but induces the formation of horns in females (Kijimoto *et al.*, 2012). Thus, *dsx* typically promotes male horn development and suppresses female horn development, conditional on nutritional intake in larvae. In other species, *dsx* knockdown caused large branching horns in previously hornless males, while resulting in a single horn for females (Kijimoto *et al.*, 2012). This illustrates a dramatic reversal in what is normally a sexually dimorphic trait and provides an example of how labile regulatory inputs (e.g., nutritional conditions or sex specific variables) can differentially interact with highly conserved gene expression to produce novel morphologies.

Insights

Prospects for Advancing Inquiry

The turtle shell, bat wing, and beetle horns capture only a small subset of novel structures currently under investigation. These case studies illustrate the emphasis in Evo-devo on changes in gene expression during development as the primary explanatory factor for novelties. At the same time, they demonstrate how explanations require multiple disciplinary contributions, such as the morphology and paleontology that helps to delineate the character state of the ancestral lineage to establish a phylogenetic context for explaining the turtle shell or bat wing, or the role of developmental ecology that assists in accounting for the growth dynamics of beetle horns. In conclusion, we describe three dimensions of inquiry – conceptual, empirical, and theoretical – that hold promise for future inquiry into the origins of evolutionary novelty.

Inquiry related to the conceptual dimension can advance our understanding of the origin of novelty by intentionally exploring different definitions of novelty. Many researchers operate with a single preferred conception of novel structures. If we think of these conceptions as different models (Wagner, 2014), then switching between them focuses our attention on different properties of biological systems and encourages analyzing the evolutionary significance of different causal factors. The key is to recognize that distinct standards or criteria of explanatory adequacy accompany these different models and foreground some factors while relegating others to the background. Research on the origin of beetle horns is an exemplar in this regard, moving back and forth between developmental genetics and evolutionary ecology. Additionally, new concepts can suggest new explanatory expectations, such as character 'swarms' and 'variational modalities' (Wagner, 2014). Explanatory accounts derived from different definitions may be more complementary than competing, especially those that appeal to different kinds of developmental mechanisms or adaptive benefit. Progress with respect to explaining the developmental evolution of novel structures is nurtured when explanatory aims are articulated precisely, their scientific significance is widely comprehended, and the standards that determine the elements and structure of an adequate and integrated explanatory framework are as explicit as possible (Brigandt and Love, 2012).

Inquiry related to the empirical dimension can advance our understanding of the origin of novelty by increasing the manipulative capacity of experimentation and augmenting our inferential capacities. The ability to precisely change genetic variables and ascertain their phenotypic effects has long played a key role in explaining novelty, but new technologies, such as CRISPR-Cas genome editing (Sander and Joung, 2014), will provide more discriminating tests of hypotheses for putative novelties in particular species. Continued sequencing efforts, both to catalog genes and characterize their expression profiles (e.g., via RNA-seq; Wang *et al.*, 2009), will be critical as well. However, as noted, explaining the origin of novel structures requires a combination of disciplinary approaches and therefore empirical advances are needed on multiple fronts. Morphological and paleontological investigations have illustrated this dramatically in the case of the tetrapod limb

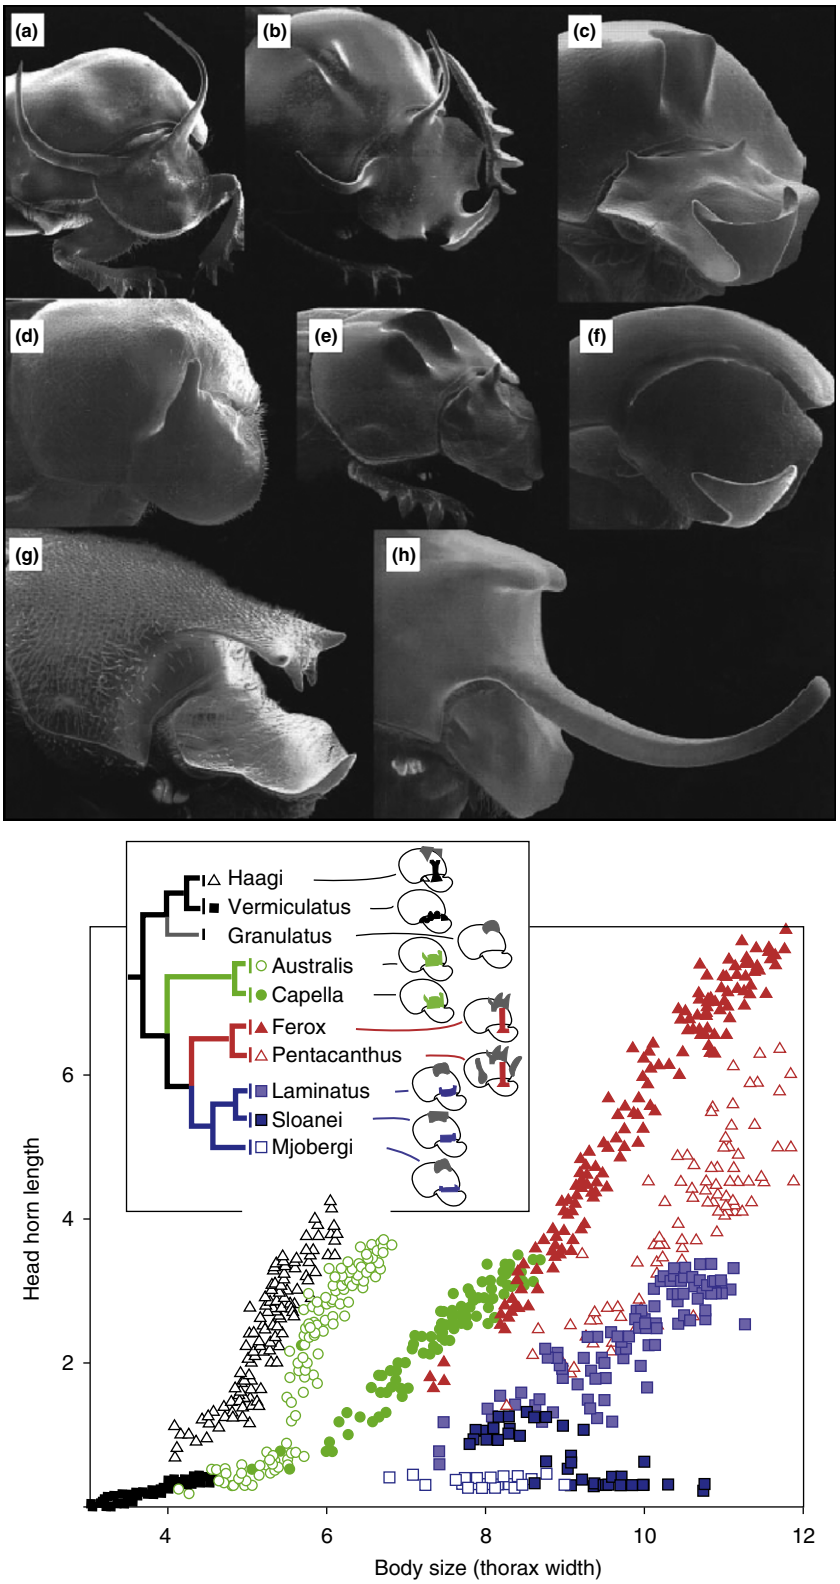

Figure 4 Top. Photographs (a–h) showing the diverse shapes, sizes, and locations of beetle horns within the genus *Onthophagus*. Bottom. Scaling relationships between horn length and body size for nine species of *Onthophagus* beetles. Modified from Emlen, D.J., 2000. Integrating development with evolution: A case study with beetle horns results from studies of the mechanisms of horn development shed new light on our understanding of beetle horn evolution. Bioscience 50, 403–418; Emlen, D.J., Lavine, L.C., Ewen-Campen, B., 2007. On the origin and evolutionary diversification of beetle horns. Proceedings of the National Academy of Sciences of the United States of America 104, 8661–8668.

(Shubin *et al.*, 2006). Integrating developmental genetic and physico-chemical mechanisms can augment our understanding of how new traits originate (e.g., Sheth *et al.*, 2012). Finally, increasing phylogenetic resolution can change how existing empirical data from various approaches bear on explanations of novelty (e.g., Kocot *et al.*, 2011). Investigating evolutionary novelties that represent the best available juxtaposition of these empirical tools is likely to generate the deepest insights, though it may mean choosing new and unexpected model systems (Wagner *et al.*, 2014).

Inquiry related to the theoretical dimension can advance our understanding of the origin of novelty by probing more quantitative dimensions of the genotype–phenotype map and drawing out abstract generalizations across disparate systems. The former provides a bridge to the rich tradition of population genetic theorizing that has been perceived as antagonistic to Evo-devo's developmental explanations of novelties (Nunes *et al.*, 2013). It also introduces different concepts into explanatory accounts (e.g., pleiotropy or epistasis) that expose new angles to understand the origin of qualitatively distinct variation at particular phylogenetic junctures (e.g., Pavličev and Wagner, 2012; Rice, 2012). More abstract generalizations can be derived from particular forms of theorizing by identifying commonalities across taxa and levels of organization, such as shared network architecture in metabolism and gene regulation (Wagner, 2011). Furthermore, this theorizing need not be concerned only with population level modeling. While the jury is still out on Wagner's genetic theory of homology (Wagner, 2014), it has distinct advantages in suggesting specific kinds of manipulative experiments in different taxa. Overall, it will be innovative combinations of these different types of advances in conceptual, empirical, and theoretical dimensions that harbor the most promise for increasing our understanding and providing deeper explanations of the developmental evolution of novel structures in animals.

Glossary

Abaxial The side of a laminar organ located further away from the axis.
Adaxial The side of a laminar organ located closer to the axis.
Centripetal The growth direction of organs from the outside to the inside.
Co-option The acquisition of new functional repertoires by a gene, different from the preexisting ancestral ones or the recruitment of an alternative gene to that commonly associated with a feature.
Ectopic The expression of a gene or occurrence of a feature outside of the common place or position.
Flower primordium (a) The earliest recognizable developmental stage of an organ, often formed exclusively by parenchymatic homogeneous tissue.
Gametogenesis The process by which haploid spores undergo division and differentiation to form mature gametes. In land plants the spore formation by meiosis is followed by mitosis generating a multicellular haploid phase in the life cycle.
Groundplan The phylogenetically fixed patterns of (mostly) floral structure referring to the organization of parts.
Heterochrony A shift in the timing of a developmental event.
Heterologous transformation The gene functional characterization experiments that commonly use overexpression of a target gene from a non-model species in a model organism.
Homeotic A shift in the identity of an organ or any developmental feature.
Homolog The biological features (genes, organs, structures) sharing common ancestry.
Horizontal gene transfer The transfer and acquisition of genes between different species using alternative mechanisms to reproduction and heritage.
Meristems The pluripotent cell groupings in the plant body.
Metatopy The placement of organs or structures out of their regularly expected positions resulting often from abnormal growth.
Orthologs The genes derived from speciation events that correspond to the same copy across related organisms.
Paralogs The genes derived from duplication events that correspond to gene copies.
Páramos High mountain Andean biomes found below the permanent snowline, with extreme temperature fluctuations from day to night, composed of grasses, unique rosette, and cushion plants.
Pluripotency The developmental potential in cells without a committed identity of differentiating into any cell type.
Radialization The loss of ab/adaxial identity in a laminar organ resulting in a cylindrical structure.
Regulatory module The interactions between a few transcription factors that have been phylogenetically and functionally conserved from the collection of hierarchical genes in a complete gene regulatory network.
Resupination The rotation or recurving of a structure during development.
Shoot apical meristem (SAM) The site of active cell division in the apex of the shoot that allows for the maintenance of pluripotent cells and open growth in plants above ground. It constantly nourishes three generating layers: the protodermis, ground tissue, and procambium.
Sporogenesis The process by which diploid cells undergo meiosis to form spores.
Subfunctionalization The partition of ancestral functions among gene copies from an ancestral single, often pleiotropic gene.
Synorganization The integration of floral organs by changes in symmetry and organ fusion.
Whole genome duplication (WGD) The event by which a cell or an organism retains two copies of the entire genome.

Introduction

Plants, unlike animals, grow continuously from embryonic cell groups called meristems, which are responsible for primary and secondary histogenesis, organogenesis, and ultimately, morphogenesis. In addition to the plant genetic and epigenetic machinery, these processes are driven also by a number of environmental conditions. Plant lifespan and indeterminate (sometimes called open) growth and organogenesis contrast with the lack of cell migration and the mechanical constraints of intercellular communication caused by the cell wall. All plant organs are formed from three fundamental tissues (protodermis, procambium, and ground meristem; Foster and Gifford, 1980; Steeves and Sussex, 1990), from which no more than 20–25 cell types are formed upon complete differentiation, only 10% of the estimated number of cell types in vertebrates. Additionally, their limited individual movements prevent plants from escaping predators, finding better sources of nutrients, or avoiding harsh environments (Steeves and Sussex, 1990; Cronk, 2009). Instead, plants have developed unique signaling systems that integrate their growth, physiology, and phase transitions with environmental conditions. Thus, postembryonic development in plants is often modular and cyclic, as the position and fate of

 doi:10.1016/B978-0-12-800049-6.00142-6

meristems are highly predictable over time, including the development, growth and renewal of stems, leaves, and reproductive organs.

Indeterminate growth and morphogenesis have allowed plants to achieve an incredible array of modifications in form, both above and below ground that often result in convergent features in response to a particular environment, although root growth is less predictable and occurs at a more random fashion in comparison with the aerial shoots. Examples of convergent life forms are several mosses, ferns, and angiosperms from cold, high mountain areas, which grow as 'cushion plants' (**Figure 1(c)**) due to the reduced size, tightly congested branching, compact leaves, and clonal growth at the ground level. Other examples are leaf shape, starch storage organs, and flower elaboration for pollinator attraction, some of which are explained below.

As a result of the remarkable variation in plant form in response to the environment, a major challenge arises when attempting to recognize homologous structures. Comparative morphology takes into account key approaches, traced back to the morphological writings on plant metamorphosis by J. W. von Goethe, the German poet, philosopher, and one of the most outstanding members of the *Naturphilosophie* school. Goethe proposed that all plant organs are nothing but leaves, more or less contracted, or expanded during the individual but continuous metamorphosis (Goethe, 1790; Foster and Gifford, 1980). This explanation was the onset of the modern concept of serial homology, based on positional and developmental similarities of intraindividual structures (Foster and Gifford, 1980; Rutishauser and Sattler, 1985; Weberling, 1989; Endress, 1994). Thus, independently of how an organ looks, if is derived laterally from the shoot apical meristem it is a leaf or a leaf homolog, and if it occurs axillary to this leaf (i.e., an axillary meristem), it is a branch homolog. Following this same idea, during the reproductive phase of the plant, a lateral organ formed along the inflorescence axis is a bract homolog. In turn, a bract subtends a floral meristem, which is a branch homolog formed by floral organs. In flowers, axillary meristems are suppressed, and internodes along the floral axis are extremely shortened or lacking; thus, floral organs develop in a very limited domain called the floral receptacle, often in a centripetal sequence, as follows: sepals, petals, stamens, and carpels. Their order, position, and function allow their identification in most flowers, as they organize into the typical four whorls, calyx, corolla, androecium, and gynoecium, respectively. Sometimes extra whorls arise or there are extraordinary events of switch of functions, homeotic and heterochronic shifts, fusion of parts, or even inverted positions of whorls. Some of these processes will be discussed below in the section of floral morphology. These developmental and evolutionary traits challenge the interpretation of homology in flowers, but at the same time makes the study of floral morphology one of the most fascinating topics in contemporary plant biology (Weberling, 1989; Endress, 1994; González and Pabón-Mora, 2015).

Development is an additional criterion emphasized here that can be used to test plant homologous structures, as homologous structures should follow a common ontogenetic pathway that can be traced during early organogenesis and histogenesis (Hofmeister, 1862; Foster, 1928; Wardlaw, 1952; Gifford, 1954; Cronk, 2009). One of the most outstanding examples is the identification of structural homologies in fruits. Fruits undergo drastic morphogenetic, ontogenetic, and histogenetic modifications from the same floral organ, the carpel(s); they have been highly exposed to selective forces for at least 120 My, and have developed extremely efficient mechanisms for food storage and seed dispersal, which ultimately have allowed flowering plants to be dominant on Earth (Roth, 1977).

A third approach, key to comparative morphology is the study of developmental genetic mechanisms underlying organ position, identity, and polarity in plants (Steeves and Sussex, 1990; Cronk, 2009). It has been established that specific transcription factors alone or in combinations are responsible for the identity of the different lateral organs during vegetative and reproductive growth. In particular, molecular developmental biology studies in model plants, including *Antirrhinum majus* (Plantaginaceae), *Arabidopsis thaliana* (Brassicaceae), and *Oryza sativa* and *Zea mays* (Poaceae), have identified specific genetic modules that are turned on to control, for instance, leaf differentiation, polarity, and shape. Leaf morphogenesis is known to be regulated by genes that control differentiation of the adaxial or upper face versus the abaxial or lower face, like the HDZIP-III transcription factors, and other genes that control determinacy and leaf dissection, like the KNOX and the TCP genes (Kidner and Timmermans, 2010; Koenig and Sinha, 2010).

Similarly, floral organ identity has been attributed to specific combinations of transcription factors, in this case MADS-box and APETALA2/ERF proteins. They are turned on at specific time points after floral meristem initiation to control the identity of each primordium and to regulate downstream targets accordingly to the role of each organ. In stamens and carpels, downstream target genes of organ identity genes include those responsible for sporogenesis and gametogenesis, whereas in petals they often include epidermal changes such as papillae differentiation and pigment accumulation to attract pollinators (Coen and Meyerowitz, 1991; Weiss, 2000).

Homologous structures, besides sharing a common position, and the same ontogenetic trajectory, are also expected to be controlled by the same genes. However, expression, functional and evolutionary studies of genes involved in leaf and flower morphogenesis in non-model organisms have shown that gene lineages have functionally evolved independently, often resulting in the recruitment of gene homologs into different functions across taxa. Integrating gene lineage evolution studies into evolutionary and developmental questions has turned out to be extremely informative, as plant genomes are the result of cumulative rounds of whole genome duplication or WGD (Soltis *et al.*, 2010, 2014; Jiao *et al.*, 2011). Thus, plant genomes vary dramatically in terms of copy number from a particular gene family, their regulation and likely their interaction partners, thus, raising the possibilities that gene functional evolution has been affected by gene and genome duplications. Specific case-by-case scenarios have been described by Adams and Wendell (2005), Flagel and Wendell (2009), and Wendell (2015), among many others. Recently, numerous reviews have addressed comparative floral development and the understanding of floral evolution from an evo-devo approach, highlighting some case studies of plant

adaptation and innovation that have investigated the relationships between gene duplications, gene regulatory networks, and morphological diversification (Specht and Howarth, 2014; Glover *et al.*, 2015).

Here, we provide an overview of plant life forms and morphology, including leaf shape, inflorescence architecture, flower and fruit morphology, and briefly comment on the underlying genetic bases for organ identity. Finally, we discuss novel structures in two case studies of non-related plant lineages with parallel evolution of similar flower synorganization and fruit variation. The reader will notice that most of the examples are in tropical plants, as one of our goals is to find non-model organisms among the fascinating repertoire of shape variation in the tropics.

Habit or Life Form

Land plants or embryophytes dominate the Earth in terms of number of species and diversity of life forms, life histories, and niches they occupy. Their forms have evolved most likely from small aquatic plants that needed water most of the time as a substrate and a vector for reproduction, to large woody plants that can reach up to 80+ meters tall and 6+ meters in diameter. Embryonic tissues, called meristems, have provided land plants the great advantage of continuous primary growth (i.e., in length), as well as secondary growth (i.e., in width) and elaboration of an efficient vascular system for water and nutrient transport. With the acquisition of vascular tissue, every major lineage of land plants diversified more or less independently into extraordinary life forms, including herbs, either annual or perennial (**Figures 1(a)–1(c)**); shrubs, with more or less woody, highly branched individuals without a distinct trunk; climbers, either vines (herbaceous) or lianas (woody) (**Figure 1(d)**); and trees, which are woody plants usually 5+ meters tall, with a main trunk that clearly differs in growth from lateral or higher order branches (**Figure 1(e)**). Two life forms that are frequent in alpine and high mountain environments are the cushion plants, when one or more individual produces numerous branches that tightly grow just above the ground (**Figure 1(c)**); and the rosette plants, when the leaves are tightly arranged on the distal portion of elongated (simple or compound) stems that can reach up to 10 meters tall (**Figure 1(j)**).

Epiphytic plants, that is, those plants that grow on other plants without taking nutrients from them, appear also in every major lineage of land plants, including members in the bryophytes, ferns and allied, and flowering plants (**Figures 1(e)–1(g)**); only a few instances of epiphytes (e.g., *Zamia pseudoparasitica*, Zamiaceae) are known to occur among gymnosperms. Epiphytes are much more frequent in wet, tropical forests. Flowering plant families with a high number of epiphytes are bromeliads (**Figures 1(e)** and **1(f)**), orchids (**Figure 1(g)**) and aroids, among others. Notably, epiphytism and changes in metabolism have been linked with the orchid radiation, a family with notorious diversification of life forms and floral displays reaching over 25 000 species (Silvera *et al.*, 2009; Givnish *et al.*, 2015). Although epiphytes are more abundant among monocots, a few eudicot families also show a number of epiphytic species, including the Ericaceae, Gesneriaceae, Melastomataceae, and Rubiaceae (Benzig, 1989).

Parasitic plants are extraordinary life forms among several lineages of seed plants, including one gymnosperm and members of at least 12 non-related lineages of flowering plants (Heide-Jørgensen, 2008). They have developed structural and physiological mechanisms that allow them to take part or all of the nutrients they need from their hosts, usually other flowering plants. Four categories of parasitic plants are recognized, depending on how invasive and obligate such mechanisms are: (1) facultative hemiparasites are those that maintain its photosynthetic properties and can survive with or without the host; this is the case of the 'Indian paintbrushes,' the common name for several species of *Castilleja* (Orobanchaceae; **Figures 1(i)** and **1(j)**). (2) Obligate hemiparasites, which still keep their photosynthetic repertoire but cannot complete their own life cycle without a host; this is the case of many families of the order Santalales, three of which (Eremolepidaceae, Loranthaceae, and Viscaceae, commonly known as mistletoes) exhibit conspicuous parasitism and some of the most penetrating organs, called haustoria (**Figures 1(k)** and **1(n)**), which can even break through hard, tropical woods, such as those of Fagaceae, Rosaceae, or Salicaceae, among many others; some can even develop epicortical roots and secondary disk-like haustoria (**Figure 1(n)**). Common hemiparasites in the tropics also include the 'dodders,' *Cuscuta* (Convolvulaceae), which develops series of discoid holdfasts directly from the soft but strangler coiled stems (**Figures 1(o)** and **1(p)**); unlike vascular systems in haustoria of most parasitic plants, which are mainly formed by xylem, those in *Cuscuta* are also formed by phloem. (3) Holoparasites are those that lost all the photosynthetic properties, as well as all or most of its vegetative organs, as the Apodanthaceae (**Figures 1(q)** and **1(s)**), the Hydnoraceae and the Rafflesiaceae. (4) Myco-heterothrophic plants, when the host–parasite is mediated by underground fungi forming a tripartite system that also causes complete suppression of photosynthesis and extreme modifications in the vegetative body of the parasite; examples are *Monotropa* (Ericaceae; **Figure 1(t)**) and all members of the Balanophoraceae (**Figure 1(u)**).

Current research topics in the study of plant parasitism are: (1) Morphological and physiological changes in both the parasitic and the host plant with emphasis in the molecules that can be exchanged both ways (e.g., Vaughn, 2003; Birschwilks *et al.*, 2006). (2) Genetic changes in both parasite and host, in particular the occurrence of horizontal gene transfer (HGT) and the profound genomic rearrangements and reduction particularly in the parasite mitogenomes (e.g., Skippington *et al.*, 2015); these mechanisms are of great interest in the understanding of processes downstream of the first infection, as well as the maintenance of the parasitic strategy not only during ontogeny but also during evolution (e.g., Mower *et al.*, 2010; Yoshida *et al.*, 2010; Xi *et al.*, 2012, 2013). (3) Comparative transcriptomic analyses of the unique modified root system into a haustorium, the highly modified intrusive organ responsible for host penetration and nutrient taking. Recent studies of different parasitic plants during early stages of haustorial establishment have identified a number of key 'parasitism' genes that include proteases, cell wall modifying enzymes, and extracellular secretion proteins (Yang *et al.*, 2014).

Leaves

Leaf Morphology Variation

Leaves are lateral organs that usually perform photosynthesis. Leaves are extremely diverse in architecture, size, form, and function. A major trend in leaf evolution is the switch from leaves with one midvein (in lycophytes such as Selaginellaceae and Lycopodiaceae, and some fern allies such as Equisetaceae; Figures 2(a) and 2(b)) to leaves with dichotomous venation (as in most ferns and the gymnosperm *Ginkgo*; Figures 2(c) and 2(d)) to leaves with complex vein systems along a midvein in other gymnosperms (such as Cycadales and some Gnetales, Figure 2(e)), and most flowering plants (Figures 2(f)–2(p)).

Leaf position along the stem is one of the most useful taxonomic traits, especially in seed plants. Leaves can be opposite, if they arise at the same node (Figures 2(d)–2(h)); or alternate, when only one leaf per node is formed (Figures 2(i)–2(k)). A special case occurs when leaves are whorled, that is when more than two leaves are formed per node (Figure 2(l)). Sometimes, chaotic leaf position is due to the formation of aerial tubers, such as in *Anredera baselloides* (Basellaceae). A metatopic phenomenon called anaphysis can drastically displace a leaf to an ectopic, supranodal position, giving rise to pseudo-opposite (such as in several Solanaceae), pseudo-whorled or pseudo-alternate leaves.

Leaves have a marked dorsiventral polarity, and very often the adaxial surface is oriented upwards. In some taxa such orientation is inverted due to resupination, that is, the torsion of the petiole. Inverted orientation can affect leaves from one side in branches with two-ranked leaf arrangement, as in *Retrophyllum* (Podocarpaceae Figure 2(i)), or all leaves, as in *Bomarea* (Alstroemeriaceae Figure 2(k)).

Leaf shape and size often varies drastically in the same individual. Variation includes changes in width and length, color, texture, and dissection. This variation occurs via three main mechanisms: (1) heterophylly, if juvenile leaves are drastically different from the adult leaves (Figure 2(n)); (2) heteroblasty, if leaves of the main branches are different from those of the higher order branches; this is evident in *Berberis* (Berberidaceae; Figures 2(o)); or (3) anisophylly, when the two (rarely more) leaves of the same node are unequal in size; this occurs in taxa with opposite (rarely whorled) leaves, such as some Asteraceae (Figure 2(p)), Melastomataceae, Rubiaceae, and Solanaceae.

Early leaf development begins with the differentiation of two portions, the hypophyll, that later will form the leaf base and the stipules (Figure 2(o)); and the epiphyll, which later forms the petiole and the lamina (Figure 2(o)).

The most conspicuous structural modification of leaves lies in the dissection (Figure 3(e)) or division (Figures 3(f)–3(i)) of the lamina into several portions (Figure 3(e)–3(i)). If the portions become completely separate from each other, the leaf is considered compound (as opposed to simple; Figures 3(f)–3(i)), and each portion is called a pinna (in ferns) or a leaflet in seed plants (e.g., *Cycas*; Figure 3(i)). Programmed cell death (PCD) can heavily dissect simple entire leaves resulting in compound or perforated leaves.

Stipules are lateral outgrowths of the leaf base in a vast number of flowering plants. They are taxonomically important and functionally diverse, although in most taxa they are vestigial and do not have any apparent function. Three of the most noticeable functions of stipules are secretion through extrafloral nectaries (e.g., *Passiflora*, Passifloraceae; Figure 3(a)), bud protection (e.g., *Trifolium*, Fabaceae; Figure 3(b)), or mechanical support as tendrils (e.g., *Smilax;* Figure 3(c)). In the case of *Cecropia* (Urticaceae; Figure 3(d)), *Ficus* (Moraceae), and *Magnolia* (Magnoliaceae) their protective role is evident as they overtop and tightly enclose the shoot apical meristem; this is why they are sometimes considered (erroneously) as terminal.

Leaf variegation occurs when some areas of the lamina are white, yellowish, gray, or other colors but green (e.g., some Commelinaceae, Figure 3(m); some Solanaceae, Figure 3(n)). Leaf structure and function changes over time occur in many seed plants that grow in temperate or cold conditions. One of the most common modifications in leaf structure and function occurs in many seed plants that grow in temperate or cold conditions. In these plants it is common that the first series of leaves on each branch are modified into scale leaves or cataphylls (Figures 3(i)–3(k)). They are extremely important for protections of the vegetative and reproductive meristems during dormancy. Other leaf modifications include: spines in cactae (Figure 3(l)); tendrils (e.g., in some Asteraceae such as *Mutisia*, in which the terminal leaflets of a compound leaf are transformed into tendrils: Figure 3(h)); trap-leaves, either by sticky, glandular hairs (such as in *Drosera*, Droseraceae), tactism such as the *Dionaea* (Droseraceae); or pitcher-like modifications such as those in Nepenthaceae or Sarraceniaceae.

Genetic Basis of Leaf Development

The genetic basis of leaf development is a major theme in developmental biology. Leaves are thought to develop in the following phases: (1) establishment of the dorsiventral, proximodistal, and mediolateral domains; (2) expansion of the lamina; and (3) differentiation of tissue-specific domains (Tsukaya, 2006; Efroni *et al.*, 2010; Nakata *et al.*, 2012). The abaxial–adaxial polarity results in functionally and structurally important differences between the upper and the lower surfaces in adult leaves. In *Arabidopsis* several transcription factors have been identified as controlling this process, including *ASYMMETRIC LEAVES1* (*AS1*), *AS2*, *CLASS III HOMEODOMAIN-LEUCINE ZIPPER* (*HD-ZIPIII*), *FILAMENTOUS FLOWER* (*FIL*)/*YABBY*, and *KANADI* (*KAN*), among others (McConnell and Barton, 1998; Siegfried *et al.*, 1999; McConnell *et al.*, 2001; Emery *et al.*, 2003; Eshed *et al.*, 2004; Zgurski *et al.*, 2005; Kidner and Timmermans, 2010). The orthologs *PHANTASTICA* (*PHAN*) in snapdragon and *LePHAN* in tomato determine the adaxial domain in leaves; thus, their mutants exhibit radialized (that is, loss of dorsiventrality) needle-like leaves, with abaxial identity surrounding only xylem tissue (Kim *et al.*, 2003; Waites and Hudson, 1995; Kidner and Timmermans, 2010). Collectively these genes are known as the *ARP* (after *AS1*, ROUGH *SHEATH2* (*RS2*, in maize) and *PHAN*). They are expressed at the site of leaf initiation and in young leaf primordia, and antagonize *WUSCHEL* and Class 1 *KNOTTED1-LIKE HOMEOBOX* (*KNOX1*) genes (Waites *et al.*, 1998; Timmermans *et al.*, 1999; Ori *et al.*, 2000;

Katayama *et al.*, 2010), which promote meristem indeterminacy (Byrne *et al.*, 2000, 2002). The ARP-KNOX gene regulatory module also antagonizes proximal (close to the axis) and distal (afar away from the axis) cell division in formed leaves. While *ARP* genes promote distal identity, *KNOX1* genes maintain proximal cell division in leaf development after this has ceased in more distal areas (Schneeberger *et al.*, 1998; Tsiantis *et al.*, 1999; Byrne *et al.*, 2000).

Leaf adaxial identity is also controlled by *HD-ZIPIII* class genes. In *phb*, *phv*, and *rev* mutants, leaves are abaxialized and a

loss of meristematic functions occur (McConnell and Barton, 1998; McConnell *et al.*, 2001; Prigge *et al.*, 2005). These genes are strongly regulated, on one hand by two microRNAs, *miR165* and *miR166* that accumulate abaxially and degrade abaxial transcripts of *HDZIPIII* genes, thereby displacing all mRNAs to the adaxial region (Tang *et al.*, 2003). On the other hand, negative regulation of *HDZIPIII* genes also occurs by the dimerization with the *LITTLE ZIPPER* (*ZPR1–4*) proteins. This interaction prevents HDZIPIII proteins from binding target DNA sequences (Wenkel *et al.*, 2007).

Promoters of abaxial identity, and thus antagonistic to the *HDZIPIII* genes, include *KANADI* and *YABBY* genes. The *kan* and *fil yab2–5* mutants in *Arabidopsis* have adaxialized leaves with altered vascular patterning, which instead of activating leaf programs, reinitiated shoot meristem genetic programs (Sawa *et al.*, 1999; Siegfried *et al.*, 1999; Eshed *et al.*, 2001, 2004; Sarojam *et al.*, 2010). It has been shown that *KANADI* homologs in rice and corn are also responsible for the specification of leaf polarity (Candela *et al.*, 2008; Zhang *et al.*, 2009). *YABBY* gene homologs on the other hand are responsible for polarity maintenance, lamina outgrowth and establishing of the leaf margin (Eshed *et al.*, 2004; Yamaguchi *et al.*, 2004; Ishikawa *et al.*, 2009; Sarojam *et al.*, 2010). Thus, *YABBY* homologs interact closely with genes that play roles in the expansion of the lamina, which include WOX transcription factors. *WOX* gene family members include the *Arabidopsis PRESSED FLOWERS (PRS)*, the maize *Narrow sheath1* and *2* (ns1, ns2) and the *Petunia MAEWEST* (*MAW*), all of which control lateral growth (Scanlon *et al.*, 1996; Nardmann *et al.*, 2004; Vandenbussche *et al.*, 2009). Interestingly, flattened unifacial leaves, which are a novel leaf form occurring in the monocot *Juncus* (Juncaceae), are the result of genetic changes

that induce abaxialization and include expression changes of *YABBY* orthologs that include the *Juncus DL* (named after the YABBY rice homolog *DROOPING LEAF*) (Yamaguchi *et al.*, 2004, 2010). Overall, data in *Arabidopsis* as well as in non-model species suggest a complex regulation of abaxial–adaxial identity, linked with marginal growth of lateral organs, proper vascular differentiation and even axillary meristem development (Champagne and Sinha, 2004; Zgurski *et al.*, 2005).

The establishment of the dorsiventral domains allows the induction of marginal growth and complexity. Genes controlling leaf complexity and leaf shape are transcription factors involved in the meristematic maintenance of the shoot apex, that often get recruited later in development in the leaf margins to regulate compound leaf development (reviewed in Champagne and Sinha, 2004; Efroni *et al.*, 2010). Leaf complexity is generally linked with the *KNOX1* genes *SHOOT MERISTEMLESS* (*STM*) in *Arabidopsis* and its ortholog *KNOTTED1* (*Kn1*) in maize, that are responsible of maintaining proper shoot apical meristem (Long *et al.*, 1996; Vollbrecht *et al.*, 2000). *KNOX1* genes are repressed by *ARP* genes during leaf initiation to acquire determinacy. However, after the differentiation of the leaf primordium, *KNOX1* genes either remain down-regulated in species with simple leaves (Nishimura *et al.*, 1998); or they can be turned on again in the leaf margin in species with compound leaves to generate new marginal outgrowth (Hareven *et al.*, 1996; Bharathan *et al.*, 2002). In the formation of a compound lamina, the antagonistic genes to *KNOX1* are the *NO APICAL MERISTEM* and *CUP SHAPE COTYLEDON3* (*NAM/CUC3*) genes, which are responsible for the formation of the leaf dissection zones (Blein *et al.*, 2008; Berger *et al.*, 2009). It is thought that this regulatory module has been maintained during angiosperm evolution to directly control leaf complexity and leaf shape (Blein *et al.*, 2008; Berger *et al.*, 2009). *KNOX1* genes regulate leaf complexity in most angiosperms studied (reviewed in Hay and Tsiantis, 2010), with the exception of pea (and close relatives) and columbines (*Aquilegia*), where other floral meristem identity genes have been co-opted to regulate leaflet formation and proper development (Hofer *et al.*, 1997; Champagne *et al.*, 2007; Pabón-Mora *et al.*, 2013).

Inflorescences

There are two main types of inflorescences, racemose and cymose. Racemose inflorescences are characterized by an apical meristem that grows indeterminately and never becomes a terminal flower (**Figure 4**). Conversely, cymose inflorescences are those in which the apical meristem sooner or later switches from an inflorescence meristem with indeterminate growth to a floral and determinate, as it ends up forming a terminal flower (**Figure 5**).

Racemose inflorescences are either simple, when all flowers are developed directly from the main axis (or rachis) of the inflorescence (**Figures 4(a)–4(j)**); or compound, when the inflorescence produces branches of second, third or more orders before forming the flowers (**Figures 4(k)**, **4(n)**, and **4(q)**). The most common types of racemose inflorescences are: (a) racemes, if flowers bear a peduncle that is subtended by a bract; racemes are often associated with the presence of flowers with bilateral symmetry, often pollinated by insects, birds, or bats (**Figures 4(a)–4(e)**). This is the case of *Castilleja* (Orobanchaceae; **Figure 4(a)**) and *Crotalaria* (Fabaceae; **Figure 4(c)**); however, racemose inflorescences can also bear radially symmetrical flowers, as in *Echeveria* (Crassulaceae; **Figure 4(b)**) or the monocot *Puya* (Bromeliaceae; **Figures 4(c)** and **4(d)**). (b) Spikes, if flowers are sessile and directly attached to the axis; in this case, bracts are often vestigial or lacking, and flowers are tightly congested and develop in spirals along the axis; spikes are often linked with the occurrence of variously reduced and small flowers, often wind pollinated, like in *Piper* (Piperaceae; **Figure 4(f)**) or *Hedyosmum* (Chloranthaceae; **Figure 4(g)**); in these two taxa, the modified spike is called amentum, as the main axis is thickened. In the latter genus, although inflorescences are unisexual, both staminate and carpellate inflorescences are indeterminate (Doria *et al.* 2012). (c) Catkins, if the hanging spikes are unisexual, as in, for example, members of the order Fagales (**Figure 4(h)**). (d) Spadices, if spikes subtended by one (rarely more) large and colorful modified leafs called the spathe, such as those found in *Houttuynia* (Saururaceae; **Figure 4(i)**) and *Anthurium* (Araceae; **Figure 4(j)**). (e) Indeterminate capitula or heads, if the internodes of the inflorescence become extremely shortened, and the flowers are congested and closely tightened on a common receptacle and usually surrounded by involucral bracts; capitula are typical in the Asteraceae (**Figures 4(k)–4(m)**), and often are formed by two different types of flowers, ligular (also known as the ray flowers) and tubular (also known as the disk flowers). (f) Umbels, if internodes are compressed giving the appearance of flowers born at the same point, as in most Apiaceae (**Figure 4(n)**). (g) Solitary flowers can be evolutionary derived from racemose inflorescences with elongate, leafy branches with indeterminate growth, and one flower per subtending leaf.

The main types of cymose inflorescences are (a) solitary flowers, if they are terminal and formed directly from the shoot apical meristem; thus, a single flower is formed at the end of a branch, like in magnolias (Magnoliaceae; **Figure 5(a)**) or at the end of the entire plant, like in some poppies (Papaveraceae; **Figure 5(b)**). (b) Monochasia, if only one branch (or second order flower) is formed on each node below the terminal flower, as in *Aristolochia maxima* (Aristolochiaceae, **Figure 5(c)**) and *Bomarea* (Alstroemeriaceae; **Figure 5(d)**). (c) Dichasia, if the development of the terminal flower is followed by the initiation of two opposite flowers below it, like in *Vismia* (Hypericaceae; **Figure 5(e)**), *Meriania* (Melastomataceae; **Figure 5(f)**) and *Lehmaniella* (Gentianaceae; **Figure 5(g)**). (e) Pleiochasia, if 4, 6, 8, or more opposite flowers are developed below the terminal flower, which is often the first to develop and reach maturity, like in *Berberis* (Berberidaceae; **Figure 5(h)**).

Cauliflory and Ramiflory

In woody plants mainly from tropical forests, it is frequent that blooming is drastically delayed with respect to the vegetative growth of the plant. Thus, inflorescences are located on lignified stems, a phenomenon called cauliflory, if it occurs on the main trunk; or ramiflory, if it occurs on higher order branches. In both cases, the inflorescence meristems remain

Figure 4 Racemose inflorescences. dormant for months or years immediately beneath the cork meristem of the cortex, usually axillary to the leaf scars. Not all cauliflorous inflorescences have the same architecture. They may be racemose, like in *Brownea* (Fabaceae; Figure 4(p)) and *Couroupita* (Lecythidaceae; Figure 4(q)), or cymes, like in *Crescentia* (Bignoniaceae; Figure 5(j)). Even in the same genus (e.g., *Aristolochia*) cauliflorous inflorescences can be racemes (e.g., in *Aristolochia leuconeura*; Figure 4(o) or cymes (e.g., *Aristolochia arborea*, Figure 5(i), and *A. maxima*, Figure 5(c); González, 1999). Such positional convergence strongly

suggests that cauliflory or ramiflory is a heterochronic mechanism and a highly adaptive strategy for pollination rather than an acquisition via common ancestry.

Pseudanthia and Peloria

The following extreme modifications occur in inflorescence architecture: (a) cyathium, if a condensed inflorescence resembles and functions as a single flower, but is in fact formed by unisexual male flowers that surround female ones, with reduced or completely absent perianth (Prenner *et al.*, 2011); the cyathia are typically found in *Euphorbia* (Euphorbiaceae; **Figure 5(k)**). (b) Aberrant flowers, or peloria, are often formed in the terminal position of otherwise racemose inflorescences; common examples of peloria are known in *Digitalis* (Plantaginaceae) and *Calceolaria* (Scrophulariaceae; **Figure 5(l)**), where a radially symmetrical flower ectopically forms at the end of the inflorescence and it is surrounded by the typical bilateral flowers. Peloria also occur in inflorescences of the basal eudicot *Gunnera* which begins its development as racemose, but a terminal flower becomes evident during late ontogeny (Mora-Osejo *et al.*, 2011). (c) Unusual displacement of flowers by metatopies, when early fusion of two or more flowering axes, or an axis and one or more floral peduncles occur; this occurs, for example, in the monocot *Agave* (Agavaceae, **Figure 5(n)**) inflorescences, making very hard to interpret the resulting branching patterns in such cases; these metatopies are classified as recaulescence (fusion of the floral peduncle with the petiole of its subtending leaf), concaulescence (fusion of the floral peduncle with the shoot axis), anaphysis (displacement of a floral bud to an ectopic, extra-axillary position) or sindesmy, when two or more axes of an inflorescence fuse with the shoot; concaulescence may result in that a lateral flower appears as terminal (i.e., pseudoterminal) position, as in *Atropa* and *Datura* (Solanaceae; **Figure 5(m)**); on the other hand, recaulescence occurs when the floral axis grows fused to the leaf basis, resulting in epiphyllous inflorescences, that is one or more flowers ectopically growing on top of the leaf or bract, as in some orchids, *Tilia* (Malvaceae) and Phyllonomaceae.

Genetic Basis of Inflorescence Development

The genetic control of racemes versus cymes ultimately depends on the instructions received by the shoot apical meristem. If the instructions are those of maintaining pluripotency it will be a raceme; conversely, if instructions are those of forming a terminal floral meristem, it will become a cyme. In *Arabidopsis* the transition from vegetative to reproductive development is controlled by a number of pathways that include hormonal outputs, autonomous competence, cold temperature responses, and photoperiodic changes (Amasino and Michaels, 2010). A major finding of the past decades has been the identification of florigen that was thought to be the key signal for the transition to flowering. Florigen turned out to be a mobile transcription factor named *FLOWERING LOCUS T* (*FT*) that is produced in leaves but translocated to the shoot apex to promote flowering. FT acts together with *LEAFY* (*LFY*) to provide the identity of the floral meristem. *FT* and *LFY* antagonize the inflorescence meristem gene *TERMINAL FLOWER1* (*TFL1*) (also known as *CENTRORADIALIS -CEN*, the *Anthirrinum* ortholog) which is also a mobile signal; in racemes *TFL1* stays active at the distal point and flowers never form, whereas in cymes it is repressed by the floral meristem genes, and thus flowers do form (Amaya *et al.*, 1999; Conti and Bradley, 2007). The interactions between *FT*, *LFY*, and *TFL1*, first reported in *Arabidopsis*, are maintained in other phylogenetically distant plants, like tomato and grasses. However, the number of gene copies has changed over time in different lineages; as a result, grasses, for instance, possess redundant copies of *TFL1* homologs as well as *FT* homologs (Molinero-Rosales *et al.*, 1999; Lifschitz *et al.*, 2006; Périlleux *et al.*, 2014; Zhang and Yuan, 2014). Inflorescence variation is one of the most outstanding plant features that will provide ground for further genetic variation and novel players, as non-model species are included in evo-devo studies. Most levels of complexity in inflorescences have not yet been assessed in terms of their underlying genetic bases.

Flowers

Flowers are the most important evolutionary novelties of the dominant plants on Earth, the Angiosperms. They are formed by a succession of extremely modified leaves along an axis with compressed internodes, and lacking axillary meristems. These modified leaves of a flower are considered individual organs. Organs on each series can initiate either in a spiral fashion (**Figures 6(a)** and **6(b)**), or in whorls (**Figures 6(c)** and **6(d)**). These organs are grouped in four (sometimes three or less) series and occupy a fixed position in the flower (**Figures 6(a)–6(f)**), as follows: the outer organs are called sepals, and altogether form the calyx; next, the petals, which form the corolla; then, the stamens, which altogether form the androecium; and the carpels (rarely only one), which are in the center of the flower and form the gynoecium. Additional floral whorls include the presence of an epicalyx in members of the Loranthaceae (**Figure 6(m)** and Malvaceae (**Figure 6(n)**), among other families, and the unique corona, occurring in Passifloraceae (**Figure 6(o)**).

The outer floral organs (altogether called the perianth) are sterile, and the inner ones are fertile. The perianth is highly variable in terms of form and function, although they often times are laminar; frequently, sepals are green and protective, while petals are colorful and play important roles in pollination (**Figures 6(e)** and **6(f)**). When sepals and petals look alike they are called tepals (**Figures 6(g)** and **6(h)**). Stamens and carpels, responsible for the sporogenesis of pollen grains and ovules, respectively, have a 3D arrangement due to the formation of internal cavities where sporogenesis and gametogenesis occur (**Figures 6(i)–6(l)**). The gynoecium, the most important key innovation of flowering plants, is syncarpic if the two or more carpels are partially or totally fused, or apocarpic if the carpels remain as individual organs. The basal portion of the gynoecium forms the ovary, which encloses one or more ovules; the distal portion of the gynoecium is usually differentiated into a style and a stigma, and both structures play critical roles during pollination (**Figures 6(i)**, **6(j)**, and **6(l)–6(n)**).

(t)–(u) Bilaterally symmetrical perianth of *Epidendrum fimbriatum*, Orchidaceae (t) and *Fumaria capreolata*, Papaveraceae (u).

In a number of taxa (e.g., papaya, *Cannabis*, cucumber, and mistletoes), flowers lack one of the two fertile series, or one of them is not functional or vestigial, giving rise to unisexual flowers (Figures 6(k)–6(l)). Unisexuality occurs primarily by arrested development of stamens or carpels; however, it does not occur following a common process across angiosperms, suggesting that unisexuality does not necessarily have homologous genetic bases in different taxa (reviewed in Diggle *et al.*, 2011).

Phylogenetic analyses of angiosperms define five major groups (Figure 7). Although early diverging angiosperms display greater variation in their floral ground plan, they are the

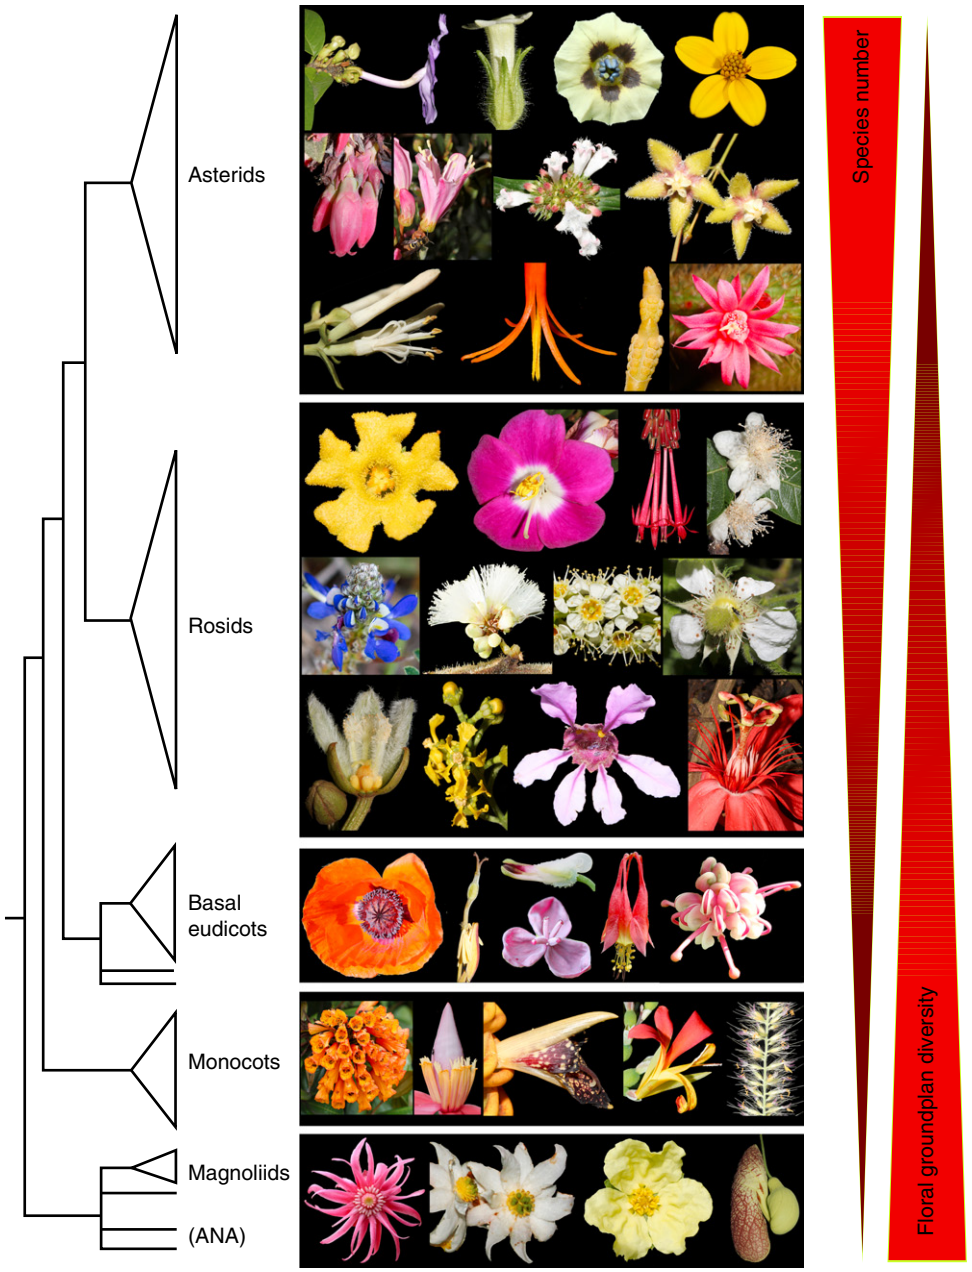

Figure 7 Trends in floral evolution. Summarized phylogenetic angiosperm tree showing the five main groups ANA, magnoliids, monocots, basal eudicots, and core eudicots (including rosids and asterids). Examples of floral variation are shown in front of each clade. Red triangles to the right indicate the inversely proportional relationship between increasing species number (e.g., core eudicots comprise approximately 75% of the total number of species) and decreasing floral groundplan variation (e.g., most flowers of core eudicots are 4–5 merous, whorled, with predominantly fused organs).

least diversified in terms of number of species (Figure 7). The early diverging angiosperms include *Amborella*, Nymphaeales, and Austrobaileyales (called the ANA grade), the monocots, and the magnoliids and Chloranthales. Whereas number of parts is often variable and high in magnoliids and basal angiosperms, most monocots flowers are trimerous (Figure 7). The remaining flowering plants are the eudicots (Wickett *et al.*, 2014); they are further divided into basal and core eudicots. Core eudicots are by far the most specious clade, as it comprises close to 75% of the flowering plant species; they comprise the rosids and the asterids (Figure 7). Flowers of core eudicots are predominantly bisexual, whorled, with 4 or 5 (rarely 6) sepals, petals, and stamens, a syncarpous gynoecium formed by 2–5 carpels. Fusion between organs is very common, and it is a determining factor driving pollination syndromes; for instance, long, tubular corollas are often hummingbird, moth, or butterfly-pollinated, while convoluted, trap-flowers are often linked with fly pollination (Proctor *et al.*, 1996). Fusion between different whorls is less frequent but, yet, it plays important roles in pollination;

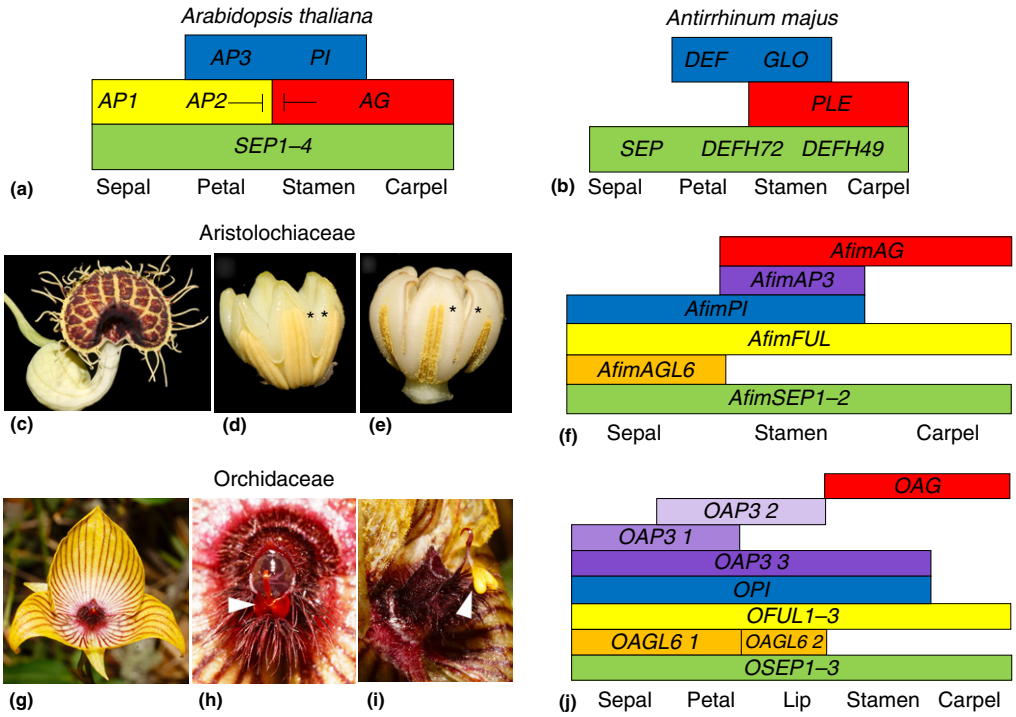

Figure 8 (a) Diagram of the ABCE model of flower development based on homeotic mutants of *Arabidopsis thaliana* (Brassicaceae); in yellow, A-class genes *APETALA1* (*AP1*) and *APETALA2* (*AP2*); in blue, B-class genes *APETALA3* (*AP3*) and *PISTILLATA* (*PI*); in red, C-class gene *AGAMOUS* (*AG*); in green, E-class genes *SEPALLATA 1–4* (*SEP1–4*). Bars represent the mutual repression between A and C-class genes resulting in unique interactions in the sterile *vs.* the fertile floral organs. (b) Diagram of the BC model, based on homeotic mutants of *Antirrhinum majus*; note the absence of A-class genes, as there are no homeotic sepal-to-petal mutants; according to this model the specification of the floral meristem is sufficient to provide sepal identity and only B and C-class genes are needed to form petals, stamens and carpels. (c)–(j) Diagrams of the models for synorganized flowers in Aristolochiaceae and Orchidaceae. (c)–(f) *Aristolochia fimbriata* flower (c), and gynostemium in its 'female' (d) and 'male' (e) phases. (f) Modified ABCE model in *Aristolochia fimbriata*, based on expression studies; note the broad expression of A-class genes, the lack of mutual repression with C-class genes and the inclusion of *AGL6* as a putative key player in perianth identity (Pabón-Mora *et al.*, 2015). (g)–(j) *Telipogon nervosus* flower (g), and gynostemium in its 'female' (h) and 'male' (i) phases; arrows point to the stamen before and after dehiscence. (j) Modified ABCE model in Orchidaceae, based mostly in data from *Oncidium* spp.; note an increase in the number of copies of A, B, and AGL6 genes; different combinations of *AGL6* and *AP3* paralogs specify sepal, petal and lip development. Redrawn based on Mondragón-Palomino, M., 2013. Perspectives on MADS-box expression during orchid flower evolution and development. Frontiers in Plant Sciences 4, 377; Tsai, W.-C., Pan, Z.-J., Hsiao, Y.-Y., Chen, L.-J., Liu, Z.-J., 2014. Evolution and function of MADS-box genes involved in orchid floral development. Journal of Systematics and Evolution 52, 397–410; and Hsu, H.-F., Hsu, W.-H., Lee, Y.-I., *et al.*, 2015. Model for perianth formation in orchids. Nature Plants 15046.

examples of such fusion between stamen(s) and carpel(s) into a gynostemium occur independently in Apocynaceae (**Figures 6(p)** and **6(q)**), Aristolochiaceae and Orchidaceae (**Figure 8**).

Several WGD events have been mapped to particular points of the phylogeny, as follows: one before the diversification of angiosperms (ε), two duplication events in the monocots (ρ, σ), one before the diversification of the eudicots (γ), and two restricted to the Brassicaceae (α, β) (Jiao *et al.*, 2011). These duplication events challenge the ongoing studies addressed to identify paralogous versus orthologous genes and their corresponding functions. Model flowering plants for genetic studies are the rosids *A. thaliana* (Brassicaceae), *A. majus* (snapdragon, Plantaginaceae), *Solanum lycopersicum* (tomato, Solanaceae), and the monocots *O. sativa* (rice, Poaceae) and *Z. mays* (corn, Poaceae). In addition, 37 plant genomes, the majority belonging to the core eudicots or the monocots, have been sequenced and are publicly available. The genetic basis of floral organ identity has been identified based on homeotic mutants of *A. thaliana* and *A. majus*. The resulting model illustrates how the expression patterns and interactions of three classes of MIKC MADS-box transcription factors and an *ERF/AP2* gene (collectively named A, B, and C-class genes) provide the identity to each floral whorl (Schwarz-Sommer *et al.*, 1990; Coen and Meyerowitz, 1991). According to the ABC model, A-class genes (*APETALA1* and *APETALA2*) establish the identity of floral meristem and provide sepal identity, A and B-class genes (*APETALA3* and *PISTILLATA*) control petal identity, B and C-class genes (*AGAMOUS*) regulate stamen identity, and C-class genes alone are responsible for carpel identity, as well as the termination of the floral meristem (Bowman *et al.*, 1989, 1991; Yanofsky *et al.*, 1990). This model was modified after the discovery of *SEPALLATA* transcription factors responsible for the floral transition and the initiation of all floral organs, thus an updated ABCE model includes E-class genes (the *Arabidopsis SEP1*, *SEP2*, *SEP3*, and *SEP4*) (Pelaz *et al.*, 2000). A caveat of the model is the lack of a mutant phenotype in *Antirrhinum* with homeotic changes in sepals and petals, challenging a universal A-function and raising an

alternative BC model where perianth is formed by default, after the specification of the floral meristem (Causier *et al.*, 2010).

One other trait that has been key for angiosperm diversification is floral symmetry, and specifically the independent evolution of a bilateral perianth (**Figures 6(y)** and **6(u)**) from a radially symmetrical condition (**Figures 6(r)** and **6(s)**). The genetic basis for floral symmetry in *A. majus* involves the asymmetric expression of four *TCP* transcription factors (acronym of *TEOSINTE BRANCHED1*, from *Z. mays*; *CYCLOIDEA*, from *A. majus* and *PROLIFERATION CELL FACTOR*, *O. sativa*): *CYCLOIDEA* (*CYC*), *DICHOTOMA* (*DICH*) and *RADIALIS* (*RAD*) controlling dorsal floral identity and an opposing gradient of *DIVARICATA* (*DIV*), controlling ventral identity (reviewed in Preston and Hileman, 2009; Hileman, 2014).

In the next section we will revisit organ identity and symmetry genes in flowers of two non-related families that show parallel evolution in synorganized perianth, stamens, and carpels.

Case Study – Floral Synorganization in Aristolochiaceae and Orchidaceae

Aristolochia (Aristolochiaceae)

The family Aristolochiaceae belongs to the order Piperales, a lineage that includes species with tiny flowers lacking perianth, like in *Peperomia* and *Piper* (Piperaceae), or with medium-sized flowers with a bipartite perianth, like in *Saruma* (Aristolochiaceae), and taxa with medium to large size, highly synorganized flowers with a single but elaborated perianth, like in *Aristolochia* (Aristolochiaceae). The bilaterally symmetrical perianth in *Aristolochia* is the result of the early fusion of three sepals that grow asymmetrically during development to form a kettle-trap mature flower with petaloid characteristics such as pigmentation and epidermal modifications including trichome formation to ensure fly pollination (González and Pabón-Mora, 2015). In addition, stamens and carpels in *Aristolochia* fuse congenitally forming a gynostemium with anthers on the outside and stigmatic lobes on the inside (González and Stevenson, 2000a, 2000b; González and Pabón-Mora, 2015; Pabón-Mora *et al.*, 2015).

Floral organ identity genes

Transcriptomic studies have shown that *Aristolochia fimbriata* possesses a single copy of each of the MADS box genes, except *SEPALLATA* (E-class genes), which has two paralogs. Given that the early diverging *Amborella trichopoda* already possesses two copies of these genes, it is likely that the *SEP* paralogs are likely a result of a duplication event prior to the diversification of flowering plants. *In situ* expression studies in *A. fimbriata* show the canonical expression patterns of B (*APETALA3* and *PISTILLATA*) and C-class (*AGAMOUS*) genes in stamens and carpels, despite the fact that these organs are fused. These studies also show expression of B-class genes only in the staminal portion of the gynostemium, and an ectopic expression of *PISTILLATA* at late developmental stages in the inner epidermis of the perianth (González and Pabón-Mora, 2015; Pabón-Mora *et al.*, 2015). Thus, B-class gene expression patterns support a sepal-derived perianth, and suggests the recruitment of *PI* in the acquisition of petal traits by the sepals in *Aristolochia* (Horn *et al.*, 2014; Pabón-Mora *et al.*, 2015).

The E-class (*SEPALLATA*) genes appear to be conserved with respect to the patterns established by the model, whereas expression of *APETALA1/FRUITFULL* homologs (A-class genes) is detected in all floral organs, leaves and fruits, suggesting pleiotropic and not perianth specific roles (Pabón-Mora *et al.*, 2012, 2015). Interestingly, the initiation of perianth primordia in *Aristolochia* is marked by the expression of *AGAMOUS-like 6* (*AfimAGL6*). *AGL6* is also turned on later on during development in the outer portion of the ovary and in the ovules, similarly to what has been observed in *Arabidopsis* (Schauer *et al.*, 2009). *AGL6* is the sister gene lineage to the *SEPALLATA* gene lineage and together, they are sister to the *APETALA1/FRUITFULL* gene lineage. Thus, it is likely that closely related genes have been recruited for perianth identity in *Aristolochia*.

Floral symmetry genes

So far, studies in all core eudicot species with bilateral flowers show asymmetrical expression of *CYC* homologs, in particular one of the three paralogs (*CYC2*) resulting after two consecutive duplication events in the gene lineage coincident with the radiation of the core eudicots. In noncore eudicots and monocots, differential expression of the preduplication *CYC/TB1* homologs seems to correlate with changes in symmetry, suggesting that at least in some taxa (e.g., Papaveraceae and Commelinaceae) they are also involved in establishing floral bilateral symmetry (Bartlett and Specht, 2011; Preston and Hileman, 2012; Hileman, 2014; Jabbour *et al.*, 2014). Nevertheless, the expression patterns of *CYC/TB1* homologs in *A. arborea* show a more or less homogeneous expression throughout the perianth in the overlapping domains with the B-class *PISTILLATA* genes, and there is no evidence of a dorsiventral gradient regulating changes in perianth growth (Horn *et al.*, 2014). Moreover, heterologous transformation studies demonstrated that *AarCYC* genes do not produce a phenotype similar to that caused by the overexpression of core eudicot *CYC2* genes, suggesting functional changes in TCP genes in *Aristolochia*. Altogether the data suggest that bilateral symmetry in *Aristolochia* flowers is not controlled by asymmetric expression of *CYC/TB1* genes; instead, they point at novel regulatory networks yet to be found controlling perianth curvature, asymmetric elongation of the median sepal and bilateral symmetry in the fused sepals in the magnoliids (Horn *et al.*, 2014).

Orchidaceae

Orchid flowers are also highly synorganized. The perianth is formed by three sepals, which often are petaloid or bilateral, two lateral petals and a medial petal (called the lip or labellum) that often is highly elaborated and distinct from the lateral petals. The androecium in most orchids consists of a single stamen, fused to the stigma into a gynostemium; pollen of most orchids aggregate into two or four sacs called pollinia, which carry the entire pollen load as a single structure. Sometimes (in the subfamilies Apostasioideae and Cypripedioideae) two or three stamens are still formed, and pollen grains do not group into pollinia (reviewed by Endress, 2015).

Floral organ identity genes

An increasing number and diversification of all MADS box genes involved in floral organ identity has occurred in Orchidaceae (Cai *et al.*, 2015). Two consecutive gene duplications in the *AP3* gene lineage have resulted in four clades, followed by the specialization of gene copies in a specific whorl (Mondragón-Palomin and Theißen, 2011; Tsai *et al.*, 2014). In particular, the lip has a unique combination of *AP3* gene copies compared to the lateral petals (Mondragón-Palomino, 2013; Tsai *et al.*, 2014). Recent studies have identified that *AGL6* genes are also key players in perianth development. Two paralogs are found from a duplication predating the evolution of orchids, one of them has specialized in providing sepal and petal identity, whereas its paralog contributes primarily to lip identity (Hsu *et al.*, 2015). Thus, gene duplication and subfunctionalization have been proposed as key drivers of perianth morphological diversification in orchids. The gynostemium identity in orchids seems to be controlled by *AG-like* genes, and a lack of expression of one *AG* paralog has been correlated with the occurrence of homeotic transformations from the gynostemium to tepals (Wang *et al.*, 2011).

The role of other MADS box genes is less clear. The *PI* genes do not seem to be restricted to the petals and stamens but have broad expression patterns. However, there are conflicting reports regarding their function, as some experiments show complementation of the *Arabidopsis pi* mutant (Xu *et al.*, 2006) and some do not, questioning their contribution to perianth and stamen identity (Tsai *et al.*, 2008). *FUL-like* genes have been found broadly expressed but have not been functionally characterized (Yu and Goh, 2000). *SEP* genes are found in all floral organs and functional analyses suggest that they play key roles in perianth identity, although their contribution to stamen and carpel identity is unclear (Pan *et al.*, 2014).

Floral symmetry genes

Floral symmetry *CYC/TB1* candidate genes have been identified in many monocots including most model species like rice and maize (Mondragón-Palomino and Trontin, 2011). Studies in Commelinaceae have shown that asymmetric expression of *CYC/TB1* genes, controlled by a dorsiventral *APETALA3* gradient, underlies shifts in symmetry, like their core eudicot homologs (Preston and Hileman, 2012). Interestingly, *CYC/TB1* genes are difficult to identify via directed cloning or by identity BLAST searches in the available transcriptomes of orchids. Only recently, one ortholog of *CYC/TB1* was isolated from *Orchis italica* (*OitaTB1*) and its expression is mostly restricted to leaves, suggesting that Orchidaceae, like *Aristolochia*, is also an exception to the acquisition of bilateral symmetry *via* the recruitment of *CYC/TB1* genes (DePaolo *et al.*, 2015). Closely related TCP genes, like *PCF-like* class I and *CIN-like* class II are good candidates for activation and repression of cell division during development, but their contribution to bilateral symmetry has not been addressed (Mondragón-Palomino and Trontin, 2011; DePaolo *et al.*, 2015). One aspect to keep in mind is that bilateral symmetry of orchid perianth may not be linked with that in the gynostemium, which strongly suggests that different candidate genes may independently control symmetry in these organs. Other candidate genes for establishing early floral bilateral symmetry, at least in Orchidaceae, may include those involved in organ fusion and abortion in the inner whorls.

Fruits

Fruits are the result of morpho-anatomical changes in the carpels after the fertilization of the ovules and represent an outstanding example of extreme ontogenetic transformation leading to a myriad of forms and seed dispersal strategies. Fruit classification takes into consideration number and fusion of carpels, tissue types, texture, and dehiscence to release the seeds (Roth, 1977). Three distinct layers on the fruit wall are often apparent: the exocarp, which includes the outermost layer, and only occasionally including hypodermal tissues; the mesocarp, often formed by multiple middle layers and the vascular tissue; and the endocarp, which consists of one to few layers in contact to the developing seeds, often inner to the vascular bundle (Richard, 1819; Sachs, 1874; Roth, 1977; Pabón-Mora and Litt, 2011; Thadeo *et al.*, 2015). Some trends can be noticed with respect to fruit evolution (**Figure 9**). Fruits that come from apocarpic gynoecia are less frequent and develop into characteristic follicles, like in the magnoliid *Illicium* (Illiciaceae) and the basal eudicot *Aquilegia* (Papaveraceae), or druplets, like in the blackberries (Rosaceae). Capsules (or dry dehiscent fruits), berries (or fleshy fruits), and drupes are by far the most recurrent fruit types, often derived from syncarpic gynoecia; however, they are evidently not homologous, as they have appeared reiteratively in many groups of flowering plants (**Figure 9**).

Dry dehiscent fruits are characterized by generating tension between a soft (parenchyma) and a hard (sclerenchyma) tissue and have limited periclinal cell division. In contrast, fleshy fruits have continuous cell division, both periclinal and anticlinal, and little or no hard tissue; thus, most edible fruits fall into this category (Pabón-Mora and Litt, 2011; Thadeo *et al.*, 2015). Drupes are unique in that they are rich in hard tissue in the inner layers, but it is deposited in a continuous layer (s), thereby avoiding tension and rupture and allowing fleshy layers to proliferate in the outer layers, like in peach and avocados. A single family, like the Solanaceae, may have many fruit types; for example, early diverging taxa such as the tobacco have capsules, whereas the remaining members of the family, including peppers, tomatoes and eggplants, have predominantly fleshy fruits (Pabón-Mora and Litt, 2011; **Figure 9**).

Novelties in fruits are common themes throughout angiosperm evolution. Morphological diversification may also include other organs besides the carpels, such as the receptacle, bracts, sepals or petals, like in the apple or the strawberry (Esau, 1967; Weberling, 1989). The structural identity of these accessory organs often require developmental studies; one such case is the fruit of the magnoliid *Hedyosmum* (Chloranthaceae; **Figure 9**), which looks like a fleshy fruit derived from an inferior ovary (Gustafsson and Albert, 1999), but it is instead a small, black drupe derived from superior ovary, and tightly enclosed by white fleshy bracts that remain until late stages of fruit development (Doria *et al.*, 2012). Corn is also a unique fruit, where the kernel or caryopsis (collectively

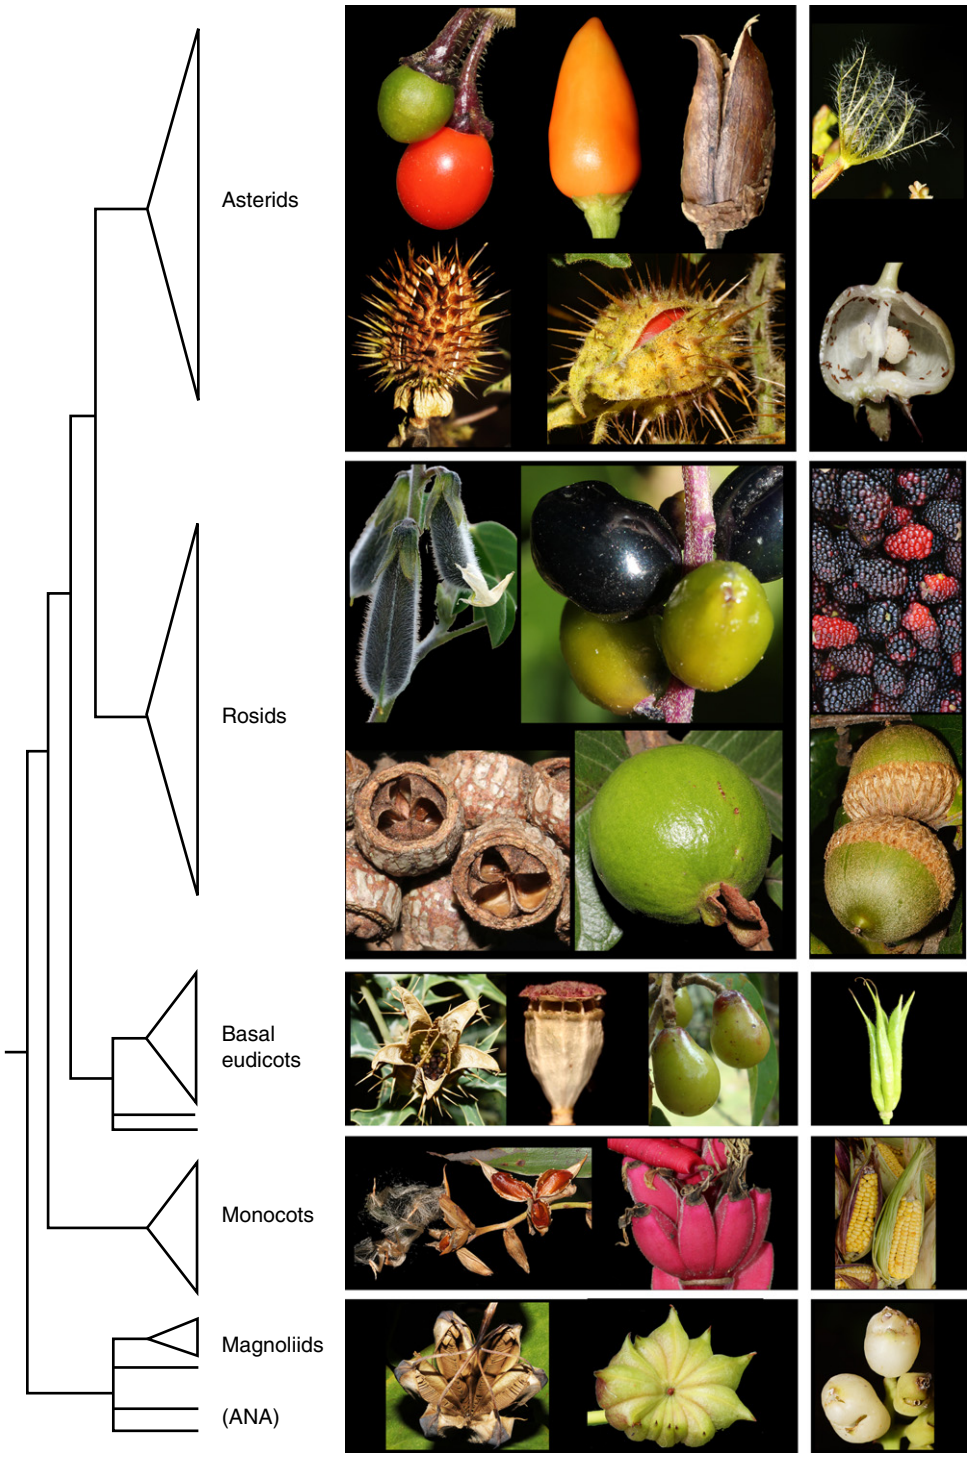

Figure 9 Trends in fruit evolution. Summarized phylogenetic angiosperm tree showing the five main groups ANA, magnoliids, monocots, basal eudicots, and core eudicots (rosids and asterids) with examples of fruit variation therein. Examples on the left and central columns correspond to dry dehiscent fruits and fleshy fruits, respectively; note that these two fruit types occur independently in all major groups. Examples on the right column correspond to particular variations of fruit types, on each major clade, from bottom to top; fleshy bracts of *Hedyosmum* (Chloranthaceae) enclosing dry drupes; corncob of *Zea mays*, Poaceae; multifollicles of *Aquilegia,* Ranunculaceae; acorns of *Quercus humboldtii*, Fagaceae; blackberry druplets of *Rubus* sp. Rosaceae; inflated berry of *Burmeistera caldasensis*, Campanulaceae; and cypsela of *Valeriana clematitis*, Valerianaceae.

grouped in the corncob, which is technically a multiple fruit) is the result of a strongly asymmetrical development of three carpels, two of which become vestigial. This phenomenon, called pseudomonomery, is also found in fruits of a number of non-related angiosperm families (reviewed in González and Rudall, 2010; **Figure 9**).

Unique novel fruits in the core eudicots include: (1) acorns, which is a dry, indehiscent nut that develops from one of the many flowers of the catkin, accompanied by a series of tightly appressed bracts. (2) Cypselas (common in Valerianaceae and Asteraceae), where an achene derived from an inferior ovary, is accompanied by a feathery calyx for wind dispersal, and (3) inflated berries (e.g., some *Burmeistera*, Campanulaceae), where a large air chamber is formed during fruit development (**Figure 9**).

The molecular basis of fruit diversity is largely unknown. However, the molecular genetic network during fruit histogenesis in *A. thaliana* is well characterized (reviewed in Ferrándiz, 2002; Roeder and Yanofsky, 2006; Seymour *et al.*, 2013). *Arabidopsis* fruits are specialized capsules called siliques; they develop from two fused carpels that dehisce longitudinally (Avino *et al.*, 2012). The silique has two valves separated by the replum, a thin persistent septum present only in the Brassicaceae. The replum and the valves are joined together by the valve margin, which is further composed of a separation layer closest to the replum, and a lignified tissue closer to the valve. The endocarp of the valves becomes lignified late in development and plays a role, along with the lignified layer and separation layer of the valve margin, in fruit dehiscence (Ferrándiz, 2002).

Developmental genetic studies have identified key players in the genetic network patterning the *Arabidopsis* fruit. FRUITFULL (FUL) is necessary for proper valve development and represses SHATTERPROOF 1/2 (SHP 1/2) (Gu *et al.*, 1998; Ferrándiz *et al.*, 2000). SHP1/2 are necessary for valve margin development (Liljegren *et al.*, 2000). REPLUMLESS (RPL) is necessary for replum development and represses SHP1/2 (Roeder *et al.*, 2003). The repression of SHP1/2 by FUL and RPL keeps valve margin identity to a small strip of cells. SHP1/2 activate INDEHISCENT (IND) and ALCATRAZ (ALC), both necessary for the differentiation of the dehiscence zone between the valves and replum (Girin *et al.*, 2011; Groszmann *et al.*, 2011). IND is important for cell lignification along the dehiscence zone, while IND and ALC are necessary for proper differentiation of the separation layer (Rajani and Sundaresan, 2001; Liljegren *et al.*, 2004). SPATULA (SPT) plays a minor role that is redundant with its paralog ALC in the specification of the dehiscence zone (Girin *et al.*, 2011; Groszmann *et al.*, 2011).

All these genes belong to three large transcription factor families. FUL and SHP1/2 belong to the MADS-box family (Gu *et al.*, 1998; Liljegren *et al.*, 2000); IND, SPT, and ALC belong to the bHLH family; and RPL belongs to the homeodomain (HOX) family (Rajani and Sundaresan, 2001; Roeder *et al.*, 2003; Liljegren *et al.*, 2004). Given that these gene lineages have duplicated at different time points during angiosperm diversification, it is unclear whether the gene regulatory network in *Arabidopsis* can be extrapolated to fruits outside Brassicaceae. Efforts have been made on multiple fronts: (1) by studying the evolution of gene families and identifying duplication time points that have changed the genetic content in specific angiosperm groups; (2) by studying gene function of pre- and post-duplication candidate genes to assess functional evolution; and (3) by taking a comparative developmental approach in families that exhibit different fruit types, and studying how gene expression and function has changed to shape dry and fleshy fruits, and the variation in between. New tools for predicting protein interactions together with more empirical data in non-model plants, hold great promise for better understanding fruit diversification.

O

Operational Sex Ratio

SM Shuster, Northern Arizona University, Flagstaff, AZ, USA

Glossary

EPP The 'environmental potential for polygamy' is a conceptual scheme for how the spatial and temporal distribution of resources necessary for reproduction allowed certain individuals to monopolize mates; EPP included the degree to which the costs of parental care might limit or enhance mate acquisition.

Estrus A period of heightened sexual receptivity, usually observed in female mammals.

Iteroparity Repeated reproductive events within an individual lifetime.

OSR The operational sex ratio, often defined as "the average ratio of fertilizable females to sexually active males at any time;" designed to measure, in terms of the excess of one sex relative to the other, the level of competition for mates in animal populations at a particular time and in a particular place.

Polyandry An animal mating system in which males mate once but females vary in their mate numbers.

Polygamy An animal mating system in which both sexes vary in their mate numbers to a similar degree.

Polygyny An animal mating system in which females mate once but males vary in their mate numbers.

PRR The potential reproductive rate is the maximum possible rate of offspring production per unit time that an individual in one sex would achieve if unconstrained by the availability of mates.

Sexual dimorphism The condition in which males and females within the same species express distinct phenotypes.

Introduction

The Operational Sex Ratio, or OSR, first defined by Emlen (1976, p. 309) as "the ratio of receptive females to potential mating males at any one time," was designed to measure, in terms of the excess of one sex relative to the other, the level of competition for mates in animal populations. The ease with which OSR could be measured, and its apparent utility as a proxy for the intensity of sexual selection, established it as one of the most widely used metrics in animal mating system research (Andersson, 1994; Klug *et al.*, 2010). Although first defined as a ratio of reproductively active females to males, the OSR is usually expressed as the reciprocal of this value because males rather than females compete for mates in most animal mating systems (Kokko *et al.*, 2012). Moreover, while the simplest quantitative description of OSR in this sense is $N_{♂}/N_{♀} = R_{O}$, where $N_{♂}$ and $N_{♀}$ are the total numbers of males and females within a population (Shuster and Wade, 2003), most measures of OSR specifically include only those individuals who are sexually receptive at a particular time and in a particular place (Ahnesjö *et al.*, 2001; Kokko *et al.*, 2006).

The OSR has proven useful for characterizing mate competition for many species, and it is particularly valuable for characterizing social circumstances within experimental populations (Krakauer, *et al.*, 2011; Weir *et al.*2011; Kokko *et al.*, 2012). However, the relationships between estimates of OSR and actual measures of sexual selection are inconsistent at best (Klug *et al.*, 2010) and at worst are likely to provide inaccurate or misleading information about the actual intensity of sexual selection (Shuster and Wade, 2003; Shuster, 2009). Because the effects of local variation in OSR on sexual selection are accounted for by other more accurate measures, it is now clear that without specific qualification, estimates of OSR cannot be interpreted as equivalent to sexual selection, and are unlikely to account for observed patterns of evolutionary change (Shuster, 2009; Klug *et al.*, 2010; Krakauer *et al.*, 2011; Kokko *et al.*, 2012).

How could such a seemingly useful and important metric as the OSR fall upon such hard times? To answer this question, I summarize below the origins of the OSR as a parameter in mating system research and review the various definitions of the OSR that have appeared in the literature since its inception. I next describe actual measures of sexual selection and compare them with estimates of OSR to illustrate what OSR actually measures and how. Lastly, I explain how data collected as part of mating system research and formerly used to estimate the OSR can be used to generate evolutionarily useful estimates of the effect of sex ratio biases in animal and plant mating systems.

The Origins of OSR

In his study of bullfrogs (*Rana catesbiana*), in which males compete vigorously for access to females, Emlen (1976, p. 309) defined the operational sex ratio (OSR) as: "the ratio of receptive females to potential mating males at any one time." Emlen clearly conceived of the OSR as a measure of the level of competition for mates, and began the convention of expressing the OSR, not as he originally defined it, but rather using the number of individuals in the more abundant sex as the ratio's numerator, and the number of individuals in the less abundant sex as its denominator. Because he calculated the OSR as the ratio of potential mating males to receptive females, Emlen's reported values for OSR for bullfrogs (Table 7, p. 309) were all greater than 1.

A year later, Emlen and Oring (1977, p. 216) modified slightly the original definition to consider multiple measurements, and defined OSR as "the average ratio of fertilizable females to sexually active males at any time." Here too, Emlen and Oring used the OSR as a measure of the level of mating competition, primarily in birds and mammals. However, the OSR was also framed as the primary determinant of mating system organization, with the prediction that (p. 216) "Where the OSR is skewed toward males, polygyny is expected; when the skew is toward females, polyandry should occur."

This statement indicates that the authors, like Darwin (1871, p. 266), considered mate availability to be the prime mover for animal mating system evolution. However, Emlen and Oring's definition of OSR also emphasized how parental care might influence who was available to mate and when. They summarized this concept with 'the environmental potential for polygamy' or EPP, a less easily measured parameter, but one which captured conceptually how the spatial and temporal distribution of resources necessary for reproduction allowed certain individuals to monopolize mates. EPP also addressed concern at that time for the degree to which the costs of parental care might limit or enhance mate acquisition (cf. Williams, 1966; Trivers, 1972). The unique insights of Emlen and Oring (1977) led to an explosion of research on animal mating systems over the next four decades, generating, literally, thousands of articles (over 4500 to date).

In many vertebrate species, the taxon featured in Emlen and Oring (1977), OSR *did* seem to provide a reliable means for visualizing the level of competition among males to monopolize resources necessary for female reproduction. Moreover, given how readily OSR could be measured in the field, and its apparent utility as a proxy for the 'intensity' of sexual selection (see note #23, p. 222), estimates of OSR soon became the standard parameter measured in mating system research, beginning in 1977 and continuing to the present day (reviews in Klug *et al.*, 2010; Kokko *et al.*, 2012; Passos *et al.*, 2014).

Emlen's (1976) field calculation of OSR, rather than Emlen and Oring's (1977) modification of it, is the form for OSR usually encountered in the literature, and it equals the measurable number of mature males divided by the measurable number of sexually receptive females. This version of the ratio serves as a useful instantaneous reproductive competition coefficient (Shuster and Wade, 2003); when OSR > 1, females are rare and competition for mates is presumed to be intense, whereas when OSR < 1, females are abundant and competition for mates is presumed to be relaxed. However, the definition of OSR has not remained consistent among researchers.

Three primary variants of the original concept of OSR now exist: (1) those that change the definition of the ratio itself, (2) those that attempt to incorporate the effects of parental investment within estimates, and (3) those that change how individuals are (or are not) included in estimates of this parameter. Regardless of how OSR is defined, in nearly all cases, OSR is presumed to predict or induce evolutionary responses by the populations in which it is measured.

Changes in Definition

As explained above, the OSR has been expressed as: (1) "the ratio of receptive females to potential mating males at any one time" (Emlen, 1976) and (2) "the average ratio of fertilizable females to sexually active males at any time" (Emlen and Oring, 1977). However, additional definitions include: (3) "the average ratio of males to females who are ready to mate at a given time and place" (Kvarnemo and Ahnesjö, 1996; Kokko *et al.*, 2012), (4) "the reciprocal of the population sex ratio" ($R_O = 1/R = N_{♂}/N_{♀}$; Shuster and Wade, 2003), (5) "the number of males and females ready to mate" (Nyman *et al.*, 2006), (6) "the ratio of matured females to males" (Yamamoto and Edo, 2006), (7) "the ratio of fertilizable females to sexually active males at any given time" (Forbes *et al.*, 2006; Prohl, 2006), and (8) "the relative number of members of each sex willing (or able) to mate at any given time" (Kemp and Macedonia, 2007).

Definition (3) is the most widely used in current literature. It makes Emlen's (1976) characterization more concrete by focusing on the actual numbers of sexually active males and females in the population, instead of the 'potential' numbers that may exist (vagueness from which definitions 5, 6, and 8 also suffer). As mentioned above, it also calls attention to parental care and the spatial and temporal circumstances in which mating competition may occur. Although Emlen and Oring's (1977) definition (2) is often cited as the source of the OSR, it is less used than Emlen's (1976) OSR, because most estimates consider OSR, as Emlen first suggested, at a single point in space and time.

Definition (4) expresses OSR as the reciprocal of the population sex ratio and therefore considers all males and females in the population, regardless of their willingness or ability to mate. Emlen and Oring (1977, p. 216) cautioned against this practice, but as explained below, a focus only on individuals 'ready' to mate is responsible for the failure of OSR to provide consistent estimates of the strength of sexual selection (Shuster and Wade, 2003; Shuster, 2009). The reciprocal of OSR ($= R$) defined as in (4) also has the advantage of expressing the population average number of available mates; per male in conventional mating systems ($N_{♀}/N_{♂}$ = average harem size, H) or per female in role-reversed mating systems ($N_{♂}/N_{♀} = 1/H$), metrics that, unlike OSR, do covary with the opportunity for sexual selection (Wade and Shuster, 2004).

Changes in Emphasis

The focus on parental care in sexual selection theory, beginning with Bateman (1948) and later with Williams (1966) and

Trivers (1972) appears to have influenced the changing view of what measurements of OSR needed to emphasize. Emlen and Oring (1977, pp. 222–223) anticipated these issues but later authors gave them quantitative expression. In particular, because reproductive costs were presumed to be substantial for each sex, Clutton-Brock and Parker (1992) introduced modifications to estimates of the OSR to consider whether individuals were in the 'time in' or 'time out' phase of their reproductive cycle. Similarly, Kokko and Monaghan, 2001; also Kokko *et al.*, 2006) explicitly considered whether costly reproduction caused individuals to be choosy or not when selecting mates.

Mitani *et al.* (1996) accounted for the effect seasonal reproduction had on reproductive availability by multiplying the adult sex ratio (ASR = $N_{adult♂}/N_{adult♀}$; Arnold and Duvall, 1994) by a coefficient that included the product of birth interval, B, and the number of days per year (365), divided by the duration of estrus, c, summed over the number of estrus cycles female experience before conception, n. The OSR estimated in this way was thus specific to iteroparous mammals with conspicuous estrus, such as primates, and was designed to reveal the degree to which iteroparity was influenced by estrus duration within and among species. However, attempts to correlate this value with the degree of sexual dimorphism (a proxy for past sexual selection) in primates required qualification. Although Mitani *et al.* (1996) found a positive relationship between OSR and sexual dimorphism in nonhuman primates, Marlow and Burbesque (2012) found a weaker one in humans, possibly because humans avoid physical combat in mating competition more than other great apes.

Changes in Personnel

Whereas the original definition of OSR focused on all individuals who were potentially receptive (cf. Emlen, 1976), later definitions focused on only individuals who were capable of mating at a particular time and place. In addition to considering the 'time in' and 'time out' phases of reproductive cycles (Clutton-Brock and Parker, 1992), the goal of this adjustment evidently was to partition breeding seasons into episodes that allowed consideration of the effects of competition for resources, competition for mates and the 'potential reproductive rates' (PRR) of breeding adults (Clutton-Brock and Vincent, 1991).

Ahnesjö *et al.* (2001) considered the fact that the ASR would likely be modified by competition for resources (usually among males, but also among females in role-reversed species such as pipefish and shorebirds), resulting in exclusion of certain individuals from breeding, and generating a post-competition ratio of 'qualified' breeding adults the authors identified as Q. Further reproductive competition was presumed to lead to the actual OSR, which described the ratio of actually reproducing females to actually reproducing males, whose contribution to offspring at that time would depend on the PRR of males and of females at that place and at that time. Other similar approaches were proposed by Kokko *et al.* (2006, 2012) and Kokko and Monaghan (2001).

Evolutionary Interpretations

Biases in OSR until recently were widely presumed to have significant evolutionary consequences, and the range of predicted outcomes is considerable (Shuster, 2009; Kokko *et al.*, 2012). The most commonly cited consequence of biased OSR was that proposed by Emlen and Oring (1977, p. 222), i.e., increased variance in mating success and a correlated increase in sexual selection intensity. However, these predicted effects now seem to depend on the species examined. Positive effects on sexual selection appear to exist in bullfrogs (*Rana catesbiana*; Emlen, 1976), St. Peter's Fish (*Sarotherodon galilaeus*, Balshine-Earn, 1996), Gulf pipefish (*Syngnathus scovelli*, Jones *et al.*, 2001), and arthropods, such as dungflies (*Scathophaga stercoraria*, Jann *et al.*, 2000) and garden spiders (*Argiope aurantia*, Foellmer and Fairbairn, 2005). In contrast, a negative effect of increasing OSR on sexual selection was shown in isopod crustaceans (*Paracerceis sculpta*, Shuster *et al.*, 2001), and no effect was shown in humpback whales (*Megaptera novaeangeliae*, Cerchio *et al.*, 2005).

Positive and negative effects of biased OSR have also been reported in the context of sperm competition avoidance. Whereas male-biased OSRs appear to favor such traits in bats (Hosken, 1997), songbirds (Moller, 1988; Møller and Briskie, 1995), and fruitflies (*Drosophila* spp., Pitnick and Karr, 1996), male-biased OSRs appear to have a negative effect on sperm competition avoidance in simultaneous hermaphrodites (Pen and Weissing, 1999) and Orange Sulphur butterflies (*Colias eurytheme*, Kemp and Macedonia, 2007). Mate selection and choosiness appear to be favored by biased OSR in broad and narrow nosed pipefishfish (*Nerophis*, *Syngnathus*, Rosenqvist, 1993; Berglund, 1995), as well as in bushcrickets (*Steropleurus stali*, Bateman, 1997) as are increased mate guarding and mating duration in green stinkbugs (*Nezara viridula*, McLain, 1981), seed bugs (*Lygaeus equestris*, Sillen-Tullberg, 1981), Chinese bushcrickets (*Gampsocleis gratiosa*, Gao and Kang, 2006), and in many Crustacea (Jormalainen, 1998).

Female-biased OSRs were widely presumed to be responsible for sex role reversals and the appearance of polyandry (Emlen and Oring, 1977; Smith, 1984; Berglund *et al.*, 1989; Forsgren *et al.*, 2004; Andersson, 2005; Simmons and Kvarnemo, 2006). Again, however, such patterns are inconsistent across taxa. For example, family sex ratio adjustment has been attributed to local biases in OSR, but the way females respond to biases varies; sex ratio biases coincide with predictions in flowering plants (*Begonia gracilis*, Lopez and Dominguez, 2003), insects (*Nezara viridula*, McLain and Marsh, 1990), silverside fish (*Menidia menidia*, Conover and vanVoorhees, 1990), as well as some oviparous lizards (*Niveoscincus microlepidotus*, Olsson and Shine, 2001; *Eulamprus tympanum*, Robert *et al.*, 2003); but other lizards, even in the same species, respond to biased OSRs in the opposite direction (*Eulamprus tympanum*, Allsop *et al.*, 2006; *Amphibolurus muricatus*, Warner and Shine, 2007).

Similarly, aggressive behavior increases in response to biases in OSR in Japanese medaka (*Oryzias latipes*, Grant *et al.*, 2000; Grant and Foam, 2002), but predicted changes in behavior and hormone levels do not always coincide in St. Peter's fish (*Sarotherodon galilaeus*, Ros *et al*,. 2003). In some salmon, aggression decreased with increasing OSR

(*Oncorhynchus nerka*, Quinn *et al.*, 1996); in zebrafish it remained unchanged (*Danio rerio*, Spence and Smith, 2005). Per capita oviposition rates appear to decrease overall with increases in OSR in *Danio* (Spence and Smith, 2005) and while female body temperature increased with increasing OSR in oviparous lizards, such influences did not affect progeny sex ratio (*Eulamprus tympanum*, Allsop *et al.*, 2006). In ortolan buntings, increases in OSR led to overall population decline (*Emberiza hortulana*, Stifetten and Dale, 2006).

Klug *et al.* (2010, p. 455) called the species-specificity of responses to biases in OSR, "the OSR/mate availability conundrum," and other reviews also document similar inconsistency (Head *et al.*, 2008; DeJong *et al.*, 2009; Weir *et al.*, 2011; Marlow and Burbesque, 2012). However, this observation on mating systems is not new. In describing the source of sexual selection, Darwin (1871, p. 208) stated, "In many cases, special circumstances tend to make the struggle between males particularly severe." This statement suggests that while heuristically plausible, the extent to which OSR biases actually lead to greater competition for mates, and thus stronger sexual selection, is highly variable.

What OSR Does Measure?

The focus on parental care in existing sexual selection theory appears to have been responsible for the changing view of what OSR is and what it should measure. If OSR is designed to measure the level of competition for mates, as stated by Emlen and Oring (1977), and if parental care requires time and energy, forcing individuals to periodically remove themselves from competition, then it does seem reasonable to consider which individuals are available to breed at any particular time. If only certain individuals reproduce at any time, including all males and females in such measurements seems likely to bias estimates of competition intensity. Methods now exist for capturing these relationships in detail (Clutton-Brock and Vincent, 1991; Clutton-Brock and Parker, 1992; Ahnesjö *et al.*, 2001; reviews in Kokko *et al.*, 2006, 2012).

However, measuring competition intensity or reproductive cost are not the same as measuring selection. Ignoring non-breeding individuals, either because they have failed in competition, or because they have temporarily exhausted their resources for providing parental care, omits those individuals whose numbers significantly increase the variance in reproductive success within that sex, which is proportional to the strength of selection. This policy of omission results in two kinds of errors in estimates of actual selection (Shuster and Wade, 2003; Shuster, 2009). When non-breeding individuals are removed from fitness estimates, a significant fraction of the among-group component of the total variance in fitness is omitted, causing the average fitness among mating individuals to be overestimated, and total variance in fitness for the population to be underestimated, respectively. Stronger sexual selection makes this error larger because more of the non-mating population is excluded (Shuster *et al.*, 2013).

A related difficulty involving field measurements of OSR is that instantaneous estimates of OSR often do not distinguish between males who mate and males who do not. As mentioned above, this issue can lead to errors in estimates of the mean and variance in fitness. Moreover, while OSR is presumed to approximate the level of mate competition, such estimates tend to overestimate the average intensity of competition during the breeding season, undermining the utility of such estimates (Shuster and Wade, 2003; Shuster, 2009).

Figure 1 summarizes these issues for two hypothetical breeding populations, each with 5 females and 5 males. For simplicity, each female is presumed to mate only once and have non-overlapping periods of receptivity. Relaxing these assumptions simply makes competition weaker overall. In population 1, each female mates with the same male in a different *j*-th interval (**Figure 1(a)**), whereas in population 2, each female mates in a different *j*-th interval with a different male (**Figure 1(b)**). That these scenarios are distinct in their influence on sexual selection is obvious (one male mates with all of the females vs. each male mates with a different female), yet each case generates indistinguishable instantaneous values for OSR in each interval ($R_{O(j)} = N_{♂}/N_{♀(j)} = 5$), as well as when summed across the breeding season ($R_{O(j)} = 25$).

Also note that the sum of the instantaneous estimates of OSR, $R_{O(j)}$, is 25 times larger than the overall estimates of OSR and of the sex ratio, R, which are identical in value ($N_{♂total}$ / $N_{♀total} = N_{♀total}/N_{♂total} = 1$). The reason for this discrepancy is that instantaneous estimates of OSR ($= N_{♂}/N_{♀(j)}$), tend to overestimate the level of competition, particularly when females are rare. This happens because the average rate of female arrival throughout the breeding season is estimated by the harmonic mean number of females per time interval ($= 1/H_{♀} = (1/T)(1/N_{♀(j)}) = 1$, where $T =$ the number of intervals; see Shuster and Wade, 2003, p. 95), which emphasizes small values. When females are rare, these instantaneous estimates of OSR contribute disproportionally to the aggregate value of OSR, making competition seem stronger than it actually is.

What OSR Doesn't Measure?

Although Emlen and Oring (1977) never claimed to measure sexual selection directly, they did imply the existence of a direct correlation between such selection and OSR. They stated (p. 222), "The greater the potential for individuals to monopolize resources or mates, the greater the intensity of sexual selection and the greater the environmental potential for polygyny." Despite this statement, it is now clear that a primary difficulty with estimates of OSR is that they don't measure selection at all (Arnold and Duvall, 1994; Shuster and Wade, 2003; Jones, 2009; Klug *et al.*, 2010).

Shuster (2009; see also Jones (2009)) summarized methods useful for measuring selection in the context of mating systems. These included (1) the difference between pre- and post-selection phenotypes, divided by the standard deviation of the pre-selection phenotypic distribution, also known as the selection differential (Lande and Arnold, 1983; Shuster and Wade, 2003), (2) the covariance between trait variation and offspring numbers, divided by the standard deviation in trait variation, also known as the selection gradient (Hersh and Phillips, 2004; Klug *et al.*, 2010; this approach can be executed using univariate or multivariate methods), and (3) the standardized covariance between mate numbers and offspring numbers, also known as the Bateman Gradient (Arnold and Duvall, 1994).

Figure 1 Estimates of the operational sex ratio (OSR) during the breeding season often fail to distinguish between males who mate and males who do not; they also tend to overestimate the intensity of sexual selection during the breeding season. Two hypothetical breeding seasons illustrate these points; each season (a–b) is represented by a 5 row × 5 column matrix; within each season, the *i*-th rows and the *j*-th columns are each numbered 1–5; the rows represent the territories on which each of the 5 males are established; the columns represent the intervals within which females may mate with males on territories; individual mating females and the pattern of mating in each season are highlighted in red. The total number of females mating with a male per territory is summarized at the right margin by $N_{i.}$; within each *j*-th breeding season interval (each column), the total number of receptive females per interval, $N_{.j}$, divided by the total number of males, K_j, equals R_j, the interval sex ratio, or the average number of females per male. The total number of males, K_j, divided by the total number of receptive females per interval, N_j, equals the interval operational sex ratio, R_{0j}. The effect of each female on overall male competition can be measured by the rate at which females appear in each interval, $1/N_j$. The average rate at which females appear across intervals is estimated by the harmonic mean of the number of females per interval, $1/H_{♀}=(1/T)(\sum 1/N_{♀(j)})=1$, where T equals the number of intervals containing females ($=5$). In season (a), each female mates with the same *i*-th male in a different *j*-th interval. In season (b), each female mates with a different *i*-th male in a different *j*-th interval. Because mating and non-mating males are not distinguished, each season generates identical and thus indistinguishable instantaneous and overall values for OSR ($R_{0j}=N_{♂}/N_j=5$; $\sum R_{0j}=25$; $R_0=N_{♂}/N_{♀}=5/5=1$. Also, because receptive females are rare in each *j*-th interval, in this case appearing one at a time, each instantaneous OSR (R_{0j}) is large and contributes disproportionately to the total OSR, which equals $(N_{♂}/H_{♀})T=\sum R_{0(j)}=25$, and exceeds the overall estimate of OSR by 25-fold. Redrawn from Shuster, S.M., 2009. Sexual selection and mating systems. Proceedings of the National Academy of Sciences of the United States of America 106, 10009–10016.

Each of these methods has strengths and weaknesses. Their primary advantage is that they identify the actual trait or traits under selection, and, based on the magnitude of the differential or the steepness of the gradient, they identify how strongly selection might operate on a particular mating phenotype. In arguing against the use of OSR as a proxy for sexual selection, Klug *et al.* (2010) asserted that such measures were the only satisfactory method for documenting the strength of sexual selection.

However, as noted in Krakauer *et al.* (2011), such methods may also generate erroneous results because traits that appear to be associated with mating success may also covary with other unmeasured traits. Accidental omission of correlated traits does not allow recognition of how the unmeasured trait

may contribute to selection, and may incorrectly assign evolutionary importance only to measured characters (Lande and Arnold, 1983; Wade and Shuster, 2010). Moreover, direct estimates of selection may overestimate the possible response to selection because they may detect significant covariance even when the total opportunity for selection is comparatively small (Hersh and Phillips, 2004).

When less is known about the phenotypes under consideration, and as a first step for detecting whether sufficient opportunity for selection exists (Hersh and Phillips, 2004), (4) the opportunity for selection, I, provides a means for estimating the maximum possible change in phenotype over a single episode of selection, wherein the variance in fitness, expressed in offspring numbers, is divided by the squared average in fitness (Crow, 1958; Wade, 1979; Wade and Arnold, 1980). When even less is known about the experimental system, estimates of the spatial and temporal distributions of mates can be documented by estimating the spatial and temporal crowding of sexually receptive individuals (m^* and t^*; Wade, 1995; Shuster and Wade, 2003) which each are proportional to the opportunity for sexual selection, I_{mates} ($= I_s$; Jones, 2009).

Shuster and Wade (2003; see also Shuster, 2009) showed how this framework, inspired by Emlen and Oring's (1977) graphical representation of the environmental potential for polygyny, can be used to partition the total variance in mating success into spatial, temporal, and sex ratio components that can be used to partition the total opportunity for sexual selection I_{mates}. In this scheme, $I_{mates} = I_{sexratio} + [{}^*I_{mates(t)} - {}^*I_{within(k)}]$, and thus estimates three parameters:

1. $I_{sex\ ratio}$ measures the opportunity for sexual selection caused by temporal variation in the sex ratio. This parameter estimates what the OSR is evidently designed to measure, but cannot because as defined, the OSR overestimates the intensity of sexual selection within intervals in which females are rare (see **Figure 1**).
2. ${}^*I_{mates(t)}$ measures the weighted opportunity for sexual selection caused by temporal variation in the availability of females. This parameter is small or large depending on whether females mate synchronously or asynchronously and is weighted by the fraction of all females that appear in each interval. Here larger fractions per interval contribute the largest effects.
3. ${}^*I_{within(k)}$ measures the weighted opportunity for sexual selection caused by spatial variation in the availability of females. This parameter is small or large depending on whether females are spatially dispersed or spatially clumped, and again, larger fractions of females per male territory contribute the largest effects. Notice too that ${}^*I_{within(k)}$ decreases the value of ${}^*I_{mates(t)}$ because ${}^*I_{within(k)}$ estimates the variance in mate numbers within individual males. Increases in the variance in relative fitness within males lead to concomitant decreases in the variance in relative fitness among males.

OSR in Experimental Situations

Despite the quantitative difficulties described above, estimates of the OSR can provide useful information on mating system competition, provided qualifications are made when these values are interpreted. Krakauer *et al.* (2011) argued that OSR can provide a useful within-species index of instantaneous levels of intra-sexual competition, conditions likely to be perceived and responded to by individuals within field and laboratory populations (Berglund *et al.*, 1986; Mobley and Jones, 2007). Weir *et al.* (2011) found in their meta-analysis of OSR studies that predictable changes occurred in aggression, sperm release, mate guarding and copulation duration, but that the nature of changes depended on the type of mating behavior and the species examined. This result suggests that OSR can be used to make the predictions Emlen and Oring (1977) found useful, provided that the nuances of the experimental system are clearly known in advance.

Summary

The utility of the operational sex ratio as an unqualified proxy for sexual selection intensity appears to be unfounded and the relationships between OSR and actual measures of sexual selection have proven inconsistent within and among species. Thus, estimates of OSR are not equivalent to those for sexual selection and are unlikely account for observed patterns of evolutionary change. Nevertheless, OSR is useful for characterizing experimental populations, and for manipulating competitive circumstances to observe behavior in particular species. Thus, the kinds of information obtained in past and present estimates of OSR and the spatial and temporal distributions of breeding adults can have evolutionary application, provided that the details of the experimental system and how changes in the level of competition among members of each sex are clearly known.

Glossary

Activated nucleotide A nucleotide with chemical leaving group that allows it to polymerize (e.g., a triphosphate or an imidazole).

Aptamer An RNA sequence that has been experimentally selected to bind to a target molecule.

Autocatalysis A chemical reaction in which a molecule (or set of molecules) catalyzes the formation of more of itself (or themselves).

Extremophile An organism that is adapted for life in extreme conditions that would not be habitable by most other organisms.

Group selection Selection that acts on a group of entities as a whole (such as animals living in a social group or molecules inside a protocell) and that favors survival of the whole group, in contrast to selection acting on individual members of a group that leads to competition between the individuals.

Ligase A ribozyme that catalyzes the linking of two RNA strands to make a longer strand.

Polymerase A ribozyme that catalyzes polymerization of ribonucleotides to make RNA sequences.

Recombinase A ribozyme that catalyzes a cross-over (or recombination) reaction between two RNA strands.

Replication A process in which a second copy of a given molecular sequence is created.

Ribozyme A catalytic RNA molecule (as opposed to an enzyme, which is a catalytic protein).

Getting Life Started

One of the most commonly accepted definitions of life comes from a discussion on astrobiology organized by NASA: "Life is a self-sustaining chemical system capable of undergoing Darwinian evolution" (Joyce *et al.*, 1994; Benner, 2010). These scientists were interested in finding a definition that would apply not just to Earth life, but to life on another planet, if we ever find it. It is very significant that evolution was included as a defining feature of life, and it seems appropriate that we should include a discussion of the Origin of Life in this *Encyclopedia of Evolutionary Biology*.

In the last decade, astronomers have detected hundreds of planets in other star systems, and the increasing sensitivity of these observations means that it is getting progressively easier to detect smaller planets that might be similar to Earth. It now seems likely that quite a high fraction of stars have Earth-like planets (Petigura *et al.*, 2013), i.e., rocky planets with a temperature that allows liquid water. One reason to be optimistic that life might be common elsewhere is that life occurs in a very wide range of environments on Earth, with micro-organisms (bacteria and archaea) being particularly versatile in their habitat. Organisms that live in conditions that appear 'extreme' to us are known as extremophiles (Rothschild and Mancinelli, 2001). For example, organisms are found in boiling hot springs at close to 100 °C, crevices in sea ice at close to 0 °C, and lakes of extremely high salt concentration. Although most organisms would die in these extreme conditions, the fact that some organisms can survive there suggests that evolution often finds a way to solve the challenges posed by unusual environments. Typical conditions on other planets might be very different from those on Earth, but the study of extremophiles on Earth tells us that we should not be too narrow in our expectations of what other kinds of planets might be able to support life.

The big unknown is how likely it is that life will evolve, given a suitable planet. It may still be very difficult for a living process to get started, even on a planet where physical and chemical conditions are appropriate for supporting life, if it arises. We still have no way of knowing how many other planets have life, and we cannot rule out the possibility that we are alone in our galaxy (or even the whole observable universe!). However, the timeline for life on Earth gives us another reason to be optimistic. It is known that the Earth and the rest of the solar system formed about 4.6 billion years ago. It is thought that there were many impacts of large meteorites and comets in the early period of the solar system that would have made Earth uninhabitable until about 4.0 or 3.9 billion years ago (Hartmann *et al.*, 2007). There is also fairly strong evidence that life existed 3.5 billion years ago, and some indirect evidence that it was present as early as 3.8 billion years ago (Buick, 2007). Hence, the time window during which life evolved is at most 0.5 billion years, and could be as little as 0.1 billion years (100 million years). Although this may seem like a long time, it is much shorter than the age of the planet. There has been life on Earth for most of the time that Earth has been here. If the time for life to evolve on Earth is in any way typical, then we expect that there are many other planets that are old enough for life to have had a good chance of originating.

Of course, this does not mean that the origin of life is 'easy.' We cannot just throw together a few chemicals in a test tube and expect that a new kind of life will spontaneously appear (otherwise someone would have done it by now!). The origin of life is probably a very unusual event that takes millions of years to occur once on a whole planet. But once is all it takes, given that life can multiply exponentially once it gets started, and can adapt to areas of a planet that are much different to the place where it originated. In summary, the origin of life is not a miracle; it is an unusual event that can be studied from a scientific point of view, with an aim of understanding how it was most likely to have occurred on Earth and how it could occur elsewhere.

Factors Pointing to RNA

Cellular organisms on Earth today use three types of biopolymers (Figure 1). DNA genes are transcribed by protein enzymes to make mRNAs. The mRNAs are translated by ribosomes (whose chief component is RNA) to make proteins. Thus, DNA, RNA, and proteins are mutually dependent on one another for replication. The RNA World hypothesis is that modern organisms evolved from a simpler system that used only RNA. In the RNA world, RNA genes would be copied by RNA catalysts (Joyce, 2002).

In addition to logical simplicity, there are many other factors that suggest this could be true. Although no cellular life forms have genes made of RNA, there are many viruses that use RNA as genetic material. RNA and DNA encode genetic information in the same way. A strand of either nucleic acid can be a template on which a second strand is assembled. Pairing between complementary nucleotides means that sequence information is passed on. When the second strand acts as a template, a new copy of the original sequence is made. RNA viruses replicate by this two-step processes. RNA virus replication is catalyzed by protein enzymes (RNA polymerases) that are encoded by the viral genome. In the RNA World, it is envisaged that there were RNA polymerases that were 'ribozymes' (i.e., catalysts made of RNA). There are no naturally occurring RNA polymerase ribozymes of this type, but there has been considerable progress in synthesizing polymerases in the laboratory, as we will discuss below. Nevertheless, there are many other types of naturally occurring ribozymes, and the ability of RNA to be a catalyst is well established.

The first ribozymes discovered were self-splicing introns (Kruger *et al.*, 1982), which splice themselves out of pre-mRNA sequences without the aid of protein enzymes. For the RNA World hypothesis, the most fundamental naturally occurring ribozyme is ribosomal RNA. From the three dimensional structure of the ribosome, it is clear that the active site for the peptide bond reaction is made of RNA (Nissan *et al.*, 2000). This suggests that the original ribosomes were made only of RNA, and that the ribosomal proteins that are present in modern ribosomes were more recent additions. Protein synthesis also depends on transfer RNAs to decode the gene sequence and messenger RNAs that contain the genetic sequence. The whole process of translation only makes sense if RNAs preceded proteins.

The vast repertoire of catalytic functions that is carried out by modern proteins is impressive. Protein sequences are relatively small and flexible compared to nucleic acids, and the amino acid side chains in proteins contain a much larger range of chemical groups from which catalytic structures can be built than do the bases in RNA. Although proteins may be more efficient and more versatile catalysts than RNA, there appears to be no mechanism in proteins equivalent to complimentary base pairing in RNAs. Thus the information in an amino acid sequence cannot be passed directly from one protein to another. Also, the traditional view of nucleic acids as having a limited range of functions, is becoming somewhat outdated (Breaker and Joyce, 2014), as new discoveries are made regarding nucleic acid functions in cells.

In some versions of the RNA World, it is envisaged that relatively complex organisms with many different kinds of RNA catalysts evolved before the origin of encoded protein sequences (Chen *et al.*, 2007). In this view, the evolution of the ribosome and the genetic code would mark the end of the RNA World. Proteins would then begin to take over most of the roles that were previously catalyzed by ribozymes. A slightly different picture is that amino acids and small peptides were essential players alongside RNA all along (Li *et al.*, 2013), and that there was never a very large repertoire of purely RNA catalysts. Using peptides as cofactors of ribozymes, or even having amino acids covalently linked to ribozymes, is compatible with an RNA World picture of early life, but it is important to remember that long protein sequences could not be encoded before the translation process arose.

The other side of the cofactor argument is that many modern proteins use either single nucleotides or dinucleotides as cofactors that associate with the folded proteins and are essential for their function. This is often seen as further evidence for the RNA World (White, 1976), with the nucleotide cofactors being relics of an earlier phase of evolution.

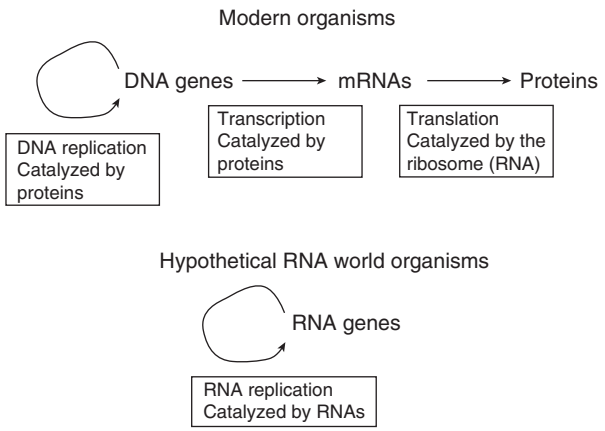

Figure 1 Comparison of the DNA + RNA + Protein system used by modern organisms with the RNA-only system that could have existed in the RNA World.

Alternatives to RNA

The factors discussed in the previous section strongly support the idea of an RNA World phase of life prior to modern DNA/RNA/Protein life, but they do not necessarily indicate that replicating RNAs were the first form of life. Maybe something preceded RNA? A variety of different kinds of biopolymers have been proposed that might do a similar job to RNA (Joyce *et al.*, 1987; Eschenmoser, 1999; Yang *et al.*, 2007; Yu *et al.*, 2012). RNA polymers have a backbone, which is a chain of ribose sugars linked by phosphate groups, and information-carrying side groups, which are the familiar four bases A, C, G, and U. Alternative nucleic acid analogues have been synthesized that have different backbone structure or different bases as side groups. Several of these alternative polymers are able to form double helical structures by pairing of complementary strands; thus, in principle, they might be able to support life. If these alternatives were chemically easier to form

than RNA or more stable in prebiotic conditions, then these might be plausible candidates for pre-RNA life. The alternative polymer would also have to be versatile as a catalyst, and it would have to be able to form a hybrid double strand with RNA. This latter point is important, because if some alternative genetic system got going first, genetic sequences that evolved in the first system would have to be transferred to the RNA system at a later date. If this transfer of information were not possible, then the RNA system would have to reinvent everything from scratch, and the earlier system might just as well not have existed.

The transfer of information from one system to another is known as genetic takeover. This idea makes sense because we know that DNA and RNA can form hybrid double strands. This happens in today's organisms during the transcription of an RNA strand from a DNA template, and during reverse transcription (which is essential for the replication of certain viruses), in which a DNA strand is synthesized using an RNA template. According to the RNA World hypothesis, DNA genes would have been synthesized originally from preexisting RNA genes. The better chemical stability of DNA and possibly the better fidelity of replication of DNA strands are thought to have given an advantage to organisms that evolved to use DNA in this way.

However, there is an important difference between a transfer of information from RNA to DNA, and a hypothetical transfer from a pre-RNA to RNA. In the former case, DNA is only being used as a gene and not a catalyst, so the DNA only needs to acquire the sequence of the RNA and not its function (e.g., the DNA gene for ribosomal RNA does not function as a ribosome). In the latter case, both the RNA and its precursor are genes and catalysts, so the function of the precursor strand as well as its sequence would have to be transferred to RNA, which seems very much more unlikely, as pointed out by Anastasi *et al.* (2007).

The term genetic takeover was originally used in a much wider context by Cairns-Smith (1982), who proposed that information in a mineral crystal might be transferred to a biopolymer system such as a nucleic acid. Another kind of system that might store genetic information is the lipid world (Segré *et al.*, 2001), which consists of globules or molecular assemblies composed of mixtures of different kinds of lipids. These would have information in their composition, but there would be no polymeric gene sequences, i.e., the molecules would not be covalently linked in a chain. An advantage of this idea is that lipid globules could self-assemble, whereas polymer synthesis (including RNA synthesis) is usually difficult because it is 'uphill' thermodynamically. If such molecular assemblies could grow and divide, they would be able to pass on their compositional information to their daughter globules. This idea works quite well in computer simulations, but it is very speculative. Neither the lipid world nor a mineral crystal scenario has been shown to work experimentally, and there is nothing like them in current biology. Alternative biopolymers similar to RNA seem more plausible, although there is no single clear candidate for an alternative. Furthermore, none of the alternatives exists in today's organisms. So if there were a pre-RNA polymer, genetic takeover must have been complete, such that no relics of the earlier system remain. It is tempting to draw an analogy with a possible future in which Earth is covered by self-replicating robots and computer systems after all human beings have died out. More seriously, however, adding extra stages to the proposed history of life makes things more complicated, and is not easy to justify in absence of more clear evidence. Here, we will proceed under the assumption that RNA, or something very similar to it, came first.

Synthesis of RNAs and Ribozymes

Although we cannot go back in time and observe the chemistry and biochemistry that occurred at the time of the origin of life, by doing chemical experiments today, we can show that the required kind of chemistry is possible and reveal what might have occurred at that time. It is helpful to think of four steps of increasing complexity, all of which must be possible if the RNA World hypothesis is true:

1. chemical synthesis of single nucleotides,
2. random polymerization,
3. template-directed polymerization, and
4. ribozyme-catalyzed polymerization.

As we will now discuss, all of these steps have been demonstrated experimentally to some degree.

A single nucleotide is a relatively complex molecule compared to an amino acid, say, or compared to common small molecules like CO_2 or H_2O. Formation of a nucleotide would involve multiple steps, and would be in competition with many other side reactions that produce other slightly different molecules. The difficulty of prebiotic synthesis of RNA has always been the chief reason for doubt of the RNA World idea (Shapiro, 2007). Nevertheless, new mechanisms of synthesis of single nucleotides have been discovered fairly recently (Powner *et al.*, 2009) that make step 1 seem reasonably plausible. Several mechanisms for random RNA polymerization (step 2) have also been studied that can make RNA strands with the aid of clay mineral catalysts (Ferris, 2005) or in association with lipid bilayers (Rajamani *et al.*, 2008). Again, these seem plausible, but we still do not know enough about conditions on early Earth to know at what rates these reactions occurred, what quantities were produced, and what local environment on Earth would have best promoted these reactions.

Random polymerization means that the monomers link in a way that is not guided by a preexisting strand or by a biological catalyst. If different kinds of monomers were involved, they would link in many different ways, so there would not be specific sequences. In contrast, step 3 is template-directed polymerization, in which an existing strand acts as a template on which to assemble the complementary strand. This is often called 'nonenzymatic' polymerization, to emphasize the fact that there is no catalyst (neither a protein enzyme nor a ribozyme) that catalyzes the reaction. Recent work (Deck *et al.*, 2011) has shown that the template-directed extension of a primer is possible with all four RNA nucleotides, significantly improving on earlier work (Hill *et al.*, 1993). In principle, sequence information can be passed from the template to its complementary strand by this process, if the error rate due to

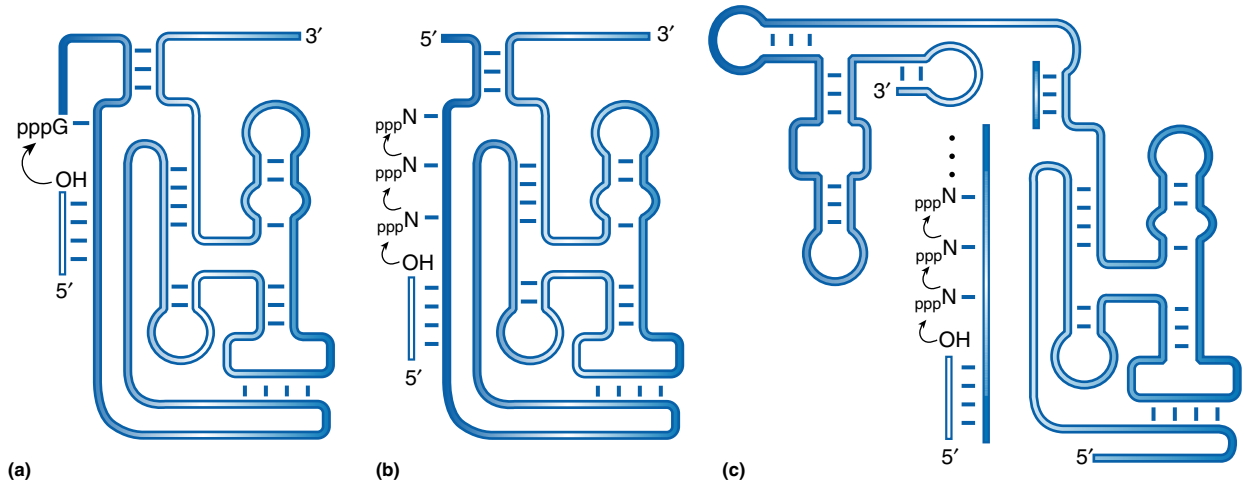

Figure 2 Three steps of *in vitro* evolution of RNA polymerases. (a) A ligase that extends itself by linking an oligomer to its own end (Bartel and Szostak, 1993). (b) A polymerase that extends a primer by addition of single nucleotides, using its own sequence as a template (Ekland and Bartel, 1996). (c) A *trans*-acting polymerase that uses a separate strand as a template to build the complementary strand of the template (Johnston *et al.*, 2001). Reproduced from Joyce, G.F., 2002. The antiquity of RNA-based evolution. Nature 418, 214–221.

incorporation of incorrectly matching bases is not too large (Rajamani *et al.*, 2010).

The origin of life lies somewhere in the gray area between chemistry and biology. Random polymerization seems definitely on the chemical side. Template-directed polymerization is in the gray area that is not quite biological. Ribozyme-catalyzed polymerization (step 4) seems to be on the biological side. In this case, there is an RNA strand that uses another strand as a catalyst to synthesize the complementary sequence of the template. In this case, the rate of the reaction is controlled by the biological catalyst and the sequence information is passed on to the new strand. Such a system would qualify as living, according to the definition of life with which we began this article.

There are no naturally occurring RNA polymerase ribozymes in modern organisms. Even viruses with RNA genomes use protein enzymes as RNA polymerases. The evidence that polymerase ribozymes could have existed is that it has been possible to synthesize them in the laboratory using *in vitro* evolution techniques. In these experiments, functional sequences are isolated from a pool of random sequences using a repeated cycle of copying and artificial selection that mimics evolution. RNA polymerases have been developed through a series of steps of increasing complexity, as shown in **Figure 2**. The simplest of these is a ligase (**Figure 2(a)**) that can link a short oligomer to its own end (Bartel and Szostak, 1993). Building on this, with further mutation and selection, a polymerase was found (**Figure 2(b)**) that extends a primer by addition of single nucleotides, using its own sequence as a template (Ekland and Bartel, 1996). Subsequently, this led to a *trans*-acting polymerase (**Figure 2(c)**) that uses a separate strand as a template to build the complementary strand of the template (Johnston *et al.*, 2001). Ribozymes of this type 2c are a key step forward because the product and catalyst are detachable, unlike 2a, so the ribozyme can catalyze multiple cycles of the reaction, and because, unlike 2b, the template sequence is not specified by the catalyst itself, so the ribozyme can copy whichever template sequences it encounters.

A polymerase of type 2c could have supported replication in the RNA world if it was able to deal with template strands that were as long as itself and if its error rate per base was small enough to avoid the error threshold (as discussed in the following section). The sequence isolated by Johnston *et al.* (2001) was able to extend the primer by up to 14 nucleotides. Subsequent work has increased this to 95 (Wochner *et al.*, 2011) and more recently to 206 (Attwater *et al.*, 2013). This latter case is equal to the length of the ribozyme itself. Although sustained self-replication of its own sequence has not yet been shown, this result is strongly suggestive that RNA-catalyzed RNA replication would have been possible in the RNA World. The step-by-step process of evolution from random chemical polymerization to a living RNA World that we envisaged in this section has been called 'the descent of polymerization' by Levy and Ellington (2001), who draws a parallel with the steps of evolution of the human species.

Evolutionary Theory

Theoretical models can highlight some of the key issues associated with the origin of life and early stages of evolution. As the precise conditions and the precise molecules involved in life's origins are not known, it is not usually possible to have detailed realistic simulations and theories at the molecular level. On the other hand, theoretical models can single out the most important factors that we expect to be relevant in the real world.

An important example of this is the quasispecies theory (Eigen *et al.*, 1988) which emphasizes that populations of molecules are subject to mutations (i.e., copying errors) during replication. In some cases, there is a maximum sustainable error rate, known as the error threshold. If the error rate is below this threshold, high-fitness sequences survive. If it is above this threshold, high-fitness sequences disappear due to accumulation of mutations. The maximum possible error rate per nucleotide is inversely proportional to the length of the

sequence. In modern organisms with large DNA genomes, replication is extremely accurate due to the presence of highly adapted DNA polymerases. Current viruses, with genomes of a few thousand base pairs, are much less accurate than cellular organisms. Early life presumably was still less accurate. This means that sequences would be severely limited in length. There are several ways in which the error threshold problem might be made a little less serious. Firstly, not every mutation in a sequence will destroy its function. There are probably a large number of mutations that are neutral or only very slightly deleterious. Thus, replication needs to maintain a population of related functional sequences rather than just a single exact sequence. Secondly, if sequences with different functions are replicated separately, error accumulation is less severe than if all the sequences are linked and replicated together (as in a modern genome). Nevertheless, accumulation of mutations is a real problem, and we can only conclude that the RNA world would have required an accurate polymerase quite early on, if it were to survive and increase in complexity.

Another important issue is that RNA polymerases, such as those in **Figure 2(c)**, do not copy themselves directly; they use another strand as a template. If the template strand has the same sequence as the polymerase, the polymerase sequence is copied. In the language of evolutionary biology, the polymerase is an altruistic cooperator, i.e., it is providing a benefit to other strands at a cost to itself. While it is acting as a polymerase, it cannot itself be a template for another polymerase. The simplest theoretical models assume a well-mixed solution in which molecules meet one another at random in proportional to their concentration. In this case, the cooperators tend to be overrun by parasitic sequences that can act as templates but not polymerases. Parasites are likely to be produced rapidly because deleterious mutations of the polymerase will produce nonfunctional sequences that can still act as templates. Theoretical models show that cooperative polymerases can manage to survive as long as there is a mechanism that promotes clustering of cooperative sequences together (Szathmáry and Demeter, 1987; McCaskill *et al.*, 2001; Szabo *et al.*, 2002; Takeuchi and Hogeweg, 2012; Shay *et al.*, 2015). One such mechanism is spatial structure that arises if molecules are bound to a surface and interacting with their local neighbors. If diffusion is slow, patches of cooperators form that replicate one another. A second mechanism operates if RNA replication is occurring inside compartments such as lipid vesicles. In this case, compartments that have few parasites can survive and divide, whereas those with many parasites become inviable. Group selection acting at the level of compartments can sometimes overcome individual selection acting at the level of molecules.

We have recently argued that several types of molecular cooperation are important in the RNA World (Higgs and Lehman, 2015). In addition to the altruistic cooperation of polymerases and templates discussed above, molecules can cooperate as part of an autocatalytic set. This is a set of molecules that together can catalyze the formation of each of the molecules in the set. However, none of them is a polymerase that can directly copy its own sequence. Theoretical models show that autocatalytic sets might emerge in a sufficiently diverse mixture of sequences that is able to catalyze reactions such as ligation of shorter strands to make a longer one (Kauffman, 1993; Hordijk and Steel, 2004, 2013). There have also been experimental realizations of this type of autocatalytic set involving ligases (Lincoln and Joyce, 2009) and recombinases (Hayden *et al.*, 2008; Vaidya *et al.*, 2012). In both these cases, non-catalytic precursor strands are assembled into longer catalytic strands. The reaction system requires a continued supply of the precursor strands; hence these systems could not survive in a prebiotic world without an additional mechanism of replicating large numbers of specific precursor sequences. In principle, however, an autocatalytic set might be possible as a scenario for the origin of life if it incorporated reactions that build up longer strands from single nucleotides and short oligomers that could be easily synthesized chemically. An autocatalytic set is complex in the sense that it is composed of many components, but the reactions involved might be relatively simple and specific. On the other hand, a polymerase ribozyme is simple in that it is a single molecule that could replicate many different templates, but the sequence itself might be long and complex. It is not yet clear, from either the experimental or theoretical viewpoint, whether a multicomponent autocatalytic set or a general RNA polymerase is more likely to emerge in prebiotic conditions.

Recombinase ribozymes (Hayden *et al.*, 2008) also illustrate a third form of cooperation. They assemble from shorter strands that are held together via RNA secondary structure formation, and they are not covalently linked initially. These strands are forced to cooperate because none of them is functional on its own. Ribozymes composed of self-assembled shorter strands might be more likely to emerge and more easy to replicate that longer sequences, because the pieces can be synthesized and replicated separately.

The RNA World hypothesis assumes that chemistry is able to create a diverse array of random RNA strands, and that eventually it manages to hit on a small number of specific catalytic sequences that are able to start the replication process. The steps creating RNA polymers, illustrated around the outer ring of **Figure 3**, are presumably slow and inefficient when

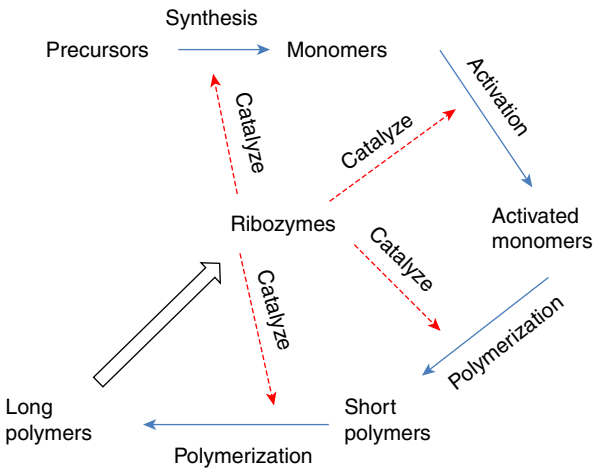

Figure 3 Getting the RNA World started. Before life, the steps leading to RNA polymerization must have occurred slowly and inefficiently. After life arose, all these steps could occur rapidly because they were catalyzed by ribozymes. This creates a living RNA World in which ribozymes catalyze their own formation.

they occur only chemically. However, if ribozymes arise in sufficient quantity, they can catalyze the reactions involved in all these steps. This sets up a feedback loop in which all reactions are rapid because they are catalyzed by ribozymes. We have referred to this as 'jump-starting' the RNA World (Wu and Higgs, 2009). The theoretical modeling shows that this requires concentration fluctuations that arise when only small numbers of molecules are involved initially. The jump from the dead to the living state occurs most easily when there is a spatial structure, such as when sequences are adsorbed to a surface and interact with their neighbors (Wu and Higgs, 2012).

This short article has presented the case that RNA was a key player in the origin of life on Earth and that the first kind of life may have been a system of replicating polymers made of RNA, or some very similar polymer capable of complementary base pairing. Although many alternative scenarios for the origin of life exist, none of them has the degree of support of RNA World hypothesis, which comes both from extensive laboratory based experiments and signals remaining in the way that modern organisms function.

Origins of Life, History of

LT Ackert Jr., Drexel University, Philadelphia, PA, USA

Introduction

The history of the 'origin of life' question is rooted in ancient philosophy and continues in research today. It was a central aspect of a wide range of philosophies, belief systems, and scientific investigations, including in the modern period, as well as the experimental physical and life sciences. This article explores several of the periods and approaches to this question (Strick, 2000). At its core, the search for the elusive answers to this question defines our understanding of our place on the Earth and in the cosmos.

Origin of Life in the Ancient Period

One of the earliest conceptions of the origin of life is found in Aristotle's (384–323 BCE) description of spontaneous generation. He believed that life is created out of a melding of the elements air, earth, water, and fire. In *Generation of Animals* he wrote that, "[a]nimals and plants come into being in earth and in liquid … in all air is vital heat so that in a sense all things are full of soul. Therefore living things form quickly whenever this air and vital heat are enclosed in anything. When they are so enclosed, the corporeal liquids being heated, there arises as it were a frothy bubble" (Aristotle, 1910, Book III, Part 11). Aristotle believed that this 'vital heat' contained the soul, or *eidos*, which was necessary to animate otherwise nonliving matter. It is the soul, which forms the matter into its necessary shape, providing an ancient explanation for the adaptation of species to their environment (Williams, 2010, pp. R84–R85). Recently, some have tried to relate Aristotle's *eidos* to the modern genetics, seeing it as an early forerunner to DNA (Vinci and Roberts, 2005). He realized the role of sperm in fertilization in sexual reproduction, yet he believed that the generative power was in its "vital heat" and that "the semen, if cold, is not generative" (Aristotle, 1910, Book I, Part 7). The details of the reproductive cycle remained outside his observing powers – for example, he concluded that in "testaceous" creatures (mollusks), "one does not generate in another; but they are formed and generated from a liquid and earthy concretion" (Aristotle, 1910, Book I, Part 23).

The Roman philosopher Titus Lucretius Carus (99–55 BCE) proposed a similar doctrine of spontaneous generation. In his epic natural historical poem, 'De Rerum Natura' (*On the Nature of Things*), he did embrace the Epicurean idea that human suffering is caused in part by a dread of the gods, but yet advocated for spontaneous generation, stating that the world takes form without the intervention of the gods (Palmer, 2012, p. 397). He claimed "they feign/That gods have established all things but for man" (Lucretius and Leonard, 1957, Book II). Though he accepted the existence of the gods, Lucretius thought they played little role in the "ordering or continuation" of the world (Palmer, 2012, p. 397). Following Democritus and Leucippus, Lucretius held a materialist atomist view of nature that informed his view on the origin of life. However, as Robert Wardy argued, a belief in an "atomic microstructure" alone does not "compel the theorist to adopt any particular ontology of macroscopic objects" (Wardy, 1988, p. 115). Lucretius, however, explained spontaneous generation due to the constant clashing of atoms that created cascades of combinations and eventually life (Lucretius and Leonard, 1957, Book II).

Seventeenth-Century Thoughts and Discoveries on Spontaneous Generation

During the early modern period, debates on the origin of life reevaluated ancient assumptions about spontaneous generation in terms of origins from nonliving matter and initiated the experimental period of its investigation (Paweletz, 2001, p. 478). Natural philosophers conducted small-scale biological experiments challenging the idea that organisms could arise from sources other than similar organisms – for example, that worms could generate out of decaying meat, or parasites out of dust. Francesco Redi (1626–97), for example, conducted a series of experiments proving that worms and maggots formed not spontaneously, but rather from another biological source. Covering meat with gauze and a perforated dome, he observed that eggs and maggots appeared on the gauze, but not the meat (Mazzarello, 1999, p. 237). He claimed that insects such as mosquitoes and flies deposited eggs that lead to the generation of new organisms (Hawgood, 2003, p. 30). Due to his inconclusive studies of plant galls, however, Redi continued to defend the origin of life by spontaneous generation in other cases. The discovery of microorganisms defined a new era in investigating the origin of life. Redi's contemporary, Marcello Malpighi (1628–94), for example, would explain the cause of galls. Using the newly invented microscope, Malpighi observed the action of microorganisms in them, eventually tracing them to cynipid gall-wasp eggs (Corrington, 1961, pp. 65–66). The still controversial observations of Antonie von Leeuwenhoek (1632–1723), the discovery of bacteria and their biological origin offered scientists a new material category of life to consider in the experimental investigation of origin of life (Corliss, 2002).

Spontaneous Generation and Uniformitarianism in the Eighteenth Century

Eighteenth-century developments in spontaneous generation research stemmed from the work of the early seventeenth century vitalists who, based on observations of toads being born out of 'slime' and maggots out of wheat grains, believed that life could arise out of nonliving matter (Pommerville, 2012, p. 10). Belief in the theory of spontaneous generation began to wane in the seventeenth and eighteenth centuries due

to observations of sperm and embryo development (e.g., Leeuwenhoek) and controlled biological experiments with negative results (e.g., Redi). Following Leeuwenhoek's work in 1677, British clergyman and naturalist John Needham (1713–81) conducted a series of experiments by boiling and stoppering mutton gravy discovering that: "the gravy swarm'd with life, with microscopical animals of most dimensions" (Needham, 1748). The Italian cleric and naturalist Lazzaro Spallanzani (1729–99) criticized this work, proposing that Needham had insufficiently heated the broth, and established a new protocol using open, stoppered, and sealed vials. Spallanzani's open vials teemed with bacteria, the stoppered vials had many fewer, and the sealed vials had none (Pommerville, 2012, p. 11). He argued that this experiment discredited the theory of spontaneous generation, yet Needham and others countered that excessive heating destroyed the vital force, initiating a debate that would persist into the late nineteenth century.

In 1735, Carl Linnaeus (1707–78) published *Systema Naturae*, a classification system for organisms from kingdoms to species. Built on the idea that organisms are more closely related to some than others, his system became a key to determining ancestral relationships in the fossil record. James Hutton (1726–97) in *The Theory of the Earth* developed the geological concepts of gradualism and deep time, which together comprised uniformitarianism, or the idea that "the present is the key to the past" (Hutton, 1795). This notion that the geological record provided "no vestige of a beginning, and no prospect of an end," challenged creationist theories of the origin of life (Hutton, 1795).

Nineteenth-Century Materialism and Cell Division

Naturalists exploring the origin of life question in the late eighteenth to mid-nineteenth century argued from a wide range of materialist frameworks. They considered matter the fundamental substance of nature and all phenomena the result of material interactions. Others favored vitalism, the idea that life is defined by the existence of a "vital spark" (soul) that separates it within the realm of the inorganic or nonliving (Bunge, 1981, p. 17; Normandin, 2006, p. 6). For the materialist Carl Vogt (1817–95), for example, the human soul is only a function of the brain, and thoughts the products of the brain, just as bile is a product of the liver (Rupke, 2000, p. 219). In materialistic views of nature, the existence of soul does not differentiate living from nonliving objects. Among those who believed in materialism were scientists such as Jean-Baptiste Lamarck (1744–1829), who supported the notion that all organisms have an innate ability to change over time (Burkhardt, 2013, p. 796). This hypothesis suggested that supernatural abilities once reserved for God could instead be performed by nature, leading some to believe that matter was the only substance in the world and there was no need for supernatural explanations.

The turn of the nineteenth century witnessed a new wave of evidence that supported materialism. The work of the German physiologist, Theodor Schwann (1810–82) helped define cell theory and garner support for materialism. In 1839, Schwann, informed by Matthias Schleiden's theory that the basic structure of plants consisted of cells, extended it to the animal world. An essential part of their research was the materialist notion that only cells formed cells (Sander, 1996, p. 8). Schleiden discovered that daughter cells are created within the parent cell in 1838. Hugo von Mohl countered with a new theory that cells were not created within, but divided from parent cells to daughter cells. This concept of cell division was first introduced in Mohl's work with green algae in 1837. His investigation showed that cells would split, then grow into full size again as separate cells. The idea that life could crystallize "out of an unspecific nonliving fluid, which can be regarded as a special case of the doctrine of spontaneous generation" was central to these novel theories of cell development (Deichmann, 2012, p. 535).

Alternation of Generations

A community of morphologists in the nineteenth century challenged the established ideas about the relationship between, and thus the origin of animal and plant life. Johannes Steenstrup (1813–97) in his *On the Alternation of Generations* represents a pioneering achievement concerning biological development in the lower classes of animals. His investigations of the 'alternation of generations' in *Medusa* and other invertebrates, he argued, revealed the plasticity and progressive development of species (Steenstrup, 1845, p. 2). His work highlighted novel ideas about cellular origin, but also the development of plant and animal life, from its simpler to more complex forms.

End of Spontaneous Generation

The ancient notion of spontaneous generation persisted into the late nineteenth century, when for much of the scientific community, they were resolved by the work of Louis Pasteur, John Tyndall, and others. Working within a quasi-Darwinian framework, these biomedical experimentalists participated in a series of popular scientific debates with the notable figures serving as the opposition, including Felix Pouchet and Henry Charlton Bastian (Strick, 2000, p. 2). In 1862, Pasteur published the results of his experiments, in which he maintained a sterilized broth in swan-neck retorts that filtered out bacteria and dust particles, but yet allowed in air, proving that decomposition had a biological origin, that is, biogenesis (Strick, 1999, p. 56). At the same time, Pouchet and Bastian provided convincing experimental evidence in support of spontaneous generation. Pouchet's research showed that bacteria growth occurred in "previously boiled and sealed infusions made from … hay," supporting Bastian's theory of heterogenesis – that germs and microbes originated only from inorganic material (Strick, 1999, p. 57–61). While these debates were resolved more politically than experimentally, others contributed new evidence. For example, John Tyndall's light scattering experiments supported the ideas that atmospheric dust consisted of organic materials and germs and likely contaminated Pouchet's experiment (Strick, 2000, p. 22). Pasteur's arguments and long series of experimental evidence led to a consensus among the scientific community that biogenesis was the correct theory for the origin of life.

An alternate hypothesis based on the work of Thomas Huxley, Ernst Haeckel, Carl Nageli, August Weismann, Eduard Pfluger, and others, called abiogenesis proposed that "life emerged during the course of the evolution of matter and life on earth was a natural product of terrestrial processes" (Kamminga, 1982, p. 67–68).

Panspermia

In the nineteenth century, physicists William Thomson (1824–1907) and Hermann von Helmholtz (1821–94) developed panspermia – from the Greek *panspermos* meaning 'containing all kinds of seeds' – a theory of the cosmic origin of life, in which "seeds of life were spread from star to star" (Anon., 2006, p. 54)." In *Worlds in the Making*, Svante Arrhenius (1859–1927) proposed an evolutionary and thermodynamic version of panspermia that discussed the conditions of bacterial spores and plant seeds to determine the likelihood of survival in interplanetary and interstellar space. He was the first to discuss the unearthly qualities of bacteria and the mode of transportation (the force of starlight) of these cosmic voyagers (Arrhenius and Borns, 1908). More recently, Fred Hoyle (1915–2001) and Chandra Wickramasinghe (1939–), arguing from a neo-Darwinian perspective, asserted that bacteria (traveling on comets) could survive in space because they must originate from space (Hoyle and Wickramasinghe, 1996). Thus, panspermia can explain the quick evolution of life on earth.

The Biogeochemical Hypothesis

Up to the 1920s, the question of the origin of life was discussed mostly in biological and chemical terms. The debate hinged on whether life was spontaneously created in one flash of organic synthesis, or whether life formed slowly by a combination of inorganic and organic reactions. The growing field of colloidal chemistry, or the study of homogeneous solutions suspended with microscopic particle, fueled this debate. Biochemists argued whether colloids would be able to effectively trap and concentrate organic precursors in such a way as to create life. The argument then proceeded into a familiar debate over spontaneous generation, which had yet to be resolved. Despite the lack of consensus, one general principle was agreed upon that profoundly changed the discussion going forward: the origin of life could be explained in purely chemical terms (Farley, 1974, pp. 159–163).

This conception of a purely chemical origin of life gave J.B.S. Haldane (1892–1964) and the Soviet scientist Aleksandr Oparin (1894–1980) the opportunity to synthesize the prior debate into one clear hypothesis. In 1929, Haldane, discussing the role geological conditions played in the origin of life, proposed the idea of an anoxic early earth, rich in proto-organic compounds (Kamminga, 1988, p. 7). In chemical terms, organic molecules could arise anew only in the absence of oxygen, which permitted ultraviolet (UV) radiation (energy) to initiate the photochemical organic synthesis (Rutten, 1962, pp. 48–49).

Oparin extended Haldane's concept further, hypothesizing a series of steps in the chemical evolution of life. Drawing on geochemistry, astronomy, evolution, and colloidal chemistry, Oparin developed a grand origin theory. In Earth's early history, he stated, inorganic molecules were broken down by UV rays to form organic molecules and a 'primeval soup' (Miller and Orgel, 1974, pp. 11–12). These molecules would then have coalesced into a coacervate colloid, which would concentrate organics, allow proteins to gradually form, and through competition eventually evolve into the first life forms. This revolutionary synthesis of biology, chemistry, and geology would set the next stage in the experimental era of the study of life's origin.

What Is Life?

During the twentieth century, attempts to define 'life' came to bridge the physical and social sciences and the humanities. Debates became personal, emotional, and often mired in cyclical rhetoric and beyond the reach of practical explanations, no matter the philosophical and scientific contexts. A novel set of questions came from Erwin Schrödinger (1887–1961), who asked in a public lecture *What Is Life*, explored three important issues related to the origin of life: resistance to entropy, permanence of genetic material, and its replication – all of which occurred bounded in the living cell. His work was significant less for its portrayal of contemporary ideas in origin of life scientific research, but more for the influence it had on its investigation in the 1950–70s, and especially molecular genetics (Olby, 1971, pp. 130–135).

Origin of Life: Urey–Miller's Experiments

In 1952, inspired by Oparin's work and advised by Harold Urey, Stanley Miller (1930–2007) conducted a new classic experiment that demonstrated how amino acids and other organic compounds – that is, the basic building blocks of life – could be synthesized under primitive Earth conditions. Miller's idea was a prebiotic synthesis experiment in which an electrical energy source would be discharged on a mixture of methane, ammonia, water vapor, and hydrogen (replicating primitive earthly conditions). During the experiment, a mixture of primitive earthly gases were circulated through a water solution and zapped with electric sparks (substituting for natural lightning). The results of the continuous sparking were 'biochemically significant' compounds such as amino acids, hydroxyl acids, and urea (Miller, 1953). Numerous scientists replicated and expanded these investigations since, finding a large number of amino acids that are integral to life, and many others that are not.

RNA/DNA Biochemistry

In the field of evolutionary biochemistry, two important questions exist: how did life originate, and how did it evolve? In particular, biochemists look at components of a cell to help make that determination. The cell's nucleic acids RNA

(ribonucleic acid) and DNA (deoxyribonucleic acid) are necessary components in the formation of proteins; likewise, proteins are necessary in the formation of nucleic acids. In 1967, Carl Woese (1928–2012) attempted to determine which came first, nucleic acids or proteins, leading to the RNA World Hypothesis. He proposed that RNA was the precursor to life by mixing proteins, RNA, and DNA (Woese, 1967). Following Woese, in 1982, Thomas Cech discovered a type of RNA that can act as a chemical catalyst, scientists did not know whether proteins or nucleic acids came first; however, with this discovery it was determined that some forms of RNA can replicate itself, thereby solving the question that RNA came first in the evolution of Earth's first life (Gesteland *et al.*, 1999).

In 1967, biologist Lynn Margulis (1938–2011), drawing on the Russian tradition, published her theory of symbiogenesis, which added a new dimension to evolution that allowed for the combination of existing genomes in a new symbiotic organism, at both the cellular and organismic levels (Khakhina *et al.*, 1992). Margulis proposed that a major transition in the origin of life occurred when nuclear information transferred between bacteria and eukaryotes (Margulis, 1999).

In the 1980s, Andrew Ellington noted that the chemicals that constitute life formed without living matter first by replicating themselves and later by evolving into reproducing life forms. His investigation of the evolution of dehydrogenase isozymes – enzymes found in single-celled organisms lacking a defined nucleus – led him to develop a method to engineer nucleic acid species known as 'aptamers' through repeated *in vitro* selection. Today, Ellington is extending and accelerating his evolutionary engineering approach to whole organisms and biotechnologies (Ellington, 2008).

'Life' in Recent Philosophical Debates

The question 'What is life?', a long standing topic of philosophical debate, has in recent years become increasingly scientific. Carol Cleland, a leading philosopher at CU Boulder, challenges the traditional approach taken by philosophers and scientists in answering it; instead of looking for 'definitions of life,' she notes, we should develop a general theory of living systems that might exist in the universe – life on Earth is only one possible example of life (Cleland and Chyba, 2007). Informed by recent work in philosophy and evolution, Iris Fry concludes that similarities in Earth's microbiology and biochemical makeup support a theory of common origin (Fry, 2000).

Another issue is the Earth-centric view that is pervasive. In the infinite universe it is a distinct possibility that life could form in multiplicate, with nonliving materials without necessarily being on Earth. Life arising more than once from nonliving materials could occur elsewhere than Earth, but it could also have occurred on Earth. It is within the realm of possibility that even with extraterrestrial life all life could have a similar origin, or not. Microorganisms, for example, might survive interplanetary travel on meteors eventually to land on planetary bodies with environments that can sustain life (Cleland, 2013).

Astrobiology: The Past, the Present, and the Future

The origin of life question, and its corollary the existence of intelligent life, is a primary focus of exo/astrobiology (Brack *et al.*, 2001). By applying the principles of natural sciences (biology, chemistry, and physics) to explain the mechanisms behind the origin and evolution of life, astrobiologists are developing search parameters for life on other planets. Strong programs have existed since National Aeronautics and Space Administration's (NASA) first program in 1959, and continue in numerous institutes, such as Ariel Anbar's team at Arizona State University. The aim is to study the past, current, and future mechanisms that allow Earth to be a habitable planet and how those mechanisms might apply to extraterrestrial life (Des Marais *et al.*, 2008).

Conclusion

The history of the origin of life described above is a necessarily narrow view that excludes equally important perspectives that occurred in religion, literature (especially science fiction), and the humanities as well as many other scientific fields. A comprehensive account of attempts to understand the origins of life would ideally include the ideas of non-Western science and philosophy, especially Islamic, and those of the very earliest civilizations (Babylonia, India, China, and Africa). It would also require a more thorough discussion of the philosophical debates on the origin of life during the early Modern period, including Bernard Fontenelle (1657–1757). It is however an effective summation of the history of scientific attempts to answer this time-honored subject of inquiry.

Paleobiogeography and Fossils

DAT Harper, Durham University, Durham, UK

Glossary

Biome Community of animals and plants occupying defined area.
Climograph Graphic summary of key climatic parameters.
Cosmopolitan Citizen of the world, living everywhere or nearly everywhere.
Dispersal The spread of organisms from their sites of origin.
Endemicity Restricted to particular district or area of the world.
Neontologist A specialist researching living organisms.
Obduction The edge of an oceanic crustal plate is thrust over the edge of an adjacent continental plate.
Orogen A zone of mountain building, usually the collision of two continents.
Panbiogeography Connects the disjunct distributions of organisms across the globe.
Phenetic Generally refers to the external features of an organism.
Phytogeography Distribution of plant taxa across the globe.
Province Area of the globe characterized by endemic taxa.
Realm Large areas within ecosystems sharing similar history.
Terrane Fragment of crustal material.
Vicariance The range of an organism is split by barriers.

Introduction

The fossil record stretches back some 3.5 billion years and is a unique archive for the evolution of life on our planet, illustrating how the biosphere has changed through deep time and informing us of possible patterns and trends in the future. The geographic distribution of fossil organisms has played a fundamental role in understanding Earth history, particularly the movements of the continents and the location of diversifications and extinctions together with the track of biotic migrations. All living organisms have a well-defined geographic range, from large to small, usually dependent on factors including climate and latitude. The mapping of current biogeographic patterns and their analysis have informed the parallel investigations of biogeography in deep time. Today, the Earth is divided into six main provinces: Nearctic, Palearctic, Neotropical, Ethiopian, Oriental, and Australasian (Figure 1). These biogeographic provinces owe much of their origin to the ground-breaking and perceptive research of Philip Sclater and Alfred Russel Wallace in the 1880s. Provinces are characterized by 'endemic taxa' that have restricted ranges in contrast to 'cosmopolitan' or worldwide taxa. Provinces today tend to be defined at the species level, while those from the geological past use genera. But continental configurations and positions have changed through time as have faunal and floral provinces. Key to the positioning of the continents and oceans are palaeomagnetic data; the orientation of iron minerals is frozen in a number of types of rocks acting like minute compass needles, indicating the latitude where they formed. In addition, types of rocks such as bauxites, coals, desert sandstones, evaporites, and glacial deposits can also fix the latitudinal position of a continent or microcontinent. The continents have been on the move for at least 2 billion years. The supercontinent of Rodinia formed about one billion years ago in the late Precambrian, breaking up into at least eight continents during the Early Palaeozoic (Figure 2(a)). These recombined to form the supercontinent of Pangea (Figure 2(d)), during the later Palaeozoic, itself breaking up to form Gondwana and Laurasia in the early Mesozoic (Figure 2(e)). Palaeontological data were instrumental in demonstrating the drift of the wandering continents, prior to plate tectonic theory, and such data continue as an integral part of palaeogeographical analysis.

Biogeographic provinces are today delimited by biotic barriers. Firstly, corridors, such as seaways or mountain passes, are always open for migration, secondly, filters restrict the passage of organisms, and thirdly, sweepstake routes are only occasionally open. These three concepts underpin 'dispersal' models. On the other hand continental areas and various types of volcanic arcs, split and move, driven by plate tectonics; this provides a mechanism to amalgamate or fragment provinces forming a basis for 'vicariance' models.

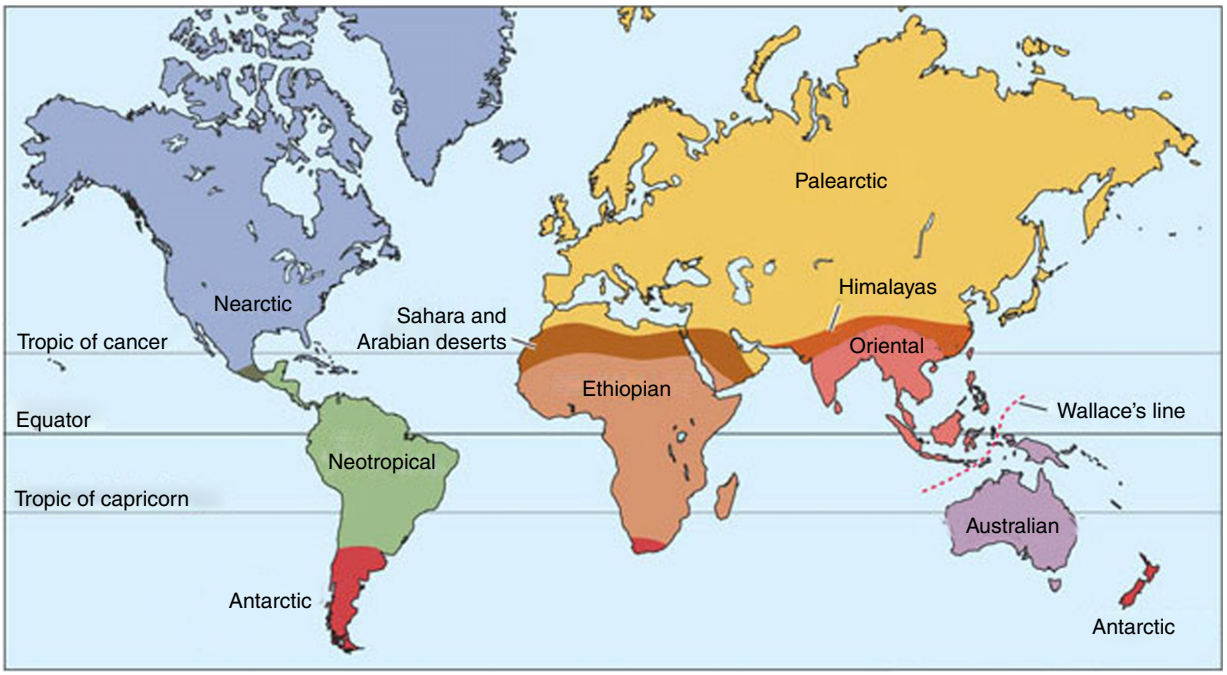

Figure 1 Major biogeographic regions of the world.

Historical Background

Two key approaches have dominated the analyses of palaeobiogeographical patterns of organisms through time. Both are rooted in historical concepts developed by 'neontologists' and both are predicated on the geological process of plate tectonics. The dispersal and vicariance models form two different camps and have two different origins. The Swedish systematist, Carolus Linnæus or Carl von Linné (1707–78) believed that biogeographical distributions were due to the subsequent dispersal of species from an island paradise located in the tropics, where land areas had emerged with the retreat of the seas. In his view all species originated and dispersed from a single 'center of origin,' enabled by ecological conditions. Georges-Louis Leclerc, Comte de Buffon (1707–88), however, considered that the distributions of living organisms were controlled by fluctuating climatic and environmental conditions. He established one of the first principles of biogeography: birds and mammals occupying the same environments but in geographically isolated regions will be different, forming the substance of Buffon's Law. On this basis he classified the globe into the New and Old World. Karl Willdenow (1765–1812) is widely credited with the first major synthesis of plant biogeography, but it was Alexander von Humboldt (1769–1859) who is generally viewed as the pioneer of 'phytogeography'. Following several surveys of the indigenous flora during his expeditions in South America, his key contributions on the biogeography of plants were published and distributed to a more global audience, in the late eighteenth and early nineteenth centuries, gaining wide popularity.

The study of Modern biogeography, however, was initiated by Augustin-Pyramus de Candolle (1779–1841), whose classification of the modern flora defined some 20 botanical regions and introduced the concept of endemism, the basis of biogeography, and the definition of biogeographic units. Deep time, however, was already crucial in the development of the historical dimension to biogeography. Charles Lyell (1797–1875), the 'father of modern geology,' encouraged the development of biogeography in the nineteenth century through his major opus, *Principles of Geology*, first published in 1830–33 (Lyell, 1830–1833). Lyell rejected the ideas of evolution developed by French scientists (such as Jean-Baptiste Lamarck, 1744–1829) and proposed a 'centers of creation' theory to explain the geographical distribution of species. Charles Darwin (1809–82) integrated that approach into his model for evolution, applying the concept of adaptation of organisms across time and space in *The Origin of Species*, first published in 1859. Darwin's (1859, p. 353) tenet "…that the view of each species having been produced in one area alone, and having subsequently migrated from that area as far as its powers of migration and subsistence under past and present conditions permitted is the most probable" challenged both the 'center of origin' and 'vicariance' models, changing the direction of the science. Darwin, however, in his analysis had no mechanism to account for horizontal continental movements (1859, pp. 357–358); convincing evidence for plate tectonics and seafloor spreading was yet to be established. Models involving allopatric speciation and subsequent dispersal thus anchored his theory.

Prior to Darwin's '*Origin*' scientists were beginning to develop a framework for our understanding of modern biogeographical provinces. For example, Philip Lutley Sclater (1829–1913) published on the general geographical distribution of birds in 1858, complementing Alfred Russel Wallace's (1823–1913) fundamental concepts of the geographical

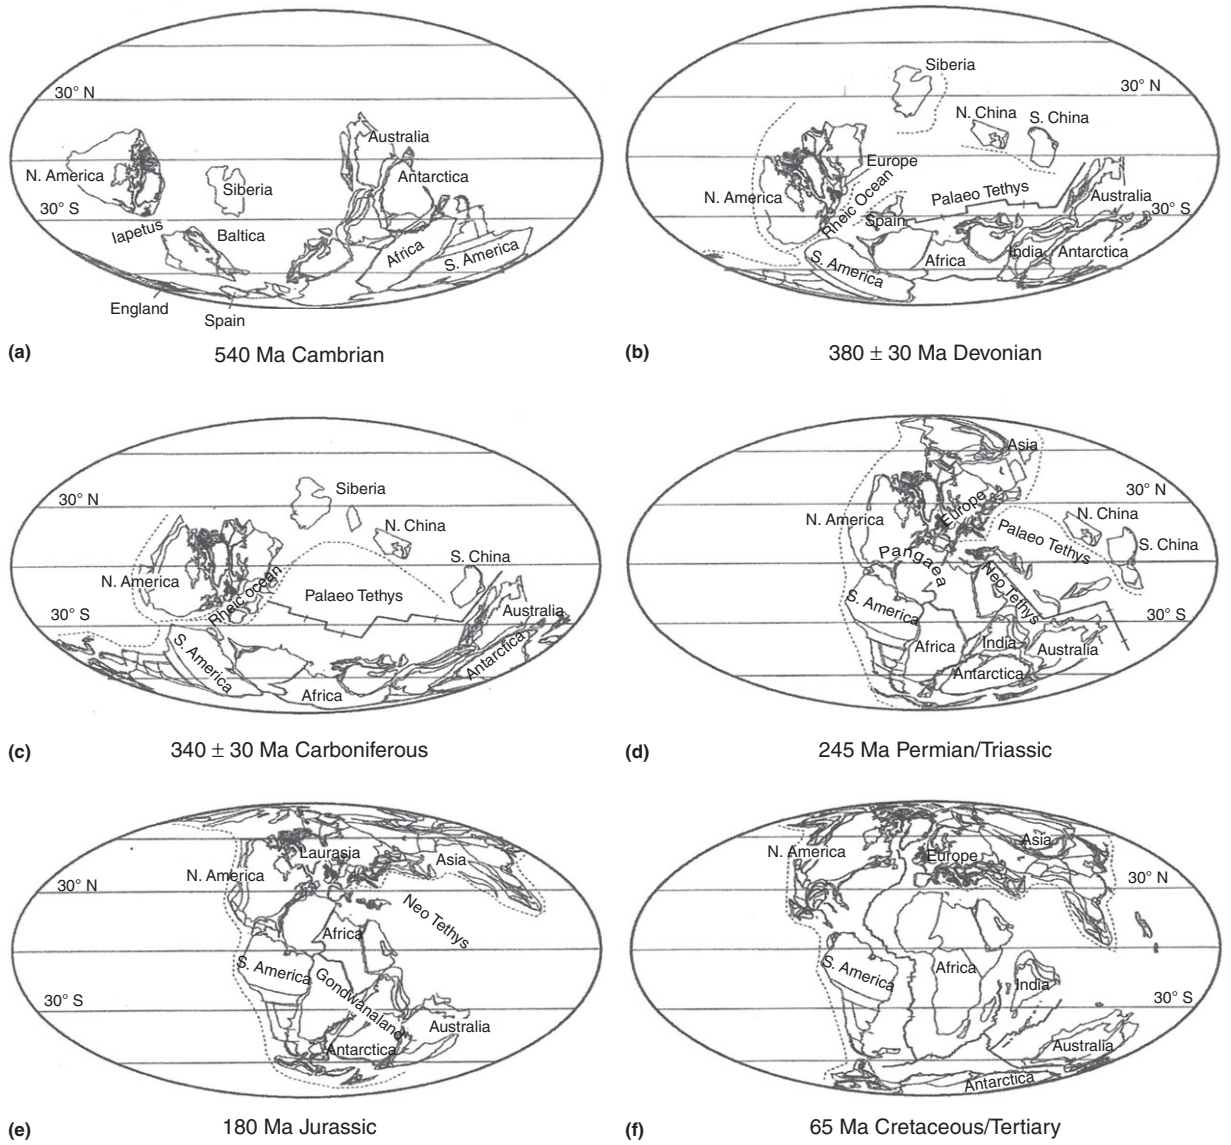

Figure 2 Collage of the main continental plates through the Phanerozoic. The Early Palaeozoic was characterized by low- and high-latitude provinces separated by the Iapetus Ocean. During the Late Palaeozoic, the Rheic Ocean separated Old and New World provinces, whereas the Mesozoic was characterized by Boreal (high-latitude) and Tethyan (low-latitude) provinces. Reproduced with permission from Benton, M.J., Harper, D.A.T., 2009. Introduction to Paleobiology and the Fossil Record. Chichester: John Wiley & Sons Ltd.

distribution of animals in 1876, based on many years of research on the Malay Archipelago. The first nomenclatural terms were introduced in these papers, and they are still widely used today: while Sclater divided the world into six biogeographical 'regions,' Wallace labeled these faunal distributional areas, 'realms.' Both Wallace and Sclater divided the world into six more or less similar units: the 'Nearctic,' 'Neotropical,' 'Ethiopian' units belong to the 'New World,' while the 'Palaearctic,' 'Oriental,' and 'Australian' units were attributed to the 'Old World' (Figure 1). This first major subdivision attempted to divide landmasses into major geographic belts, reflecting affinities and differences among terrestrial biotas, that remains widely accepted today. The major biogeographical units were separated by 'lines.' A prime example of such a sharp boundary between two different biogeographical units is of course 'Wallace's line,' that is located between the Indonesian islands of Borneo and Sulawesi (Celebes), and Bali and Lombok. This line was and is largely accepted, but has subsequently been modified by more recent authors, and represents the limit between the 'Oriental' and the 'Australian' realms.

It was not before the second part of the twentieth century, however, that palaeobiogeographical models integrated the concept of plate tectonics. The German meteorologist Alfred Wegener (1880–1930) proposed the theory of continental drift in the 1910s (Wegener, 1915), based on the similarity of faunas and floras across the southern continents during the Carboniferous and Permian (Figure 3) that had subsequently drifted apart. It was only in the 1960s, that geological evidence for 'plate tectonics' was widely accepted by most geologists.

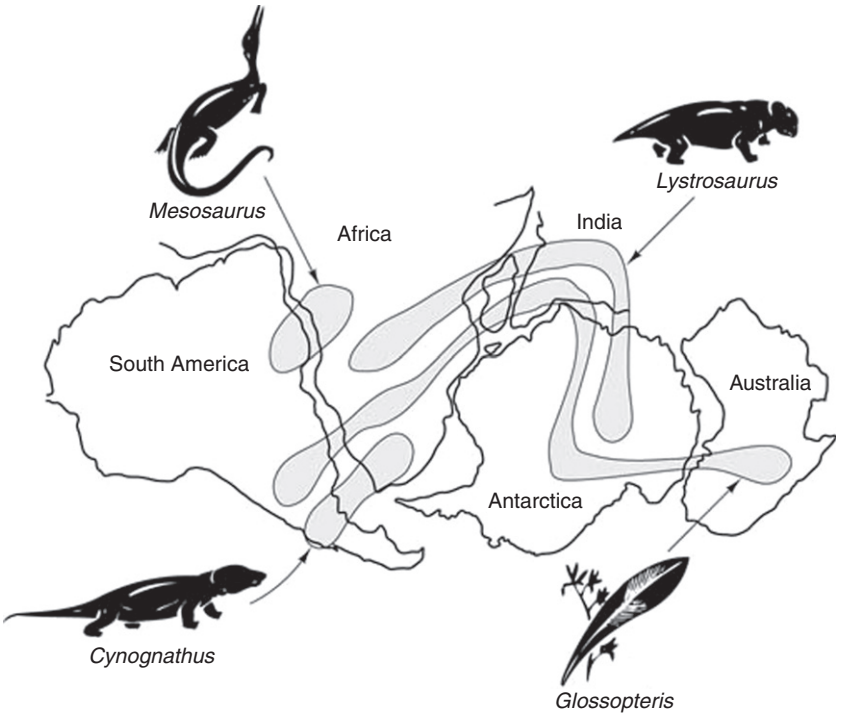

Figure 3 Carboniferous and Permian distributions of the *Glossopteris* flora and the *Mesosaurus* fauna, the Late Permian–Early Triassic *Lystrosaurus* fauna and the fit of Gondwana. The tight fit of Gondwana and the correspondence of fossil faunas and floras across the southern continents suggested to Wegener (1915) and others that South America, Africa, India, Antarctica, and Australia had drifted apart since the Permo–Triassic. Reproduced from Smith, P.L., 1988. Paleobiogeography and plate tectonics. Geoscience Canada 15, 261–279, with acknowledgement.

This paradigm shift integrated the concept of moving continents with the hitherto perplexing distributional patterns of fossil organisms through deep time.

Although in the absence of evidence for continental movements biogeography was dominated by 'dispersalists,' the botanist Léon Croizat (1894–1982) had predicted movements of the continental masses (e.g., Croizat, 1958) prior to the acceptance of plate tectonic theory. He introduced the concept of 'panbiogeography', which consists of an annotated geographical map with lines or tracks that join the known distributions of living, related organisms across the different areas of the globe. For example, tracks of terrestrial organisms traverse the oceans and hence cannot be explained by present-day geography. Croizat introduced the concept of 'vicariance', which is the separation of an ancestral biota into two or more biotas through the formation of a geographical barrier which prevents gene flow between populations. This concept is an alternative to the idea of dispersal from a center of origin, the model promulgated by Linnæus, Buffon, and Darwin. Croizat's ideas were initially rejected by biogeographers, but with the advent of plate tectonics his work was accepted by many, particularly those promoting cladistics methodologies.

Palaeobiogeographers were able to understand and to develop completely new models for the distribution of fossil organisms in the Mesozoic and Cenozoic eras, i.e., for the post-Pangean world. However, pre-Pangean palaeobiogeographic distributions are still more challenging, where biotic data can only frame and test palaeogeogeographic reconstructions.

Some Basic Concepts

Biogeographers and palaeobiogeographers describe and analyze the distributions of a single taxon or groups of taxa. An initial step is to determine the geographical range of a species or assemblage, for example, plotting the data on geographical or palaeogeographical maps. These maps can then provide evidence of physical barriers, such as mountain belts or oceans, delimiting the ranges of different organisms. Patterns of distribution used by biogeographers can be either spatial (e.g., based on altitude, depth, or latitude) or temporal (e.g., based on climatic, or seasonal changes). Since the 1970s biologists have worked in collaboration with mathematicians and statisticians to understand distributional patterns, in particular using the development of sophisticated multivariate statistical techniques that allow quantification of the degree of similarities (or differences) of the distribution of different communities or species. A large number of similarity indices have been proposed in the last few decades. The same methodologies have been applied to the distributions of fossil organisms using a similar range of multivariate analytical techniques (Hammer and Harper, 2006).

There are, however, a number of key terms that have been variably applied to both living and fossil distributional data. For continental environments, the term 'biome' has been introduced and is still widely used by botanists. Biomes include, for example, tropical rain forests, temperate grasslands, or boreal forests or tundras. They capture easily recognizable terrestrial biogeographic regions that can be easily plotted on

'climographs', i.e., simple diagrams depicting the mean annual precipitation versus the mean annual temperature. The term has also been used by palaeobiogeographers for marine fossils (e.g., Cecca, 2002), although the term 'community' is more commonly used by neobiogeographers for marine biotas. Marine communities include, for example, coral reefs, estuaries, upwelling zones, continental shelves, or the open ocean. In addition, 'biogeographic regions' and 'climatic regions' are used to delimit biogeographic units in the oceans today. The distinction of these is more complicated and nuanced, as natural barriers limiting the distribution of species and communities are less evident, the ocean being in places a large and continuous aquatic habitat.

Biogeographic regions of the marine realm are essentially partitioned by water temperature, creating broad latitudinal zones that may be influenced and perturbed by oceanic currents, or interrupted by the presence of continents, islands, or archipelagos. Today, the major 'biogeographic regions' of the world's oceans are, essentially from North to South, the 'Arctic,' 'Subarctic,' 'Northern Temperate,' 'Northern Subtropical,' 'Tropical,' 'Southern Subtropical,' 'Southern Temperate,' 'Subantarctic,' and 'Antarctic' regions. On the other hand, several major 'climatic regions' have been defined. These are the 'Arctic,' 'Northern Boreal,' 'Southern Boreal,' 'Tropical,' 'Equatorial,' 'Northern Total,' 'Southern Total,' and 'Antarctic' climatic regions (Figure 1).

It is particularly challenging for palaeontologists to trace these different units back into deep time, particularly prior to the Jurassic Period, when no *in situ* oceanic crust is preserved: what were the key assemblages or communities, biogeographic units, and climatic zones in the Early Palaeozoic, for example? Since barriers, of various types, play a significant biogeographic role at any given time and may define and preserve biogeographic signatures in more recent distributions. Former areas of 'endemicity' still exist: for example, the disjunct distribution of Modern lungfishes indicates that they were endemic to the ancient supercontinent of Gondwana, which is no longer a geographic area in the modern world.

There is a myriad of terminology within (palaeo-) environmental and (palaeo-) geographical studies, for which no clear rules have been established but for which some common usage of terms exists; to these, the (palaeo-) ecological context adds additional data. The environments that occur on the continental shelf are referred to as neritic, while those in the open ocean are considered pelagic, divided into epipelagic (<200 m water depth), mesopelagic (<1000 m), bathypelagic (<4000 m), and abyssopelagic (<11000 m). In addition, the life mode of marine organisms allows a classification into benthic or planktonic life styles, with some organisms occupying intermediate positions. Benthic organisms are bottom-living animals that may live on the seafloor (epifauna) or below the sediment (infauna). Organisms in the open waters are usually divided into floating (plankton) and freely swimming (nekton) organisms. Understanding the life modes of organisms, in the oceans, is critical in determining their utility in palaeobiogeographic studies. In general terms, planktonic organisms have the most widespread distributions but even within the benthos there are nuances, with those shallow-water assemblages and species have more restricted distributions than those in deeper water. More over even within plankton groups some species may be more widely distributed than others.

With the fragmentary knowledge available on the distribution of fossil species and assemblages, it is generally impossible to fully understand the life mode or the life habitat of marine organisms. It is therefore not always evident to palaeontologists how to apply these terminologies. A common problem for palaeontologists, for example, is to clearly distinguish between the influence of palaeogeographical (e.g., latitude) and of palaeoecological (e.g., water depth) parameters on the distribution of a fossil organism, particularly when dealing with planktonic and neritic species. These variables are often difficult to quantify in deep time and involve some speculation. Nevertheless, the relative extent of animal distributions during the Early Palaeozoic has been sketched out, emphasizing the role of mobility of respective groups of animals and their larvae, and their relationships to biofacies, more specifically water depth (Fortey and Cocks, 2003). This has invited debate as to whether there are 'good' or 'bad' fossils for palaeobiogeographic analyses. Clearly, those with more widespread distributions, commonly occurring in deeper water, are less good geographic proxies than those restricted to shallow water and tied to a particular continent and latitude.

Reconstructing Ancient Geography

Palaeobiogeography had a fundamental influence on our understanding of continental drift and subsequently plate tectonics. The predrift positions of major continental masses can be reconstructed back through time with reference to the contiguity of ancient provinces. But many continents have complex margins of accreted material, such as microcontinents and volcanic arcs, whose origins are unclear. As noted previously, since no *in situ* crust exists prior to the Jurassic Period, palaeogeographers must, using biotic data, climatically sensitive sediments and palaeomagnetic evidence, locate the sites of such arcs and microcontinents within ancient oceans prior to their accretion. Terrane models recognize that mountain belts or orogenic zones consist of a collage of tectonic units with unique geological histories mutually separated by tectonic structures such as faults. Many 'terranes' have their own distinctive biogeographic signatures. Virtually all 'orogens' can now be interpreted in this way.

There is now a large literature on palaeobiogeography. More recent contributions and compilations strongly focus on vicariance (e.g., Lieberman, 2000), the biogeography and palaeobiogeography of the Indo-Pacific and related regions (Renema, 2007) and on data capture, management, and analytical techniques (Upchurch *et al.*, 2011). Deep time is well represented by compilations of the Palaeozoic and its biotas (McKerrow and Scotese, 1990) and of the Early Palaeozoic (Harper and Servais, 2013). These data are supported by a number of readily available computer-based palaeogeographic reconstructions through time, for example, BugPlates, Colorado Plateau Geosystems Inc., and the Paleomap Project. Smart phone apps, for example, Ancient Mobile History, provide an interactive and visual journey through time as the continental configurations and positions changed during the last 550 million years.

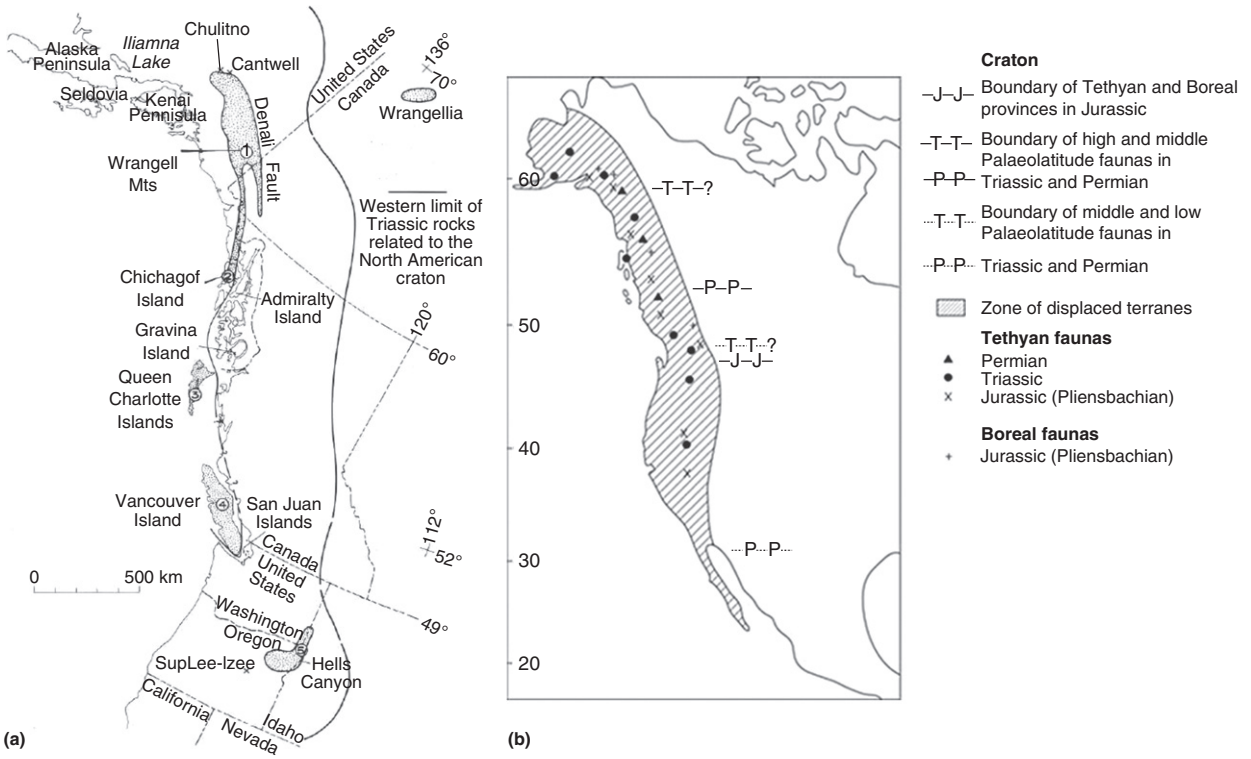

Figure 4 (a) Map showing distribution of Wrangellia and limit of Triassic continental shelf deposits (high-latitude). Reproduced from Jones, D., Silberling, N.J., Hillhouse, J., 1977. Wrangellia—A displaced terrane in northwestern North America. Canadian Journal of Earth Sciences 14, 2565–2577, with acknowledgement. (b) Displaced faunas in terranes within the North American Cordillera together with changing provincial boundaries on the craton. Postulated latitudinal boundaries on the craton during the Permian, Triassic, and Jurassic are indicated and confirm the northern movement of these displaced terranes. Reproduced from Hallam, A., 1986. Evidence of displaced terranes from Permian to Jurassic faunas around the Pacific margins. Journal of the Geological Society 143, 209–216, with acknowledgement.

Critical to any palaeogeographical reconstruction is the understanding of biogeographic patterns in these analyses. (Palaeo)Biogeographic units are generally recognized by key species in common, or genera, families, and higher taxa. More preferable than merely charting the distribution of a single key taxon, is the analysis of large databases of distributional information by multivariate methods (see below). Palaeobiogeographical studies have thus followed three parallel approaches. First, many analyses have focused on the occurrences of key genera or families to help map provincial data. Second, by way of contrast, a number of authors have used the whole-data approach, analyzing statistically all the available data from given time slices using a range of multivariate methods. Third, the biogeographical distributions of taxa have been mapped onto phylogenetic trees for some areas of the phylum. Moreover, the concept and application of provinces have differed between author groups (see below), with some authors basing their provinces entirely on the distribution of taxa, whereas others have tied them to continental palaeoplates.

One classic area for the study of terrane geology is the North American Cordillera. Here the ancient mountain belt on the Pacific-facing margin of the North American continent is composed of a collage of microcontinents or terranes. During the Mesozoic, high-diversity, low-latitude Tethyan province faunas are generally quite distinct from the lower-diversity, high-latitude Boreal faunas and can be used to fingerprint high and low-latitude terranes. The mosaic of terranes, now plastered onto the west coast of the States, probably originating at lower latitudes. For example, in an east – west traverse across these terranes there is a progressive northward displacement of Tethyan-type faunas of early Jurassic age; some of the more exotic, far-traveled terranes may have moved over 1300 km (Newton, 1988); for example, the Triassic rocks of the large, exotic Wrangellia terrane (Jones *et al.*, 1977) originated at low, tropical latitudes and were emplaced northwards along the edge of the North American craton (**Figure 4(a)**) during the Mesozoic. The terranes are distinguished by their biogeographical signatures, narrating a unique pathway through time, simulating Viking funeral ships. Another way of assessing the origins and tracks of these terranes involves plotting the boundaries between the provinces on the craton through time (**Figure 4(b)**).

Analyzing Ancient Biogeography

Two main types of biogeographic analysis are widely used based on either 'phenetic' (dispersal) or 'cladistics' (vicariance) methods. Cladistic methods construct trees by relying on

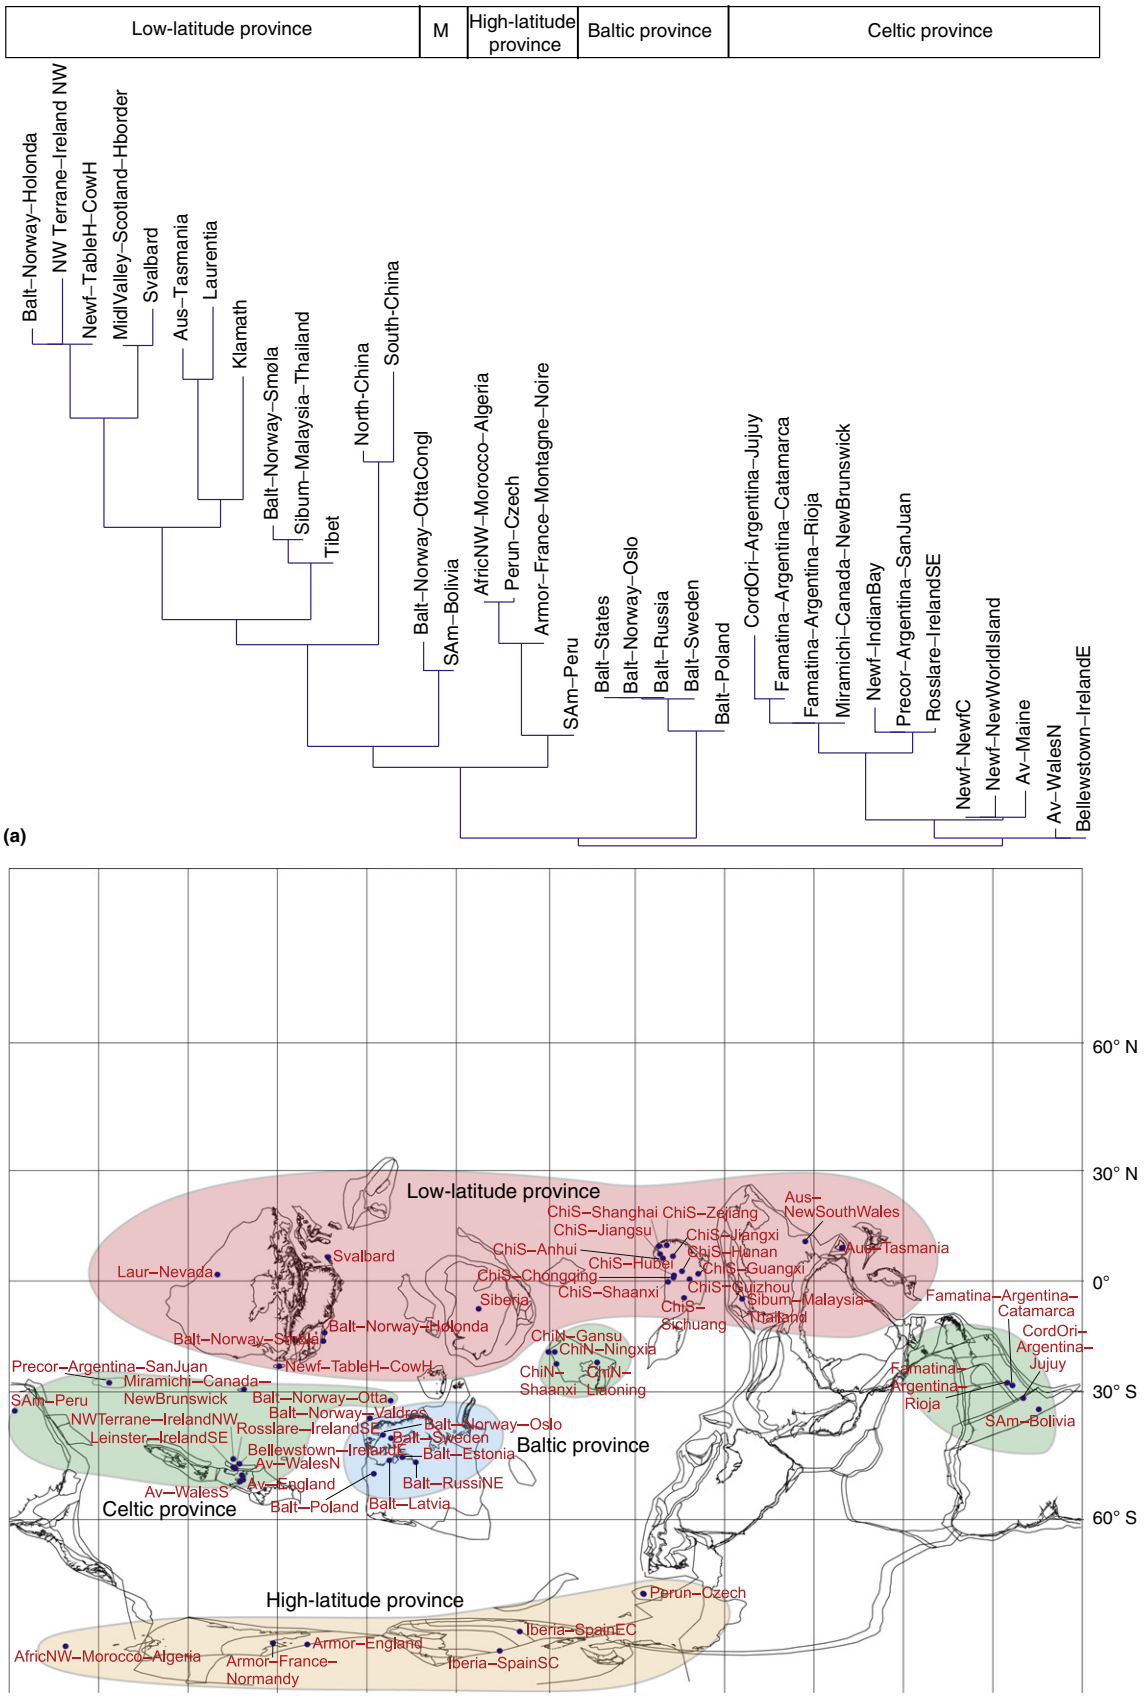

Figure 5 (a) The 'phenetic' cluster analysis of Mid Ordovician brachiopods from the entire World; (b) mapped onto a predrift reconstruction for this interval. Reproduced from Harper, D.A.T., Servais, T., 2013. Early Palaeozoic Biogeography and Palaeogeography. London: Memoir of the Geological Society, with acknowledgement.

assumptions about ancestral relationships as well as on current data, i.e., a province has since fragmented with the creation of subprovinces characterized by new endemics, essentially analogous to apomorphies in taxonomic cladistics. Phenetic methods construct trees by considering the current states of characters without regard to the evolutionary history that brought the species to their current phenotypes; phenograms are based on overall similarity. There are a large number of distance and similarity measures to choose from (Shi, 1993; Hammer and Harper, 2006). A few of the commoner coefficients are listed below:

$$\text{Dice coefficient} = 2A/2A + B + C$$

$$\text{Jaccard coefficient} = A/A + B + C$$

$$\text{Simple matching coefficient} = A + D/A + B + C + D$$

$$\text{Simpson coefficient} = A/A + E$$

A is the number of taxa common to any two samples, B is the number in sample 1, C is the number in sample 2, D is the number of taxa absent from both samples, and E is the smaller value of B or C.

On the basis of an intersite similarity or distance matrix a dendrogram can be constructed linking first the sites with the highest similarities or the closest distances. When the distance or similarity matrix is recalculated to take into account the first clusters, additional sites or genera are clustered until all the data points are included in the dendrogram. Clearly the first clusters have the greatest significance and less importance is usually attached to later linkages. Alternatively some form of ordination, for example, principal components or coordinates analyses can be used to display the similarities of sites based on the taxon compositions of localities (Harper, 1992; Hammer and Harper, 2006). This approach, using total data, has proved useful for defining ancient provinces, based on clusters of taxa (usually genera) characteristic for given ancient provinces. Mapping of the provinces onto base maps forms the basis for understanding the changing distribution of provinces through time. A cluster analysis is presented for a large matrix of fossil brachiopods from all various localities throughout the world some 450 million years, when the world was very different; the key clusters are mapped onto the Mid Ordovician globe (**Figure 5**).

Biogeographical Patterns through Deep Time

Prior to the Jurassic Period there is no oceanic crust preserved in place, most now has been obducted onto continental margins or squeezed into mountain belts during plate collisions. Nevertheless a large spectrum of biogeographic units has been established for much of the Phanerozoic based on a variety of fossil groups, ranging from a complexity of provinces during the Great Ordovician Biodiversification Event (GOBE: Harper and Servais, 2013) to more clearly latitudinally controlled during the Mesozoic, with generally Boreal and Tethyan

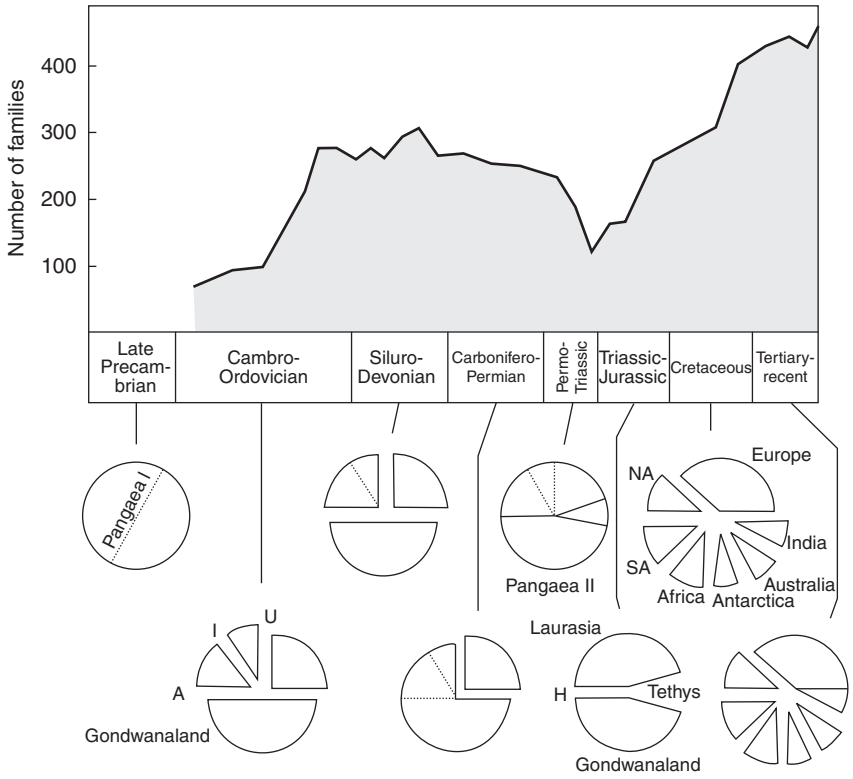

Figure 6 Changing familial diversity of skeletal benthos through time in relation to plate configurations: high diversities are apparently coincident with times of greatest continental fragmentation, for example, during the Ordovician, Devonian, and Cretaceous–Cenozoic. A, pre-Appalachian-Variscan Ocean; H, Hispanic Corridor; I, Iapetus Ocean; U, pre-Uralian Ocean. Reproduced from Smith, P.L., 1988. Paleobiogeography and plate tectonics. Geoscience Canada 15, 261–279, with acknowledgement.

provinces. During the GOBE, the wide dispersal of continental, microcontinents, and volcanic arcs provided mechanisms for allopatric species, increasing dramatically the total marine (γ) diversity of the planet. Similar radiations on land were coincident with the construction of Pangea as forests spread, together with terrestrial, animal-based communities in the later Palaeozoic. Biogeography and climatic gradients are also related to patterns of changing biodiversity. In broad terms low latitudes support high-diversity faunas; biodiversity decreases away from the tropics toward the poles. Studies on modern bivalve, bryozoan, coral, and foraminiferan faunas show marked increases in diversity toward the equator, and since many cool-water species breed later in life, individuals may be larger than their tropical counterparts. The latitudinal diversity gradient has also been found in paleobiogeography. For example, diversity gradients across early Jurassic ammonoid faunas have proved informative in palaeogeographic reconstructions; Tethyan faunas occupying tropical belts were generally more diverse than counterparts at higher latitudes.

Many authors have suggested that changing plate configurations, oscillating between fragmentation and integration, have affected biodiversity through time (Figure 6). For example, the huge early Ordovician radiation (GOBE) of marine skeletal faunas may be related to the breakup of Gondwana (Harper, 2006), the end Ordovician may be associated with an amalgamation of microcontinents and terranes (Rasmussen and Harper, 2011), while the end-Permian extinction event coincides with the development of the supercontinent of Pangaea,

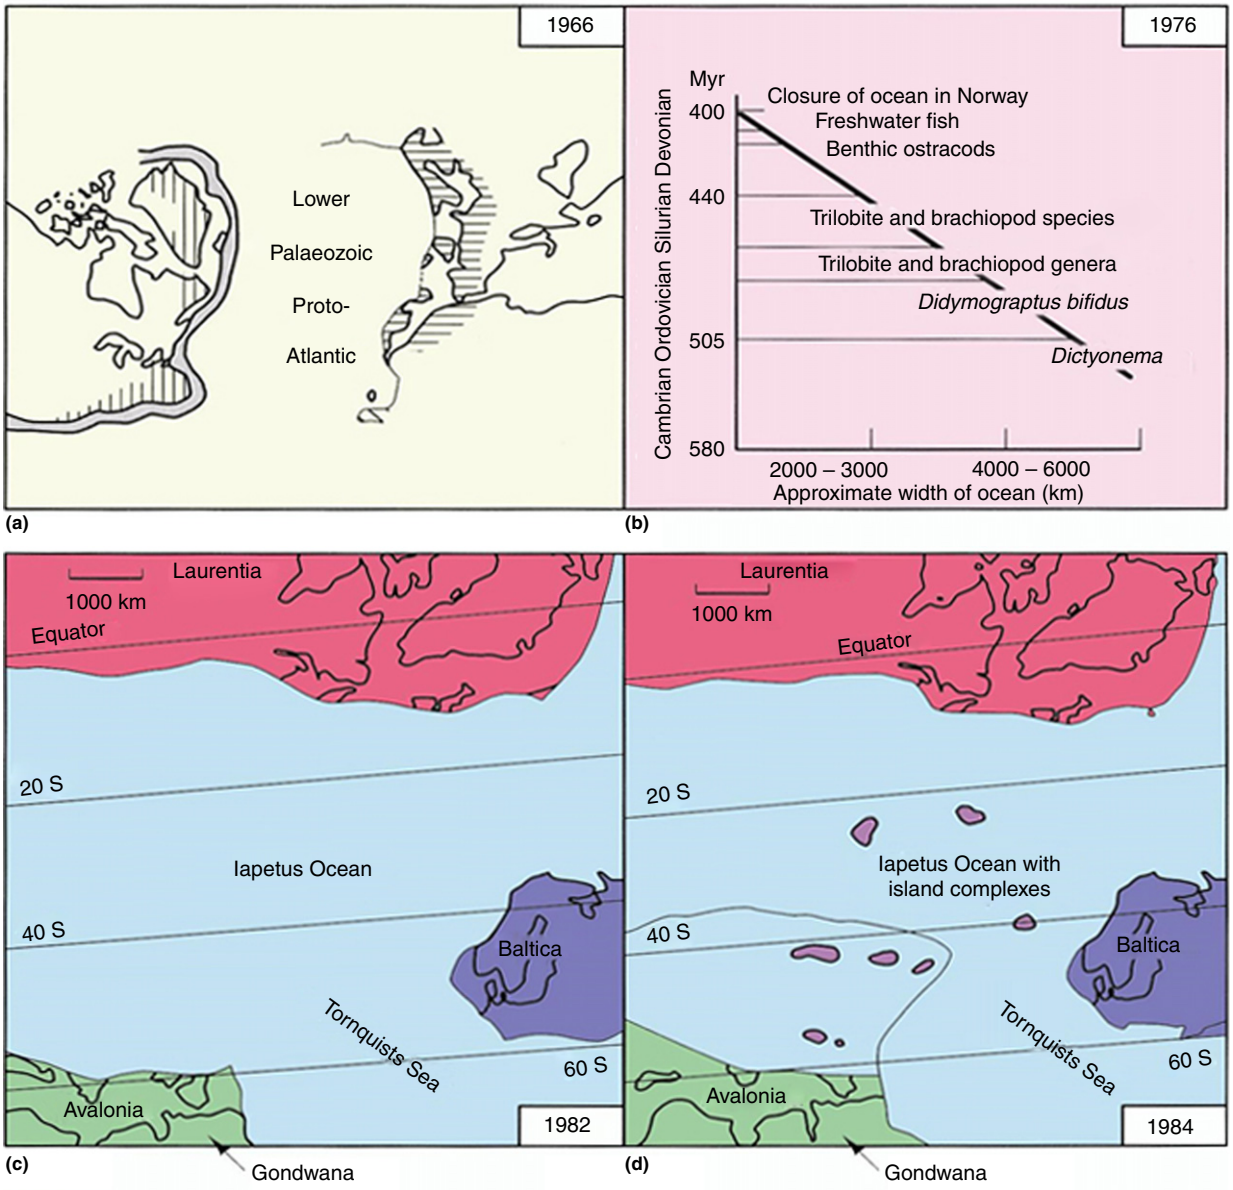

Figure 7 Changing ideas on the development of the Early Palaeozoic Iapetus Ocean and its faunas: (a, c, d) palaeogeographic reconstructions; (b) the mobility of organisms across a closing ocean. Figures 7(a)–7(d) reproduced from Harper, D.A.T., 1992. Ordovician provincial signals from Appalachian-Caledonian terranes. Terra Nova 4, 204–209, with acknowledgement.

and changes in the seaways within and around it (Shen and Shi, 2002); more recent diversifications have occurred during the late Mesozoic fragmentation of this supercontinent.

Islands are key players in biogeography. The majority of fossil island complexes are now entrained in the world's mountain belts where the remnants of oceanic crust occur together with associated microcontinents and volcanic arcs. Islands have fulfilled roles as both cradles and museums of taxa, volcanic arcs, and microcontinents providing the locus for species pumps (e.g., Darwin's finches and tortoises) and conversely peripheral isolates (e.g., the Dodo of Mauritius), exposed to extinction. Moreover the role of islands as stepping stones for both marine and terrestrial biotas is well substantiated. Patterns of migration, by larval island hopping during two of the most active magmatic and tectonic periods, have been established in the Ordovician (e.g., Jin and Harper, 2015; Rasmussen, 2011) and the Cretaceous (e.g., Harper *et al.*, 2005; Skelton *et al.*, 2013).

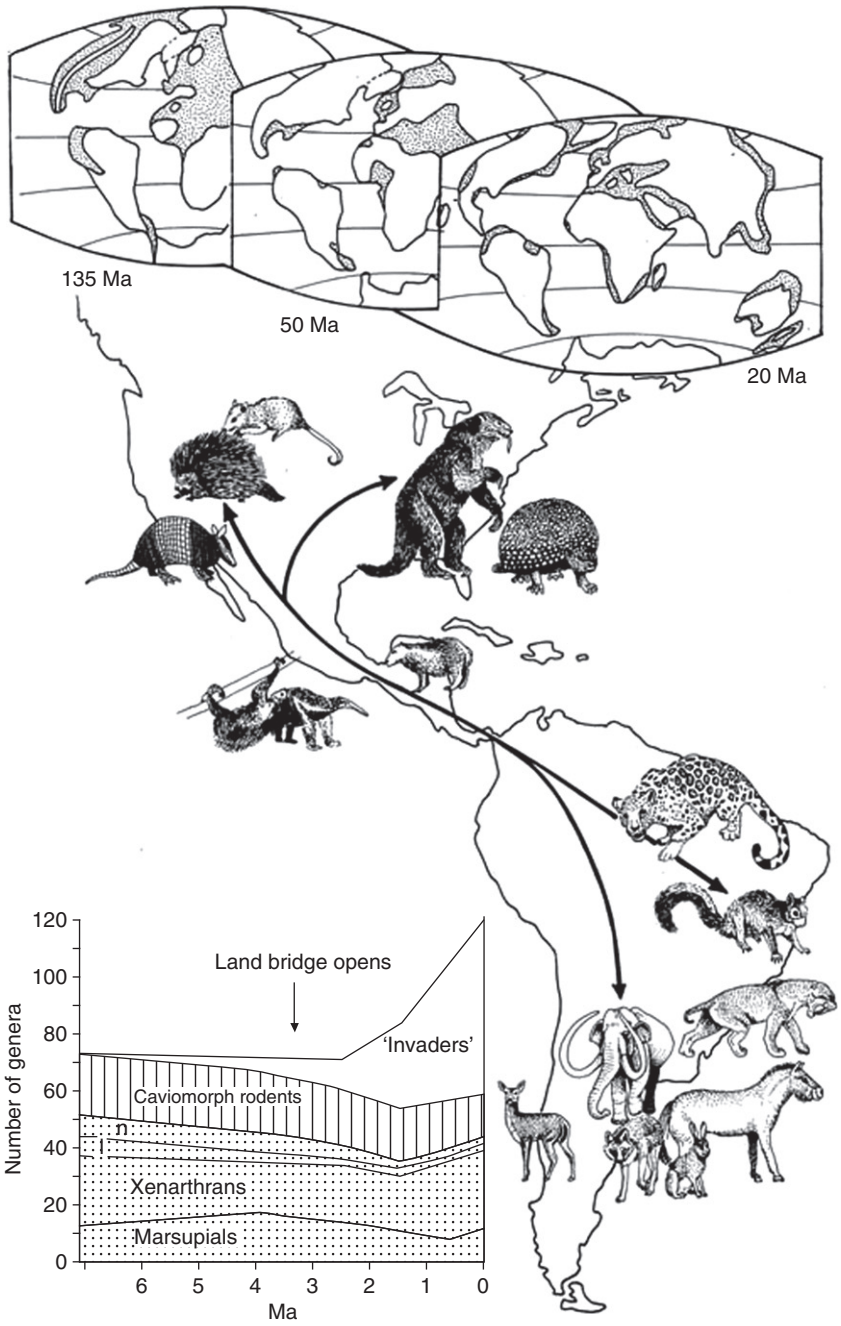

Figure 8 The emergence of the Isthmus of Panama promoted the great American biotic interchange (GABI) between North and South American terrestrial vertebrates together with the radiation of the shallow-water marine benthos of the Caribbean Sea. l, litopterns; n, notoungulates. Reproduced with permission from Benton, M.J., 2005. Vertebrate Palaeontology. Chichester: John Wiley and Sons Ltd.

The Ordovician history of the Lower Palaeozoic Iapetus Ocean provides an ancient laboratory to study the origin and evolution of a marine ecosystem punctuated by islands (**Figure 7**). Tuzo Wilson's classic study in 1966 (Wilson, 1966), in the vanguard of plate tectonic theory, depicted a two-dimensional ocean with orthogonal opening and closing between Europe and North America. The ocean first opened during the late Precambrian with the breakup of a supercontinent, and developed during the Cambrian. 10 years later McKerrow and Cocks (1976) presented a score chart of faunal mobilities against time during ocean closure. Thus, at its widest in the late Cambrian, possibly extending as much as 4000 km across, only planktonic graptolites were similar on both sides of the Iapetus. But as the ocean closed, first pelagic graptolites and later the mobile and eventually fixed benthos, the trilobites and brachiopods, could cross the seaway. By the late Silurian, benthic ostracodes scuffled their way across and by the Devonian, with more or less complete closure, freshwater fishes were similar in Europe and North America. Almost 10 years on Fortey and Cocks (1982) described the ocean in terms of a low-latitude Laurentian continent, a high-latitude Gondwana, and Baltica. The smaller Avalonia rifted from Gondwana during the late Cambrian – earliest Ordovician and together with Baltica moved toward Laurentia during the Ordovician. Neuman (1984) filled the Iapetus Ocean with islands, small suspect terranes with peculiar faunas of endemics together with taxa having otherwise mixed provincial affinities. More recent contributions by Trond Torsvik and his colleagues (Torsvik, 1991) have emphasized that Baltica rotated anticlockwise as it moved toward the equator picking up various terranes as a nappe pile on the edge of the craton. These island complexes functioned as both species pumps and refugia (Harper and Mac Niocaill, 2002; Harper *et al.*, 2008). Both cladistic and phenetic techniques have been used to analyze the large amount of distributional data from within and around the Iapetus Ocean, all confirming in broad terms current palaeogeographic reconstructions of the ocean system (McKerrow and Scotese, 1990; Harper and Servais, 2013).

The removal of oceanic barriers by, for example, land bridges during continental convergence, can also have dramatic consequences for both sides of a closing seaway. For example, the emergence of the Isthmus of Panama has connected North and South America; however it has isolated the Atlantic and Pacific oceans. South America was essentially isolated from North America for most of the past 70 million years, and was dominated by diverse specialized mammalian faunas consisting of marsupials, edentates, unique ungulates, and rodents. However, 3 million years ago the emergence of the Isthmus of Panama provided a land bridge or corridor between the two continents and many terrestrial and freshwater taxa were free to move across the isthmus; the Great American Interchange (GABI) allowed the North American fauna to invade the south and essentially wipe out many of the continent's distinctive mammalian populations (**Figure 8**). South American mammals were equally successful in the north and some such as the armadillo, opossum, and porcupine still survive in North America. Webb (2006) has discussed the dynamics of the interchange suggesting immigrants from the larger area of North America outnumbered those from the south.

Paleobiological Revolution, History of

P Princehouse, Institute for the Science of Origins, Case Western Reserve University, Cleveland, OH, USA

Glossary

Konstruktions-morphologie Also known as constructional morphology, later further elaborated as morphodynamics is a paleobiological theory pioneered by Adolf Seilacher that radically situates fossil and modern species in their ecological and adaptive milieux with particular emphasis on understanding not only the role of natural selection but especially how species' adaptive and evolutionary possibilities are constrained by factors such as the materials available to build their bodies, and the developmental pathways they inherit from their ancestors.

Morphospace A construct developed to include the sum total of all physical and environmental possibilities that could potentially exist in the entire biological realm. Among salient issues of interest is the great quantity of morphospace not filled by any extant or extinct organism. For example, why are there no clams with three shells?

Neontologist A scientist who studies extant species without regard for the fossil record.

Orthogenesis An almost universally discredited theoretical construct descending from an original basis in Lamarckian explanations in which trends in evolutionary history result from an internal driving force that causes evolution to unfold along constrained trajectories, often moving toward greater and greater complexity. Orthogenetic views generally leave very little room for natural selection to shape the course of evolution. The idea flourished in the late nineteenth and early twentieth centuries, primarily among paleontologists.

Phylogenetic constraints Fundamental systems of development, architecture, and biochemistry that limit the directions future evolutionary change can take due to the past evolutionary history of the lineage. For example, bilateral symmetry or deuterostomy or the organizational effects of major gene families.

Phylogenetic patterns Large-scale topology of evolutionary histories arising within and among clades.

Saltation A largely discredited theory that speciation happens very rapidly, due to either macromutations or large-scale chromosomal shuffling, sometimes via a one-generation leap.

Speciosity A speciose clade is an evolving lineage consisting of a large number of species.

Vicariance biogeography Vicariance is a process whereby the geographic range of a species or higher taxon, or ecological community, is split into independent subpopulations by the formation of a physical or biological barrier. These daughter populations maintain parallel ecological roles and accumulate changes due primarily to stochastic factors such as genetic drift. For example, Asian and African rhinoceroses or elephants.

Variously lauded and maligned, the rise of paleobiology as a discipline marked a major shift within the broad field of evolutionary biology in the 1960s and 1970s. Paleobiology – as much a movement as a discipline – called for a revolutionary integration among subfields marginalized by the Anglo-American modern synthesis of the 1930s and 1940s, and cleared the way for ascendant disciplines such as evo-devo.

Although the term was first coined by Yale paleontologist Charles Schuchert (1858–1942) in 1904, and saw occasional use from time to time, it was not widely recognized until a group of paleontologists led by Tom Schopf convinced the Paleontological Society to found the quarterly journal *Paleobiology* in 1975.

The Prehistory of Paleobiology

In addition to Schuchert, historians, and scientists alike have advanced a variety of candidates as founder of paleobiology.

Transylvanian aristocrat, adventurer and Albanian sovereigntist Baron Franz Nopsca von Felső-Szilvás (1877–1933), attempted to develop a new discipline he called Paleophysiology. This terminology captures many elements of the later paleobiology movement, especially the push to envision extinct species not as stages, trends, or tendencies on an evolutionary trajectory but as fully formed entities enmeshed in complex ecological communities to which they were adapted just as well as modern-day organisms are to their current environments. Inspired to become a paleontologist by dinosaur bones found by his sister on the family estate, Nopsca may have seen a parallel between these organisms as paleohistorical actors and the claimed transhistorical nationhood of Albania as an intrinsic entity. As historian of science David Sepkoski has documented (Sepkoski, 2012), promoters of paleobiology have frequently been heavily and often very consciously influenced by the philosophic influences of their views on human history (**Figures 1** and **2**).

Viennese paleontologist and eventual Göttingen professor Othenio Abel (1875–1946) mounted large expeditions in Europe, Africa, and the Americas primarily concerned with vertebrate paleontology. His efforts to promote a theoretical grounding in post-Lamarckian orthogenesis led him to entirely internal mechanisms for evolution and beyond that to a mystical romanticism that at least teetered on the verge of the supernatural (Abel, 1929, 1931; Beurlen, 1932, 1937, 1949). It is not clear to what extent his scientific work aligned with his Naziism but both interests revolved around expectations of inexorable broad trends in history, frustrated by local

conditions – such as adaptation to local environment in paleobiology and what was called the 'judaification' of the universities in human history. Working with Louis Dollo (1857–1931), the two developed their view of paleobiology and in 1928, Abel began publishing the German language journal *Paläobiologica*. It appears they developed the term without having heard Shuchert's prior use (Figure 3).

Synthetic Paleobiology

Due to Abel's association with Naziism, as well as with Lamarckian notions, the term paleobiology did not become a

Figure 3 Othenio Abel (1875–1946).

part of the established lexicon associated with the synthetic theory of evolution. Well before the modern synthesis and unlike most North American paleontologists, German paleontologist Rudolf Wedekind and his student Otto Schindewolf (1896–1971) opposed Lamarckian inheritance of acquired characters and stayed abreast of developments in genetics, particularly Richard Goldschmidt's work. Goldschmidt (1878–1958), perhaps uniquely among geneticists in the early third of the twentieth century maintained an equal regard for the importance of microevolution and macroevolution. Although Schindewolf and Goldschmidt were saltationists, they did accept a role for natural selection and they embraced both the continuous variation of the Morgan/Chetverikov school of genetics, and the macromutations that Hugo DeVries (1848–1935) had credited as the source of new species. Without naming Abel's views specifically as paleobiology and writing entirely within the German view of synthetic evolution, Schindewolf forcefully rejected the views of paleontologists such as Abel and Karl Beurlen (1901–85) and skewered any suggestion of nonmaterial influences in his synthetic work *Paläontologie, Entwicklungslehre und Genetik: Kritik und Synthese* (Reif, 1994, pp. 439–440).

> Wherever the bases of firmly established knowledge are missing or seem to shake, mystical lines of thought expand. In the case of evolution a wrongly conceptualized holism has seduced authors to abandon causal research and strict scientific analysis. Irrational circumlocutions have replaced clear terms and approaches, without providing any heuristic value....For the time being, scientific analysis of organic evolution is limited by the assumption that mutations (of the genes) are ultimate causes. The irrational remainder cannot be resolved any further with the epistemological means available to natural science.

Schindewolf instead stated his goal to unite all evolutionary disciplines within a mechanistic framework: "On this general basis will be given a robust synthesis and a mutual completion of the discoveries from the experimental, exact-inductive methods of research on heredity and from the historic-deductive character of paleontological research" (Schindewolf, 1936, p. 90). Although the spirit of paleobiology was abundantly in evidence, the term was not.

The Paleobiological Impulse

Unlike the view of evolution in Germany, which placed paleontology in a more central theoretical role, proponents of the new synthetic theory in English-speaking countries tended to focus instead on genetics following the work of evolutionary genetics such as Theodosius Dobzhansky (1900–75). The emphasis on genetics and the turn toward an evolutionary biology as a whole, did not escape the notice of paleontologists and evolutionary theorists such as George Gaylord Simpson, who argued vigorously for the importance of paleontology and did the most to bring his area in line with the synthetic theory as it was emerging in the early 1940s: "Not long ago, paleontologists felt that a geneticist was a person who shut himself in a room, pulled down the shades, watched small flies disporting themselves in milk bottles, and thought that he was studying nature." Simpson said geneticists viewed the paleontologist "like a man who undertakes to study the principles of the internal combustion engine by standing on a street corner and watching the motor cars whiz by" (Simpson, 1944, pp. xxvii–xxviii). However, he said, those of differing evolutionary disciplines were finally able "to realize that we do have problems in common and to hope that difficulties encountered in each separate type of research may be resolved or alleviated by the discoveries of the other."

Following along these lines, paleontologists such as Bernhard Kummel (1919–80) encouraged their paleo students to maintain contact with 'neontologists.' An important example is Kummel's student David Raup (1933–2015), who worked nearly as much with zoologist Ernst Mayr (1904–2005) as with Kummel. Raup's 1956 dissertation drew evolutionary conclusions about living echinoids and found close parallels in fossil lineages.

By 1960, the word paleobiology had shed any mystical and political associations and was again available for usage as an indication of an outlook in which extinct organisms could be seen as arbiters of biological theory – interesting and valuable in their own right – rather than as mere documentation that evolution had happened. Setting off a flurry of intellectual activity along these lines, Gus Cooper in his 1958 presidential address to the membership of the Paleontological Society announced that "paleontology is in reality paleobiology" (Cooper, 1958).

This proclamation served as a wake-up call to the field of paleontology that times were changing. In the larger scheme of US paleontology in the 1950s and early 1960s, evolutionary theory was not a major bone of contention. Implementing the goals of the modern synthesis might have been interesting, but most PhD students in geology prepared their dissertations envisioning careers as biostratigraphers for oil companies. Many of these students' dissertations were not significantly different in focus or methodology from those done in the twenties. As long as the evolutionary patterns preserved in the fossil record were consistent and reliable predictors of the location of oil-bearing deposits, practitioners did not need to concern themselves directly with the biological processes acting to produce these patterns of evolution.

But, increasingly, young paleontologists were fascinated by theory and looked to their field to offer exciting new perspectives. David Raup focused his attention on one of the most challenging puzzles in the field – the stunning diversity in shape and size among fossil and extant gastropods. The result was a tour de force in which Raup reduced this great multiplicity to just four parameters. Raup invented a computer model to generate gastropod shell patterns on an oscilloscope. *W*, represented the size ratio of successive generating curves; *D*, the distance of the generating curve from the axis, and *T*, the proportion of the height of one generating curve that is covered by each ensuing turn. Adjusting these parameters created forms resembling oysters, snails, whelks, and other mollusks. What had been a bewildering array of variation – assumed to be due to the action of natural selection building new adaptations to specific local contexts – was tamed by a mathematical computer model. Morphology could be subject to simple constraints on architecture, rather than the all-encompassing action of selection. Raup's coiling parameters were a revelation about the power of paleobiology (Raup, 1962, 1966).

Entering graduate school with Norman Newell (1919–2004) at Columbia University just as Raup's model was making a splash, young Stephen Jay Gould (1941–2002) threw himself into the study of invertebrate morphology. A dinosaur aficionado since the age of 4, Gould became increasingly enthusiastic about the evolutionary synthesis in high school, especially through Simpson's *Tempo and Mode in Evolution* (1944) and turned his attention toward invertebrates as good indicators of patterns and processes at work in evolutionary transformations. At Columbia and the associated American Museum of Natural History, Gould had access to spectacular fossil collections and coursework with hero of the modern synthesis, Theodosius Dobzhansky. Precocious and prolific, Gould believed in pushing the envelop on everything he put his hand to. Newell encouraged him to search broadly and introduced him to the work of Schindewolf and his student Adolf Seilacher (1925–2014), who had done extensive field work in contact with Preston Cloud's (1912–91) US Geological Survey group. Seilacher was developing his theory of *konstructions-morphologie* (later expanded to morphodynamics), including a model that came to be called Seilacher's triangle, in which organisms were perceived through a three-way causal nexus of multiple constraints on variation: functional (including ecology, selection, and adaptation), phylogenetic (including developmental), and fabricational (material and architectural). Seilacher had a gift for imagining extinct organisms fully situated in their home environments and this led to a radically detailed paleobiological vision – and many more questions. Why was morphospace so sparsely populated, and largely in clumps. Many morphologies and ecological roles seemed to offer highly beneficial evolutionary opportunities. Would these neglected spaces become populated in the fullness of time? Or were there evolutionary constraints that natural selection could never overcome? That no matter how advantageous such lifeways might be, the adaptive landscape offered no route to them due to the limits placed on lineages by virtue of their prior evolutionary history? To better understand the lifeways of extinct organisms, Seilacher soon collaborated with Raup on computer models to generate trace fossils such as tracks, trails, and burrows.

Gould's primary interest throughout his career was the evolution of form and he became fascinated by Wentworth

Thompson's (1860–1948) and Julian Huxley's (1887–1975) work on allometry and maintained a correspondence with Huxley throughout graduate school. Huxley provided a fateful boost to Gould and to the paleobiological revolution when he recommended that the prestigious Cambridge Philosophical Society journal *Biological Reviews* request a review article on allometry from Gould, who was still only a graduate student at the time. A domino effect from this review ensued establishing Gould's reputation as a promising paleontologist, and contributed to his professorship at Harvard and tenure before age 30.

Niles Eldredge (1942) had been an undergraduate at Columbia University when Gould entered graduate school and the two became friends, sharing a passion for theory – including one of Eldredge's special enthusiasms, speciation. By the time Gould moved on to Harvard, Eldredge had become Newell's heir apparent at the American Museum of Natural History. Gould and Eldredge together had a platform from which to help launch paleobiology's new fortunes a few years later via a new theory on speciation – punctuated equilibria.

Paleobiology's New Start

Concomitant with theoretical movements in the 1960s, the practice of paleontology shifted away from an emphasis on detailed monographs specializing on individual taxonomic groups (e.g., horses, trilobites, scleractinian corals, and trigonian clams) – documents mirroring the interests of petroleum geologists as they tracked morphological changes through the stratigraphic column. The post-Sputnik generation of paleontologists focused on picturing fossils more holistically as living organisms – as producers and products of energy flow within ecological communities, on patterns in the history of life. At the same time they sought a theoretical grounding in the same vein as the physical sciences. They mounted a reductionist search for evolutionary mechanisms as inferred by comparisons across taxa. Thomas Schopf (1939–84), for example, wanted to find the 'gas laws of paleontology.' Stephen Jay Gould later described Schopf's ambition: "Tom had a sublime vision of regularity. He yearned to convert an empirical field, manifestly short of ideas to unite its fascinating particulars into a science based on experiment, construction of null hypotheses, rigorous testing and the possibility of rejection to move forward toward an agreement that all could share" (Gould, 1984). As the United States increased the funding and profile of science in the 1960s, the paleobiological community expanded, with a concomitant move from contemplative isolation to vigorous collaboration.

Yale University played a pivotal role in the transformation from taxonomically oriented, monographic paleontology to an interactive, dynamic paleobiology. A critical mass of enthusiastic students including Richard Bambach, Peter Bretsky, Jeremy Jackson, Jeff Levinton, Jerry Ricekin, Steve Stanley, Sara Stuart, Ken Walker, and undergraduate Robert Bakker among many others began working very closely with evolutionary ecologist G. Evelyn Hutchinson (1903–91).

Although it was the students' coordination with Hutchinson that really caught fire, the changes at Yale were in large part instigated by paleontologist Lee McAllister. Inspired by the growing funding for science in the wake of Sputnik, and with degrees in business and philosophy and an amateur interest in geology, McAllister saw the subfield of paleontology as an underachiever that lacked leadership, just the sort of field for a young man looking to make a splash. Securing a PhD in short order with a dissertation on Devonian bivalves, he landed a position at Yale, vowing that if not admitted to the National Academy of Sciences by age 40, he would quit science and go into administration. McAllister's students came to number among the most prominent paleontologists in the US, but he was not to achieve his goal of the National Academy. McAllister went into administration after the Paleontological Society awarded the first Schuchert Prize in 1973 to David Raup, who was by then recognized as a brilliant theorist who combined mathematical wizardry with sensitivity to organic form. Raup soon thereafter was inducted into the National Academy of Sciences, and McAllister became a highly successful dean at his alma mater, Southern Methodist University. McAllister taught at Yale for scarcely a decade and had no more than a dozen students, yet these students were highly productive and went on to play prominent roles in the budding new paleobiology movement (Princehouse, 2003).

McAllister added the bracing air of ambition to the mix, urging students to investigate new sources of evidence, so much so that the students objected to what they saw as less than pure-hearted motives, but even radical dinosaur paleobiologist Bakker admits McAllister must get credit for it. Whomever and whatever was responsible for the dynamic spirit of Yale paleobiology, the chemistry was certainly there for this young group of students in the sixties (Princehouse, 2003).

McAllister's first graduate student was Richard Bambach, who studied, he said, "seafood through time" (Bambach, 1993). Love led Bambach to his initial interest in paleontology. In eighth grade, he developed a crush on classmate Ann Cooper, daughter of Smithsonian brachiopod paleontologist G. Arthur 'Gus' Cooper – who later announced the modern project of paleobiology. Spending time at the Cooper residence, young Bambach was captivated by all the books on fossils, and fell even harder for paleontology than he had for Ann Cooper. Subsequently, Bambach enrolled as an undergraduate geology major at the Johns Hopkins University in 1952, working with Harry Volks and Tom Amsden. There followed a stint at the Smithsonian, then the Navy, and then graduate school at Yale where Bambach worked with McAllister, Hutchison, Don Rhodes, and John Ostrom, receiving his PhD in 1967. At Yale he had the opportunity to participate in geological field work, especially with Chuck Masters, a graduate student employed by Amoco, mapping Cretaceous facies changes in Northwest Colorado. In the paleobiological and paleoecological atmosphere what otherwise in traditional biostratigraphic hands might have been more useful to the petroleum industry than to evolutionary theory, Bambach's dissertation on Silurian *Arasaque* clams from Nova Scotia sent him down to New Haven harbor to make ecological comparisons with modern clams, much as Raup had done with echinoids. McAllister had been searching the literature for ecological data on clams and, somewhat in the spirit of numerical taxonomists Robert Sokal and Peter Sneath, had developed an index of morphology, ecology, and behavior.

Bambach and fellow graduate student Steve Stanley xeroxed his notebooks, noted conflicts, and refined the analysis. In 1972 Stanley drew on this to develop the hypothesis that predation stimulated rapid evolution of novelties in the Cambrian explosion, forcing prey animals to evolve defenses such as shells, rapid swimming, and burrowing. These had secondary effects in opening up evolutionary possibilities: hard shells led to filter feeding, and burrowing introduced animals to new food resources. In 1975 Stanley introduced the highly influential concept of species selection.

The paleobiological approach in South Africa goes back at least to the days of Raymond Dart (1893–1988), who emphasized the ecological adaptations of *Australopithecus*. Getting her PhD at the University of the Witswatersrand shortly before Stanley's species selection paper appeared, Elisabeth Vrba (1942) was well equipped to join the fray. Like Stanley's macroevolution work, her turnover-pulse hypothesis explored higher level macroevolutionary phenomena, such as vicariance biogeography, extinction, and speciation arising especially due to major changes in climate. Her work on exaptation with Gould was highly influential in helping paleobiologists conceptualize the meaning(s) of adaptation (Gould and Vrba, 1982).

In California interest in paleoecology also caught on, coupled with a focus on biodiversity. There, the movement was spearheaded by James Valentine, who credited G.G. Simpson as his primary influence: "He was an evolutionary theoretician; ...he showed that the fossil record...could be used as a source of evolutionary information from which theories could be built" (Princehouse, 2003, p. 217). Valentine's landmark 1967 paper on mathematical models and 1973 book on evolutionary paleoecology were seminal. From there he followed his morphological interests with a focus on systematics, addressing questions such as how to define complexity. This led him to a theory based the evolution of fundamental body plans. On his view the only objective measure of complexity is the number of distinct tissue types generated in the developing embryo. These serve as the basis for the origin of phyla and the enduring shared fundamental organization of their constituent members.

A Chancy Young Man's Game

Throughout the fifties, dissertations were written and paleontology inspired by the modern synthesis appeared to be flourishing. Simpson's early work bringing paleontology to the synthesis was influential as well as inspirational. But young paleontologists increasingly felt the synthesis was moving toward a more restrictive, gradualistic, selectionism that tended to relegate paleontology to a bookkeeping role. They felt other subfields expected them to document the fact of evolution, but not to be a potent source of evolutionary theory. Following the 'central dogma' of genetics that information flows from the genes to the rest of the organism, another central dogma seemed to be developing in the discourse of evolution – that theory flows from genetics to other evolutionary subdisciplines. Bambach credits Simpson's early *Tempo and Mode in Evolution* (1944) as fundamentally important to his vision of the emerging field of paleobiology, whereas he found Simpson's later *Major Features of Evolution* (Simpson, 1953) less important and inspiring. Young paleontologists respected Simpson immensely, but they also worried that perhaps Simpson had sold the field short.

Into that rather orderly social scene burst some self-described 'young turks' looking to turn the study of evolution on its head – as well as some who were simply following up what seemed most interesting to them. The beginning of the modern era of paleobiology was highlighted by the near-simultaneous appearance of four major works between 1967 and 1969: Norman Newell's paper on the episodic nature of extinction, Peter Bretsky's summaries of marine invertebrate assemblages through time, *The Fossil Record*, a proceedings volume from a conference cosponsored by the Geological Society of London and the Paleontological Society that provided the first comprehensive database designed specifically for studies of the nature of the history of life, and James Valentine's work charting the diversification through time of microscopic forams, and various metazoa. As with noting exactly when speciation takes place in a gradually evolving lineage, it is difficult to identify just when the change in question took place in the field of paleontology. It had not arrived yet in 1960, but the new research program was in full swing before 1975 when the movement gave rise to a new flagship journal *Paleobiology* edited by Tom Schopf.

Thomas J.M. Schopf had a thoroughgoing commitment to science and its methods and processes. He combined this broad orientation with a deeply felt desire to turn paleontology into a source of theory that would be recognized as such by scientists in any field. In his understanding this meant working up theories – especially mathematical theories – and testing them empirically, taking the risk of being wrong in a straightforward Popperian manner. Gould admired the way Schopf consciously directed all the energy he could muster to developing and promulgating his rather radical view of life's order. Gould later summed him up: "Tom Schopf was a brave man." Schopf said his main motivation was "to bring the approaches and information of biology to bear upon paleontology." He was especially concerned with bringing theory into paleontology "to make that field less anecdotal, more rigorous and less tied to descriptive work" (Gould, 1984). Although Schopf's gas laws of paleontology did not catch on, Bambach and others credit Schopf's contribution as a major driver of the effort to pioneer the new field of paleobiology (Princehouse, 2003).

At Ohio State, Schopf wrote his thesis on conodonts, and had a life-long interest in ectoproct bryozoa. Although Schopf did not have the social and curricular foundations of the students from the East Coast schools, he absorbed the spirit of the modern synthesis and learned a great deal of population biology on his own. Schopf's autodidacticism continued throughout his life. When the new genetic sequencing techniques were first being developed, Schopf took a sabbatical to apprentice himself in a molecular biology lab at the California Institute of Technology. His father, William J. 'Jim' Schopf (1941–), was a paleobotanist for the United States Geological Survey in Columbus, Ohio who instilled in Tom a nearly obsessive work ethic in a milieu of very conservative paleontology. This combination eventually landed him a position at the University of Chicago. Tom Schopf and his

brother, J.W. 'Bill' Schopf, were inspired by their father's example to want to make major contributions (Princehouse, 2003). For Bill Schopf, this meant exploring the very earliest organisms. For Tom Schopf, always competitive with his brother, it meant a conscious effort to reinvent the field. To turn it into a 'chancy young-man's game' (Gould, 1984).

Establishing Paleobiology

Schopf was midwife to the new movement. He used, in Gould's words, "socially impolitic ways to seek laudable goals" (Princehouse, 2003, p. 207). He organized people, brought them together, and convinced them to work together – even though he, himself, did not have the most charismatic personality. He organized key conferences, big and small, edited the influential volume *Models in Paleontology*, that contained Eldredge and Gould's first punctuated equilibria paper, and he created the journal *Paleobiology*. More than any other single person, Schopf shaped the movement. He was a ruthless editor, rejecting half the manuscripts submitted to *Paleobiology*, a practice unheard of in paleontology in those days. As Neil Shubin said, he "simply didn't have a off switch" (Shubin, 2013). He was single-minded in his efforts to move the profession into a sound theoretical channel.

Schopf sought to develop the practical aspects of the new theoretical field. A major focus was to systematically bring together people whom he thought could pioneer new methodologies and theories for paleobiology. Schopf targeted Gould, in part due to his revolutionary interests but aided by his proximity when both were in Woods Hole. This gave Gould a deeper understanding of Schopf than those who met him only at conferences. Schopf's students at Chicago found him a hard taskmaster, but intellectually very exciting. Instead of sticking just to the fundamentals of the field, Schopf's introduction to paleobiology class explored cutting-edge theory. Students asked themselves who were the then relatively unknown Raup and Gould that Schopf referred to so much. His discussions of theory, grand pattern, and Seilacher's *konstruktions-morphologie* were a little daunting to students, but they did not realize just how unusual their education was. Rebecca German later commented: "For Tom to embrace that was far more revolutionary than we realized" (Princehouse, 2003, p. 209).

A pivotal moment in the history of paleobiology took place over winter break in 1972 when Schopf invited Raup, Gould, and Dan Simberloff, a math major turned ecologist and former grad student of E.O. Wilson (1929–) with an interest in paleontology, to the Marine Biological Laboratories (MBL) at Woods Hole, Massachusetts to take a sharp look at clade diversity with an eye to applying population genetics to the fossil record. Raup said Schopf had the idea that if he could put "a small group, maybe representing several subdisciplines, together in a quiet environment conducive to brainstorming that we might be able to come up with some new and better ways of looking at the history of life" (Raup in Princehouse, 2003). Simberloff had been present at a similar retreat, which had resulted eventually in MacArthur and Wilson's island biogeography theory. This was Schopf's model for such a meeting, and beyond that he was hopeful that an expanded model could be created by substituting speciation rates and geologic time for the immigration rates and short-range time of the island biogeography model. Gould described Schopf's role in the collaboration: "Tom was just a real go-getter. You can't say he was a politician, because he was too undiplomatic a personality. He wanted to get things happening and liked to do it institutionally if he could."

A relatively rare combination at the time, young Simberloff was quantitatively inclined as well as a naturalist and made use of a prized possession, an early Texas Instruments programmable calculator. The four discussed the state of the field and proposed potential models and methods for four days, with Gould's student Jack Sepkoski (1948–99) joining on the last day. One feature of the disciplinary landscape that impressed them was the colossal database that paleontology and associated stratigraphy represented and with which very little had been done except for traditional taxonomic studies for monographs and informing biostratigraphy for petroleum companies. Much of the comprehensive *Treatise on Invertebrate Paleontology* had been published by that time and using it as a data source Sepkoski was already putting together databases working with Gould. Sepkoski later joined forces with Raup at Rochester and the University of Chicago to produce complexly integrated paleobiological work on biodiversity and extinction throughout the history of life on earth, including the controversial result that mass extinctions occur at regular 26 million-year intervals. They interpreted this regularity to suggest an extraterrestrial phenomenon such as a twin star to our sun. If found, Raup wanted it to be named Nemesis. Alternatively, Gould suggested Siva, the Hindu god who destroyed with one hand and created with the other – since mass extinctions usually cleared the way for the evolution of novel forms.

The MBL group wanted a fresh look that was quantitatively based. The idea developed to explore a null hypothesis in which everything in the history of life was simply random. As Gould (Princehouse, 2003, p. 213) put it: "Any non-random model requires that you make a causal theory about the world, and we wanted to see what you could do minimally."

Schopf's intuition that putting the right people together with an explicit mission succeeded. Though they did not come away from the meeting with a manifesto per se, their perception of the field's importance and its potential reoriented their thinking and that orientation soon bore fruit. Raup, who had experience with mainframe computing took the equations Simberloff produced from the meeting and developed full-fledged computer programs to produce simulations of evolutionary history. This became known as the MBL model.

The MBL model relied on Monte Carlo random number techniques. They wanted to break evolutionary biodiversity down to its minimal sufficient parameters. Natural selection was to be avoided at all costs. The lineages would have three possible fates each generation: a bloodline could go extinct, or it could stick together as one lineage, or it could split into two lines. At the beginning of each simulation, random numbers were generated to use as 'seeds' for each clade. At first the chance a lineage would persist into the next generation and branch was greater than the risk of going extinct. When the 'island' reached an equilibrium point beyond which the carrying capacity was exceeded, the program switched over to giving each lineage an equal chance of branching or extinction

to keep the population right around this stable size. Within the set of species that survived, each line had an equal chance of splitting or continuing solo into the next generation. The run ended when any of three things happened: a set length of time ran out; all lineages went extinct; or when the population reached 500 lineages – which was all the computer's memory could handle!

Higher taxa were formed when a lineage reached a certain speciosity. These clades where then represented in the visualization diagrams long in use in paleontology. These 'spindle diagrams' charted the birth and death of a higher taxon. In real-world paleontology, the spindles were defined by points marking the first and last known occurrence of the group in question and the breadth of body of the spindle indicated its relative florescence. The simulations produced interesting results – familiar patterns including evolutionary radiations and mass extinctions. Traditionally, species with similar lifeways were not expected to share a niche. So when a pattern emerged from the fossil record in which one clade waxed simultaneously with another's waning, the assumption was that this was driven by natural selection's competitive exclusion principle. The MBL simulations allowed another possible interpretation: that these were just ships passing in the night.

A series of papers resulted, demonstrating that even in a random system, patterns would emerge that paleontologists were accustomed to interpreting as due to natural selection building Darwinian adaptations. Most stunning to Raup and Gould was a project the two worked on to simulate the evolution of morphology per se, not just biodiversity. To their astonishment they found emergent properties arising without any selection toward that goal but as an intrinsic element of complex systems (Raup and Gould, 1974). This was very unexpected and ran sharply counter to the the primary perception of causality in biology and paleontology at the time. The work was highly controversial but provided an alternative model against which to evaluate claims of long-range adaptation and inexorable adaptive trends in the history of life. The ultimate goal was not just building abstract models, but in comparing them to actual data. Gould set Sepkoski – also skilled with computers – to work tabulating every known occurrence of every fossil species known into a form suitable for computer analysis. A decade later he was still at it. Eventually Sepkoski produced what Gould felt was sorely needed in the field: hard data against which to compare the null hypothesis MBL model.

In California, James Valentine and Jere Lipps among others were posing similar theoretical questions about what could be inferred from the enormous mass of paleontological data that had been published by Preston Cloud's USGS group in successive volumes of the *Treatise on Invertebrate Paleontology* and in the many new journals appearing, such as *Lethaia* (which published Seilacher's triangle paper) and *Micropaleontology*. Valentine and his students rigorously explored the heuristic value of random models, tying them in with increasingly sophisticated understandings of the fossil record, population biology, and genomics. Similar interests and approaches led to good-natured and productive competition between the Raup–Sepkoski group in Rochester and Chicago and the Valentine–Lipps group in California. Both groups generated a host of innovative hypotheses about causes behind the large-scale patterning of biodiversity, mass extinctions, and other prominent features of the history of life. These new traditions were soon seen in such developments as the integrative biology department at Berkeley and Neil Shubin's laboratory at Chicago, a hybrid where fossils are prepared alongside wet lab experiments on embryology and development.

Paleobiology Comes of Age

Central to the paleobiological revolution were not so much the establishment of new institutions and technologies (though computers, and the founding of the journals *Lethaia*, *Palaeos*, and *Paleobiology* played significant roles) but a new preoccupation, largely on the part of paleontologists, with questions of a particular sort. Where the modern synthesis centered on the explanatory power of natural selection acting on copious random mutation, the new approach concerned parameters. What opportunities and constraints existed in genetic, developmental, and ecological systems? How did these evolutionary parameters bear on the long-term patterns of the evolutionary history of life on earth? Can process and pattern be uncoupled? If not, then how isomorphic are they and why?

The 'young turks' pursued the direction mapped out by G.G. Simpson's major synthesis work *Tempo and Mode in Evolution*. They read widely across evolutionary disciplines, but did not acquiesce to the role they perceived as having been assigned to paleontology. Michael J. Benton commented that some "will recall palaeontological meetings at which fun was made of the work of statistical palaeontologists. Some … were based on valid concerns, but others were founded on a pessimistic view of the potential of palaeontology" (Benton, 1999). Echoing Cooper's (1958) address, Bambach indicated that paleobiologists "practice an exceptionally broad interdisciplinary subject. We are no longer the 'handmaiden to stratigraphy" (Princehouse, 2003, p. 224).

The power and prestige of paleobiology was greatly enhanced beginning in the 1990s when the fields of genomics and evolutionary developmental biology ('evo-devo') began providing additional understanding of the mechanisms of morphological variation. Although paleobiologists, especially Gould (1977), played some role in inspiring the evo-devo movement, its force came largely from within the fields of molecular biology. That the new framework had been developed quasi-independently from multiple different evolutionary subfields bolstered the claims – and reputations – of those who had come to similar conclusions based on fossil evidence. Genomics and evo-devo supplied a physiological basis for phenomena such as quick morphological change, mosaic evolution, widespread parallelism among related lineages, etc. Issues that until recently had been the almost exclusive province of paleontology. The paleobiological revolution had come full circle and unified with these new fields to produce a richer, more adequate, more fully synthesized evolutionary theory.

Parallel and Convergent Molecular Evolution

DD Pollock and ST Pollard, University of Colorado School of Medicine, Aurora, CO, USA

Glossary

Adaptation It refers to long-term evolutionary modification and maintenance of functional traits or molecules in an organism in response to natural selection. Adaptation does not necessarily imply optimization because a trait may have constraints in how much it can be modified, and also because it is sufficient to improve a trait until it is 'good enough.'

Ancestral reconstruction It is the process by which ancestral traits or sequences that no longer exist in living organisms are inferred. In recent decades, ancestral protein molecules have been reconstructed and expressed in the laboratory to test their function and obtain more direct inference of how functions have evolved over time. Because of the multiplicative accumulation of uncertainty in ancestral reconstruction among all sites in an alignment, because of coevolution or epistatic interactions among sites, and because of laboratory experimental uncertainty, such inferences cannot be assumed to be exact reconstructions of sequence and function, but are often presumed to be strong indicators of trends in functional evolution.

Branch pairs They are two branches (sometimes called edges) on a phylogenetic tree that are compared as paired lineage segments for which the amount of convergent evolution can be measured.

Convergent evolution It occurs when two biological traits in two separate lineages independently evolve to similar end points. At the molecular level, a key goal is to distinguish between convergent events that have arisen because of adaptation, and possibly neutral convergent events that occurred by random drift and were thus not driven by positive natural selection.

Divergence It refers to the process of traits or sequences becoming more different between lineages over evolutionary time by the accumulation of differences in each lineage that are not convergently replicated in the other.

Evolutionary distance It refers to the expected number of substitutions that occurred between species or along branches of a phylogenetic tree. Evolutionary distance in neutral evolution is the product of the mutation rate and time, and thus its expectation is proportional to time if the mutation rate is constant, although the outcome of actual number of substitutions along a lineage is subject to stochastic variation.

Homology It refers to traits in an organism that are descended from a common ancestor. In molecular evolution, in gene families that have incurred duplications, homologous genes are divided into orthologs, which are only related by speciation events, and paralogs, which are related by gene duplication events.

Homoplasy It is a cladistic term that refers to traits that cannot be resolved as having occurred just once on a phylogenetic tree, and thus must have arisen by convergence. Such traits cannot be resolved parsimoniously with other traits on a phylogenetic tree, and thus confound phylogenetic inference using cladistics methods.

Long branch attraction It is the phenomenon by which the accumulation of nonadaptive convergent events, or homoplasies, which is predictably greater between longer branch pairs than between shorter branch pairs, will lead to false phylogenetic signal that tends to 'attract' or falsely join long branches if the true phylogenetic signal is not sufficiently strong.

Multiple sequence alignment It is the process by which positions in different sequences are ordered with respect to each other such that all corresponding sites in the alignment represent inferred homologous positions.

Neutral evolution It is evolution that occurs by random drift, meaning that the probability of fixation of new alleles is proportional to their starting frequency. At sites that evolve neutrally without selective constraint (and without certain interfering mutation repair processes), the substitution rate is expected to be equal to the mutation rate.

Parallel evolution It is sometimes used as a synonym for convergent evolution and homoplasy, or may refer to convergent evolution that occurs in experimental replicates, or in closely related species under similar ecological pressures to adapt. At the molecular level, it may sometimes be used to indicate convergent evolution with the same or similar molecular mechanism, or involving the same genes, and at the amino acid level it may refer to convergent evolution from the same ancestral amino acid. In this article we advocate that the term should be deprecated.

Phylogenetic inference It is the process by which evolutionary relationships, or branching order and timing, among species or sequences, is inferred.

Position In a functional molecule such as a protein it may refer to the amino acid location along the sequence and in three-dimensional space. Positions in difference sequences may be related to each other as inferred homologous sites in a sequence alignment.

Sequences They refer to the ordered components of biological molecules such as DNA (made up of four different deoxyribonucleic acids), RNA (made up of four different ribonucleic acids), or proteins (made up of twenty different amino acids).

Sites In an alignment of amino acids or nucleotides it refers to aligned positions that are inferred to be homologous, and thus related by substitutions alone rather than insertion or deletion events.

Introduction

The idea of convergence is central to the study of evolution because it addresses the key concepts of adaptation and replicability. Roughly, convergence happens when two biological traits in two separate lineages independently evolve to similar end points. The concept can cover a broad range of evolutionary events, from convergence of function and morphology to gene duplication, expression levels, and sequence. At the organismal scale, convergence is usually assumed to involve adaptation in response to similar selective pressures from the environment, but at the molecular scale this is not always so. There is a great deal of excitement to the current study of molecular evolutionary convergence because in the age of genomics, large amounts of information are becoming available that can be used to elucidate the molecular mechanisms of phenotypic convergence. Researchers can now ask detailed questions about whether the convergence of aquatic mammals to life in the sea (Foote *et al.*, 2015), echolocation in bats and dolphins (Parker *et al.*, 2013; Liu *et al.*, 2010), or song in different groups of birds (Zhang *et al.*, 2014) involve similar genes expressed in similar locations with similar amino acid changes.

Integrating Molecular Convergence from Molecules to Phenotypes

To understand and dissect the mechanisms of convergence, it is necessary to consider how phenotypic convergence of organisms is achieved across multiple organizational levels, from molecules to phenotypes. Adaptive pressures act on organisms as a whole, and the response will be integrated from amino acid changes that alter functional aspects of proteins, regulatory and transcriptional changes that alter when and where molecules are expressed, and interactions among system components. We discuss here just a few of the many examples available in the literature, particularly pointing out a couple of noteworthy recent genome-wide convergence analyses.

Molecular convergence of amino acids in proteins was first observed in lysozyme as an adaptation to expression in the acidic environment of the stomach as a digestive enzyme in cows (ruminants) and colobine monkeys (Stewart *et al.*, 1987). This was later augmented by observation of amino acid convergence in RNAses in the same environments (Schienman *et al.*, 2006; Zhang, 2003). A recent example is that of convergence in the molecule prestin, involved in adaptation to echolocation in dolphins and bats (Liu *et al.*, 2014; Davies *et al.*, 2012). The example of adaptive convergence at positions involved in modulating proton transport in cytochorome C oxidase between snakes and agamid lizards (Castoe *et al.*, 2009) is the largest and densest (per amino acid position) example of convergence that we are currently aware of, and is large enough to allow characterization of the types of amino acids and positions involved in convergence (Figure 1). The adaptive burst in the ancestor of all snakes is also notable for having generated follow-on convergent events in the subsequent phylogeny of snakes, some of which are also convergent with amino acid changes in the ancestor of another tubular legless squamate, *Rhineura* (Castoe *et al.*, 2008). These events provide examples of convergence to the same amino acid at the same position, physicochemical convergence to amino acids with the same functional group (hydroxyl, or -OH) at the same site, and convergence to add positively charged amino acids in a tightly clustered region at the base of a proton channel (some at the same amino acid position and some at different positions).

Convergence on the genome level has been observed in laboratory experiments involving phi bacteriophage, *E. coli* in high temperatures, and yeast under nitrogen starvation (Wichman *et al.*, 2000; Tenaillon *et al.*, 2012; Hong and Gresham, 2014). A general observation under the conditions of these studies (involving selection on a large number of possible genes) is that although adaptive changes were observed repeatedly in the same genes (i.e., convergent usage of genes), it is rare to observe convergence of the same amino acid at the same position in the same gene because there are so many alternative adaptive responses. Foote and colleagues (Foote *et al.*, 2015) considered convergent evolution in the much larger mammalian genomes that adapted to a marine environment. Echoing the viral and microbial results, they showed that while there was widespread convergence between three different marine mammals at the amino acid substitution level, they were unable to separate what might have been adaptive from the noise of what is expected with such a large number of statistical comparisons. Further analysis of genes showing signs of positive selection in multiple marine mammal lineages detected convergent changes plausibly related to adaptation to a marine environment, but the point remains that the proportion of convergent changes is small, and many adaptive responses are not convergent in replicates under both experimental and natural conditions.

Molecular adaptation is also thought to occur rapidly through regulatory change. Zhang and colleagues assessed expression levels of genes associated with song learning in birds and found that increased expression levels of certain genes were often convergent in the song-learning nuclei (Zhang *et al.*, 2014). In a somewhat more complex example, convergent evolution of the transcription factor SP1 in mammals and birds (to different amino acids, but at the same position) appears to have convergently altered its structure and binding specificity. This then caused convergent evolution at hundreds of SP1-regulated binding sites in both mammals and birds (Yokoyama and Pollock, 2012). This system further demonstrated follow-on convergence in regulatory networks, as there were later convergent amino acid substitutions in homologous SP transcription factors in various mammal and bird lineages that co-regulate some of the same regulatory modules by binding to SP1 binding sites. Notably, these convergent changes in the co-regulatory paralogs were at the homologous position as the older convergent changes in SP1, and to the same amino acid as in chicken SP1.

A Conceptual Understanding of Convergence and Parallelism

Despite its importance, and despite its deceptively simple definition, the exact meaning and characterization of convergence is not always clear. This echoes the lack of clarity

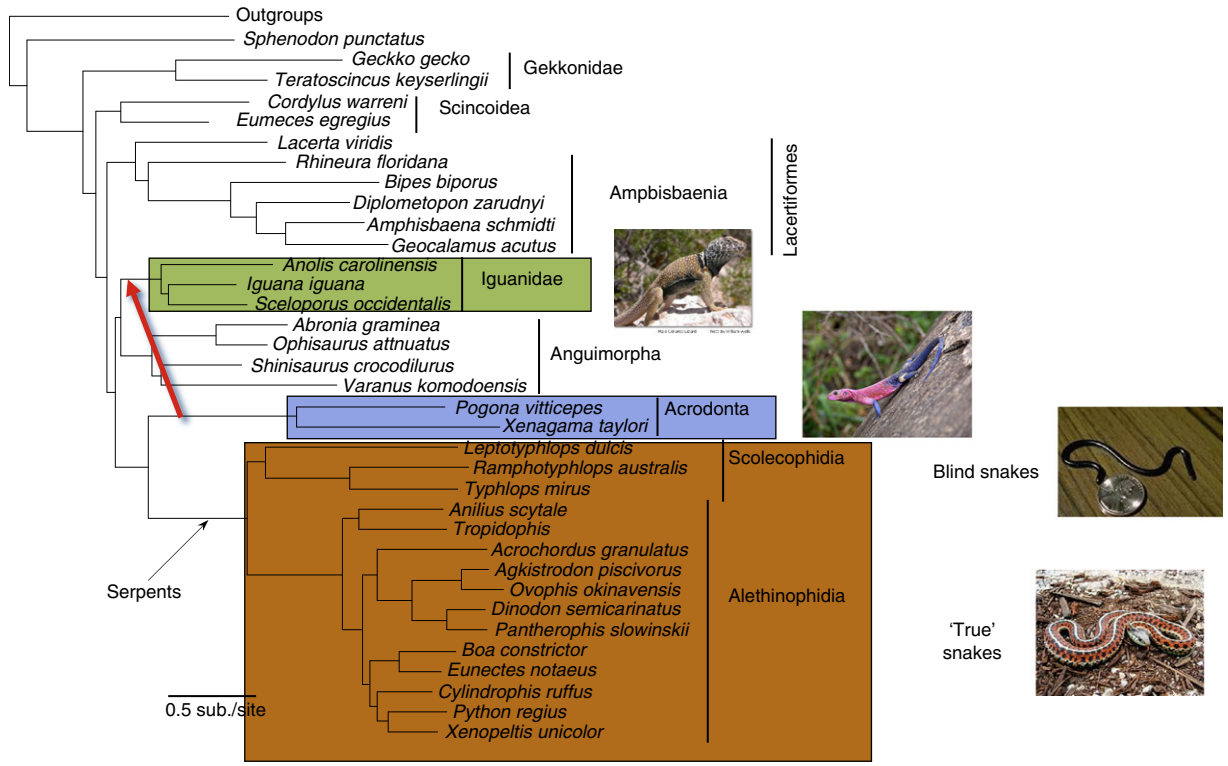

Figure 1 The effect of convergence on phylogenetic tree reconstruction. This figure shows that the mitochondrial data links the acrodont lizards (blue box) in a sister relationship with the snakes (orange box), although most nuclear and morphological evidence suggests that they should be grouped with iguanid lizards (green box), as shown by the red arrow. Detailed analysis showed that the mitochondrial phylogeny was driven by convergent amino acid substitutions at otherwise usually conserved sites. When the 500 codons that most support the mitochondrial tree are removed, the remaining mitochondrial data suggests the same tree as the nuclear data. A similar result was seen if the top 5% most convergent amino acid sites are removed. Modified from Castoe *et al.*, 2009. Evidence for an ancient adaptive episode of convergent molecular evolution. *Proceedings of the National Academy of Sciences of the United States of America* 106(22), 8986–8991.

surrounding the term 'adaptation' itself, which can be difficult to distinguish from selection and can be notoriously difficult to prove. The uncertainty over what is and is not convergence is further confounded by the common use of the term 'parallel evolution,' which is sometimes used as a synonym of convergence or in different ways that can appear mutually exclusive to one another. The intended meaning of the authors is not always clear. At the organismal level, parallel evolution embodies the idea that closely related organisms might respond to similar selective pressures in similar ways. As discussed in a comprehensive review by Arendt and Reznick (Arendt and Reznick, 2008), the idea of parallel evolution thus sometimes applies exclusively to phylogenetic considerations (how closely related the two species are), exclusively to mechanistic considerations (whether the pathways used to effect the phenotypic change are the same), or some mixture of the two. These authors argue strongly and convincingly for the general use of 'convergence' and deprecation of the use of 'parallel evolution,' a usage also followed in the comprehensive review by Christin, Weinreich, and Besnard (Christin *et al.*, 2010) and at the MapOfLife website (mapoflife.org). At the molecular level, the use of parallel evolution has sometimes been focused down even to the trivial level of the individual amino acid, adding another usage to distinguish the cases where the common ancestor is the same (parallel) or different (convergent) (Zhang and Kumar, 1997). Using the same data to argue nearly the opposite of Arendt and Reznick, Rosenblum and colleagues (Rosenblum *et al.*, 2014) advocate for using the term 'convergence' only for the phenotypic level, and 'parallelism' only for the molecular level.

The clearest message from these discussions in the literature is that the difference between parallel and convergent evolution is unfortunately muddled, highly controversial, and unlikely to be settled soon. From a practical standpoint, this means that a reader interested in the subject will need to search for both terms, and will need to read carefully to try to understand the usage intended by each individual author, to the extent that it is clear.

In this article, we will follow the usage of Arendt and Reznick, using 'convergence' as the general term and advocating that the use of the controversial term 'parallelism' should be deprecated. This is strongly motivated in part by our own studies of convergent evolution in mitochondrial genomes (Castoe *et al.*, 2009) and on coevolution and epistasis (Pollock *et al.*, 2012), and in part because it makes writing on the topic simpler and more clear. In considering convergent amino acid changes in proteins, for example, we are most concerned with which convergent amino acids caused a convergent structural or functional change, and not whether the convergent events on each lineage arose from a common

ancestor. Because of coevolution and epistasis, the effect of an amino acid replacement may be dependent on the entire protein, and the effect cannot be assumed to be constant over time. Furthermore, given the variation in the evolutionary process across positions in a protein, it is clear that sorting sites by whether or not they have a common ancestor has the perhaps unintended consequence of biasing the groups depending upon rates of evolution at each position. The rate at which sites evolve affects their tendency to contribute to adaptive convergence because of the well-known relationship between function and conservation: the most functionally important positions are usually most conserved and also most likely to be utilized to effect adaptive change (Castoe *et al.*, 2008).

The position we take on usage should not be construed to imply that the distinctions that authors are trying to make when they use the term 'parallel evolution' are unimportant. On the contrary, they involve extremely important questions about how adaptation works, what matters in terms of the changes that occur during an adaptive event, and the degree to which adaptive pathways are replicable. It is clear that the answers to these questions are tied up in the degree of constraint in the adaptive potential of the biological system, and how those constraints change over time. What functional modifications are theoretically accessible to a system, or to an individual protein, at any point in evolutionary time? How does the realm of accessible modifications change over time? Do slightly different adaptive pressures applied to an organism result in similar or very different molecular evolutionary responses? What amount of functional change in a protein or a regulatory system as it evolves over time will lead to different evolutionary responses to similar adaptive pressures? It is our belief that rather than to say an adaptive event 'is parallel' as opposed to convergent, it is better to be clear on precisely what questions are being asked and answered about the degree of taxonomic similarity between the lineages in question and the degree of functional similarity between any of the molecular components.

Discriminating Adaptive and Nonadaptive Molecular Convergence

Perhaps the greatest problem in the study of molecular convergence is how to discriminate adaptive molecular convergence from nonadaptive molecular convergence. There have been a number of claims of large-scale adaptive molecular convergence over the last decade (Parker *et al.*, 2013; Rokas and Carroll, 2008) that have later been thoroughly refuted (Castoe *et al.*, 2009; Thomas and Hahn, 2015; Zou and Zhang, 2015). The primary reason for these mistaken claims is that commonly used evolutionary models do not adequately predict expected levels of convergence under neutrality (Castoe *et al.*, 2009), although in some cases use of indirect tests of convergence and failure to apply proper comparative controls may also have played a role (Thomas and Hahn, 2015; Zou and Zhang, 2015). It has been thought that more realistic models that vary across sites may be adequate to predict convergence levels (Lartillot *et al.*, 2007), but it has been recently shown that the situation is complicated and may require models that vary over time as well as across sites (Goldstein *et al.*, 2015). Unfortunately, such complex models are not well specified with existing datasets, and we can expect intense future analysis and development of approaches to determine the best way to predict molecular convergence using models of amino acid substitution.

In the absence of good predictive models, an alternative approach is to use empirical observation. Such an approach is based on the idea that we expect adaptive molecular convergence between lineages (or branches on a phylogenetic tree) to be rare or moderately rare, whereas we expect that nonadaptive convergence is everywhere. Thus, in principle we can infer the amounts of convergence levels among branch pairs and then determine which branch pairs have excessive convergence relative to the main distribution. However, one additional factor to be considered is that we expect the amount of convergence to somehow be scaled by the total amount of evolution on each of the two branches being compared. To see this, consider that to be convergent, a pair of substitutions must occur at the same site on both branches, and the probability of substitution at each site and branch will be proportional to the total amount of substitution along that branch.

An example of such an empirical approach was developed and implemented by Castoe and colleagues in their analysis of adaptive convergence between ancestral snakes and agamid lizards (Castoe *et al.*, 2009). This approach avoids the direct dependence of convergence on branch lengths by making use of a discovered strong general correlation between convergence (abbreviated C) and paired divergence (abbreviated D), defined as substitutions in two separate lineages that independently evolve to different end points (as opposed to the same end point in convergent events). In this analysis, we found that predicting convergence from branch lengths was much worse than prediction from paired divergence events, which may be related to inaccuracies in the evolutionary model used to predict the mitochondrial phylogenetic tree as well as variation in rates among sites and over time, which may have made the average branch lengths inapplicable to the convergence predictions for the sites involved.

The idea that the ratio C/D of paired convergence and divergence events should be constant and would thus arise naturally from the data makes some degree of intuitive sense. This is because given that paired substitutions at the same site on two different branches have occurred, all else being equal the probability that such events are convergent or divergent should be equal among branch pairs. However, it should be considered that all else is not necessarily equal, in that the ancestral amino acids may have changed over evolutionary time, the composition of the sites that make up the paired substitutions may have changed, and the evolutionary process at some or all sites may have changed. We recently found that nonadaptive amino acid convergence rates do decrease over evolutionary time of separation between branch pairs, with dependence on the specific ancestors involved, the rate of substitution at the sites involved, and a fluctuating evolutionary process due to epistasis or coevolution (Goldstein *et al.*, 2015). Thus, these are important interacting effects, and it is a major challenge to incorporate them adequately in future predictions of adaptive convergence.

Molecular Convergence, Ancestral Reconstruction, and Phylogenetic Inference

Phenotypic and molecular convergence can both in principle be inferred through the observation that distantly related groups of species contain similar traits, while many other species, more closely related to each of the convergent species than they are to each other, do not. However, as we begin to understand how molecular convergence events have led to phenotypic convergence, we generally need to pinpoint when the convergent events occurred with as much accuracy as possible. In other words, we need phylogenetic trees with diverse representation of relevant species to break up critical branches on the trees as much as possible, and then we need to infer on which branches the putative convergent events have occurred. It is useful to do this to understand the timing and possible environmental correlates, but it is essential to do this to limit the large numbers of neutral or unrelated substitutions that are bound to occur on long unbroken branches. To make these inferences, one must also perform ancestral reconstruction to estimate the state of each position at nodes (branching points) of the phylogenetic tree, a process that has error and which may be biased at the sequence as well as the functional level (Krishnan *et al.*, 2004; Williams *et al.*, 2006).

Although phylogenies are necessary to dissect the mechanisms of molecular convergence, both adaptive and nonadaptive convergence may interfere with phylogenetic inference. The example of Castoe and colleagues (Castoe *et al.*, 2009) makes it clear how adaptive convergence can positively mislead phylogenetic reconstruction by systematically and falsely linking distant branches. This can be understood by seeing that if there are a lot of convergent events, the false signal at the sites involved may overwhelm the true phylogenetic signal at the more reliable neutral and well-behaved (or at least not systematically biased) sites. It may then be more parsimonious to resolve the changes on a tree that would make the convergent sites appear to have substituted only once. This problem is made worse by the tendency of adaptive convergence to occur at functionally important sites that are otherwise conserved, and thus often thought to constitute a more reliable signal than variable sites. Although we expect adaptive and convergent events of the magnitude and density of the snake example to be rare, smaller events are more difficult to detect, may be more common, and if they occur between closely related and difficult-to-resolve branch pairs they may easily overwhelm the true phylogenetic signal.

Nonadaptive and possibly neutral convergence should have less obviously deleterious effect on phylogenetic inference because it is widespread and not focused on particular lineages. However, if the substitution models used in phylogenetic inference do not adequately predict levels of convergence (often called homoplasy in this context because the effect is worst for cladistic methods such as parsimony that do not have an explicit model), then there will be bias toward falsely joining long branches. Thus, the observation that most current models inadequately predict nonadaptive convergence levels is of considerable concern. Furthermore, the recent discovery of exceedingly high convergence levels in closely related lineages, with a decrease in these levels over time, is also of obvious concern (Goldstein *et al.*, 2015). Because this is also expected to be unbiased toward any particular branch pair, it appears that the greatest concern is that it adds considerable noise to inference of the most difficult phylogenetic branching problems, and that certainty and confidence in some phylogenetic results may be poorly understood.

Conclusion

Although there are open questions in how to best detect molecular convergence and how to improve our models to understand it better, genome-wide studies as well as focused biochemical studies have begun to reveal general mechanisms of how molecules effect phenotypic convergence. These are exciting times for the study of molecular convergence. Broad generalizations are beginning to emerge, but big questions remain about when and why adaptation to environmental conditions repeats itself in different organisms with different levels of relatedness. Elucidating the details promises to keep evolutionary biologists occupied for many decades to come.

Parallel Speciation

AM Westram, University of Sheffield, Sheffield, UK
K Johannesson, University of Gothenburg, Tjärnö, Strömstad, Sweden

Glossary

Biological species concept Species concept according to which a species is defined as a group of individuals that are reproductively compatible with one another, while being reproductively isolated from other such groups.
Candidate genes Genes that have been shown to be associated with a trait of interest in previous work. Here, traits of interest will be those that show adaptive divergence or may reflect barriers to gene flow. Candidate genes may be inferred from observations in the same or other taxa.
Epistasis The effect of an allele is affected by the genotype at another locus.
Gene expression The process by which genetic information is translated into gene products. The amount of mRNA transcribed from a gene gives an indication of the extent to which a gene is 'used' in the cell.
Genome scan Method that is used to identify genomic regions potentially affected by divergent selection ('outlier loci'). It utilizes the fact that effective gene flow in such genomic regions is reduced, increasing measures of differentiation relative to the rest of the genome. However, results need to be treated with caution as other processes (e.g., background selection, local adaptation without gene flow) might produce outlier loci as well.
Homologous traits Traits (in different taxa) that originate from the same ancestral trait.
Phylogenetic species concept Species concept which uses a phylogenetic tree to define a species.
Pleiotropy When a single allele affects multiple phenotypic traits. This can lead to constraints on the evolution of these traits.
Quantitative trait locus (QTL) mapping Method by which genomic regions affecting a trait of interest are identified. Crosses of individuals with different trait values are used to generate individuals in which the genomic background is randomized, so that a statistical association between trait and genes underlying it can be detected.
Reinforcement Process in which the evolution of prezygotic barriers (e.g., mate choice) between two interbreeding populations is favored when hybrids are less fit due to the presence of postzygotic barriers.
Reproductive barrier Trait or genomic region that contributes to reproductive isolation, reducing effective gene flow between populations. Reproductive barriers may act at the pre- or postzygotic stage.
Standing genetic variation Genetic variation is present within a population. Adaptive standing genetic variation can facilitate rapid and recurrent adaptation as novel mutations are not needed.

What is Parallel Evolution?

Selection can drive the evolution of phenotypic traits. However, phenotypic change does not necessarily mean that a trait is under selection. Changes can evolve by chance, especially in small populations. A pattern that represents strong evidence for the role of selection is when the same trait evolves repeatedly in the same direction in independent populations, always associated with the same environmental transition (in space or in time) (Figure 1). For example, sticklebacks have repeatedly lost their plate armor when colonizing freshwater habitats from an ancestral marine population. If this loss had been observed only once, chance could be a reasonable explanation – for example, the founder population colonizing freshwater might by chance have been different from the average of the ancestral marine population. However, because the pattern has been observed repeatedly in multiple, geographically distant locations, it is most likely generated by a nonrandom process – selection.

The repeated evolution of similar changes in homologous phenotypic traits is referred to as 'parallel evolution.' However, the exact definition of the term varies across the literature, sometimes narrowing down its scope, for example, to cases where closely related taxa are concerned, or where the same gene is responsible (see Box 1). We stick to the classical definition in this text, arguing that phenotypes are what is under selection. Taxa may be closely related (populations of the same species) or very distantly related.

At least two pieces of evidence are required to demonstrate parallel evolution driven by selection. (1) Repeated associations of a certain phenotype with a certain environment. This will require sampling across multiple locations, characterization of environmental factors and phenotyping of individuals. (2) Evidence that the phenotype has evolved repeatedly (as opposed to a single origin, followed by the colonization of multiple locations; Figure 2(a), Box 2). For this, phylogenetic information is often necessary. However, even if the same phenotype appears repeatedly, in distinct clusters in a phylogenetic tree, evidence for parallel evolution is not conclusive. This is because gene flow between geographically close populations in different environments may obscure the true phylogenetic relationships (Figure 2(b)). Combining molecular data and modeling is a possible approach toward resolving this issue (e.g., Butlin *et al.*, 2014; see Box 2). Tracing the correct phylogeny is particularly important in systems where instances of parallel evolution are closely related and gene flow is possible, which is expected for many cases of parallel evolution.

 doi:10.1016/B978-0-12-800049-6.00076-7

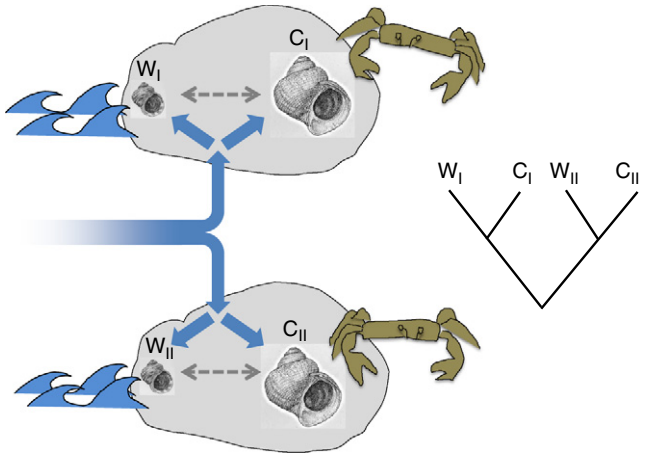

Figure 1 Parallel evolution is the repeated evolution of similar phenotypes under similar regimes of selection, in two or more geographic locations.

Box 1 Definitions of parallel evolution

Simpson (1961) – 'The independent occurrence of similar changes in groups with a common ancestry and *because* they had a common ancestry.' In contrast, convergence involves the evolution of similar characteristics without common ancestry.

Wake (1991) – While convergence is driven by external factors (selection), parallelism is the combined effect of external and internal (genetic) factors.

Zhang and Kumar (1997) – Parallel evolution happens when the same substitution at a nucleotide site occurs in two independent lineages, derived from a common ancestral state. In contrast, convergent evolution occurs when the same derived state is reached from different ancestral states.

Wood *et al.* (2005) – Parallel genotypic adaptation: The same gene evolves to affect a trait in the same way, in independent populations; different substitutions may be involved as long as the same gene is affected. Convergent evolution happens when nonhomologous loci affect the same trait.

This article – Parallel evolution is when homologous traits evolve in a similar fashion in independent populations or species. This contrasts with convergence, which is when nonhomologous traits evolve to become increasingly similar.

Parallel evolution is interesting because it can demonstrate the role of selection in divergence (and speciation, see below). Especially in systems with a large number of 'replicate' populations (e.g., Bernatchez *et al.*, 2010; Johannesson *et al.*, 2010; Roda *et al.*, 2013a), parallel evolution offers great potential to understand how selection shapes adaptive phenotypes and how repeatable/deterministic evolution is (e.g., Soria-Carrasco *et al.*, 2014). In the following, we discuss evidence for parallel evolution and parallel speciation. Now that various genetic and genomic tools are available, researchers also begin to understand the genetic mechanisms underlying parallel evolution. Shared standing genetic variation, novel mutations and gene flow may all play a role in generating shared phenotypic patterns (Johannesson *et al.*, 2010), as we discuss in the final section of this article.

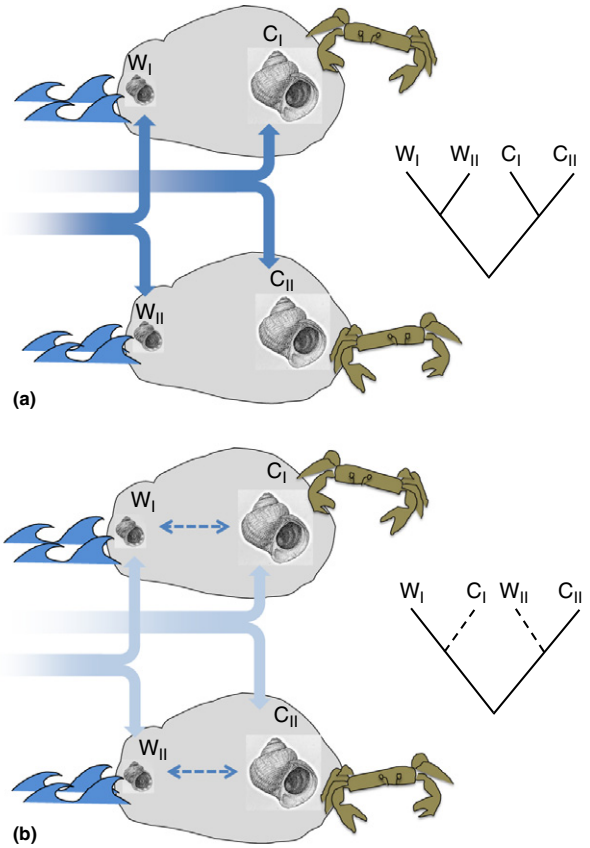

Figure 2 Separate evolution of distinct phenotypes (ecotypes) followed by secondary overlap in distribution in two or more geographic locations results in a phylogenetic relationship between phenotypes different from a parallel relationship (a). If hybridization is possible (ecotypes not completely reproductively isolated) ecotypes will become locally similar and the apparent phylogeny might look similar to a parallel phylogeny (b).

Evidence for Parallel Evolution

Under controlled conditions in the lab, the repeated application of the same selection pressure has shown parallel

Box 2 Single vs. multiple origins

An alternative hypothesis to parallel evolution of pairs of phenotypes is a single origin followed by secondary overlap in distribution of the two phenotypes, along with local hybridization in multiple locations (Grahame *et al.*, 2006; Johannesson *et al.*, 2010; Bierne *et al.*, 2013). To separate single origin and multiple (parallel) origins of phenotypes requires more than a simple glance at a phylogenetic tree as secondary gene flow may have removed the traces of the true phylogenetic origin of each local population (see **Figure 2**). Approximate Bayesian Computation (ABC) provides a toolbox (e.g., Wegmann *et al.*, 2010) for a more formal test of the two hypotheses. Different historical demographic models can be constructed and compared using a number of statistic measures obtained from input of comprehensive molecular data (e.g., heterozygosity, F_{ST}, Tajima's D). This approach was successfully used by Butlin *et al.* (2014) to separate two demographic models; 'old divergence' and 'parallel divergence' of ecotypes of *Littorina saxatilis*. However, the evolutionary history of divergence may be complex, necessitating a lot of simplification when formulating demographic models and making final resolution challenging.

phenotypic evolution in multiple studies (see e.g., Rice and Hostert, 1993). Even though a multiple-colonization scenario can often not be completely rejected (Bierne *et al.*, 2013), many cases from nature also suggest parallel evolution.

These empirical studies have provided evidence for parallel evolution in response to various parallel selection pressures, including biotic as well as abiotic factors; for example, predation regimes, water chemistry, or food availability (Elmer and Meyer, 2011). Parallel evolution can affect a variety of morphological, physiological, or behavioral traits – for example, color patterns (Manceau *et al.*, 2010), toxin resistance (Soong and Venkatesh, 2006), or courtship behavior (Boughman *et al.*, 2005) in animals, and tolerance to soil conditions in plants (reviewed in Ostevik *et al.*, 2012). Sometimes complex phenotypes involving multiple traits have evolved in parallel. For example, in the marine snail *Littorina saxatilis*, divergent ecotypes have evolved on rocky shores in multiple locations across Europe, adapted to crab predation versus wave action (Johannesson *et al.*, 2010). Adaptations include changes in shell morphology, size, and behavioral traits, among others.

Empirical studies have also shown that parallelism is a continuum. In a given system, some traits may evolve in parallel, while others do not. For example, lake-stream stickleback pairs show parallel divergence across locations in many traits, but in this case armor traits do not evolve in parallel, probably because of predation differences among lakes (Kaeuffer *et al.*, 2012). Such patterns may be explained by the fact that there are multiple axes of selection in each location (here: each lake), some of which may be similar across locations (generating parallel evolution), while others may be different (generating nonparallel patterns). Even if traits evolve in the same direction in different locations, the extent of change may differ. This may be because the strength of selection is not the same, or because different populations face different constraints and trade-offs, or are differently affected by genetic drift and/or gene flow. Alternatively, different populations might just have had a different amount of time available to adapt. For example, *Astyanax* fish have repeatedly colonized cave environments, and phenotypic changes in response to the cave environment have occurred repeatedly, including reduction of eyes and pigmentation, both of which are not necessary in the dark caves (Jeffery, 2009). However, while old cave populations show pronounced eye reduction, populations of more recent colonists retain a higher variability in eye traits (Strecker *et al.*, 2012).

Parallel Speciation

Divergent selection might not only cause distinct phenotypic adaptations, it might also generate reproductive barriers between populations, thereby contributing to speciation (Nosil, 2012). The role of divergent selection in speciation has long been under debate, and its relative importance compared to other processes is still not clear (Butlin *et al.*, 2012). Parallel speciation – the parallel evolution of reproductive barriers – can provide strong evidence (Johannesson, 2001).

Divergent selection between populations may automatically introduce some postzygotic reproductive barrier, through selection against immigrants or hybrids (Nosil, 2012). However, this barrier will mainly be restricted to the genomic regions under selection as well as tightly linked sites (Charlesworth *et al.*, 1997), while having little effect on gene flow across the rest of the genome (unless selection is extremely strong) (Barton, 1983). Still, divergent selection may drive reproductive isolation beyond this effect by introducing additional barriers, thereby initiating or facilitating the speciation process (Schluter and Nagel, 1995; Nosil, 2012). For example, in benthic versus limnetic sticklebacks, body size is under divergent natural selection but also important in mate choice (Boughman *et al.*, 2005). In this example, both a premating and a postmating barrier are generated by divergent selection. Similarly, divergent ecological selection might cause individuals to prefer the habitat they are best adapted to, also generating nonrandom mating (Funk, 1998). There are a variety of other mechanisms by which divergent selection may generate reproductive barriers, supported by variable amounts of evidence (for an extensive review see Nosil, 2012).

One of the strongest pieces of evidence for the role of divergent selection as a driving force in speciation occurs where reproductive barriers emerge in parallel in independently evolving populations across similar environmental transitions. Any other mechanism of speciation (e.g., divergence via environment-independent sexual selection; Lande, 1981) would not predict repeatable patterns.

Finding conclusive evidence for parallel speciation in natural systems can be challenging. Schluter and Nagel (1995) defined three criteria: (1) Phylogenetic independence. As for parallel evolution, phylogenetic data (mostly mtDNA sequences in the past, but now large numbers of markers across the genome), and potentially modeling, are necessary to establish that reproductive barriers evolved repeatedly. (2) Reproductive isolation between populations inhabiting different environments. Reproductive isolation involves pre- and/or postzygotic barriers in addition to the extrinsic barrier that is automatically generated by divergent selection alone. (3) No (or less) reproductive isolation between

populations from similar environments. Furthermore, it is important to identify the adaptive mechanism in order to demonstrate the role of natural selection.

According to these criteria, if divergent ecological selection leads to reproductive isolation, individuals from similar environments should be less reproductively isolated, even if they originate from distant geographical locations. In contrast, individuals from different environments should show reproductive isolation even if they are geographically and phylogenetically close. Consequently, at this stage there is a conflict between the biological species concept (which would argue that populations with little reproductive isolation, i.e., those from the same environment, represent a species) and phylogenetic species concepts (which would argue that phylogenetically close populations, i.e., those from same location but different environments, represent a species). Points (2) and (3) require tests of reproductive isolation, ideally pre- and postzygotic. Many studies, however, mainly test prezygotic isolation, using mating trials in the lab (e.g., Rundle *et al.*, 2000).

If same-environment populations are geographically close, gene flow between them might occur and eventually lead to their fusion (e.g., Richmond and Jockusch, 2007). Alternatively, location-specific divergence processes (e.g., reinforcement; Butlin, 1987; Servedio and Noor, 2003) may introduce reproductive barriers that also generate isolation between populations from the same environment (Ortiz-Barrientos *et al.*, 2009), violating criterion (3). Similarly, 'same-environment' populations might differ with regard to environmental characteristics other than the ones under study, leading to divergence between these populations. For these reasons, demonstrating examples where parallel speciation has reached completion may be difficult. However, evidence for the early stages of parallel speciation has been found (but does not indicate whether speciation will reach completion or not) and will be discussed below.

Evidence for Parallel Speciation

Demonstrating phylogenetic independence is not a problem for laboratory experiments under controlled conditions, in some of which evidence for parallel evolution of reproductive barriers could be found (see Rice and Hostert, 1993; Nosil and Harmon, 2009). For example, Kilias *et al.* (1980) maintained *Drosophila melanogaster* lines under different environmental conditions and observed that premating reproductive barriers evolved between lines from different, but not from the same environment. However, not in all studies could parallel evolution of reproductive barriers be observed, and sometimes barriers evolved in some, but not other lines (Nosil and Harmon, 2009). Evolution may find different ways to respond to the same selection pressure, and in that case barriers may not evolve in parallel.

With respect to field populations, there are many putative cases of parallel evolution of reproductive barriers in animal taxa. The marine snail *L. saxatilis* is an example in which all three criteria explained above have been tested. *L. saxatilis* has repeatedly evolved distinct ecotypes, one of which is adapted to the wave action on the steep cliffs it inhabits, while another one lives in boulder fields or other crab-inhabited areas and is adapted to crab predation. Both ecotypes occur in close proximity (tens of meters) and are connected by gene flow. A recent study combining multiple molecular markers and ABC modeling supports the hypothesis that the ecotypes have evolved repeatedly and potentially in the face of local gene flow in distinct geographical locations (Sweden, Spain, and the UK), and in independent regions within each country (Butlin *et al.*, 2014) (criterion (1)). Both genetic and behavioral data show that reproductive barriers have evolved between individuals from different environments, even if they are geographically in contact (Hollander *et al.*, 2005; Panova *et al.*, 2006; Johannesson *et al.*, 2008) (criterion (2)). Finally, mate choice experiments have shown less isolation between populations of the same ecotype from geographically distant populations than between those of different ecotypes from the same geographic location (criterion (3)) (Hollander *et al.*, 2005).

Similar to *L. saxatilis*, other examples of parallel speciation are characterized by multiple occurrences of similar environmental transitions. These often involve selection imposed by interaction with other species, for example, different predation regimes (Nosil *et al.*, 2002; Langerhans *et al.*, 2007). Systems showing parallel speciation may be characterized by geographical features restricting migration between same-environment populations, allowing for a certain degree of independent evolution. For example, multiple fish taxa have repeatedly evolved benthic and limnetic forms in different lakes, adapted, for example, to different food sources and predators (Schluter and McPhail, 1992; Bernatchez *et al.*, 2010). Another example is the evolution of morphological divergence and reproductive barriers between *Gambusia* fish inhabiting predator-free versus predator-containing blue holes (Langerhans *et al.*, 2007).

A trait that has been associated with parallel evolution in multiple animal systems is body size (e.g., in sticklebacks and *Littorina* snails; McKinnon *et al.*, 2004; Hollander *et al.*, 2005). Because this trait is often differently selected across environments (e.g., due to predators with different feeding strategies), but may also be involved in mate choice, it might be predestined to generate reproductive barriers repeatedly.

There are fewer known examples of parallel speciation in plants, and for these, evidence is often less strong (Ostevik *et al.*, 2012). Putative plant examples are often associated with adaptation to different soil conditions, such as metal tolerance in locations close to mining sites (Ostevik *et al.*, 2012). Notably, it has been proposed that recurrent formation of hybrid species in sunflowers may in part be supported by adaptation to a specific habitat type (Schwarzbach and Rieseberg, 2002), that is, may have a component of parallelism. Although examples of parallel speciation are less common in plant species, there are nice examples of parallel evolution of traits involved in local adaptation (e.g., Roda *et al.*, 2013a), which impede gene flow at and nearby selected loci.

Molecular Basis of Parallelism

It is important to note that parallel changes in phenotype, or the parallel evolution of reproductive barriers, may be generated by different underlying mechanisms in different locations. The genetic basis of parallel evolution has

received increasing attention in recent research, as various molecular techniques now allow for the study of large numbers of genetic markers. One question is to what extent parallel evolution is caused by the same genes, and maybe even substitutions in the same nucleotide position (Elmer and Meyer, 2011).

At least three factors determine the extent to which the genetic basis of parallel phenotypic patterns is shared (e.g., Johannesson *et al.*, 2010). (1) Shared standing genetic variation. When parallel evolution occurs in closely related taxa, genetic variation dating back to the time before the populations split may still be present (Barrett and Schluter, 2008). Shared adaptive genetic variation may be utilized by selection in multiple locations. In this case, the same nucleotide positions in the same genes will be under selection across locations. (2) Gene flow. A small amount of gene flow might be sufficient to transport strongly adaptive alleles between locations (Morjan and Rieseberg, 2004; Hedrick, 2013). Similar to standing genetic variation, the same genes and nucleotide positions will then be under selection in different locations. (3) Novel mutations. Adaptation might be based on mutations that occurred after the split from the common ancestor. If different genes are involved in the adaptive process in different locations, distinct novel mutations are a likely cause. However, novel mutations might also occur in the same genes, or even the same nucleotide position, in particular if there are genetic constraints that favor mutations in certain genomic regions (Renaut *et al.*, 2014).

Theory predicts that the relative importance of these processes depends on multiple factors. In closely related taxa, adaptation from shared standing genetic variation is more likely than from novel mutations (Barrett and Schluter, 2008) for two reasons – closely related taxa share most variation and new adaptive mutations take time to emerge. Furthermore, the genetic architecture of the trait evolving in parallel might play a role. If a trait is controlled by a large number of genes (polygenic), many possible genetic changes may lead to similar phenotypic outcomes, thereby increasing the potential for independent genetic solutions. Changes in a trait controlled by a single gene would likely involve the same genomic region repeatedly. However, even if multiple genes control a trait, these might vary with regard to their potential for adaptive evolution. For example, some genes might be constrained by a low mutation rate, pleiotropic effects on other traits, or epistatic interactions with other genes. These effects might concentrate adaptive evolution on a small number of genes (Stern and Orgogozo, 2009), and, if they are shared among populations, make a shared genetic basis of parallelism more likely. This again should increase the probability of a shared genetic basis in closely related taxa, as their genetic setup is more similar.

Studying the genetic basis underlying parallel phenotypic traits is now possible with increasingly comprehensive methods, focussing on candidate genes, large numbers of markers, or whole genomes (Elmer and Meyer, 2011). There are several ways to understand in how far parallel evolution is due to evolution of the same genomic regions.

Candidate gene approaches focus on genes that are known to be associated with a trait of interest at least in some taxa. Sequencing such genes in multiple taxa may reveal whether similar genetic changes have occurred in populations with similar phenotypic changes. Some studies have also gone a step further and genetically modified such loci to find more direct evidence for their functional role (Colosimo *et al.*, 2005). The disadvantage of these approaches is that other, unstudied loci may contribute to the evolution of a given trait as well.

Mapping approaches (e.g., quantitative trait locus (QTL) mapping) allow for the identification of the genetic basis of phenotypic traits even if no candidate loci are available. The extent to which the identified genomic regions are shared will inform about the similarity of the genetic basis across populations (e.g., Rogers and Bernatchez, 2007).

An alternative approach is a genome scan, which uses genetic markers (or whole genomes) to identify genomic regions potentially affected by divergent selection between populations connected by gene flow (Luikart *et al.*, 2003). If such divergent genomic regions are shared among multiple instances of parallel evolution, a similar genetic basis may be involved (e.g., Hohenlohe *et al.*, 2010; Jones *et al.*, 2012; Soria-Carrasco *et al.*, 2014). Genome scans also have the potential to detect divergent loci underlying unstudied/unknown parallel traits. Analogous approaches can be used to detect whether parallelism is caused by similar changes in gene expression (St-Cyr *et al.*, 2008).

Studies using these and related methods have detected evidence for all of the three mechanisms explained above. Studies focussing on phenotypic traits known to evolve in parallel have often found that standing genetic variation plays a great role in parallel adaptation, potentially related to its capacity for rapid evolution (as opposed to novel mutation). For example, alleles at the *Opsin* gene are involved in multiple cases of divergence between cichlid fish in different light environments (Seehausen *et al.*, 2008), and the same alleles at the *Eda* locus were repeatedly associated with stickleback plate armor reduction (Colosimo *et al.*, 2005). There is also some evidence for the role of gene flow; for example, an adaptive allele of the arginine kinase gene, associated with adaptation to sheltered (as opposed to wave-exposed) habitat, has spread among multiple locations in the snail *Littorina fabalis* (Kemppainen *et al.*, 2011). Some evidence for the role of the same *de novo* mutation occurring repeatedly has also been found, for example, in the repeated adaptation of sand goby rhodopsin to similar light environments (Larmuseau *et al.*, 2010).

However, there are also examples where parallel adaptations are based on different mutations within the same gene, or even in different genes. The pelvic reduction repeatedly associated with stickleback freshwater colonization is based on different mutations in the *cis*-regulatory region of the same gene (*Pitx*) (Chan *et al.*, 2010), and parallel shifts in *Arabidopsis* flowering times may be caused by different nonfunctional alleles at the same locus (Shindo *et al.*, 2005). Different genes are involved in the repeated evolution of light coloration in beach mice in adaptation to dune habitats (Hoekstra *et al.*, 2006; Steiner *et al.*, 2009).

A recent meta-analysis of mapping and candidate gene studies suggests that parallel evolution is frequently caused by the same genomic regions (Conte *et al.*, 2012), which could be explained either by shared standing genetic variation, gene

flow, or independent mutations in the same genomic regions. The results may indicate that evolution is constrained and only a limited number of genes are available to change a given trait.

However, genome scan studies, which do not focus on specific traits but on the sharing of loci under divergent selection across the genome, often find relatively small proportions of shared loci, even among closely related or geographically close instances of parallel divergence (Kautt *et al.*, 2012; Deagle *et al.*, 2012; Perrier *et al.*, 2013; Gagnaire *et al.*, 2013; Roda *et al.*, 2013b; Soria-Carrasco *et al.*, 2014; Westram *et al.*, 2014; Ravinet *et al.*, 2016). This might suggest that location-specific divergence processes play a greater role than what would be expected from observed patterns of phenotypic parallelism. However, even if sharing is limited at the level of SNPs or small genomic regions, it has sometimes been found to be higher at the level of genes or genomic regions. Some recent studies have found that sharing may be increased at the level of genetic or functional pathways, which again highlights that evolution may find different molecular solutions that generate similar phenotypic functions (e.g., Roda *et al.*, 2013b; Renaut *et al.*, 2014).

Hence, it is too early to draw conclusions about the relative importance of different genetic mechanisms underlying parallel evolution and speciation. However, in agreement with theoretical predictions, there is some correlation between the age of divergence and the probability of gene reuse (Conte *et al.*, 2012). Nevertheless, there are many known exceptions to this pattern – even very distantly related taxa may use the same genes or even nucleotide positions for adaptation, as observed in divergence between light and dark coloration, where the same gene (*Mc1r*) is used across a wide variety of taxa (reviewed in Arendt and Reznick, 2008; Manceau *et al.*, 2010). On the other hand, closely related taxa (populations within species) may use different genetic mechanisms to generate similar phenotypes (e.g., Renaut *et al.*, 2011). The extent of a shared genetic basis may depend on a complex interplay between the age of divergence, the complexity of the genetic setup, the extent of present connections via gene flow, mutation rates and effective population sizes, genetic constraints, and chance.

A large part of the work on the genetic basis has focused on parallel evolution in general, rather than on the traits most important for speciation. Much more comprehensive research is therefore also needed to identify the loci and the mechanisms underlying the parallel evolution of reproductive isolation.

Conclusion

Parallel evolution and parallel speciation provide strong evidence for selection as the driving force in divergence and speciation. Many putative examples have been found in nature. However, a lot remains to be done – for example, distinguishing parallelism clearly from a single origin can be difficult (**Box 2**). Advances in modeling as well as experimental approaches will bring more clarity. There is also little information about how frequently similar selection pressures actually do lead to parallel evolution, as opposed to cases where evolution finds completely different solutions to the same problem. We begin to understand the genetic basis of parallel evolution, but the relative contributions to genetic change of standing genetic variation, novel mutation, and gene flow, as well as the role of constraints, and stochasticity, need much further study.

Acknowledgments

We thank Roger Butlin for comments on the first draft and discussion of the topics presented here, and Daniel Ortiz-Barrientos for comments on the manuscript. This work was funded by NERC and Swedish VR and Formas through the Centre for Marine Evolutionary Biology (www.cemeb.science.gu.se).

Parsimony Methods in Phylogenetics

JV Freudenstein, The Ohio State University, Columbus, OH, USA

Glossary

Alignment The process of hypothesizing homology for DNA or RNA sequences by arranging them so that columns represent corresponding (homologous) positions.
Apomorphy The advanced or derived state of a character.
Character A unit of information that is used in phylogenetic reconstruction. A structure or feature that is hypothesized to be homologous among taxa.
Clade A monophyletic group of taxa on a tree.
Cladistics The approach to classification that emphasizes clade membership over degree of difference.
Cladogram A character diagram in tree form for a group of taxa.
Consensus tree A tree that summarizes the information among a group of other trees.
Heterochrony Relative shift in development among different parts of an organism.
Homology Sameness; correspondence of a structure or feature among organisms because of its presence in a common ancestor.
Homoplasy Lack of perfect fit of a character to a tree; incorrect homology assessment due to convergence or reversal.
Long branch attraction Inaccurate grouping of long branches as a group because changes on the branches are interpreted wrongly as synapomorphies.
Maximum likelihood A method in which a model is used to evaluate phylogenetic trees such that the likelihood (probability of the data given the tree) is maximized.
Monophyly A property of a group of taxa when the group contains a common ancestor and all of its descendants.
Occam's Razor The rule, attributed to William of Occam, that observations should be explained with as few assumptions as possible.
Ontogeny The developmental pattern of an organism.
Optimization A method for determining the character state assignments at nodes of a tree.
Outgroup A taxon used to determine the character polarity for a group on taxa under analysis.
Paraphyly The property of an assemblage of taxa when the assemblage contains a common ancestor but not all of its descendants.
Phylogenetic reconstruction The act of producing a hypothetical tree of evolutionary relationships for a group of species.
Plesiomorphy The primitive state for a character.
Polarity The direction of a character, whether a state is primitive or advanced.
Synapomorphy A shared, derived (advanced) character state that unites a group of taxa.
Taxon (taxa) Any taxonomic unit from species up through kingdom.
Taxonomy The discipline of building classifications of biological taxa.
Terminal A taxon; the biological units in a phylogenetic tree.
Tree A depiction of relationships among taxa.
Weighting The assignment of differential importance/influence of evidence in an analysis.

Parsimony

Parsimony is a method for the construction of hierarchic character patterns for biological taxa. The resulting patterns, called cladograms, can be interpreted as approximations of the phylogenetic history for a group of taxa. A distinctive aspect of this approach is the preservation of the unit nature of character evidence from the original data to the final cladogram. This provides for straightforward assessment of character transformations on the tree. The approach called 'cladistics' is today often taken to be synonymous with the parsimony method, although the term was first applied to the taxonomic approach of basing groups strictly on clade membership and is therefore more properly a taxonomic approach rather than one of tree construction. For additional treatments of and perspectives on parsimony see Felsenstein (2004), Schuh and Brower (2009), Wiley and Lieberman (2011), and Wheeler (2012).

History and Philosophy

The parsimony approach to tree construction was developed during the time that explicit character-based methods of phylogenetic reconstruction were being codified. The German entomologist Willi Hennig was a key figure in the development of these methods; many of the individual elements that he employed existed before Hennig's work, but he synthesized them into a cogent methodology. Hennig's (1950, 1966) approach to phylogenetic reconstruction was not an explicitly parsimonious one in that he employed a parsimony algorithm, but it was implicitly so. He used careful analysis of individual characters and plotted putative homologies on trees in a way that best reconciled the characters to each other. Moreover, Hennig had a rule for hypothesizing homology that has come to be known as the Auxiliary Rule. It states that if instances of a feature among species pass the worker's criteria of similarity, then they are to be hypothesized as homologous. In other words, one does not hypothesize nonhomology without a justification for doing so; this is an application of parsimony. Subsequent workers built on Hennig's foundation and argued for parsimony as an explicit criterion for preferring particular topologies. James S. Farris is a key figure in the development of theoretical and practical aspects of parsimony.

 doi:10.1016/B978-0-12-800049-6.00205-5

The central idea behind parsimony follows from the general principle in science that the simplest explanation for a phenomenon – the one that requires the fewest ad hoc assumptions – is to be preferred. The origin of this notion is often attributed to William of Ockham (ca. 1285–1349), although Boehner (1990) cites an earlier statement of this notion in a manuscript by Odo Rigaldus (d. 1275). The use of parsimony as a framework for phylogenetic analysis is also rooted in the idea of falsification – that individual characters are hypotheses that test each other. Putative homologies that pass this test are corroborated, while those that do not are falsified. However, the character pattern remains a hypothesis and is always subject to further test by the addition of new information.

Parsimony can be viewed as one of a larger family of maximum likelihood (ML) approaches, one that occupies an extreme on that spectrum. Rather than specifying individual parameters such as character state frequency and rate of change that comprise a model under typical ML approaches (including Bayesian analysis), parsimony employs a minimal model, equating all character changes in terms of cost, under the rationale that we do not know how costs should differ. Further, by not incorporating a priori assumptions via models, we obtain a pattern that is most appropriate for interpretation of process, since assumptions about it were not already included. This minimal model has been termed the 'no common mechanism' model and it has been shown to be equivalent to an ML analysis where each character has its own instantaneous rate matrix (Tuffley and Steel, 1997). Because it does not use a more complex model, parsimony does not attempt to account for unobserved character state changes to the extent that ML does. This means that at times it may suffer from the misinterpretation of autapomorphies on long branches as synapomorphies that unite them, the phenomenon known as 'long branch attraction,' although ML is also susceptible to this. A key assumption of the ML approach is that the model employed is correct. In the end, the choice between parsimony and model-based methods such as ML is a decision between the potential benefits and costs of models – whether a minimal approach, with its potentially unbiased solution with respect to process, is judged better or worse than the more complex model approach, which, to the extent that the model is correct, may give a more accurate solution. The choice may depend on the data under study. Whereas at least some molecular data might fit a model well because of the physicochemical mechanism of change that underlies those data, morphological data would be expected to be difficult to model, since we may have no particular expectation for a regular pattern of character change.

A pertinent question is whether the use of the parsimony approach implies the belief that evolution is itself parsimonious. Those who advocate model use will often say that it does because on the spectrum of models, it is the one that fits a scenario where evolution would take the shortest path, and one uses a model that one believes will fit the system. However, from another point of view, one that views parsimony as the minimal model possible, it does not – it is rather the most model-free way of analyzing the data and is not intended to imply anything about the process. From this perspective, it is an implementation of Occam's Razor in attempting to account for the character pattern using the fewest ad hoc hypotheses of character change. In this way, the most parsimonious tree is also the one with the most explanatory power (Farris, 1983).

The Basic Procedure

Evidence

A parsimony analysis begins with the scoring of character information from an assemblage of species (or higher-level taxa). The methodology was developed with morphological characters in mind, but it may be used for any data that can be coded as characters with discrete states. Individual characters are hypotheses of homology; they are proposed based on similarity of form and relative position for a feature observed in the collection of study species. The parsimony approach works with raw character data rather than with distances derived from them, meaning that inherently distance-based datasets are not amenable to analysis with parsimony.

In order to be informative, a character must have variation among the species of interest. The alternative (and mutually exclusive) instantiations of a character among the taxa in the study are called 'character states.' The characters are scored for each species in the study and the information is organized into a taxon x character matrix.

With morphology, the judgment of which variable unit in the organisms constitutes a character is a somewhat subjective one because of the complexity of structural features. The key is to recognize corresponding minimal units of structural variation among the study species. DNA sequences are more straightforward in that there are only four possible states – A, C, G, and T. However, the more complicated task lies in deciding how these states correspond among the multiple sequences when insertions and deletions have occurred. In other words, sorting the states into characters is the challenging part. The process of doing this is known as 'alignment' and there are various approaches to it. The resulting DNA alignment, as with a morphological character matrix, remains a hypothesis of homology, since it is a proposal of historical relationships among features.

Trees

Next, the character matrix is evaluated for fit to the different possible trees that can be constructed from the group of study taxa or 'terminals.' In all but the simplest of cases this must be performed by computer because the number of possible trees increases exponentially as the number of terminals increases. The number of unrooted trees for $n \geq 3$ terminals is

$$\frac{(2n-4)!}{(n-2)!\,2^{n-2}}$$

For just a few terminals, it is possible to evaluate all possible trees by constructing them and counting the number of steps required to accommodate all character changes on each tree. Even with continually increasing computational power, for all datasets except those with a small number of terminals the number of trees is too large to proceed with this type of exhaustive evaluation. Instead, branch-and-bound or heuristic

methods of searching tree space must be used. These normally involve creating a starting tree and then manipulating it by repositioning branches, altering character weights iteratively, or other methods of seeking to escape local optima in the landscape of possible trees.

Once a reasonably thorough search of the tree space is completed, the optimal trees – those that require the fewest character changes – are saved and interpreted. If a single tree is optimal, this is straightforward. However, it is often the case that numerous optimal trees will be recovered, especially for data matrices with many terminals. In this case, it is useful to use consensus trees to aid in interpreting the trees. The most useful of these is the strict consensus, in which only clades that are present in all of the most parsimonious trees are present. This provides the harshest assessment of the information in common among all of the trees. Adams consensus trees are useful for detecting taxa that are unstable in placement among sets of optimal trees.

Character Polarity

Analysis of a data matrix results in an optimal tree or collection of trees. These are fundamentally unrooted, in that they have no particular direction with respect to character change. In order to interpret groups of taxa on the trees in a historically meaningful way, it is necessary to provide directionality to the tree. Early on in systematic studies, decisions about character directionality or 'polarity' were often made on a character-by-character basis, based on assumptions by the investigator from presumed knowledge about how a particular character behaved in other groups, by the distribution of states in species at the presumed center of origin of a group as opposed to other areas, by which state appeared first in the geological record, or by the number of species that had one state as opposed to another ('common-is-primitive'). By the time of the codification of the parsimony method in the 1970s, the generally usable approaches had been reduced to ontogeny and the outgroup method. The ontogenetic criterion relies on the sequence of states being observable in development, and states that plesiomorphic states will appear earlier in development than apomorphic states. This approach is often described as the direct criterion in that it depends on processes that have stored information on the historical sequence in the developmental sequence. It is not infallible, however. Ontogeny is susceptible to heterochronic shifts, such that an apomorphic feature may be eliminated from the end of a sequence, making it appear to be absent, although it is not plesiomorphically so. The approach that is perhaps most widely used is one that is sometimes referred to as an indirect approach because it does not utilize a stored historical record in the way that ontogeny does. Rather, it uses other extant (or fossil) taxa to polarize the characters. The idea is that using a species or group of species that is outside of the ingroup can serve to determine the plesiomorphic state for characters in the ingroup. If there is more than one state for a character among the ingroup species, the one that is also present in the outgroup is defined as plesiomorphic. Because it uses species outside of the ingroup, it is referred to as the outgroup method. It is indirect ultimately because it is a relational method that essentially pushes the question of polarity to a higher, or more general, level. The outgroup method suffers from problems as well. The most crucial one would be if an ingroup taxon were to be chosen as the outgroup. This would direct at least part of the tree in the wrong way. Because it is relational, the method assumes that there is always another taxon that may be chosen as outgroup, but since the number of species in the tree of life is finite, at some point the question cannot be pushed to a higher level – in other words, how do we root the whole tree of life with this method? It may also be the case that for any particular character, the apomorphic state was gained independently in the outgroup and in the ingroup, which would make it appear as though the truly apomorphic state in the ingroup is plesiomorphic. For this reason, more than one outgroup is usually included in an analysis.

Tree Properties and Metrics

The tree that results from a parsimony analysis is a network of species or higher taxa that are connected in a mathematically optimal arrangement. Nodes on the tree represent hypothetical ancestors (Figure 1), which may or may not correspond to a taxon that actually existed. The assignment of character changes to nodes on the tree can be determined via a process called optimization. This process utilizes parsimony (or another approach) to propose an optimal arrangement (or arrangements if more than one) of characters at the nodes. From this pattern, the optimal placement of character transformations on the tree is determined. This reveals those characters whose homology statements have been confirmed and those that are shown to be homoplastic – indicating lack of perfect fit to the tree because of convergence or reversal. Advanced character states (apomorphies) that unite branches (clades) on the cladogram are called synapomorphies and are evidence for relationship in a cladistic framework. Apomorphies that appear only once on a tree indicate a perfect fit and require no ad hoc hypotheses to explain their distribution. Apomorphies that appear two or more times on the tree indicate that the initial hypothesis of homology – that all of the instances of that state identity are due to a single origination in a common ancestor – has been falsified because occurrences beyond one require ad hoc hypotheses (of convergence or reversal) to explain the character pattern. That is not to say that

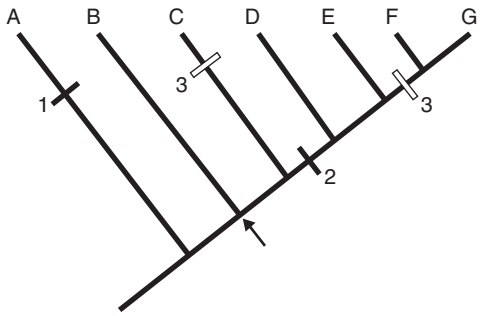

Figure 1 A cladogram (tree) showing a hypothetical ancestor (node, at arrow), an autapomorphy (character 1), a synapomorphy (character 2), and a homoplastic character (character 3).

multiple instances of a specific state change on a tree cannot all function as synapomorphies if they all serve to unite groups of species. An apomorphy that appears on a single terminal is an autapomorphy and provides no evidence for relationship, but may be of interest for study of character patterns. Under what is known as the process of reciprocal illumination, falsifications of homology can prompt the researcher to look again at the character states as they are manifest in the study collection to reassess whether they appear to be truly the same, perhaps in the light of a more detailed analysis. If they continue to be indistinguishable, then the coding should remain as it was, but if differences in the states as they appear in the different groups are judged to be significant enough, one may be justified in coding them as different states.

It is useful to describe a tree in terms of the fit of its characters. The degree of homoplasy can be assessed for individual characters by calculating the consistency index (CI; Kluge and Farris, 1969), which is

$$\mathrm{CI} = m/s$$

where s is the number of steps for that character on the tree and m is the minimum number of steps (= the number of states in that character – 1). It ranges between $0 < \mathrm{CI} \leq 1$. The ensemble consistency index for the whole dataset is just

$$\Sigma(m)/\Sigma(s)$$

This gives one measure of the fit of the data to the tree. Another such measure is the retention index (Farris, 1989), which takes into account how well characters function as synapomorphies on the tree even though they may be homoplastic. The formula for the RI is given as follows:

$$\mathrm{RI} = (g - s)/(g - m)$$

where g is the maximum number of steps possible for a character; it is calculated by assuming that each taxon that has an apomorphic state acquired it independently, such that the character is mapped as an autapomorphy for each. Like CI, RI has a range of $0 < \mathrm{RI} \leq 1$. In this case, characters that function strongly as synapomorphies (i.e., with fewer autapomorphies) will have high RI and those that do so weakly will have low values.

Character Weighting

Although parsimony analysis is most often performed with equal weighting for all characters, various ways have been developed to incorporate weighting into the analysis in order to utilize assumptions about character change. The simplest approach is to select individual characters to be upweighted or downweighted a priori if there is reason to believe that they should be emphasized or de-emphasized relative to others. Some broader weighting approaches are occasionally described as different 'types' of parsimony, but are in fact just weighting schemes. They can be depicted as transformation matrices (Figure 2) and typically are used to differentially weight particular classes of transformations. The method known as 'Dollo Parsimony' is based on the assumption that parallel acquisitions of a feature are less probable that a gain and a loss of the same feature. Hence, in Figure 2, transformations from 0 to 1 are upweighted to high cost, such that the algorithm will attempt to place the character changes in a way that the parallel changes are minimized. Another approach is known as 'Camin-Sokal Parsimony,' in which reversals are prohibited; here, infinite weights are given to reversals. The most general approach to coding via a transformation matrix is to specify transformation costs between any two states, which is sometimes known as 'generalized parsimony.'

When a character is coded as having multiple mutually exclusive states, a choice can be made between organizing the states into a particular transformation series (additive/ordered coding) or allowing the transformation between any two states to be of equal cost (unordered/ nonadditive coding), in which case it is the remainder of the characters that will determine the series for that character. The nonadditive option should be used unless there is a clear justification for ordering of the states. Note that there is a difference between having an ordered character and specifying its polarity. In most cases, what we are really specifying with an ordered character is character state 'adjacency,' which accounts for the cost of transformation between particular states rather than direction, since polarity of the character will usually be determined via the outgroup or ontogenetic method.

Other methods of weighting that act on the fit of characters to the tree have been developed. The first of these successive weighting (Farris, 1969) is an iterative procedure that downweights characters based on the level of their homoplasy, the idea being that good characters are those that are most consistent with the tree. The analysis is run multiple times, each time downweighting the characters proportionally to their homoplasy, until no further changes in the tree occur. An alternative approach is known as implied weighting (Goloboff, 1993). In this method, characters are weighted according to their fit to the tree and no iterations are performed. The best tree under this procedure is the one with best fit to the weighted characters. Fit is determined by a weighting function that may be adjusted by specifying the magnitude of a weighting constant, k. Increasing k penalizes characters less as their homoplasy increases (i.e., most of the penalty is in the

first few additional steps in a character). There is no non-arbitrary way of choosing k and exploration of a range of k values will indicate how sensitive the analysis is to its value.

Uses of Parsimony Trees

A cladogram can be used as the basis for a classification, as well as for studying character change and diversification, biogeography, and coevolution. Although different approaches to classification may use the pattern differently, a key concept is monophyly. A monophyletic group comprises a common ancestor (a hypothetical ancestor on a cladogram) and all of its descendants. Most taxonomists now recognize only monophyletic groups of species as real groups that are eligible for naming. Paraphyletic assemblages are defined based on shared plesiomorphies. Although they may be useful in everyday language (e.g., reptiles, invertebrates), they do not designate groups that have the same historical status as monophyletic groups.

Pathogen Epidemiology

WP Hanage, Harvard T.H. Chan School of Public Health, Boston, MA, USA

Glossary

Basic reproductive number Often written R_0, this is the average number of onward transmission events resulting from the introduction of a single index case into a completely susceptible population.

Coalescent The Coalescent is a retrospective population genetic model that attempts to trace all alleles of a gene in a sample population to their most recent common ancestor (MRCA). This produces a gene genealogy. Coalescent theory seeks to understand the statistical properties of this genealogy under different selective or demographic scenarios.

Incidence New cases of disease occurring within a specified time period.

Malthusian fitness Where the population is growing in size, individuals that reproduce more quickly gain an advantage and will come to predominate even if their total net number of onward infections is less than more slowly growing competitors.

Phylodynamics The use of phylogenetic data to infer elements of epidemiological processes that have given rise to it, by examining the shape and topology of the genealogy as estimated from sequence data (see 'The Coalescent').

Prevalence The frequency of a disease in a population at a particular time point. Often expressed as a proportion or percentage.

Reproductive number Also known as the reproductive ratio or rate, this is the average number of onward transmission events produced from each infection.

SIR model In an SIR model hosts move from the susceptible compartment (S), to the Infected (I) and then (if they survive infection) into a separate resistant (R) compartment. This allows us to model immunity, by allowing hosts in the R compartment to be less likely to be successfully infected. An extra level of complexity can allow immunity to wane over time such that eventually hosts in the R compartment return to the S one – resulting in an SIRS model.

SIS model In an SIS model, hosts initially susceptible (S) become infected (I) and upon clearing the infection immediately becomes susceptible once more (S). Such simple models may be used where little or no immunity results from infection, or may be a useful approximation in the case that antigenic variation on the part of the pathogen is so rapid that immunity is negligible.

Superspreader An individual who infects a disproportionately large number of secondary hosts relative to the majority of cases of infection.

Zoonoses Any case where transmission of infectious agents occurs between different species of animals, most often used when disease is transmitted from nonhumans to humans.

Modern infectious disease epidemiology contains two distinct intellectual lineages: mathematical models are used to explore disease dynamics and the consequences of interventions (Anderson and May, 1991; Grassly and Fraser, 2008), while analysis of the genetic variation in pathogen populations is used to 'type' and define strains associated with resistance, virulence, or other features of interest. Recently these have been starting to come together with population genetic analyses of genetic (and increasingly genomic) variation that can tell us about the history of the sampled sequences. This has been termed 'phylodynamics' as a result of the combination of phylogenetic methods with the study of disease dynamics (Grenfell *et al.*, 2004).

Epidemiology is a population science that studies the patterns of disease incidence, attempting to infer causes and consequences. Classical epidemiology, for instance, might seek to identify risk factors for a given condition, which might be environmental or genetic. This allows us to identify interventions to minimize the risk of disease. In the case of a transmissible disease, the situation is somewhat different. The spread of infectious disease is a dynamic process in which the increasing numbers of cases increase the risk to the rest of the population. Similarly, as people recover they may become immune (or more pessimistically they may succumb to disease – it makes little difference to the infecting organism) and be removed from the system. Hence the numbers of hosts available to be infected change over time. To describe the changing state of the population, infectious disease epidemiology makes use of mathematical models comprising sets of differential equations, or statistical models that are defined using a probabilistic framework. These models can then be used to explore the impact of vaccination or other interventions.

The Reproductive Number

A crucial parameter in infectious disease epidemiology is R: how many successful transmission events and new infections result on average from one infection. With an unlimited pool of susceptible individuals, this is equivalent to R_0 or the basic reproductive number. It is easy to intuitively relate these numbers to the course of an outbreak. If the reproductive number is >1, the expected number of new cases will increase, whereas if it is <1, then the numbers will fall. It is important to distinguish the incidence from the prevalence. Incidence is the number of new cases per unit time, whereas prevalence is the overall frequency of the disease in the population. The incidence can be falling but the prevalence can continue to

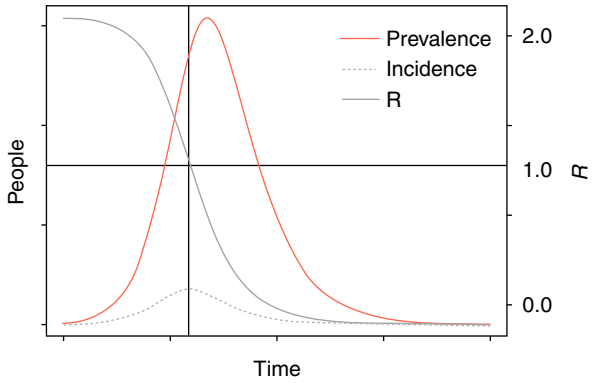

Figure 1 An idealized epidemic curve showing how the prevalence, incidence, and reproductive number R vary over the course of an outbreak. The illustrated case is the result of an SIR model, in which recovered hosts become entirely resistant to infection and as a result the prevalence returns to zero. The point at which the decline in the availability of susceptible hosts means each case causes on average just one onward infection is that where $R=1$, and is indicated. Note that this is coincident with the peak incidence, which precedes peak prevalence as described in the text.

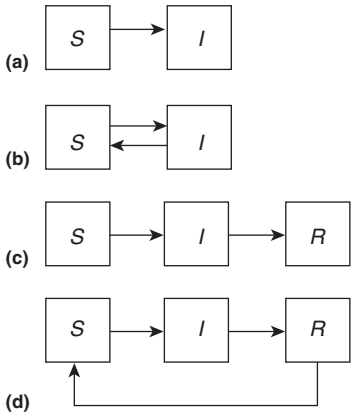

Figure 2 Four simple compartmental model structures referred to in the text: (a) shows an SI model in which hosts become infected and never recover; (b) shows an SIS model in which recovery is possible as shown by the additional arrow; (c) shows an SIR model in which a recovered population is resistant to infection; and (d) a SIRS model incorporating waning immunity. The rates with which hosts transition between compartments can then be described using differential equations.

rise, albeit at a slower rate. This is illustrated in Figure 1, which shows an idealized epidemic curve, and how R changes over the course of the outbreak. While in the illustrated case the epidemic burns out after the pathogen has run out of hosts to infect, if sufficient susceptible hosts are continually introduced (e.g., by birth or waning immunity) the disease can become endemic.

Although the expected final size of the outbreak falls rapidly as R_0 decreases, it is possible for outbreaks to occur in the case where R_0 is less than 1. To understand how this can happen we have to remember that R_0 is an average value, and by chance initial cases may result in an above-average number of onward infections. The effects of this can be probed using a stochastic approach, in which events are modeled as randomly sampled realizations from a probability distribution. While such models aim to capture the typical contact and transmission dynamics in a population, they can be confounded by rare cases of extreme behavior. For instance, a so-called 'superspreader' event may by chance infect many new hosts, starting an outbreak that persists until all the transmission chains descending from it die out (Lloyd-Smith *et al.*, 2005; Garske and Rhodes, 2008). For a real example of such a superspreader event, consider the early stages in the 2003 SARS (severe acute respiratory syndrome) outbreak in Hong Kong, when a single infected person infected at least 13 and possibly as many as 20 others staying at the same hotel (Braden *et al.*, 2013). The estimated R_0 for SARS is much lower than this unusual event would lead you to suspect (Riley *et al.*, 2003).

We can construct a simple transmission model by dividing the population into compartments, and then writing down equations for the rate of movement of individuals from one compartment to another in each time step. The simplest models contain just two compartments: susceptible and infected (Figure 2(a) and 2(b)). The results are a so-called SI or SIS model. In the first example, hosts move from being susceptible to being infected, and in the second, to infected hosts can clear the infection and become susceptible again. The slightly more complicated SIR model adds a 'resistant' compartment (Figure 2(c)), reflecting immunity that prevents infection while waning immunity can be incorporated in a SIRS framework where after a period of time hosts in the resistant compartment move back to S (Figure 2(d)). This flexible approach can be extended to include important features such as vaccination (McLean, 1995) (in the simplest case of a 100% effective vaccine, each vaccinated susceptible would move to the resistant compartment), and host population structure. This is important in multiple contexts; for instance the child–child contact rate is very high in daycare settings and hence the transmission rate too, which can have important consequences for model results (Schenzle, 1984). Similarly, humans vary greatly in the number and sort of sexual contacts they make, which is important to modeling sexually transmitted infections. In the case of vector-borne diseases, whether the vector is a biting insect or a health care worker (as in nosocomial infections), they can and should be incorporated into the model. It is easy to see intuitively how the endemic prevalence of disease depends on the supply of new susceptibles, either from birth or waning immunity.

Transmission Routes and the Target of Selection

Infectious agents can be categorized by how they get from one host to another, and whether this involves any intermediate hosts or environments. Some pathogens spread without spending significant time in the environment, examples being influenza or sexually transmitted infections. Vector-borne diseases in contrast rely on an additional host for transmission, often a biting insect. A considerable burden of disease also results from pathogens that transmit between humans rarely if at all. These infections arise from environmental exposure to the pathogen, and can include zoonoses – infections acquired from other species. In each case it is useful to consider which traits of the pathogen will be scrutinized by selection.

In the case of directly transmitted pathogens it is of paramount importance to colonize new hosts; in other words, maximize the reproductive number. Note that this does not necessarily mean causing disease, merely transmission, although some features of disease such as sneezing may be adaptive traits. As immunity builds in the population the effective reproductive number will fall, and one possible means of increasing it is immune escape, and there is typically evidence of strong diversifying selection on those antigens that can yield protective immunity (Li *et al.*, 1995). Vector-borne pathogens must successfully survive in and transmit between the host and the vector species, and *vice versa*. Again, we expect and observe strong diversifying selection on those antigens targeted by the immune system.

One area of particular interest is the evolution of virulence. It is commonly stated that virulence reflects an adaptive mismatch between the host and the pathogen: it is to the advantage of both parties that virulence be minimal, such that the host can continue to transmit for a long period of time without limits on the numbers of contacts they make. Empirical evidence for this comes from the example of myxomatosis in Australia, where the myxoma virus was introduced to control rabbit populations. With extraordinary vision, Frank Fenner of the Australia National University collected and stored isolates of virus collected from wild rabbits over decades, and showed evidence for both gradual attenuation of the virus, and adaptation of the rabbit population to become more resistant (Fenner, 1956).

While this argument sounds persuasive, it is also regarded with suspicion as an example of group selection. Surely more rapidly growing parasite variants should be selected during infection and, if this is linked to virulence, produce disease (Levin and Bull, 1994)? The tension between the two selective pressures – for growth within the host, and for transmission within the host population – is dependent on the link between virulence and transmission (Lipsitch and Moxon, 1997; Vale *et al.*, 2011). If by causing disease, a pathogen transmits to more new hosts than it would do otherwise, then virulence will be increased even if the result is the death of the host or the clearance of the infection (Anderson and May, 1982). This explains virulence in terms of the theory of life-history tradeoffs. A crucial factor is the availability of new hosts, because if opportunities for transmission are rare it will select for variants that do not kill their hosts before they can transmit (Lipsitch and Nowak, 1995; Lenski and May, 1994). In an outbreak situation, virulence can be temporarily selected even if the virulent strain infects fewer hosts per infection than its competitors, provided it does so more quickly. Selection for more rapidly growing variants is also termed Malthusian fitness (Orr, 2009).

The question of whether virulence is adaptive is not of merely academic interest. HIV-1 infection includes a long asymptomatic period in which the viral load (the amount of virus particles in peripheral blood) fluctuates around a value known as the 'set point' (Mellors *et al.*, 1996). It has been proposed that the set point viral load has been the object of selection to maximize transmission, the result of a trade off between the effect of set point viral load on infectiousness and the duration of the asymptomatic period (Fraser *et al.*, 2007). If set point viral load is too high, then infected individuals have fewer opportunities to transmit before developing AIDS whereas if it is too low, they are not infectious enough to efficiently transmit the virus. For natural selection to act on set point viral load, it must be a heritable property. That is to say, the set point viral load of the infector and infected must be correlated. If it is not, then there is no heritable variation on which natural selection can work. Subsequent work has produced evidence that set point viral load is indeed heritable, and correlated with viral genotype (Hollingsworth *et al.*, 2010; Alizon *et al.*, 2010).

Virulence has also been suggested to be adaptive in malaria transmission. Here, the greater the numbers of parasites in peripheral blood (higher parasitemia), the greater the chance that a mosquito becomes infected while feeding. Parasitemia is also correlated with severity of disease. If disease can limit onward transmission, 'imperfect' or partially effective vaccines have been proposed to select for strains capable of growing to a higher titer in both hosts receiving the therapy and those who are not (Gandon *et al.*, 2001; Barclay *et al.*, 2012). This could lead to an increase in virulence in the absence of vaccination – and given known inequities in access to health care, such a perverse outcome could have a major impact on some patient populations. However, unpicking which factors contribute to virulence is extremely difficult and the goal of virulence management remains an aspiration rather than an actuality (Dieckmann and International Institute for Applied Systems Analysis, 2005).

Molecular Epidemiology: The Short and Long Term

It is often important to be able to link individual cases of disease on the basis of the similarity of the infecting pathogen, such as in defining an outbreak or identifying drug resistant lineages. These are examples respectively of short-term and long-term epidemiology. To address such questions, the variation in the pathogen population must be assayed in some way, and the results compared. This is now almost always done using molecular variation, i.e., nucleic acid sequences and the proteins they encode. How much variation is present in the population, and of what sort, is the result of evolution, and how data from molecular epidemiology studies are interpreted is a question of phylogenetics. Increasingly, populations of viruses and bacteria are characterized using genomic methods, and it is likely that in the near future whole genomes will become the standard for molecular epidemiology (Croucher *et al.*, 2013).

Molecular epidemiology catalogs the variation in the pathogen population as different 'types' that can be distinguished. Historically these have often been defined using antibodies to distinguish between different variants of cell surface markers and divide the population into serotypes. Pathogens of all kinds have been distinguished using this approach: viruses, bacteria, and protozoa. When we speak of a case of influenza caused by 'H5N1,' we are referring to the serotypes of the surface proteins hemagglutinin and neuraminidase, which in this case are those associated with 'avian flu.' In *Escherichia coli* and *Salmonella*, the 'O' antigens (oligosaccharides) are combined with the 'H' antigens (flagellar proteins) to provide a discriminating serotyping scheme.

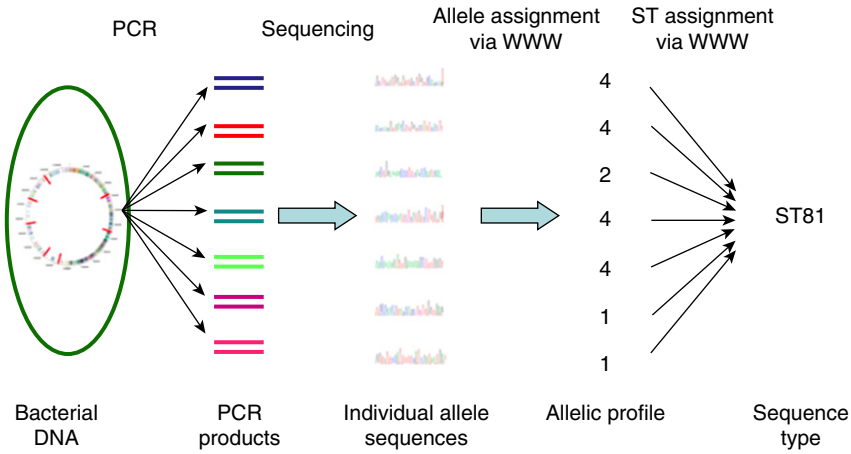

Figure 3 Illustration of the Multi-Locus Sequence Typing approach. The sequences of multiple housekeeping loci are determined, and then allele numbers assigned via an internet database, which together make up the allelic profile. This in turn determines the Sequence Type or ST, also assigned by interrogating an internet database. The example shown is for ST 81 in the *Streptococcus pneumoniae* typing scheme. While the illustration shows sequences determined by Sanger sequencing, increasingly data from genomic approaches are accepted.

Salmonella enterica alone can be divided into more than 2500 serovars (Grimont and Weill, 2007). The O:1 and O:139 serotypes of *Vibrio cholerae* produce a phage-borne toxin, cholera toxin, which causes the disease that bears its name (Finkelstein, 1996). More than 200 serotypes of *V. cholerae* are known that do not produce cholera toxin or cause cholera (Shimada *et al.*, 1994).

Serotyping and other typing methods that assay phenotypes suffer from limited discrimination: they use a tiny fraction of the diversity associated with a strain, and the variation they assay is frequently produced by intense diversifying selection from the immune system. The ideal data for typing are unambiguous and easily portable between labs. We also want to be able to describe how the types we identify are related. We can group serologically related strains as serovars or serogroups, but the relationships within and between these cannot be ascertained in detail. A single serological type can contain many different genotypes, and any horizontal transfer of the locus determining serotype can lead to distantly related lineages being indistinguishable by this method.

Outbreak analysis is a short-term question requiring highly discriminating methods. The response is to assay multiple, rapidly changing regions in the entire genome. Examples of such regions are restriction sites, sites at which PCR primers can bind, or regions of repeat sequences, where the numbers of repeats can change rapidly. Pulsed Field Gel Electrophoresis (PFGE), which uses restriction sites, is an excellent example. Genotypes are distinguished by banding patterns on a gel resulting from changes in the position and numbers of restriction sites. PFGE remains a commonly used method in this context (e.g., Choi *et al.*, 2014).

PFGE and related methods are less useful for evolutionary or population genetics. The selective impacts of the changes are unknown, because we do not know where the restriction sites lie in the genome. While we can identify closely related banding patterns, beyond very closely related strains relationships become hard or impossible to discern. Practically it is difficult to compare results between laboratories. As sequencing has become easier and more accessible, it has become standard to use nucleic acids as the source of assayed variation. In bacteria, a popular approach is to sequence multiple loci scattered around the genome that encode core metabolic or 'housekeeping' functions. This allows the analysis of synonymous SNPs that are unlikely subjects for diversifying selection. The approach, first applied to *Neisseria meningitidis*, is termed multi-locus sequence typing (MLST) (Maiden *et al.*, 1998), and is illustrated in **Figure 3**.

Unlike bands on gels, the sequence data used by MLST are unambiguous. This means that the effort of collecting data on the allelic variants found in the community can be distributed to researchers worldwide. Individual labs in remote locations can determine the sequence of the loci used in the MLST scheme, and then compare them with an online database (mlst.net and pubmlst.net). If the allele is novel, it may be added to the database for future users. Each isolate is defined by the combination of alleles at the MLST loci. Each unique allele is identified by an integer, and the combination of these makes up the allelic profile and the sequence type (ST). MLST has been applied to numerous organisms. One of the side effects of the data collected by epidemiologists has been in the study of homologous recombination (reviewed in this volume by Feil). The wealth of discriminating data collected for MLST has shown that in many named species, recombination is a more frequent source of change at the MLST loci than mutation.

Genomic Epidemiology

The genomic revolution promises to have a profound effect on molecular epidemiology. While in the past, whole genome analyses were the preserve of virologists, it is now economical and, more importantly, easy to obtain quality data on a far higher proportion of the bacterial (or protozoal) genome than afforded by previous methods. Genomic methods have been applied to outbreaks of diseases including tuberculosis (Gardy *et al.*, 2011; Walker *et al.*, 2013), *E. coli* infections (Grad *et al.*, 2012; Mellmann *et al.*, 2011) and cholera (Katz *et al.*, 2013;

Eppinger *et al.*, 2014), and are becoming folded into the routine epidemiologic work of public health authorities.

The pace of change in this field is such that any detailed discussion of technology will be shortly superseded. Nevertheless, important principles can be defined. At present multiple technologies for sequencing exist, and moreover, multiple approaches for putting raw data together to make a genome. The great majority of studies are more properly called 'genomic' rather than 'whole genome' methods, because in hardly any cases have genomes been completely sequenced. Instead, a very high proportion of the genome is determined. While high-quality draft genomes can be used for many interesting things, they are not finished: we do not know the sequence of the chromosome all the way round from the origin of replication.

Which parts of the genome get missed? This depends on the sequencing platform and the methods of assembly, but typically highly unstable regions such as repeats are problematic. These are of course the regions that are most useful for short-term questions in epidemiology. In their absence, we can look at single nucleotide polymorphisms elsewhere in the genome. In comparing very closely related isolates that may differ at a handful of SNPs, the possibility of false positives becomes acute, so we must deal with the fact that different technologies and analytic approaches have different error rates (Croucher *et al.*, 2013).

Taken together, the profusion of genomic methods means that rather than removing ambiguity in the comparison of closely related isolates, new sources of ambiguity have been discovered. At the level of resolving more distantly related isolates into major lineages, equivalent to MLST, genomics has been highly successful and revealed both considerable variation within closely related STs, and perhaps surprisingly shown that MLST in most cases effectively identified the major lineages. The potential of methods that can sequence through unstable repeat regions with high fidelity is real, but has not been conclusively shown at the time of writing. This is likely to change, but for the benefit to be felt the technology will have to be cheap enough for many labs to use.

Phylodynamics and Using DNA Sequence to Study Transmission

The most exciting recent development at the interface of evolutionary biology and epidemiology has come about from the proliferation of sequence data combined with methods capable of making inferences about the history of a sample of sequences from the structure of the genealogy underlying them. A key concept is the coalescent (Kingman, 1982), which describes the genealogy of a sample of sequences in terms of how often their lineages 'coalesce' or come together to form an internal node in the tree. Combined with a molecular clock that relates the accumulation of sequence divergence to time, this allows us to infer events that have happened in the history of the sequences, most notably and relevant for epidemiology, changes in population size. The basic rationale is readily grasped, and accessible software is available to implement the methods (Drummond *et al.*, 2012; Bouckaert *et al.*, 2014).

As stated above we describe the structure of a genealogy by looking at how often the lineages coalesce, relative to the branch length, which in the case of a molecular clock is a proxy for time. The most valuable data are sequences sampled over time, providing 'measurably evolving populations' that can be used to estimate the clock rate (Ewing *et al.*, 2004). An alternative approach is to model transmission as a birth death process, as discussed in Boskova *et al.* (2014).

The rate of coalescence over the tree is simply related to population size by reflecting that in a smaller population individuals are more likely to share a parent in the previous generation by chance. In fact the probability two individuals share the same parent in the previous generation is the reciprocal of population size. As a result the rate of coalescence is higher in smaller populations. This allows inference as to whether the population is expanding, has experienced a bottleneck, or any of multiple other demographic and other processes.

The ability to study changing population size from sequence alone can be used, with an estimate of the serial interval or time between infection and transmission, to estimate the reproductive number. Analysis of sequence variation has been used to study pathogens including Influenza (Hedge *et al.*, 2013), *V. cholerae* (Katz *et al.*, 2013), MERS (Cauchemez *et al.*, 2014) and the recent Ebola outbreak (Gire *et al.*, 2014). This work has shown the potential of the approach. While these analyses are readily approached using the BEAST suite of programs (Bouckaert *et al.*, 2014; Drummond *et al.*, 2012), as usual it should not be assumed that default parameters are appropriate.

Using sequence data to infer demographic history is distinct from using it to infer recent transmission. At the extremely local level it is hoped that we might be able to define infector and infected using high-resolution sequence data alone. Indeed, highly resolving methods that stop short of the whole genome have been used as a valuable complement to classical contact tracing for the control of gonococcal disease (Bilek *et al.*, 2007). At a higher level we might ask whether cases of disease occurring some distance apart are due to closely related pathogens, which might imply transmission over greater distances – for an example, involving wind-borne transmission of avian influenza see Ypma *et al.* (2013b). The overall principle is that the transmission tree is considered closely related to the phylogenetic tree (Ypma *et al.*, 2013c). To be useful this need not be the precise resolution of who infected whom; different epidemiological events like superspreading (Ypma *et al.*, 2013a) may leave distinct signatures in the resulting tree structure (Colijn and Gardy, 2014). Software packages are becoming available that implement multiple methods to probe sequence data to provide the detailed history of an outbreak (Jombart *et al.*, 2014a,b). However, concerns exist over the potential for within-host evolution to produce sequence diversity that can obscure true transmission networks (Didelot *et al.*, 2014; Worby *et al.*, 2014). The amount of diversification that occurs within the host is not known in most cases, but may be large (Nasser *et al.*, 2014). Coupled with the uncertainty arising from imperfect sampling and other missing data, it is likely that the most valuable uses of sequence data will be as a complement to traditional epidemiologic approaches (Ypma *et al.*, 2012).

Conclusion

Infectious disease epidemiology is a practical science, concerned with minimizing the impact of pathogens on public health. As both pathogens and their hosts have evolved, evolutionary biology is relevant to understanding the nature of their interactions for fitness, and also in resolving the history of pathogen transmission. Mathematical models can explore the consequences of different selective scenarios, and molecular data can define strains and the genetic variation that is the raw material on which natural selection acts. Recent advances, especially in the rapid determination of sequence data, are bringing evolutionary biology ever closer to the clinic.

Pest Management, Evolution and

NA Johnson, University of Massachusetts-Amherst, Amherst, MA, USA

Glossary

Biological control The use of other organisms to control a pest species is called biological control.

Mutagenic chain reaction (MCR) A technique that uses CRISPR/cas9 genome-editing technology to convert heterozygotes into homozygotes in both the soma and the germline.

Niche explosion A hypothesis to account for some highly abundant and highly polyphagous species. It posits a positive feedback loop between niche breadth and population size. Many putative niche explosion species are pests.

Pest species Organisms that threaten harm to human health, agriculture, the economy, or ecosystems.

Selfish genetic elements (SGE) Stretches of DNA that enhance their own transmission at the expense of the fitness of the organism.

Overview

Pest management is the applied science that attempts to suppress pest species and/or mitigate the damage they cause. Pests are generally defined as organisms that threaten harm to human health, agriculture, the economy, or ecosystems. In this entry, pests will be limited to animal pests, though plants can often be pests, which are usually called weeds.

Pests are often associated with invasive species, but there is a difference between the two categories. By definition, invasive species are non-natives, but native species can become pests. Still, considerable overlap exists between pest management and the control of invasive species.

Retarding Resistance

Pest management, especially for that of insect pests, often involves the use of chemical pesticides. Although pesticides have been very successful in treating some pests, they have been less so with others. One reason that pests are difficult to contain via insecticides is that the pests evolve resistance to the insecticide (Georghiou, 1972; Mallet and Porter, 1992).

The problem of insects evolving resistance is not new; and principles from evolutionary biology have long been applied to address and possibly retard the evolution of resistance. Writing in 1972, the entomologist George Georghiou (1972, p. 158) concluded 'The accumulated evidence from intensive world-wide chemical control of insects during the past quarter of a century indicates that resistance to the selecting insecticide almost always develops.' As Georghiou (1972) summarized, early work in the evolution of resistance found the resistance is more likely to evolve and will evolve more rapidly if the selection is very intense, provided the population has sufficient genetic variation. Although the evolution of resistance to insecticides is nearly universal, the rate of evolutionary response varies depending on the type of insecticide used, presumably due to different responses by the insect pest. Georghiou (1972) recommended very intense selection is the best way to create a strain of insect highly resistant to the chemical dieldrin because resistance is due primarily to a single genetic factor. So, moderate chronic exposure is less likely to be conducive for evolving resistance, and thus, would be more useful for management. In contrast, resistance to DDT and carbamates is multifactorial and often involves recessive alleles. For these insecticides, resistance is most likely to evolve under a moderate chronic exposure (Georghiou, 1972).

Limiting the evolution of resistance is particularly useful when pesticides have been engineered by genetic modification into transgenic crops. Herein, the crops contain the toxins that kill pests. Various strategies to decrease the rate of evolution of resistance are used including the use of mixtures wherein plants with the toxin are planted with plants without the toxin, and rotations wherein the toxins are used at different times and places (Hoy, 1998). One mode of rotation is the use of refugia, regions where there are no toxins for the pests to adapt to. These methods all attempt to limit the evolution of resistance by reducing the amount of selection.

Mallet and Porter (1992) modeled the evolution of resistance under a variety of the conditions assuming a two-stage insect life cycle, similar to what Colorado potato beetles have, and found that refugia always performed better than mixtures in retarding the evolution of resistance. Indeed, if insects can readily move from one plant to another, then in some cases, the use of mixtures can paradoxically lead to faster rates of evolution of resistance than the absence of mixtures. These conditions include very intense selection, low (but non zero) dominance of the resistance allele, and relatively high rates of movement (Mallet and Porter, 1992).

Biological Control

Biological control uses other organisms to control the population of the pest species. Typically, the natural enemies (predators, parasites, pathogens) are used in this effort, though the use of a competitor is also feasible (Roderick and Navajas, 2003).

Evolution is central to biological control as both the target pests and their natural enemies are evolving. Indeed, evolution is both an advantage and a disadvantage of biological control. Because the natural enemy is evolving along with the pest,

 doi:10.1016/B978-0-12-800049-6.00304-8

it should be able to counter the evolution of resistance by the pest. Evolution of the control agent, however, leads to the prospect of unintended consequences.

The classic case of biological control is the use of the *Myxoma* virus to control rabbits in Australia (Futuyma, 1998; Roderick and Navajas, 2003). Introduced to Australia in the middle of the nineteenth century, rabbits soon became a serious pest on that continent. In 1950, the *Myxoma* virus was introduced, and it soon greatly reduced the population size of the rabbits. The surviving rabbits evolved resistance, but the virus evolved counter-measures. However, the virus also evolved to become somewhat less virulent. This case shows the reciprocal interplay between evolutionary biology and applied pest control. Evolutionary principles were used in the control of the rabbits but the co-evolution of the virus and rabbits has also stimulated much work in the evolution of resistance (Futuyma, 1998; Roderick and Navajas, 2003). Another case of the use of pathogens for biological control is the fungus *Entomophaga maimaiga* that has been used to control gypsy moths in the northeastern United States (Hajek *et al.*, 1996; Roderick and Navajas, 2003).

Evolutionary change of microorganisms such as viruses and bacteria used in pest control is very well documented. The extent to which agents of biological control that are macroorganisms (arthropods, for example) evolve during the control is not clear (Roderick and Navajas, 2003).

Population genetic techniques that can identify sudden and severe population crashes are particularly useful because they can be used to assess the effectiveness of eradication programs, especially when direct censuses are difficult or impossible to obtain (Rollins *et al.*, 2006). Roderick and Navajas (2003) also note that traditional population genetic approaches that are used to assess dispersal and gene flow in the control agents may be flawed. These traditional methods assume that the population is at migration-drift equilibrium, which is unlikely for recently colonized populations. Additional non-equilibrium methods will be required in these cases (Roderick and Navajas, 2003).

Wolbachia

One agent that is promising for biological control is *Wolbachia*, a bacterial endosymbiont. It has captured the attention of many evolutionary biologists because it is extremely common (found in more than half of arthropod species) and because it has a wide array of effects on its hosts (Werren *et al.*, 2008). These properties make this bacterium a promising vehicle for insect pest control.

Wolbachia reproductive manipulation effects vary from strain to strain (and host species), and fall into the general categories of cytoplasmic incompatibility, parthenogenesis-inducing, feminization, and male killing (see Werren *et al.*, 2008, for a review). Cytoplasmic incompatibility appears to be the most common effect. Herein, *Wolbachia* modifies the sperm of infected males. In crosses between males from infected strains and females that are either uninflected or have *Wolbachia* from a different and incompatible strain, the modification that came from the sperm leads to embryonic mortality. The eggs from females of the same strain (or other compatible strains) have also been modified so as to rescue the toxic effect of the modified sperm. Thus, viability is unaffected in offspring between crosses of males and females from the same *Wolbachia* strain or compatible strains (Werren *et al.*, 2008).

Wolbachia has been suggested as a possible control agent for pest species, particularly for insects. Pilot studies have found that in some cases, the bacterium could help control pest species by increasing the extent of cytoplasmic incompatibility, reducing egg hatch rates and thus population sizes. Xi *et al.* (2005) have provided proof of principle of this application, showing it is feasible in laboratory populations of the mosquito disease vector, *Aedes aegypti*.

A particular strain of *Wolbachia* may be useful in combating dengue fever through the control of its pest vector *A. aegypti* (Schraiber *et al.*, 2012). Dengue fever is a viral disease that affects millions of people each year, and whose prevalence is increasing both with respect to numbers of new cases and geographic regions affected (Kyle and Harris, 2008). The disease has interesting dynamics in infection that in humans it requires two weeks or more of incubation of the virus in the mosquito (Schraiber *et al.*, 2012). For this reason, shortening the lifespan of the mosquito should reduce the transmission rate of the virus, potentially mitigating or even eradicating dengue epidemics. Fortunately, there is a strain *Wolbachia* that reduces lifespan in flies. This strain has been engineered into *A. aegypti* and reduces its lifespan in laboratory populations (McMeniman *et al.*, 2009).

The question is whether this longevity-reducing *Wolbachia* could spread in real mosquito populations. Modeling approaches to this question are complicated by the need to consider the effects of cytoplasmic incompatibility, the fitness effects from longevity reduction, and spatial dynamics of the spread. A recent modeling effort from Schraiber *et al.* (2012) is rather discouraging. They (Schraiber *et al.*, 2012, p. 31) conclude, 'Our results paint a somewhat grim picture: model predictions based on laboratory data suggest that lifespan-shortening *Wolbachia* either may not spread at all, or would take over a century to spread through a large city.'

Selfish Genetic Elements

In recent decades, the use of agents for biological control has expanded beyond whole organisms. Biologists are now using genetic elements within the pest organism for its control.

Selfish genetic elements (SGE), which are stretches of DNA that enhance their own transmission at the expense of the fitness of the organism, have received increasing attention by evolutionary biologists in recent decades (Burt and Trivers, 2006). These elements may have practical applications in managing pest species.

Several different kinds of SGE exist and some of these have been proposed or even are being used to control pest species (Burt, 2003, 2014; Sinkins and Gould, 2006). The use of different types of SGE will be considered below, but there are some commonalities. Typically, elements with desired properties are engineered into the pest species in laboratories, and then these SGE-carrying pests are introduced into the wild populations, typically with the aim of reducing population

size. In some respects, these SGE techniques are extensions of the traditional sterile male technique, which involved releasing large numbers of sterile males in order to reduce the population sizes of pests and which led to the elimination of the cattle-infesting screwworm fly in 1966 (Gould, 2008).

Burt (2014) makes the distinction between self-limiting and self-sustaining introductions. Self-limiting introductions are those where the element-containing pests are not expected to sustain themselves in the population. Such introductions have the disadvantage of usually requiring multiple treatments but these are less likely to have negative consequences. In contrast, self-sustaining introductions are designed to spread through the target population and reach high and sustained frequencies in those populations (Burt, 2014).

Population genetic models are typically used to address various questions about the dynamics of introductions of SGE into wild populations, especially for self-sustaining introductions. These questions include: Will the elements increase in frequency when rare, and under what conditions? Another question is; Will the elements reach internal (not zero, not one) equilibrium? Under some conditions, a minimal frequency is needed for element to spread to higher frequency. If this minimal frequency is sufficiency high, a large number of pest individuals with engineered element need to be released.

The elements that have been proposed to for pest control applications include meiotic drive elements, MEDEA, transposable elements, and homing elements. Very recently, genomic editing techniques have been used to develop the mutagenic chain reaction.

MEDEA

First discovered in *Tribolium* flour beetles, the MEDEA (maternal-effect dominant embryonic arrest) selfish genetic element has an unusual phenotype, causing lethality at the embryonic stage in individuals who lack the element but whose mother had the element (Beeman *et al.*, 1992; Wade and Beeman, 1994). Synthetic MEDEA elements have been created, and this bodes well for their use as a control agent (Chen *et al.*, 2007).

Because it kills off individuals without the element, it can spread through populations (Wade and Beeman, 1994; Ward *et al.*, 2011). In fact, if there is no fitness cost to MEDEA, it will spread to fixation, though rate of extinction of the non-MEDEA element can be very slow. If there is a fitness cost, an internal equilibrium is possible, depending on the extent of the cost and its dominance. Moreover, within family (soft) selection can enhance the spread of the element (Wade and Beeman, 1994; Ward *et al.*, 2011). Ward *et al.* (2011) note that the initial rate of increase of MEDEA is very slow unless the initial frequencies of the element are rather high. In most cases, to drive MEDEA to near fixation in 10–20 generations requires introducing large numbers of MEDEA-carrying insects.

Homing Elements

One class of SGE that have attracted interest as a means of pest management is Homing elements, which are also known as endonuclease genes (HEGs) (Burt and Trivers, 2006; Sinkins and Gould, 2006). These encode endonucleases that cut the copy of chromosomes that lacks the HEG. They can do this because the endonucleases recognize specific sequences flanking the HEG, but do not cut when the flanking sequence is interrupted by the HEG itself (Sinkins and Gould, 2006).

The Mutagenic Chain Reaction

The Mutagenic Chain Reaction (MCR) is a powerful technique that uses CRISPR/cas9 genome-editing technology to convert heterozygotes into homozygotes in both the soma and the germline (Gantz and Bier, 2015). As a consequence, allele frequency can rapidly increase toward fixation in populations, and gene replacement at the population level is made practical for a wide range of species (Gantz and Bier, 2015; Unckless *et al.*, 2015).

At least under laboratory conditions, the MCR is very powerful. In fact, it is so powerful, that there are concerns about accidental exposures and other consequences. Unckless *et al.* (2015) modeled the population genetic consequences of the MCR technique. They discuss how the MCR system can be designed so that it should reach fixation if above a threshold frequency, but go extinct if accidentally released at a low frequency.

The Evolution of Generalist Pests and the Niche Explosion

Evolutionary biology principles and studies can also address why some species become pests. Many pests have become pests due to changes in the environment, often due to human activity. Some species, however, may be evolutionary disposed to becoming pests. In addition to having very large population sizes, some pest species such as some species of scale insects and bagworm moths have extraordinarily broad niches and are able to feed on an extraordinary diversity of host plants (such as species from dozens of different plant families). Normark and Johnson (2011) noted several characteristics associated with this syndrome of highly abundant and highly polyphagous insects including flightless adults, passively dispersing early larvae, feeding on woody plants, and obligate parthenogenesis. Normark and Johnson (2011) proposed the 'niche explosion' hypothesis to explain this syndrome. This hypothesis poses a positive feedback loop between population size and host range. Species that acquire sufficiently high population sizes and sufficiently wide host plant use can become caught in this loop with each factor increasing the other. Although this feedback loop has not been directly tested, its principles appear sound. Demographic and population genetic processes should support population size leading to increased niche breadth. Demographic factors also support increased host range resulting in increased population size (Normark and Johnson, 2011). Parthenogenesis is likely a consequence, and not necessarily a cause, of the very large population size of niche explosion species. As the advantages of sexual reproduction over parthenogenesis decline with large population size (Otto, 2009), the disadvantages of sex would be expected to dominate in these extraordinarily abundant

species. An implicit assumption of the niche hypothesis model is that tradeoffs between performance on different hosts are sufficiently rare (Normark and Johnson, 2011). If tradeoffs are commonplace, they would be expected to constrain the evolution of niches. The existence of tradeoffs is a long-standing controversy in evolutionary ecology (Futuyma and Moreno, 1988; Futuyma *et al.*, 1995; Jaenike, 1990; Forister *et al.*, 2012). Peterson *et al.* (2015) systematically addressed performance tradeoffs in armored scale insects, a group that includes several extremely abundant and extremely polyphagous pest species. They developed a phylogenetic model of host plant evolution and applied that model to extensive collection records (23 810 individual specimen records) of host plant use from armored scale insects. In most cases, the model found positive pairwise correlations between evolutionary changes in scale insect presence on different host plants. This result suggests that adaptation to one host plant facilitates adaptation to other host plants, and stands in strong contrast to the pattern expected if tradeoffs were pervasive (Peterson *et al.*, 2015).

Philosophy, Evolutionary Biology and

JM Kaplan, Oregon State University, Corvallis, OR, USA

Introduction: Philosophy and Evolutionary Biology

The interaction between philosophy and evolutionary biology has been particularly a fruitful one. Evolutionary biology has generated a considerable number of conceptual puzzles that have attracted interest from both biologists and philosophers. And evolutionary biology has generated a considerable number of controversies, both internally (arguments among practicing biologists) and in public discourse surrounding the discipline; in both cases, philosophers have participated in these debates. Finally, evolutionary biology has sometimes been thought to have implications for some traditional philosophical problems, making some long-standing positions in philosophy either more or less plausible.

In this article, some of the key issues and positions in each of these broad areas will be briefly sketched. First, the role that philosophy has played in conceptual analysis within evolutionary biology will be explored. In many fields, questions arise that are not strictly speaking about the subject area, as they involve primarily conceptual issues rather than empirical questions. In evolutionary biology, questions regularly arise that cannot be answered merely by gathering more data. They are, for example, questions about the meanings of terms, or the best perspectives from which to view certain phenomenon. Empirical evidence is often relevant to answering these questions – indeed, since some of the questions turn on the fruitfulness of particular perspectives, whether in fact a perspective is to be preferred will depend in part on whether it will really lead to more fruitful future research than alternative perspectives. But no particular empirical findings or experimental results are dispositive in these cases. Next, the role of philosophy in controversies surrounding particular aspects of evolutionary biology and the relationship between evolutionary biology and public discourse will be addressed. Philosophy has often weighed in on particular debates within evolutionary biology, suggesting that in particular areas reasonable evidentiary standards are not being upheld, or suggesting that standards of evidence differ unreasonably between different areas. And philosophy has played a role in the analysis arguments surrounding, for example, the teaching of evolutionary biology in public schools. Finally, some of the ways in which it has been suggested that evolutionary biology might bear on traditional philosophical problems will be noted. The fact that humans are the product of biological evolution, it has been suggested, at least makes some more or less traditional philosophical positions less plausible, and makes others more plausible, and may play a part in settling some philosophical disputes.

Before getting into these arenas, it is worth noting that the philosophy of biology has been, with only a relatively few exceptions, the philosophy of 'evolutionary' biology; the central questions and challenges that philosophers have taken up have emerged primarily (though not entirely) from evolutionary biology, broadly construed. This sometimes results in the philosophy of biology giving a skewed impression of the state of biological research, suggesting that most biological research is deeply wrapped up in evolutionary analyses. While Dobzhansky's (1973) dictum that "nothing in biology makes sense except in the light of evolution" may well be true, it is worth remembering that in practice, many research agendas in biology do not make continual or robust use of evolutionary biology in their day-to-day work. Philosophy of biology's focus on evolution to the exclusion of other domains, and its habit of seeing other domains through the lens of the questions most relevant to evolutionary biology, may in some cases be misleading.

Philosophy and Conceptual Analysis

There are questions in evolutionary biology that are not merely biological in nature, but rather centrally involve conceptual issues. The distinction is not always clear in practice, but in principle, it is the distinction between questions that can be answered by further research into the biological phenomena in question and questions that are better viewed as being about how to interpret the results of research, or how to think about an area of research. So for the most part, questions regarding when, say, some particular trait arose in a particular lineage are biological questions – if we want to know when, for example, swords arose in a particular lineage of swordtailed *Xiphophorus* fish, the question may be difficult to answer definitively, but it is generally agreed what kinds of evidence are relevant to answering it (see, e.g., Marcus and McCune, 1999; Basolo, 1990). Contrast this with the ongoing debates surrounding the nature of species (the 'species problem'). Hey (2001) lists some two dozen species concepts, and notes that these are, with a few exceptions, generally viewed as "competitors for the single best meaning" (p. 326). But it should be obvious, by now, that the inability of biologists to settle on a single best species concept is not because of a lack of biologically relevant data; indeed, one cannot easily imagine what new biological discoveries even in principle could determine, once and for all, that one of these competing concepts was the correct or the best one. Rather, any solution proposed must try to make sense of the different work that species concepts do in biology, and (perhaps) recognize that no single concept can do everything that one might have wished a species concept could do (see, e.g., Hey, 2001, 2006; Dupré, 2001). Similarly, arguments surrounding the ontological status of species – whether species are best thought of as individuals (Ghiselin, 1974; Hull, 1978), or as sets (see Kitcher, 1984), or kinds of some sort (see Boyd, 1999) – is not a question that more biological data on the behavior of individual organisms or of populations would permit us to settle.

It is of course not always clear whether a question is primarily a (more or less) straightforward biological question, or whether it involves important arguments over conceptual

 doi:10.1016/B978-0-12-800049-6.00306-1

issues. Consider, for example, the current debates surrounding the necessity and/or the advisability of an 'extended evolutionary synthesis' (e.g., Pigliucci, 2007; Pigliucci and Müller, 2010), and the related arguments surrounding 'Developmental Systems Theory' (e.g., Oyama *et al.*, 2001) and 'Devo-Evo' (e.g., Hall, 2000). There are, obviously, a number of more or less straightforward biological questions that are relevant to arguments surrounding the advisability (and/or necessity) of these projects (though that doesn't, of course, mean that the questions are easy to answer). For example, how often is selection on heritable but nongenetic variation in fact relevant to a population's evolution? Are changes in heritable but nongenetic developmental resources in fact implicated in any major evolutionary transitions? (see, e.g., West-Eberhard, 2003; Jablonka and Lamb, 2005; for a more skeptical view, see, e.g., Hoekstra and Coyne, 2007). But there are also deep conceptual issues – for example, insofar as some problematic concepts of 'information' (understood as both a developmental and heritable resource) became part of the standard stories surrounding accounts of evolution in the modern synthesis understanding of the relationship between evolution and development, more rigorous analyses of the meanings and uses of information in biology can be relevant to understanding some of the concerns to which proponents of 'extended synthesis' and related views see themselves as responding (see, e.g., Moss, 2004). Or more generally, while arguments surrounding whether it makes sense to think in terms of some privileged class of 'replicators' that can be meaningfully distinguished from 'interactors' in evolution make use of empirical facts about development and evolution, they involve, critically, disagreements about conceptual issues, as well (see, e.g., Stereln and Griffiths, 1999 and cites therein).

The broad areas of research noted above – the species concept, the ontology of species, and extensions or modifications to the so-called modern synthesis – represent a few of the areas where the philosophy of biology has engaged with issues that emerge from the conceptual foundations of evolutionary biology. Below, several additional places where this kind of conceptual analysis seems important, and where philosophers and biologists have engaged in this kind of conceptual analysis, are sketched. This is not meant to be a complete list, but rather representative of the sort of work that the philosophy of biology is involved with.

Levels of Selection/Multilevel Selection Theory

Williams (1966) provided a strong critique of sloppy group-selectionist thinking, and this work is often credited with introducing gene-selectionism into evolutionary biology (Dawkins, 1976 popularized this approach). Gene-selectionism, narrowly understood, never attracted the full support of more than a minority of practicing evolutionary biologists, but the position was nevertheless quite influential. More generally, the questions raised by this work – What is it that gets selected? At what levels can selection operate to produce adaptations? What is it that is adapted? Is there an important distinction between replicators and interactors, and if so, what work does that distinction do? – remain active areas of both empirical research and contention regarding the proper interpretation of both the questions and the results of the research.

So, for example, consider the question of what should count as 'group selection.' Most would agree that group selection is the proper account of a situation in which the groups themselves (1) survive and reproduce as wholes and (2) where the features of the group that lead to fitness differences between groups are not the same features as the features that make the individuals making up the groups more or less fit (see **Figure 1(b)**). But what of the case where the fitness of individual organisms depends upon the group (the context) to which they belong – Is that also an example, or is it merely a perfectly ordinary case of individual fitness depending upon the environment in which the organism finds itself (**Figure 1**; see, e.g., Okasha, 2006; Okasha and Paternotte, 2012)?

Some of the questions in this area are fairly technical, but no less conceptually loaded for all that. Okasha's (2006) work on the different formal approaches to multilevel selection (the Price equation, Contextual Analysis, etc.) reveals both the deep mathematical compatibilities of what are sometimes interpreted to be competitors for the best approach (see also Kerr and Godfrey-Smith, 2002), as well as the places where, while each approach makes the correct predictions, only one approach seems to provide a causally satisfying explanatory story. What is the proper role of multilevel selection theory within evolutionary biology – (merely) proper accounting of evolutionary change, or providing accounts that not only get the right answer, but seem causally compelling? If there is often only one account that is correct, what kinds of biological facts determine which account is the correct one?

The Organism and Individuality

Organisms are usually thought to be of central importance to evolutionary biology, and in any event would seem to be a central ontological category for biology more generally. But individuating organisms – determining where particular individual organisms begin and end – has long been recognized as a challenge. Complex vertebrates would seem to be paradigmatic cases of individual organisms ('pace,' perhaps, the near ubiquity of commensal bacteria in vertebrates). On the other hand, the eukaryotic cells that makes up vertebrate bodies clearly seem not to be individual organisms, but rather parts of a more complex whole. But what to make of, for example, eubacteria that engage in obligate mutualism within particular environments (see, e.g., Dupré and O'Malley, 2009)? And are the colonies of eusocial organisms best thought of as collections of individual organisms (only some of which reproduced) or as some kind of organism-like entity in their own right (e.g., Hamilton *et al.*, 2009)? Note that some have suggested that this problem is closely related to issues involving multilevel selection – the move to having to think in terms of 'collectives' in order to make sense of the evolution of a population is at least part of what it means for those 'collectives' to count as biological individuals (Korb and Heinze, 2004; Okasha, 2006). Answers to one set of conceptual questions will sometimes influence the way other related questions are viewed.

Niche Construction

Lewontin (1983, 1985) noted that a standard view of adaptation was that of populations of organisms adapting to the

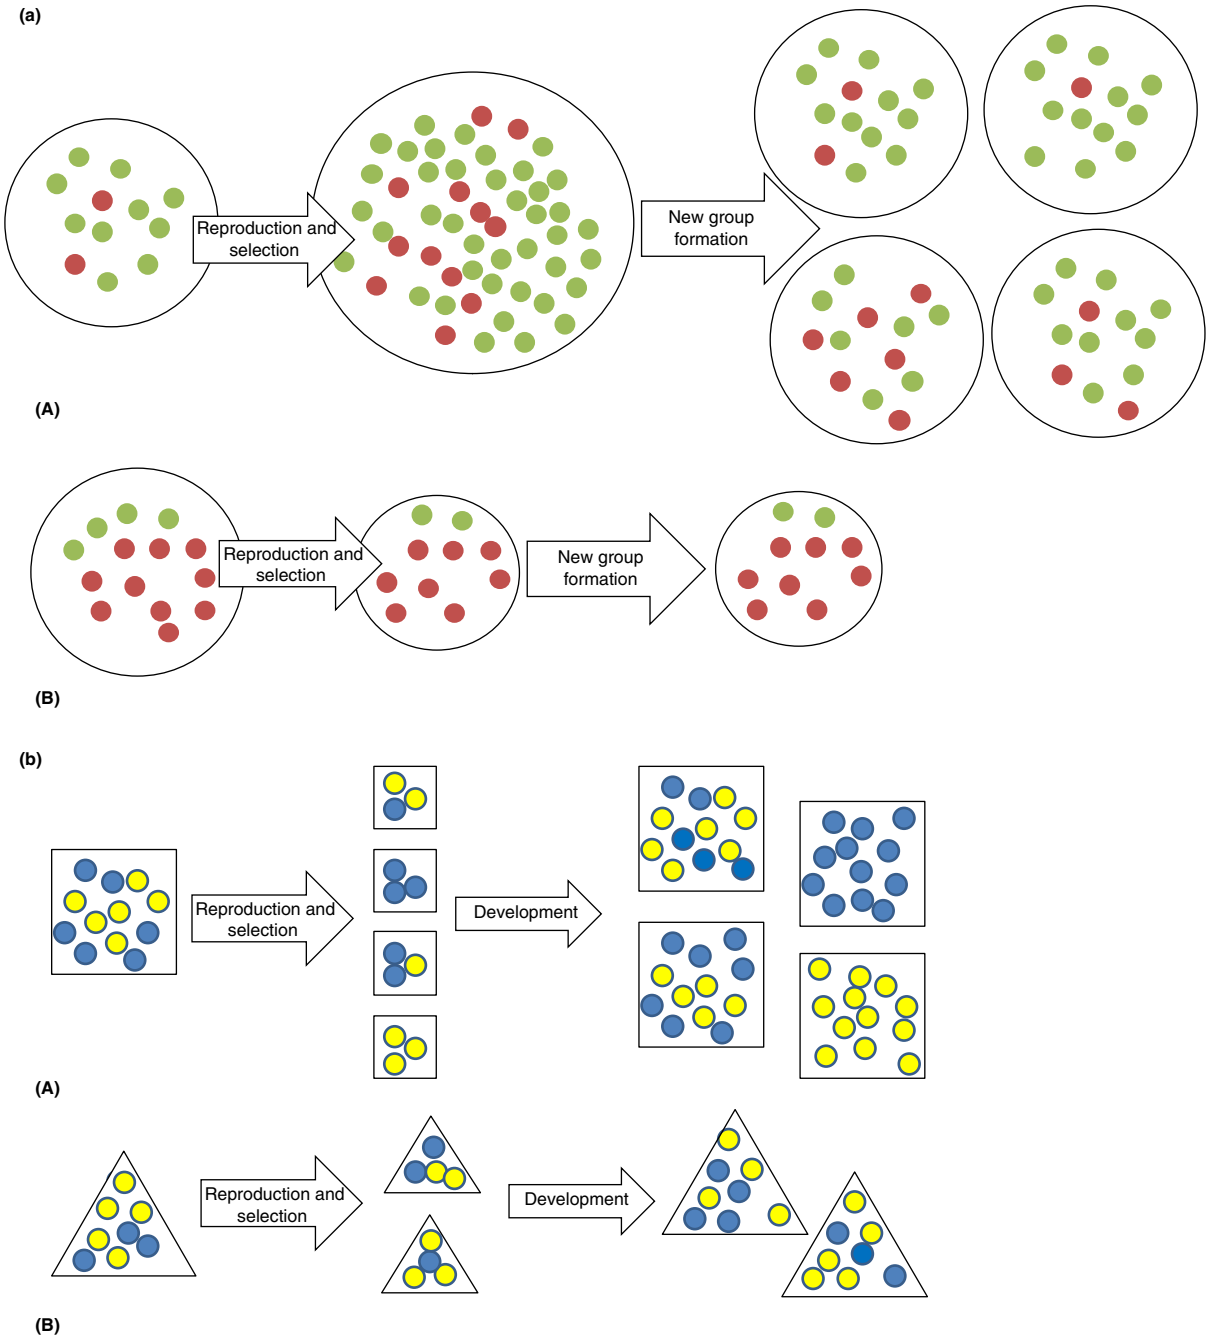

Figure 1 (a) Within each population, red (selfish) individuals are fitter than green (altruistic) individuals. However, individuals of both kinds in groups with a higher proportion of altruistic individuals (A) have higher fitness than individuals in groups with a higher proportion of selfish individuals (B). Given certain assumptions about how new groups form, under various conditions the proportion of groups comprised mostly of altruists can increase, despite being at a selective disadvantage in both kinds of groups. Note that the success of a group is simply a function of the success of the individuals that make the group up, and that the properties of the group are determined only by the fraction of individuals with particular traits that make up the group. In multilevel selection theory, this is known as MLS1 (multilevel selection 1); see Damuth and Heisler, 1988. (Adapted from Okasha, S., 2006. Evolution and the Levels of Selection, vol. 16. Oxford: Clarendon Press.) (b) Collectives (populations) of type 'A' are fitter than collectives of type 'B,' because of a feature of the collective itself; the feature that makes the collective fitter is not a feature that influences the fitness of the individuals ('particles') in the collective directly, and one cannot derive the fitness of the collective from the fitness of the individuals that make it up. The fitness of the collective is determined by how many decedent 'collectives' it leaves, not the number or fitness of the individuals within the collective. Selection at the lower levels (the particles within a collective) is at least partially decoupled from the fitness of the collectives. In multilevel selection theory, this is known as MLS2 (multilevel selection 2); see Damuth and Heisler, 1988. (Adapted from Okasha, S., 2006. Evolution and the Levels of Selection, vol. 16. Oxford: Clarendon Press.)

external environment, where changes in the external environment were conceived primarily as exogenous – "the environment proposes, natural selection disposes" (Gould, 2002, p. 31). But this view, he argued, was fundamentally mistaken. There was not, according to Lewontin, an eternal environment independent of the organisms that made it up, at least not in any meaningful sense. This critique had at least three distinguishable threads. First, the niche of an organism, Lewontin argued, could only be determined by observing the actions of the organisms itself. There were no 'preexisting' niches to be filled, there was no privileged way of diving up the world. Second, and closely related, what counted as a feature of the environment was determined not by the external world per se, but rather by how the organisms in fact lived in it. For example, what kind of environment 'water' is depends critically on the size of the organism trying to live in it; ways of moving through water that are very effective for large ocean predators (e.g., sharks and dolphins) would be hopeless for microorganisms (for whom water behaves less like the low-viscosity liquid most people are familiar with, and more like a very high-viscosity material such as warm tar – see, e.g., Yates, 1986). Finally, Lewontin suggested that the fact that organisms actively modified the environments in which they lived, through their actions in the world, had important implications for correctly understanding the ways that fitness differences emerged from the reciprocal relationship between organisms and their environments.

One research path articulating some of the implications of these observations is known as 'niche construction' (Odling-Smee *et al.*, 2003, 2013). It is uncontroversial that for some organisms, proper development requires environments deliberately formed by their parents or other conspecifics – nests, for example, are an important part of the developmental environment of many organisms. And the environment in which most beavers, say, are born is very different from what it would be like without previous generations of beavers creating and maintaining those environments (see, e.g., Naiman *et al.*, 1988). But what to make of these facts is controversial – does niche construction fundamentally change how evolution should be understood, or is niche construction rather a small wrinkle that does not require any profound changes to the usual understanding of evolution and the environment?

In a somewhat different context, Dawkins argued that the effects of genes should sometimes be seen as extending beyond the organisms that housed them, such that features of the environment could be thought of as part of the gene's 'extended phenotype' (see Dawkins, 1982); Dawkins does not, however, wish to endorse the whole niche-construction package, which he views as too detached from genetic differences that can influence fitness more or less directly (Dawkins, 2004). For Dawkins, part of the value of gene-selectionism is that it permits one to track the effects that genes have on the external environment (nest-building behaviors, parasites subverting their hosts' behaviors, etc.) in the same way as genes that have their effects in the 'usual' way – on the phenotypes of the organisms that house them (see, e.g., Hughes, 2013 for a review of the extended phenotype in parasitism). For Dawkins, while it is ultimately the genes that are the beneficiaries of selection, selection can act on genes through the external environments associated with those genes in just the same way it can act on genes through organismal phenotypes so-associated. In this way, questions about the role of the organism (or the genes of organisms) in producing environments gets tied to questions about the levels at which selection operates, and the nature of selection more generally.

The Nature of Selection, Fitness, and Drift

There have been a number of positions defended on the nature of selection, of fitness, and drift. It is sometimes claimed, usually by people ignorant of the basics of evolutionary theory, that evolution by natural selection rests on a tautology, because fitness is defined in terms of actual reproductive success; if the fit are simply those that survive, differential fitness cannot explain evolutionary change (see, e.g., Bethell, 1976). But this mistake is revealing – expressing precisely what fitness is, and what natural selection and drift are, is more difficult than it is sometimes imagined.

Probably the dominant view today is some variant of a propensity view – fitter organisms are those that, all else being equal, have a propensity to leave more offspring (or grandoffspring) than their less-fit counterparts in the range of environments in which organisms of that type are found (see, e.g., Mills and Beatty, 1979). Natural selection is responsible for those propensities, and drift is the main reason that actual outcomes fail to match those propensities (see, e.g., Richardson and Burian, 1992). One can understand evolution, on a closely related view, by thinking of selection and drift as separable forces, each of which has a distinct kind of impact on population dynamics (see, e.g., Sober, 1984). But more recently, some have argued that the natures of selection and fitness have been fundamentally misunderstood. According to defenders of the 'statisticalist' position, neither selection, nor drift, are properly thought of as processes nor as causes of evolution per se; rather, they are best thought of as ways of characterizing particular kinds of outcomes (e.g., Matthen and Ariew, 2002). Others have argued that defenders of these views move too quickly from statistical interpretations to rejecting casual efficacy, and suggest that a causal interpretation of fitness and drift can still be defended (e.g., Millstein, 2006, 2009).

This debate may seem quite distant from the concerns of practicing biologists. But one might reasonably ask what is being measured when biologists attempt to detect selection and measure fitness differences in the wild, and whether what is being measured in those cases fits in reasonably well with the notions of fitness that emerge from formal work in, for example, population genetics (see, e.g., Pigliucci and Kaplan, 2006). The debates over the proper interpretations of fitness highlight some of these conceptual difficulties.

A different kind of issue related to the nature of selection emerges from consideration of the in-principle minimum requirements for evolution by natural selection to occur. Under what conditions, in other words, can we legitimately expect cumulative selection to result in adaptations? Evolutionary biology is concerned primary with the actual state of the world, and the features that living things in fact have that permit evolutionary change. But explorations of the more general question of what abstract features of systems make evolution by

natural selection possible can shed light on important features of actual world (see, e.g., Godfrey-Smith, 2009).

Adaptations and Functions

What is it for a trait to be an adaptation, and how does being an adaptation differ from being adaptive? Below, arguments surrounding adaptationism are considered, from the standpoint of the project of critique – philosophy has played a role in arguments surrounding the appropriate evidentiary standards for adaptive hypotheses. But before one can argue about the evidence required to support the claim that some particular trait is an adaptation for performing some particular function (or set of functions), one needs to know what it means to claim that a trait is an adaptation. (Godfrey-Smith (2001) provides a good summary of the ways in which the debates surrounding adaptationism has often been ambiguous between empirical, explanatory, and methodological projects.)

Here, biologists themselves provided what many regarded as the definitive solutions, with Williams' (1966) notes regarding the 'onerous' nature of adaptive explanations (p. 41), and Lorenz's (1966) claim that "Unless selection is at work, the question 'What for?' cannot receive an answer with any real meaning." (p. 11) point toward what the clearly dominant view is. For a trait to be an adaptation for performing some function, the explanation for its current form and prevalence in the population in question must be due to past selection on traits with variation in their ability to perform that function. It is worth noting, though, that this position is not universal; in his textbook *Evolution*, Futuyma (2009) notes that some biologists still defend an ahistorical definition of adaptations (p. 284), though this is clearly a minority position. Gould and Vrba (1982) introduced a complication with their term 'exaptation' for traits that are now used by an organism in a way that increases fitness, but which did not arise in the population because of their association with that use; however, neither the terminology nor the concept ever caught on. Indeed, Godfrey-Smith's (1994) 'Modern History' view of functions entails that for a trait to be functional, and hence to be an adaptation, it must have been subject to selection for that function in its relatively recent evolutionary history, whatever else it was or was not selected to do in the more distant evolutionary past.

The Nature of Populations

The concept of a population plays important roles in evolutionary biology, but, again, stating precisely what constitutes a population is more challenging than is often recognized. There is no consensus on necessary conditions for some collection of organisms to form a biologically meaningful population. Some authors have tried to identify how, in practice, working biologists in different fields in fact pick out populations (see, e.g., Winther and Kaplan, 2013) while others have defended stronger claims regarding what biologists ought to be picking out when they identify populations (e.g., Millstein, 2010). Some of the interest in this work comes from investigations of population structure using genomic data; especially when applied to human population structure, how to interpret the results of such research remains controversial (see, e.g., Weiss and Fullerton, 2005). But more generally, whether a collection of organisms is itself a population, rather than merely being part of a larger population, can have important implications for conservation efforts (including the application of the Endangered Species Act, in the United States) and for thinking about the evolution of the (putative) population (see, e.g., Allendorf and Luikart, 2009).

The Gene Concept

Stotz and Griffiths (2004) identify a number of different gene concepts in regular use in different domains in biology. Genes are sometimes conceived of as difference-makers – relatively abstract entities associated with phenotypic differences (this gene concept is very roughly what Moss dubs the 'Gene-P' concept; see Moss, 2004). It is this concept of the gene that is most like Mendelian genes, and also most like the genes referred to in much of population genetics. But genes are also regularly thought of as particular physical strands of DNA – physical molecular entities. These physical stretches of nucleic material are used in various ways during development, and Moss dubs the gene thought of in this way the 'Gene-D' concept (Moss, 2004).

Even the most cursory investigations reveals the difficulty with reconciling genes as difference makers related to phenotypic traits (roughly, Mendelian genes) with molecular genes (stretches of DNA that involved in protein synthesis and its regulation) (see, e.g., Sterelny and Griffiths, 1999, Chapter 6 'Mendel and Molecules'). There is no one-to-one relationship between stretches of DNA and gene-products; a given stretch of DNA can produce multiple different proteins (e.g., alternative splicing) and a particular protein may be produced by the interactions of multiple different stretches of DNA that are transcribed separately (Stotz and Griffiths, 2004). Researchers working in different traditions identify different kinds of things as genes, and hence even those who work primarily on molecular genes can count them differently – some, for example, focus on the total number of discrete gene-products (proteins), and others on the number of distinct functional elements, etc. (Griffiths and Stotz, 2006).

Indeed, the arguments surrounding the claims emerging from ENCODE regarding the functionality of so-called junk DNA emerge in part from arguments surrounding what will count as a gene, as well of course from arguments surrounding the nature of biological functions (see Graur *et al.*, 2013). Is having a sequence similar to sequences that are actively used in development enough to call something a gene, or need there be evidence that the sequence is actually used – that, for example, when transcribed the transcription products are in fact put to biological use? Does a sequence have to be used in some way during development, such that the details of the sequence itself matters, or does the fact that some sequence (rather than none) is needed (to serve as a 'spacer' perhaps) suffice to identify something as a gene (Graur *et al.* (2013) call the latter sequences 'indifferent DNA,' pp. 586–587)?

Philosophy and Evidentiary Questions

Above, it was noted that one issue raised by the debates surrounding adaptationism was just what, precisely, was required in

order for a trait to be an adaptation. But even after one has settled upon the definition of adaptation, there may still be arguments regarding the minimum evidence required in order to appropriately claim that a particular trait is in fact an adaptation for performing such and such a function. Gould and Lewontin's (1979) famous 'Spandrels' paper criticized the so-called adaptationist program in part by claiming that too many biologists were willing to argue that a trait was an adaptation on the basis of far too weak evidence; indeed, they claimed that often the mere qualitative agreement between a plausible-sounding selective story and contemporary behavior was regarded as sufficient for accepting the selective story (587ff). Contrast this, for example, with the work done to defend the claim that the sword-tails of male sword-tailed *Xiphophorus* were an adaptation to a preference that female *Xiphophorus* had for males with sword-tails. Here, observational work established that females really were more likely to mate with males that had longer sword-tails. Phenotypic manipulations were used to determine if it really was the tails that were doing the work, and phylogenetic analyses supported the claim that the female preference for males with sword-tails predated the appearance of males with sword-tails. The hypothesis that the swords arose in response to female preference, and that what explains the presence of the sword-tails is past selection based on female preference, seems, in this case, rather well supported, albeit not without some complications (see Basolo, 1990; Marcus and McCune, 1999). On one reading, one of Gould and Lewontin's complaints in 'Spandrels' was that this level of careful investigation and testing was too rarely exercised (for a summary of some methods available for testing adaptive hypotheses, see, e.g., Rose and Lauder, 1996; Pigliucci and Kaplan, 2000).

Claims about human psychological adaptations were seen by Gould and Lewontin as particularly sloppy and ill-supported, and most philosophers who waded into the debates surrounding human sociobiology tended to agree. Kitcher's (1987) *Vaulting Ambition* was a book-length critique of what Kitcher argued were the poor evidentiary standards being deployed by so-called sociobiologists. More recently, one can see David Buller's extended critique of 'evolutionary psychology' (see **Box 1**), in *Adapting Minds* (2005), as fitting into the same framework – Buller argues that evolutionary psychologists have been too quick to draw (often quite sweeping) conclusions based on too little (and often fragmentary) data. Lloyd's (2005) work on the human female orgasm takes a similar critical tack – that in the human case, particular hypotheses involving traits as adaptations are too often made on the basis of poor evidence. Part of the problem is that it is very difficult to rigorously test hypotheses regarding adaptations in humans (especially for psychological or behavioral traits) (see **Table 1**; see, e.g., Kaplan, 2002).

While most philosophical discussions of issues surrounding arguments for and against the need for an extended synthesis, or DST as a plausible research program, etc., have focused on the conceptual issues engendered by these arguments, some philosophers have taken on the interpretations of the empirical data, arguing, for example, that a careful review of the evidence makes certain positions untenable (see, e.g., Oyama *et al.*, 2001; Moss, 2004). Here, the results of biological research are deployed in order to support particular research programs, and to make particular analyses seem more plausible.

Box 1 Evolutionary Psychology

As suggested in the main text, philosophers of biology have been interested in evolutionary psychology for a number of reasons. But what is the object of that interest? Buller (2005) distinguishes between **E**volutionary **P**sychology (capitalized) and **e**volutionary **p**sychology (while useful, this distinction is not universally used). The former is a particular research tradition associated with a particular set of claims and methodological practices, and the latter is any attempt to use evolutionary biology in the service of understanding human behaviors (and it is worth remembering that researchers engaged in evolutionary psychology will sometimes endorse some but not all of the basic claims and methodological practices of Evolutionary Psychology, so the lines are not as crisp as this might make them seem; see, for example, Confer *et al.*, 2010). The latter, evolutionary psychology, is at least in principle uncontroversial – since the human brain is the product of biological evolution, and since its larger size and greater complexity are metabolically expensive and of relatively recent origin, the idea that the brain is an adaptation for some kinds of psychological abilities or other is fairly straightforwardly correct. Even here, though, Lewontin (1998), for example, charts a very pessimistic course regarding what, precisely, we might learn about the evolution of human cognition, given the limitations of evidence available (see **Table 1** for some of these). But the former, Evolutionary Psychology, is associated with much more controversial claims. In its more or less canonical form, these include:

1. 'Massive modularity' – The human mind is made up of a very large number of 'modules,' each of which evolved to 'solve' some particular adaptive problem.
2. 'Human universals' – The adaptations that make up the human mind are universal in the human species.
3. 'Stone age minds' – The particular problems the human mind evolved modules to solve are those that were most important to our ancestors in the so-called 'environment of evolutionary adaptedness'; for many traits, especially those that are supposed to be uniquely human, this is assumed by EP practitioners to be the Pleistocene (2.6 million to 11 700 years ago).
4. 'Adaptive thinking' – Reflecting on the problems faced by our ancestors, and considering what solutions would have been both biologically possible and adaptive, is a useful technique for generating hypotheses regarding the existence of mental modules. One can then test for these hypothesized adaptations by thinking through the cognitive consequences of their existence, and making predictions about how people will behave on that basis.

(See, e.g., Cosmides and Tooby, 1997; Downes, 2014; Tooby and Cosmides, 1990).

Different sorts of objections have been raised to these basic claims, such as: the empirical evidence for modularity of the sort proposed in (1) is weak, and the arguments that the mind must be modular in that way problematic; there is no reason to think that the mental problems faced by different human populations were universal as in (2) (consider: the evolution of lactase persistence in some but not all human populations); it is at least plausible that the problems faced during human evolution were not stable (3), but rather the result of living in cultures that changed with the changes in the people making them up, so there never was an environment of evolutionary adaptedness, even in aggregate; the suggested methodology (4) is not the primary methodology deployed in the study of nonhuman adaptations, including behavioral adaptations in nonhuman animals (see, e.g., Buller, 2005; Downes, 2014; Lewontin, 1998; Stereln and Griffiths, 1999). In addition, as the main text makes clear, there are objections to the many of the specific hypotheses put forward by practitioners of EP.

Table 1 Human adaptations: Why testing hypotheses regarding adaptations is so difficult for traits in humans

Technique	*Evidence generated*	*The trouble with humans*
Phenotypic manipulation (laboratory or field)	Fitness consequences of the traits in question, causal mechanisms associated with traits and fitness consequences	Ethical constraints + no controls in natural cases
Transplant studies	Fitness consequences, hypotheses re: selective pressures, hypotheses re: local adaptations	Ethical constraints + few ways to control for confounding variables in natural cases
Laboratory evolution	Robustness of pathways, strength of constrains	Ethical constraints + very poor model organism
Optimization analyses	Quantitative plausibility of qualitative assessments, sensitivity, path-dependence	Little knowledge of relevant selective history or specific functions for many of the traits of interest
Phylogenetic analyses	History of trait, homology (shared-derived trait) versus homoplasy (independent derivation of trait)	Sparse clade; very few reasonably close extant relatives
Comparative method/regression analyses	Relationship between trait and environmental variables, strength of relationship, relationship between trait and fitness	Very little known about environment/trait relationships, little known about trait/fitness relationships, little known systematic variation between populations within species

Notes: For more on testing hypotheses involving putative adaptations, see, for example, Rose and Lauder (1996) and Pigliucci and Kaplan (2000). For some of the specific difficulties in the case of testing adaptive hypotheses involving human traits (especially human psychological or behavioral traits), see, for example Kaplan (2002).

In a somewhat similar vein, arguments surrounding adaptive and fitness landscapes rely on the results of empirical research to support particular positions regarding the advisability (or coherence) of particular models (and metaphors). Here, some philosophers have argued that relatively recent advances in modeling make certain uses of fitness landscapes problematic (see, e.g., Pigliucci and Kaplan, 2006; Kaplan, 2008; Pigliucci, 2012); others have argued that these objections are at least overstated, and at most apply to only some potential uses of fitness landscapes (see Skipper and Dietrich, 2012; Svensson and Calsbeek, 2012).

Finally, philosophy has played some role in the debates surrounding the teaching of evolution in public schools in the US context; Michael Ruse, for example, was called as an expert witness in the famous 'McLean v. Arkansas Board of Education' (1981) case regarding the teaching of creation science and several philosophers testified at the 'Kitzmiller v. Dover Area School District' (2005) trial regarding so-called Intelligent Design. And more recently, Kampourakis (2014) has written on how educators might work to overcome what he regards as conceptual barriers to students' properly understanding evolutionary biology.

The Implications of Evolutionary Biology on Philosophical Problems

This article has so far mainly focused on the ways that philosophers of biology, and biologists working on conceptual issues in a philosophical way, have approached issues arising in evolutionary biology. But some have argued that evolutionary biology might have implications for traditional philosophical problems. On one view, this might be part of the expected progression of what were thought to be philosophical problems succumbing to scientific investigation – the claim that as more and more fields become empirically firmly grounded, less is left for philosophy. Some questions about basic ontology are now, for example, generally thought to be best addressed by physics, and not by philosophical investigation. And insofar as one thinks that design arguments of the sort defended by Paley (1802) (someone not generally considered a philosopher) and criticized by Hume (1779) (a canonical philosopher) were part of a philosophical tradition, evolutionary biology of course completely undermines them as reasonable philosophical questions (contemporary defenders of intelligent design theses notwithstanding). But whether evolutionary biology will result in similar usurpations of what are now thought of as traditional philosophical questions remains a live issue.

For example, one question that has received a fair bit of attention is the extent to which evolutionary biology might provide insights relevant to moral philosophy ('evolutionary ethics'). Certainly, insofar as our abilities to engage in moral reasoning require sophisticated cognitive systems, the fact that our ability to so-engage is the result of our recent evolutionary history must be at least relevant to understanding how moral reasoning is possible. But how it is relevant remains opaque. If our ability to engage in moral reasoning was the result merely of our ability to engage in particular general sorts of abstract reasoning (a view that would seem in line with, for example, Kant's interpretation of morality and its relationship to our moral abilities), then evolution would explain nothing in particular about our moral lives, but merely how we became the sorts of being capable in engaging in that kind of reasoning (compare: it is only because of the sorts of being we evolved to become that, for example, modern set-theory is possible, but the details of our evolutionary history are generally believed to be broadly mute on the issues considered interesting by set-theorists). On the other hand, if our moral lives emerged from earlier pro-social behaviors, and if selection acted on our abilities to engage successfully in those kinds of behavioral repertoires, then the details of our evolutionary history might

explain, for example, some common intuitions or the reasons that certain ways of organizing our moral lives are more common than others. There is, with such work, often the concern that the 'naturalistic fallacy' is lurking nearby – in this case, for example, one might worry that even a complete explanation of how particular tendencies related to our moral abilities evolved would not reveal anything about how we ought to behave (but merely about how we in fact tend to actually behave) (see, e.g., FitzPatrick, 2014; Ruse, 1986).

Other research areas that might be thought to impact on some traditional areas of philosophical enquiry include at least the following. Work on the evolution of language and communication more generally might have some implications for some issues in the philosophy of language (e.g., Ruse, 1986; Skyrms, 1996). Evolutionary epistemology – the study of evolution's role in the formation of beliefs about the world – may impact some approaches to epistemology in philosophy; it has in any event inspired some new approaches (see, e.g., Millikan, 1984; Godfrey-Smith, 1996). Some people have made claims about the implications of evolutionary biology for our understanding of the genesis and maintenance of religious beliefs and practices (Norenzayan and Shariff, 2008); while not precisely a philosophical issue, it seems related. Some philosophers have turned to evolutionary thinking in their work on esthetics (e.g., Voland and Grammer, 2003). And, of course, some of the kinds of claims sometimes associated with some (particularly problematic) articulations of sociobiology (and later, evolutionary psychology) were thought to have implications, for example, the range of plausible political positions, the possibility of eliminating particular kinds of sexism or racism, etc.; though these positions never got much traction either in philosophy or biology properly speaking, they still attract some support.

Even where evolutionary (or biological) reasoning and empirical work are not the last word, it is worth noting that philosophical positions that are wildly at odds with broadly accepted biological theories are liable to be criticized harshly, especially if they fail to confront the empirical research that would seem to undermine them. For example, in her devastating review of McGinn's *The Meaning of Disgust*, Strohminger (2014) notes that McGinn fails to even mention "the most widely accepted theory of disgust today," namely that it is an adaptive behavioral extension of the immune system for pathogen avoidance (p. 214). While biology might only rarely settle a philosophical question, it can at least make certain avenues far less promising. At the very least, philosophers interested in explaining the etiology of particular human behaviors need to be aware of the contemporary biological work in the fields that they address.

Final Thoughts

There is, and has been for many years, a rich and ongoing exchange between philosophy and evolutionary biology; indeed evolutionary biology has been involved with philosophical questions from its very founding. Biologists interested in the conceptual foundations of their research areas have been forced to engage in conceptual analysis – forced, in other words, to tackle philosophical questions. Indeed, the line between the philosophy of biology and biology proper has often been blurred by both biologists and philosophers. Is Gould and Lewontin's famous 'Spandrels' paper a biology paper, or a paper in the philosophy of biology that just happens to have been written by two practicing biologists? Is Okasha's (2006) *Evolution and the Levels of Selection* a philosophical work that just happens to be valuable to practicing biologists and hence regularly cited in primary research articles in straightforwardly biological journals, or is it (also) a contribution to biology itself? And the philosophy of biology has involved, and continues to involve, many fruitful collaborations between practicing research biologists and philosophers (Eliot Sober, one of the founders of the philosophy of biology as a separate discipline, has published with R.C. Lewontin, with D.S. Wilson, and with S. Orzack; Elizabeth Lloyd, has published with Lewontin, with M. Feldman, with C.G. Anderson, and with Gould; Peter Godfrey-Smith has published with Kerr, as well as with Bergstrom; etc.).

The relationship between evolutionary biology and philosophy has been valuable for both fields. Philosophy has brought a kind of conceptual rigor to bear on some foundational issues in evolutionary biology, and has, at times, played an important role in helping to clarify the complex role that evidentiary standards played in the acceptance (or rejection) of particular hypotheses. Evolutionary biology has opened new avenues of exploration in a number of traditional philosophical domains, and, in providing answers to some questions traditionally thought of as philosophical, has solved (or perhaps dissolved) some philosophical problems. This article merely sketches the broad outlines of some of these areas.

Phylogenetic Approach to Studying Developmental Evolution: A Model Clade Approach

DG Howarth and MP Dunn, St. John's University, Jamaica, NY, USA

Glossary

Blastoderm A stage in the early development of animals in which a layer of cells lines the periphery of the embryo.
***cis*-regulatory element** A sequence of DNA that is located in the vicinity of a gene coding region and which is responsible for its transcriptional regulation (see also, Enhancer).
Clade (monophyletic group) An ancestor and all of its descendants. Can be used to describe organism or gene phylogenies.
Core eudicot A monophyletic clade comprising over 70% of flowering plants.
Corolla The petals of a flower, collectively.
Enhancer A short, usually locally acting, region of DNA near a gene locus that is bound by proteins acting to modulate the transcription of the gene in a spatially and temporally specific fashion.
Labrum One of the mouthparts of the arthropod head, a flap-like structure covering the mandibles.
MicroRNA A short noncoding RNA molecule that functions in posttranscriptional gene regulation.
Ortholog Genes found in different species that are both derived from the same gene in an ancestral species.
Pair-rule gene A suite of genes expressed in seven discrete bands in the early insect embryo perpendicular to the anterior–posterior axis.
Paralog Genes found within a species that are derived from an ancestral gene duplication.
Petaloid bracts Modified leaves that resemble petals.
Pollination syndrome A suite of floral characteristics (color, morphology, etc.) providing adaptation for pollination by a specific pollinator type (bee vs. moth vs. hummingbird, etc.).
Synapomorphy Shared derived character, an evolutionary transition that happened in the ancestor of that clade.
Transcription factor A protein that binds to DNA in a sequence-specific fashion and alters the rate of DNA transcription.
***trans*-regulatory element** Genes that modify or regulate the expression of genes at a distance (see also, transcription factor).
VIGS Virus-induced gene silencing, a RNAi method for gene knockdown.

Toward the Use of Phylogenetics in Evo-Devo

Comparing ontogeny across species to examine similarities and differences among organisms is an old discipline. In the late twentieth century there was a resurgence of this field, Evolution of Development (Evo-Devo), with the growing numbers of molecular and developmental tools becoming available in key model species (Gould, 1977; Hall, 2012). The discovery of shared major developmental genes, such as HOX and MADS-Box genes (Averof, 1997; Chanderbali *et al.*, 2010; Coen and Meyerowitz, 1991; Gehring, 1985,1998; Janssen *et al.*, 2014; Soltis *et al.*, 2006), further fueled interest in comparing shifts in the molecular basis of traits across disparate species. The research was initially very broad, with researchers comparing the growing gene expression and functional data in model systems, aiming to find common ground across all animals or plants. Insights have been gleaned by the observation that many important signaling and transcription factor families are similarly utilized or co-opted for the developmental growth of certain traits across disparately related model organisms (Boyle *et al.*, 2014; Gerstein *et al.*, 2014). This research was hindered by the fact that genomic information and gene expression and functional tools were only available in model species. The next step was to study fine scale differences among different varieties, sister species, or a small species complex encompassing model systems. The most notable group was within the small Drosophilid species complex including the fruit fly, *Drosophila melanogaster* (Green II and Extavour, 2012; Jeong *et al.*, 2006; Prud'homme *et al.*, 2006).

All of this information led us into the twenty-first century with a growing awareness that large amounts of the genetic basis of development are similar across broad phylogenetic groups and that many of the differences among species were largely due to gene regulation and likely shifts in the timing or location of gene expression with or without gene duplication (Abzhanov *et al.*, 2008). Comparison of gene expression and function in model organisms, especially in organisms with morphologically similar but nonhomologous structures, has highlighted the frequent genome tinkering of similar genetic pathways to result in similar structures (Carroll, 2008; Gehring and Ikeo, 1999; Olson, 2006; Panganiban *et al.*, 1997). Examples of traits co-opting the same gene regulatory network to independently generate a similar structure continue to grow. Two compelling examples are the separate evolution of sight in animals (Arendt, 2003; Gehring and Ikeo, 1999) and the independent evolution of bilateral symmetry in flowers (Hileman, 2014; Specht and Howarth, 2015), which both independently co-opt the same gene regulatory network repeatedly. Likely due to the fact that most comparative studies examining the genetic basis of trait changes were comparing closely related sister species complexes, it was initially hypothesized that most evolutionary change has been due to *cis*-regulatory mutations (Carroll, 2008). However, growing

 doi:10.1016/B978-0-12-800049-6.00137-2

evidence indicates that changes in the patterns of gene expression, either through *cis*- or *trans*-regulation, is a more thorough explanation (Hoekstra and Coyne, 2007; Specht and Howarth, 2015). Examining gene expression across multiple species could shed significant light on these hypotheses.

With the growing availability of techniques to assay gene expression and function in non-model systems, researchers have been increasingly branching out into emerging model species (Abzhanov *et al.*, 2008). In fact, a significant portion of current Evo-Devo research revolves around examining a gene that has a known function in model organisms and examining it in a distantly related non-model organism. These comparisons are often determining if changes in gene expression and/or function are correlated with a trait change. For instance, Janssen *et al.* (2014) examined HOX gene expression in a single species of a small ecdysozoa phylum, Onychophoran, and compared it to known arthropod expression, concluding that discrete spatial expression in different HOX gene paralogs predates the specialization of arthropod segments. These kinds of comparisons have been highly informative and provide clues about a candidate gene's role in developmental patterning that we may not have concluded from model systems alone. That said, they are still a snapshot of a single organism. In the last few years modern techniques for assaying gene expression and function have become much cheaper and more approachable across multiple species, and we are starting to see research across clades. These gene expression and function studies across multiple species at once, which often encompass multiple trait gains, losses, or modifications, utilize a more 'model clade' approach. Utilizing not just model species, but also model clades, could more rapidly provide clues about the genetic basis of evolutionary change.

Model Clade Approach

In recent years it has become easier to assay gene expression and function in nontraditional model organisms. Techniques such as qPCR and RNA-seq have become potentially useful tools in any organism to examine fine scale differences in the level of expression temporally, spatially, or across species (Boyle *et al.*, 2014; Gerstein *et al.*, 2014; Morrison *et al.*, 1998; Pantalacci and Sémon, 2015; Pfaffl, 2001; Roux *et al.*, 2015). Additionally with RNAi technologies, functional studies of non-model organisms have become more reachable (Dinesh-Kumar *et al.*, 2003; Fire *et al.*, 1998). With these new techniques, many researchers have branched out into new emerging model species. These species have been chosen with several key characteristics in mind, such as having large numbers of individuals available either in the lab or the wild, having reliable tools for expression analysis, and having at least one functional tool available (Abzhanov *et al.*, 2008). Additionally, many new model species are chosen because they either represent an undersampled part of the tree of life, they have a breadth of traditional genetics and/or morphological research already to build on (such as *Heliconius* butterflies; Joron *et al.*, 2006), or they are closely related to current model species but vary in key traits. All of these attributes are important things to consider when working on new model species.

With improved research technologies, however, we can search out not just good potential model species, but also potential 'model clades.' A model clade would be a group of species within a defined clade that could be targeted for gene expression and/or functional studies. These species do not need to be sister species, necessarily, but could be chosen to sample across each of smaller groups across a clade. The benefits of a clade-based approach include a number of factors that give us more power to interpret gene expression and function and how it plays a role in morphology. For instance, a model clade could include not just a single shift in a trait of interest (like comparing a model to a non-model, for instance), but multiple similar shifts. This gives us more than one data point, and therefore the potential to uncover patterns in gene utilization or regulation. Perhaps even more informative, a model clade can include early transitional forms of the trait. Most research logically focuses on model species with highly derived (i.e., strong phenotypes) complex traits, usually in the crown group of the clade. In other words, we examine species with strongly bilaterally symmetrical flowers (Hileman, 2014; Luo *et al.*, 1996) rather than species that have nearly radially symmetrical flowers. When we are uncovering novel genes, it is often necessary to examine species that have a highly derived form of the trait so that we can more easily assay morphological changes. However, once we have an hypothesis of the gene's role, examining it across a clade that includes potential steps in increasing complexity can add a significant amount of understanding to how the gene evolved and is utilized by organisms.

A model clade would have a number of factors that would make it useful: (1) A well-supported species phylogeny. This allows for a simpler comparison of gene trees to a backbone species tree to uncover gene duplication or loss events or other genomic changes. (2) Character traits that are mapped across the phylogeny. Ideally a model clade would have either interesting transitional forms or multiple similar morphological shifts in the trait of interest. (3) Finally, a model clade should have multiple species spread throughout the clade that are easy to obtain and amenable to gene expression and/or functional techniques.

Dipsacales, an Example of a Model Clade for Floral Symmetry

We have used Dipsacales as a model clade to examine the evolution of the developmental pathway specifying floral symmetry. By choosing several species across the Dipsacales, a diverse clade of plants with multiple different patterns of floral symmetry, we are able to examine and track multiple character transitions across a large group of closely related organisms. In addition to identifying single character transitions among sister species, using a broad clade approach allows us to identify distinct morphological shifts among entire lineages of species, thereby examining the developmental context of species diversification.

The Dipsacales provides a group of plants with (1) a well-resolved species phylogeny to track trait changes (Backlund and Donoghue, 1996; Bell *et al.*, 2001; Bell, 2007; Judd *et al.*, 1994; Pyck, 2001; Winkworth *et al.*, 2008a; Zhang *et al.*, 2003),

(2) tremendous morphological diversity, especially in many floral characteristics and floral symmetry which have been mapped across the phylogeny (Donoghue *et al.*, 2003), and (3) a number of sample species which are horticulturally viable and can potentially be manipulated with modern developmental and genetic tools (Berger *et al.*, 2015; Boyden *et al.*, 2012; Carlson *et al.*, 2011; Howarth and Donoghue, 2009, 2005; Howarth *et al.*, 2011). Having a robust Dipsacales phylogeny provides a solid basis for inferring the location of evolutionary changes in flower characters (Donoghue *et al.*, 2003), as well as a secure framework within which to infer the evolution and duplication of known floral symmetry genes and their relation to morphological changes. A variety of floral forms are found in Dipsacales (**Figure 1**), including radially symmetrical, pseudo-radially symmetrical, bilaterally symmetrical, and asymmetric flowers as well as stepwise losses of stamens (Donoghue *et al.*, 2003). It is likely that Dipsacales was ancestrally radially symmetrical and therefore that bilaterally symmetrical flowers originated independently within this lineage (Donoghue *et al.*, 2003, 1998; Ree and Donoghue, 1999; Winkworth *et al.*, 2008b).

We have previously sequenced candidate genes that are part of the floral symmetry gene regulatory network, with the most focus on the ECE clade of TCP transcription factors similar to *CYCLOIDEA* (*CYC*). These genes were initially characterized in *Antirrhinum majus* and highlighted as dorsal identity genes, being expressed in the dorsal petals and aborted stamen (Luo *et al.*, 1996, 1999). Our analyses have allowed us to pinpoint gene duplication events that correlate with shifts in floral shape. For instance, the shift to bilateral symmetry correlates with mirrored duplications in two different *CYC*-like genes (Howarth and Donoghue, 2005). Other researchers have now confirmed a trend in an increase in *CYC*-like genes in plants with more complex floral symmetries (Carlson *et al.*, 2011; Chapman *et al.*, 2008; Tähtiharju *et al.*, 2012). Using a model clade approach, and comparing gene copies from across a clade allowed us to pinpoint 3 *CYC*-like gene clades. Adding data from other published groups outside of Dipsacales showed that these gene duplications spanned the core eudicots (~70% of flowering plants), uncovering two gene copies that had not yet been examined in other groups (Howarth and Donoghue, 2006). We were only able to pinpoint these gene clades because of a large phylogenetic dataset in Dipsacales (Howarth and Donoghue, 2006).

Using a clade approach in Dipsacales has also allowed us to examine how changes in gene expression correlate with stepwise progressions in bilaterally symmetrical flowers (**Figure 1**). We used semi-quantitative PCR to determine gene expression through the early diverging lineages of bilaterally symmetrical Caprifoliaceae (a sub-clade of Dipsacales) (Howarth *et al.*, 2011). These studies indicated that shifts in ubiquitous expression of CYC2 genes in radially symmetrical sister groups became stepwise more dorsally restricted in each more nested clade of increasing dorsoventral specialization (**Figure 1**). An initial duplication of CYC2 genes in the ancestor of Caprifoliaceae was followed first by the dorsal restriction of both paralogs and then by the uncoupling of their expression domains, resulting in one paralog being more dorsally restricted than the other (Howarth *et al.*, 2011). These kinds of studies indicate, for instance, that *CYC* is not simply a dorsal identity gene, being restricted to only dorsal petals in highly bilaterally symmetrical species, but instead the level of restriction of CYC2 on the dorsoventral axis correlates with petal divergence along that axis, a hypothesis impossible to uncover through comparisons of individual CYC2 paralogs to *Antirrhinum CYC* alone.

Phylogenetic Evo-Devo Studies

An increasing number of studies are incorporating a clade approach in examining Evo-Devo questions. Thanks to newer and more versatile techniques, we are able to compare gene expression or function using similar methodologies across a larger sampling of species in a clade. For instance, even in species with little previous molecular research, tissues can now be easily assayed for gene expression with semi-quantitative rtPCR or qPCR (Howarth *et al.*, 2011; Zhang *et al.*, 2012, 2013b). Additionally, because of better-understood species phylogenies and high-throughput sequencing techniques, it is now easier than ever to determine gene orthology across a group (Kellogg, 2006). While many of these studies are still using a candidate gene approach, an increasing amount of phylogenomic data is also being used to uncover and implicate novel genes, suites of genes, and microRNAs as well. We here highlight a sampling of recent studies examining Evo-Devo in a phylogenetic context across a clade.

Gene Expression across Model Clades

In plants, the buttercup family (Ranunculaceae) has been highlighted as a useful clade for Evo-Devo studies as it is sister to the rest of eudicots and it encompasses much of the floral form diversity that makes up angiosperms, especially in petal morphology diversity (Sharma *et al.*, 2014a; Zhang *et al.*, 2013a). Loss of petals occurs in many groups in the Ranunculaceae and a more recent understanding of the phylogenetic relationships suggests that the ancestral character state was petalous and that petals have been lost independently in at least seven different lineages (Damerval and Nadot, 2007; Wang *et al.*, 2009; Zhang *et al.*, 2013a). Zhang *et al.* (2013a) dissected floral tissue from five of these seven transitions and quantified gene expression of the three Ranunculaceae paralogs of the petal identity MADS-box gene *APETALA3 – AP3-1*, *AP3-2*, *AP3-3*. Using qPCR these researchers show that each loss of petals correlates with loss of expression of *AP3-3* (Zhang *et al.*, 2013a). These data more strongly suggest a similar function of this paralog across the family than a hypothesis formed from the observation of a single gene loss in one species. A similar study of B class MADS-box genes in *Cornus* (dogwood) determined that three paralogs had overlapping, yet differing expression patterns in the inflorescences of three separate species. The researchers utilized phylogenetic character mapping analyses to trace the expression of each gene on the *Cornus* phylogeny. They used these analyses to show that the two species with petaloid bracts are likely independently derived, which differs from the previous hypothesis (Feng *et al.*, 2012).

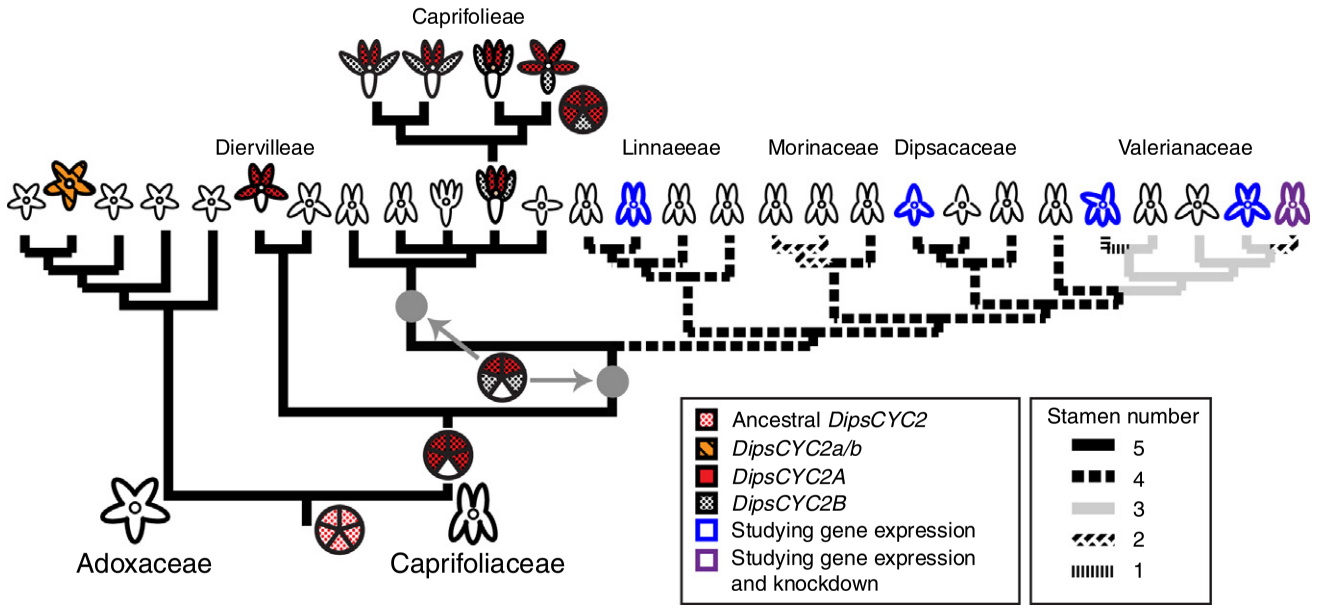

Figure 1 Illustration of Dipsacales as a model clade for studying the evolution of floral symmetry. We are studying the ontogeny and molecular basis of shifts in floral shape across species from each of the major clades. Floral diagrams in color indicate targeted groups. Red, orange, dotted, and striped shading indicates expression of *CYC* paralogs from the CYC2 clade (*DipsCYC2A*, *DipsCYC2a*, *DipsCYC2B*, *DipsCYC2b*, respectively). Separate independent duplications in Adoxaceae and Caprifoliaceae led to the a/b paralogs and the A/B paralogs. Five-parted circles labeling nodes indicate hypothesized ancestral expression of the duplicated paralogs across the five petals. Gray circles indicate that the transition could have happened at either node. Work is currently being continued on gene expression in groups with floral diagrams in blue. The floral diagram in purple indicates a group being studied with VIGS to assay loss-of-function morphology. The data and image are modified from Howarth, D.G., Donoghue, M.J., 2005. Duplications in *CYC*-like genes from Dipsacales correlate with floral form. International Journal of Plant Sciences 166, 357–370; and Howarth, D.G., Martins, T., Chimney, E., Donoghue, M.J., 2011. Diversification of *CYCLOIDEA* expression in the evolution of bilateral flower symmetry in Caprifoliaceae and *Lonicera* (Dipsacales). Annals of Botany 107, 1521–1532.

An increasing number of studies are examining floral symmetry candidate genes across various angiosperms and correlating expression with floral shifts (see Hileman, 2014; Specht and Howarth, 2015). Similar to previously discussed Dipsacales, three recent papers in Malpighiales have examined the expression of CYC2 gene clade members across multiple species, targeting groups with differing floral symmetries (Zhang *et al.*, 2010, 2012, 2013b). These studies, using semi-quantitative and qPCR, suggest that radially symmetrical flowers have uniform CYC2 expression that then shifts to dorsally restricted CYC2 expression only in bilaterally symmetrical groups (Zhang *et al.*, 2010). Four independent reversals to radial symmetry are correlated with either absent or ubiquitous CYC2 expression across the corolla (Zhang *et al.*, 2013b). Our lab group is similarly working on CYC2 clade expression across the Core Goodeniaceae clade, a group of plants with a well-resolved phylogeny that has multiple gains of fan flowers, in which all the petals are oriented ventrally (Han *et al.*, 2013; Jabaily *et al.*, 2012).

Other model clade approaches that have been used to map expression across a clade include examining floral development genes in Poaceae (grasses) (Malcomber and Kellogg, 2004; Preston *et al.*, 2012; Reinheimer and Kellogg, 2009), Zingiberales (gingers and bananas) (Yockteng *et al.*, 2013), and *Aquilegia* (columbines) (Whittall *et al.*, 2006). In grasses, for example, Malcomber and Kellogg (2006) showed that variation in gene expression of *TASSELSEED2* (*TS2*) across three species indicated that this gene likely plays a role in more morphological shifts across grasses than simply causing gynoecium abortion (resulting in the male flowered corn tassel) in maize. A separate model clade that has been used to assay expression is *Aquilegia* (columbines), especially for examining the evolution of developmental traits in an adaptive radiation (Abzhanov *et al.*, 2008). Examining seven independent losses of floral anthocyanins, the researchers found that, in a genetic pathway of six known genes, most of the losses were caused by changes in the downstream-most members of the pathway, suggesting convergence in loss of gene expression in floral color (Whittall *et al.*, 2006).

Among animals, there have long been calls to use mammals in a similar way that we outline here, especially in regards to studying the morphological and functional variations of the tetrapod limb (Ross *et al.*, 2013; Sears *et al.*, 2007; Sears, 2011, 2014; Stopper and Wagner, 2005). Despite strong underlying constraints in bone structure, including a distal autopod (hand/foot) with predominantly five digits (fingers/toes), mammalian limbs exhibit striking variation not just across species (i.e., human arms, bat wings, cetacean flippers, hoofed ungulates), but also from the forelimbs to hindlimbs of a given species (i.e., bat wings vs. feet). In addition to the variation in limb morphology, there are multiple well-mapped reductions in digit number throughout the clade, matching the criteria described above for a useful model clade. For example, by comparing multiple species throughout the clade, Cooper *et al.* (2014) determined that at least two different mechanisms were independently utilized to accomplish the reduction. They found that in jerboas, horses, and camels, increased apoptosis led to the reduced digit number, while a shift in anterior-posterior (thumb to pinky) patterning was behind digit reduction in the pig hoof, a mechanism recently also found in cows (Lopez-Rios *et al.*, 2014).

Perhaps one of the most well-studied clades of phenotypic variation among closely related species is the Galapagos finches. Using a candidate gene approach, Abzhanov *et al.* (2004) took advantage of the well-known group in an attempt to identify the genetics underlying the differences in beak size and shape among six species of *Geospiza* (ground finches). The expression of multiple candidate genes with roles in craniofacial patterning known from the chicken were examined for correlation with changes in beak morphology across *Geospiza*. Because they were able to examine several closely related species with specific known morphological variation, they found via in situ hybridization that the expression of one of their candidate genes, *BMP4*, varied in concert with beak depth and breadth across the clade. Species that exhibited *BMP4* expression in the beak primordium mesenchyme earlier and at higher levels developed broader and deeper beaks than those species in the clade with lower levels of expression. They corroborated this finding by misexpressing *BMP4* in the chicken beak mesenchyme, which induced similarly larger beaks. Therefore, Abzhanov *et al.* (2004) discovered a novel role in patterning beak depth for *BMP4* by examining gene expression across a clade. While it may seem obvious that studying a model clade can inform our understanding of evolution, this is a case where the use of a model clade provided a significant insight into developmental processes.

While the Drosophilid species complex was an early target of fine scale model clade studies (Jeong *et al.*, 2006), other studies have broadened the scope of the clade used to include a wider diversity of insects. Yoder and Carroll (2006) used Diptera to understand the causes of the reduction in both size and number of abdominal segments specific to the higher Dipterans such as *Drosophila*. Comparison of timing and localization of *Abd-B* gene expression between *Drosophila* and two other disparately related insect species (a locust and a firebrat) (Kelsh *et al.*, 1993; Peterson *et al.*, 1999) suggested that *Drosophila* gene expression shifts and the presence of a splice-variant protein isoform may correlate with abdominal segment loss. Using five species across the Dipteran clade, they aimed to evolutionarily pinpoint more precisely the increase in *Abd-B* gene expression and alternative splicing seen in *D. melanogaster*. However, they found that the increase in the *Abd-B* gene expression domain occurs across all Diptera and the alternative splice variant was found only *D. melanogaster*, and therefore neither correlates with the shift in abdominal segment loss that occurs specifically across higher Diptera. Using this model clade approach, the authors suggest that changes in *Abd-B* downstream target genes may be responsible for this morphological shift (Yoder and Carroll, 2006).

Using the Arthropod clade, Sharma *et al.* (2014b) examined gene expression of *cap-n-collar* (*cnc*), a transcription factor important in mandible development, in three arthropods. They found that while *cnc* is specific to segments containing the mandibles and labrum in Hexapoda, Crustacea, and Myriapoda (collectively, the Mandibulata), its expression is not localized in non-mandible-containing groups, such as the Chelicerata. This correlates hypothesized gene function (patterning development of mandibles) with the synapomorphy of having mandibles in Mandibulata (Sharma *et al.*, 2014b). All of these clade-based expression studies collectively demonstrate how much more complex the relationship between

gene expression and function is across groups than examining distantly related individual models would imply.

Gene Function or Regulation across Model Clades

Growing numbers of functional tools are becoming available, particularly for non-model species. In plants, virus-induced gene silencing (VIGS) uses the natural immune response of an RNA-mediated posttranscriptional gene silencing to knock down genes (Dinesh-Kumar *et al.*, 2003). This method does not require transformation and can potentially be used across many plant species. For instance, *Thalictrum* is being examined as a model clade for Evo-Devo in pollination syndrome shifts. VIGS has been successfully used to knock down reporter genes in three species that encompass the major pollination diversity in the group: inconspicuous flowers, showy petaloid flowers, and petaloid stamens. Gene function can be analyzed in all three species with a similar protocol, providing information about function in different morphological characteristics (Di Stilio *et al.*, 2010). A separate study published an effective VIGS protocol that can be similarly used across four Solanaceae species (Yan *et al.*, 2012). Gene function is more complex than gene expression to assay across a clade; however, methods such as VIGS provide a tool to determine how loss-of-function phenotypes of orthologous genes may differ among related wild-type morphologies.

Pinpointing the specific regulatory changes that result in trait variation is currently of great interest in Evo-Devo and addresses fundamental questions about how adaptive evolution occurs (Carroll, 2008; Hoekstra and Coyne, 2007; Specht and Howarth, 2015). Prud'homme *et al.* (2006) examined regulatory changes across the Drosophilid clade, examining two independent losses and two independent gains of wing coloration. The authors found that the two losses target the parallel inactivation of the same *cis*-regulatory element. The two gains, on the other hand, resulted from modifications of different *cis*-regulatory elements. Similarly in the plant clade Ranunculaceae, *AP3-3* expression loss (described above) is correlated with petal loss, however in each of the five studied cases, the loss occurred through different mechanisms to silence or down-regulate the ortholog (Zhang *et al.*, 2013a). These studies suggest that even when there is co-option of the same gene to build (or lose) the same trait, the gene can be differentially regulated.

Martinez *et al.* (2014) also used the Drosophilid clade, in this case to examine the evolution of the *eve* stripe 2 element (S2E), which drives the stripe 2 expression of the pair-rule gene *even-skipped* (*eve*) in the *Drosophila* blastoderm (see Borok *et al.*, 2010). While the expression of *eve* is conserved across the clade, the sequence of the S2E, a 1.7 kb region, is essentially unalignable. Seeking to understand how this region maintained conserved expression over 100 million years of sequence divergence, the authors were able to work from previous theoretical models built in their lab to model *eve* gene expression based on changes in enhancer sequence throughout the clade. Working from the phylogeny and their model, they were able to 'walk back' putative ancestral states of the enhancer to nodes of species divergence and demonstrated conserved expression of a reporter driven by their putative ancestral enhancers.

Phylogenomics

Where phylogenetics is particularly necessary and informative is determining gene orthology across multiple groups. With the growing number of published genomes, transcriptomes, and EST databases, there is a need for thorough phylogenetic analyses of various gene groups, and innumerable research projects examining molecular evolution of these genes (Becker *et al.*, 2011). An additional powerful use of phylogenomics involves analyzing genomic data across clades to uncover novel genes and microRNAs (Drosophila 12 Genomes Consortium, 2007; Stark *et al.*, 2007). The sequencing of 12 *Drosophila* genomes has provided powerful phylogenomic tools, even in providing higher-quality assemblies by using closely related species as guides. As an example, these genomes have been compared to find genes that are specific to certain clades such as 44 protein-coding genes specific to the six sampled species in the melanogaster clade, and 4 genes specific to *Drosophila melanogaster* (Drosophila 12 Genomes Consortium, 2007). Researchers further used these genomes to predict at least 41 novel microRNAs in *Drosophila*. They show that as they increase species number and divergence, they are able to find increasingly more microRNAs (Stark *et al.*, 2007), further highlighting the power of a clade-based approach.

Genomic and microarray data have also been used to uncover novel gene function in two bird clades. Using Galapagos finches, Abzhanov *et al.* (2006) examined cDNA microarrays derived from the developing beak of five finch species, comparing these data with beak length. From the microarrays, the Ca^{2+}-binding protein *calmodulin* (*CaM*) emerged as the most promising candidate, with expression of CaM being higher in species with longer beaks. As in their previous study (Abzhanov *et al.*, 2004, see above), expression levels were compared across species via *in situ* hybridization, and misexpression in the chicken corroborated the observed relationship between gene expression and phenotype. As *CaM* was not previously known to be involved in beak development, this is an example of the discovery power of the model clade approach. In a separate example, Greenwold *et al.* (2014) used genomes from 48 different bird species to compare α- and β-keratin gene evolution, indicating that the diversity among feathers may be due in part to a large expansion in β-keratin genes.

Conclusion

The growing use of a phylogenetic- or clade-based approach to Evo-Devo is suggesting that much of trait variation, and therefore evolutionary change, is due to shifts in location, timing, or intensity of gene expression. However, there is considerable variability among studies as to the genes that are shifted and the mechanisms that have resulted in the shifts. Based on the data outlined here, it appears to be much more common for the same gene to be targeted in independent morphological shifts, although this can happen through different mechanisms, such as changes within or across enhancers, or the transcription factor binding to those enhancers. It remains to be seen whether there are general patterns in how gene expression is modulated to lead to trait gains and losses, particularly whether the same molecular site or mechanism

gets utilized repeatedly across a clade. Data from model clade studies should shed light on the genetic tinkering that shapes morphological change.

Evolution has resulted in endless numbers of novel and modified morphological traits. Using a phylogenetic context allows us to pinpoint the location of trait changes among the natural biological variation of organisms, therefore, it provides the functional experiment already completed in many different diverse ways. The ability to use a model clade approach, placing morphological and genetic change in a phylogenetic context, creates the backbone of the complex evolutionary puzzle that we are aiming to put together. This context allows us to connect the remarkable group of randomly shaped and colored puzzle pieces that Evo-Devo has provided into a clearer picture of how developmental processes and evolutionary tinkering have led to diversification.

Phylogenetic Comparative Method

B O'Meara, University of Tennessee, Knoxville, TN, USA

Glossary

Brownian motion Motion of a particle being bombarded by other particles, often used as a model for continuous trait evolution.

Independent contrasts Another term for the comparative method described in this article.

Phylogeny Branching history representing evolutionary relationships.

All life on earth shares traits due to common ancestry: use of DNA for information storage, use of proteins for molecular machinery, and much more. Within smaller subgroups consisting of species all sharing a common ancestor (such a grouping is known as a clade), there are even more similarities: all mammal species are warm-blooded, have some fur or hair, and produce milk, for example. Species are not independent of each other: it may be that hair and milk production are advantageous in combination, but this has arisen once in history, not independently in thousands of mammal species.

Many statistical methods rely upon independence of data points. For example, hemophilia is more common in European royalty than in the general population. It could be that something about being a member of royalty carries this risk, but the close genetic relationships within many royal families suggests that instead this is due to sharing the gene for hemophilia in common: the frequency is due to shared ancestry rather than some causal association between traits. There are many questions relating to traits of species and correlations that seem to violate this assumption of independence. For example, primates have larger brains for their body size than other mammals, and they are also more intelligent on various measures than most other mammals. It could be that large relative brain size leads to increased intelligence, but primates share many other traits as well: binocular vision, grasping forelimbs, and more: it could be that brain size increased once in the lineage leading to modern primates due to some other reason.

Fortunately, Felsenstein (1985) developed an approach to deal with the nonindependence of species. This has become known as independent contrasts or the comparative method. The basic idea underlying this approach is that while species are not independent, the changes happening along branches are. Rather than examine the raw values at the tips of the tree, independent contrasts infers changes along pairs branches and standardizes these by time to provide transformed data points that meet the assumptions of most statistical methods. It is roughly equivalent to doing a twin study in medicine, except that rather than looking at pairs of siblings to see how a change in trait X correlates with a change in trait Y it uses pairs of branches descended from the same common ancestor.

Figure 1 shows an example of this. It has six species which share a common ancestor. The raw species values show a positive correlation between Trait X and Trait Y. However, this is largely due to an increase in Trait X in the branch leading to from the common ancestor to the ancestor of taxa D, E, F and a decrease in Trait Y on the branch leading from the common ancestor to the ancestor of taxa A, B, C. These changes happened on two different parts of evolutionary history but by using the raw species values one would think that there are six points that support this pattern. The comparative method, instead, compares along a pair of edges (shown by blue arrows). There are five such comparisons; of this, only one, the contrast between the ancestor of A, B, C and the ancestor of D, E, F, shows a strong positive correlation.

Contrasts between a pair of sister taxa, such as between D and E or A and B, just requires computing the difference between observed values. However, other contrasts must use reconstructions of states at internal nodes. In most methods for doing reconstruction at ancestral states, information from all taxa on the tree is relevant and used. In independent contrasts, only information from descendant nodes of the node of interest is used (these descendant nodes could be other nodes on the tree or tip taxa). This allows for true independence: information about C does not affect the reconstruction of the ancestor of A and B. For such reconstructions, a model must be used. This approach canonically uses Brownian motion. Brownian motion

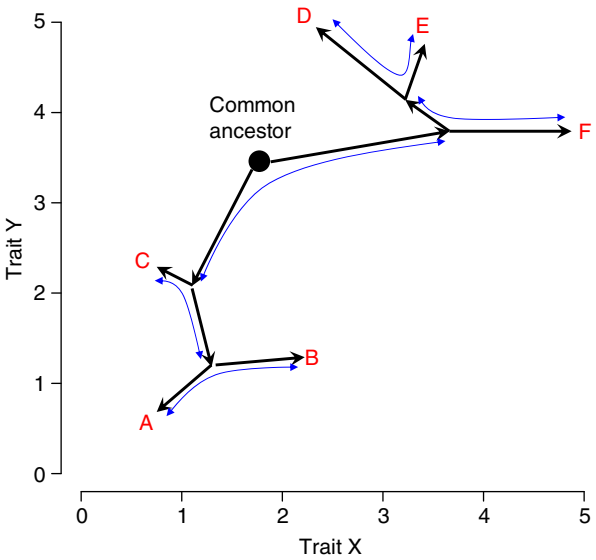

Figure 1 Black lines show the phylogeny, with end points placed corresponding to the values of Trait X and Trait Y. Blue arrows show the comparisons between nodes that are done in independent contrasts.

 doi:10.1016/B978-0-12-800049-6.00217-1

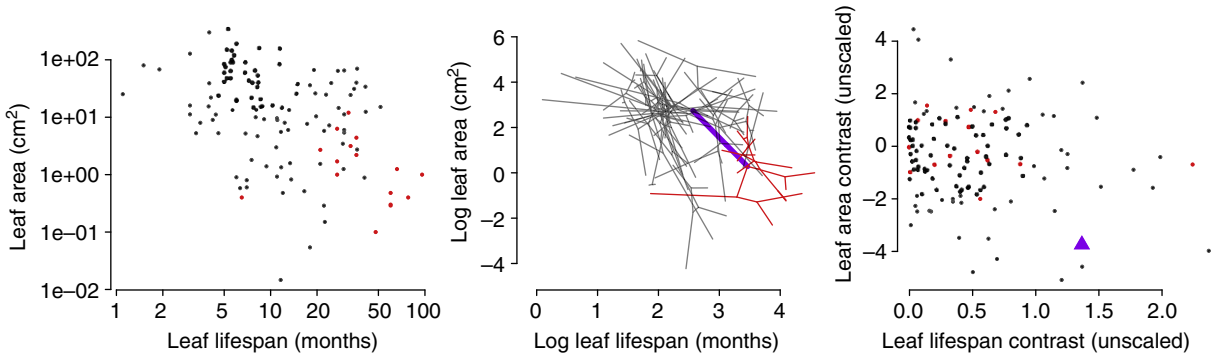

Figure 2 The left hand plot shows the raw trait values for a variety of plant species. The center plot shows the tree with nodes placed at the trait values (on a log scale). The right hand plot shows the independent contrasts. In all plots, gray or black corresponds to angiosperms, red to acrogymnosperms, and purple to the branch leading from the acrogymnosperm part of the tree to the angiosperm clade.

is a general process describing the movement of a particle being shifted due to addition of multiple other forces. Its power and generality comes from the central limit theorem: a particle being moved by the additive combination of a set of independent and identically distributed impulses will have its net displacement follow a normal distribution. For example, a species following an adaptive optimum that shifts across a landscape undergoes Brownian motion, as does a species where the trait phenotype is set by genetic drift (Hansen and Martins, 1996). One assumption of Brownian motion is that expected magnitude of a movement is the same regardless of the current trait value. This may not work for many traits: an elephant species is more likely to lose one kilogram of mass over a million years than a mouse species is (especially given that the mouse species starts out at less than a kilogram and mass has to be positive). A usual approach to deal with this is to work with log-transformed characters instead of the original characters: an elephant and a mouse species maybe equally likely to lose 5% of body mass over a million years. Contrasts down the tree are usually standardized to have unit variance; this scaling is based on the branch length which is usually in units of time, though number of generations or other metrics may be used depending on the evolutionary process. While the comparative method is implemented in many software programs (Martins, 2004; Paradis *et al.*, 2004; Felsenstein, 2005), making it straightforward to use, application of the comparative method does benefit from careful procedures to make sure its use is valid: does the data meet the assumptions, are the appropriate branch lengths being used, and so forth. Garland *et al.* (1992) provide an overview of some of the procedures which are typically followed.

A compelling example of the need for and use of the comparative method comes from Ackerly and Reich (1999). They reanalyzed published data for various seed plant traits using the comparative method. For many correlations, results were unchanged with and without adopting this approach. One counterintuitive result from using raw species values was a strong negative correlation of -0.424 between leaf area and leaf life span: plants with larger leaves held on to them for shorter periods of time. However, this is due to a single evolutionary change: flowering plants like oaks and blueberries have large, relatively short-lived leaves while non-flowering seed plants (acrogymnosperms) like pines have small leaves that they hold on to for long periods of time. Raw species values overcount this: it changed on one branch, but there is then pseudoreplication by treating each species as an independent data point. If the comparative method is used instead, that change is still present but it represents just one contrast; the larger set of all contrasts indicates that there is no correlation between an increase in leaf life span and a decrease in leaf size. **Figure 2** demonstrates this using data from Price *et al.* (2014) and a phylogeny from Zanne *et al.* (2014). The left panel shows the raw data, which suggest a negative correlation. However, plotting flowering plants in black and acrogymnosperms in red it is easy to see that much of this comes from some long-lived, small gymnosperm leaves (such as pine needles) in contrast to angiosperm leaves. The center panel shows the same information, but with the points connected by their evolutionary relationships. This is a phylogenetic tree, but with the tips placed based on the two trait values and the internal nodes placed based on reconstructed ancestral states. The crossing lines suggest that during the evolution of seed plants, the same regions of trait space were invaded multiple times. One thing to note is the purple line representing the branches connecting flowering plants to acrogymnosperms: it shows a definite displacement and may lead to much of the pattern. The right panel shows the raw contrasts (unscaled for variance) generated by the comparative method. The purple contrast represents the difference between flowering plants and acrogymnosperms and is clearly an outlier; the points in general do not show a clear pattern of increases in life span correlating with a decrease in size, suggesting that just a few changes on the branches were driving the pattern.

The comparative method has been used in thousands of empirical studies; the original Felsenstein (1985) paper has been cited over 4000 times, only recently levelling off at over 250 citations per year for each of the past 7 years. It has been appropriately used for morphological, behavioral, and physiological data for species ranging from fungi to mammals, bacteria to conifers.

There are criticisms of the method, as well. First, it imposes a requirement of getting a tree with branch lengths proportional to amount of expected change. Phylogenetic trees are becoming more available through repositories like TreeBase or Open Tree of Life, and making of phylogenies for one's group of interest has become more accessible through GenBank and other repositories of relevant data and wide availability of phylogeny

inference software, but the process is still nontrivial and sometimes extremely difficult in understudied groups. Another question is whether this is worth doing. Price (1997) compared correlations generated with raw species values with those from independent contrasts and found a correlation of 0.86; Ricklefs and Starck (1996) performed a similar analysis with the same basic outcome. This suggests that in some, but clearly not all, cases, one could ignore the nonindependence of raw species values and have the same basic results about correlations. Another concern is the introduction of error by dint of using an uncertain phylogeny, though independent contrasts has been shown to be robust, or at least conservative, to many errors (Diaz-Uriarte and Garland, 1998; Symonds, 2002). There are also concerns about its appropriateness at increasingly large scales, when rates and correlations likely vary across taxa (Felsenstein, personal communication; Losos, 2011).

Overall, however, while there are numerous other methods for investigating correlations between traits (i.e., Hansen, 1997; Martins and Hansen, 1997; Paradis and Claude, 2002; Revell and Collar, 2009; Felsenstein, 2012), the comparative method remains a staple of evolutionary analysis. It provides a robust method for returning statistically well-behaved data that can be used with standard statistical techniques to investigate trait correlation, and it is an essential part of an evolutionary biologist's skill set.

Phylogenetic Invariants

J Chifman, Wake Forest School of Medicine, Winston-Salem, NC, USA

Introduction

'Phylogenetic invariants' as a possible method for phylogenetic inference were introduced by Cavender and Felsenstein (1987) and Lake (1987). The method was intended to provide a new way for tree estimation that is capable of overcoming the usual limitations and issues of neighbor-joining or maximum-likelihood methods. Instead of estimating branch lengths and substitution parameters, and searching in tree space, phylogenetic invariants have the potential to predict whether specific observed frequencies of patterns in the real data belong to a particular tree topology. Phylogenetic invariants are equations in the expected frequencies of site patterns that must be satisfied on any probability distribution under a particular Markov model and tree.

Although invariants had attractive statistical properties, they did not perform well on simulated data as was demonstrated by Huelsenbeck (1995) and as a result doubt about their usefulness had settled among some researchers. However, since that time a lot of progress has been made in our understanding of phylogenetic models using techniques from algebraic geometry. Many useful constructions and more complicated invariants have emerged, which led to the development of several inference methods based on specific invariants associated with the bipartitions induced by an internal edge of the tree (Eriksson, 2005; Fernández-Sánchez and Casanellas, 2014; Chifman and Kubatko, 2014). Our understanding of the structure of invariants for some complicated models is not complete but it is clear that they have a lot of potential not only for theoretical analysis but also for data analysis and inference.

In this article we provide very brief introduction to phylogenetic invariants and concentrate primarily on those that have led to methods for tree estimation. We omit algebraic interpretation of phylogenetic models as the language of algebraic geometry is beyond the scope of this article, but we hope this article supplies enough flavor and demonstrates the complexity and beauty of phylogenetic invariants that will encourage the reader for further investigations. We suggest the book *Inferring Phylogenies* by Felsenstein (2004, Chapter 22) as an initial introduction to invariants. For a gentle introduction from the algebraic view point, see *Reconstructing Evolution: New Mathematical and Computational Advances*, Chapter 4, written by Allman and Rhodes (2007).

Phylogenetic Models on Gene and Species Trees

Phylogenetic models on gene trees have been introduced in earlier articles, hence in this section we just recall a few ideas for notational purposes for the general Markov model. Additionally, we provide a brief introduction to phylogenetic model under the coalescent for a species tree (for a concrete introduction to this model see Chifman and Kubatko (2015)).

Phylogenetic Models on Gene Trees

For convenience we will assume that all trees are binary, that is, all internal nodes have degree three, except possibly for a root node, which is of degree two. Let T be an n-leaf, binary, gene tree and consider the general κ-state Markov model, $GM(\kappa)$, of character evolution, with $\kappa=4$ corresponding to DNA sequences, i.e., possible states are A, C, G, and T. Taxa labeling the leaves of the tree T are identified with an integer in the set $\{1,2,...,n\}$ and the root is identified with some existing node. The probability distribution of the states at the root is represented by the vector $\pi=(\pi_1, \pi_2,\ldots, \pi_\kappa)$, with the constraints that

$$\pi_j>0 \text{ for } j\in\{1,2,\ldots,\kappa\} \text{ and } \sum_{j=1}^{\kappa}\pi_j=1$$

For each edge e of the tree T (e directed away from the root), a $\kappa\times\kappa$ Markov matrix M_e describes transition probabilities. Each (i, j)-entry of the matrix M_e, denoted by $P(j|i, e)$, gives the conditional probability that the character is in state j at the end of edge e given that it was in state i at the start. From the definition of M_e one can see that

$$P(j|i,e)>0 \text{ and } \sum_{j=1}^{\kappa}P(j|i,e)=1$$

When the process of evolutionary change is modeled by a continuous-time Markov process (e.g., general time-reversible model), we specify a rate matrix Q and edge lengths, t_e. Matrix Q has nonnegative off-diagonal entries and the diagonal entries are set so that the rows sum to zero. In this case, the Markov matrix is given by $M_e(t_e)=\exp(QT_e)$ that describes the mutation along an edge e, which represents a time of length t_e.

Computation of site pattern probabilities on gene trees is straightforward once the gene tree and the Markov model have been specified. Since the states are not observed at the internal nodes of the tree, we must sum over all possible states for these nodes. In addition we assume that the mutation process proceeds independently along each branch and thus probabilities are multiplied together along each edge e.

Example 1: Consider a gene tree as labeled in Figure 1. Let X_ℓ be the state observed for lineage ℓ, $\ell=1,2,3$ and consider

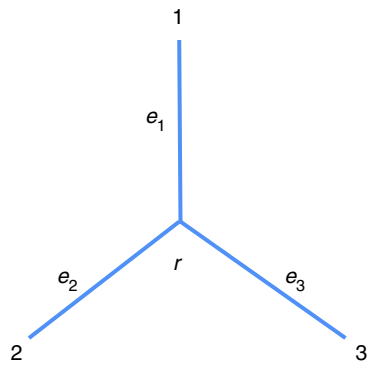

Figure 1 Three-leaf tree.

the tree to be rooted at r. Also, identify states with four bases $\{A, G, C, T\}$, that is, we let $\kappa=4$. The probability distribution of the states at the root is represented by $\pi=(\pi_A, \pi_G, \pi_C, \pi_T)$. The 4×4 Markov matrix on each edge e_i will be of the following form:

$$M_{e_i}=\begin{pmatrix} P(A|A,e_i) & P(G|A,e_i) & P(C|A,e_i) & P(T|A,e_i)\\ P(A|G,e_i) & P(G|G,e_i) & P(C|G,e_i) & P(T|G,e_i)\\ P(A|C,e_i) & P(G|C,e_i) & P(C|C,e_i) & P(T|C,e_i)\\ P(A|T,e_i) & P(G|T,e_i) & P(C|T,e_i) & P(T|T,e_i)\end{pmatrix}$$

The site pattern probability on this three-taxon gene tree for a particular observation, say AGG, at the tips of the tree is computed as follows:

$$\begin{aligned} p_{AGG} &= P(X_1=A,X_2=G,X_3=G)\\ &= \pi_A P(A|A,e_1)P(G|A,e_2)P(G|A,e_3)\\ &+\pi_G P(A|G,e_1)P(G|G,e_2)P(G|G,e_3)\\ &+\pi_C P(A|C,e_1)P(G|C,e_2)P(G|C,e_3)\\ &+\pi_T P(A|T,e_1)P(G|T,e_2)P(G|T,e_3)\end{aligned}$$

For a three-taxon tree with $\kappa=4$ states we will have $\kappa^3=64$ possible site pattern probabilities.

Let P denote the probability distribution on all possible site patterns for the n-leaf tree T under the specified Markov model. The probability distribution P is the n-dimensional $\kappa\times\cdots\times\kappa$ array with entries:

$$p_{i_1 i_2 \ldots i_n} := P(X_1=i_1,X_2=i_2,\ldots,X_n=i_n)$$

Site Pattern Probabilities for Species Trees under the Coalescent

Organismal evolution occurs at two distinct levels; at the level of the individual genes, and at the level of the species or populations as a whole. Both levels must be considered, since the evolutionary history of the species constrains the histories for the individual genes. Each individual gene has its own phylogeny, which may not agree with the species tree. One of the causes for the incongruence is incomplete lineage sorting (ILS), in which gene lineages share a most recent common ancestor much further back in time than the immediately ancestral population.

Multispecies coalescent theory is primarily used to model ILS. In particular, it models probabilities of rooted gene tree topologies within a given rooted species tree topology and branch lengths. Figure 2 is an example of all possible gene trees (blue lines) nested within the three-leaf tree representing the evolutionary history of the species (black lines that 'outline' a tree). In this figure the embedded gene trees within the species tree represent the phylogenetic histories of the lineages sampled from species a, b, and c, denoted by A, B, and C, respectively. The dotted black horizontal lines in this figure represent speciation events, times when one ancestral species becomes two distinct species, and are denoted by τ_i. The times $0<\tau_i<\infty$ are measured backward from the present time. Internal nodes in the gene tree represent gene divergence events, times when multiple gene copies arise in the ancestral population. Dotted blue lines are coalescent events that occur in the gene trees. In particular, the coalescent time $0<t_i<\infty$ is the time from the jth coalescent event to the next speciation event (looking forward in time). Highlighted portions of the tree between speciation events, denoted by P_i, are the ancestral populations. One can clearly see that the gene tree topology does not match the species tree topology in two instances (the bottom two images

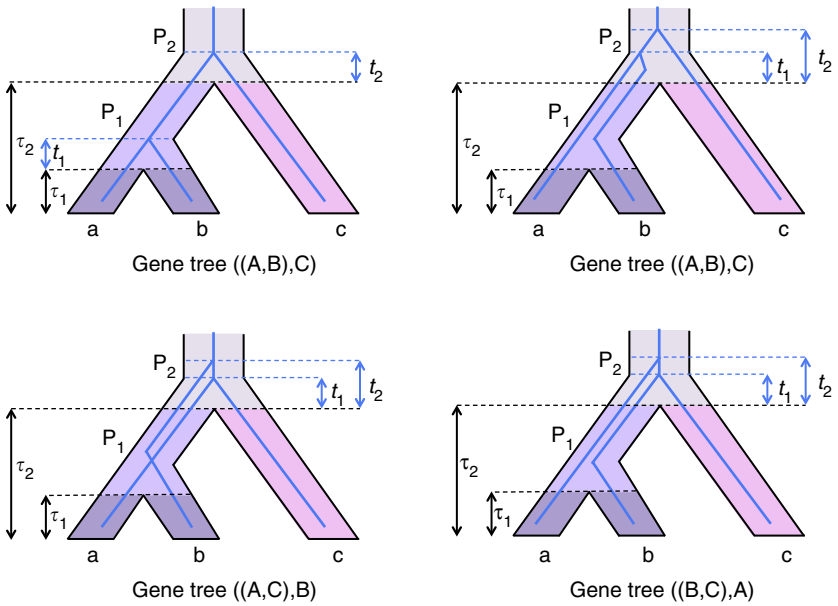

Figure 2 All possible relationships between the species tree (black, outline tree) and the gene tree (blue lines embedded within the species tree) for a three-leaf tree.

in Figure 2). This figure provides an example of ILS and highlights the crucial observation that gene trees and species trees need not agree with one another (Pamilo and Nei, 1988; Maddison, 1997; Nichols, 2001).

As in the case of gene trees it is possible to compute the probability distribution on all possible site patterns for n-taxon species trees under the multispecies coalescent model. However, the computation is rather involved: the model in Figure 2 implies that DNA sequence data evolve along gene trees, but the site patterns observed at the tips of the species tree may arise from more than one gene tree. Thus, the computation of site pattern probability at the tips of a species tree involves integrating over gene trees weighted by their probabilities under the coalescent model and then summing over all possible gene trees consistent with the given species tree. We omit the details here; the interested reader is encouraged to consult Chifman and Kubatko (2015). Let (S, τ) represent rooted, binary, n-leaf species tree endowed with a vector of speciation times τ. We will denote the probability distribution on all possible site patterns for a given species tree by the n-dimensional $\kappa \times \cdots \times \kappa$ array $P_{(S,\tau)}$ with entries $p_{i_1 \ldots i_n|(S,\tau)}$.

Phylogenetic Invariants

Consider a DNA Markov model $GM(4)$ on four bases $\{A, G, C, T\}$ for two three-taxon trees T_1 and T_2 as in Figure 3 under the molecular clock assumption, that is all leaves are equidistant from the root. Let AGA be a specific observation at the tips of T_1. Then, one can easily show that

$$p_{AGA} - p_{GAA} = 0 \qquad [1]$$

This linear function in the site pattern probabilities is an example of a linear invariant. This invariant holds for any distribution P arising from DNA Markov model $GM(4)$ on the tree T_1. On the other hand, the invariant (eqn [1]) does not hold on the tree T_2. Instead, a linear relation that holds on T_2 but not T_1 is

$$p_{AGA} - p_{AAG} = 0 \qquad [2]$$

Now, suppose we choose a submodel of $GM(4)$ on the same trees T_1 and T_2. Let the model of base change be the Jukes–Cantor DNA model, i.e., the equilibrium distribution among the four states is given by $\pi = (0.25, 0.25, 0.25, 0.25)$ and it has equal mutation rates. Under this model for both trees T_1 and T_2 the expected frequency of the pattern AGA will be the same as frequency of the GTG, that is,

$$p_{AGA} - p_{GTG} = 0 \qquad [3]$$

This is an example of a symmetry invariant, and these types of invariants are simply a consequence of a symmetry of the model. Symmetry invariants depend on the chosen model and not on the tree topology.

In general, an 'invariant' is a real-valued continuous function (usually a polynomial expression) in the site pattern probabilities (expected frequencies) that evaluates to zero on any probability distribution arising from the model. Originally, Felsenstein (1991) defined 'phylogenetic invariants' as polynomials that evaluate to zero on the expected frequencies on one tree topology but do not evaluate to zero for at least one tree of a different topology. Some researchers emphasize a difference between (1) invariants that distinguish among different tree topologies and (2) all invariants.

Phylogenetic invariants for many models have been studied using techniques from algebraic geometry and in some special cases the structure of invariants is well understood. Algebraic geometry is the study of the zero sets of collections of polynomials and its language provides powerful tools for describing and addressing probabilistic models. The study of phylogenetic models is part of a growing discipline – algebraic statistics. The richness and complexity of this subject is beyond the scope of this article but we hope this will inspire curious readers for further investigation. For a concrete introduction to algebraic statistics see Pachter and Sturmfels (2005) and to algebraic geometry see Cox *et al.* (2008).

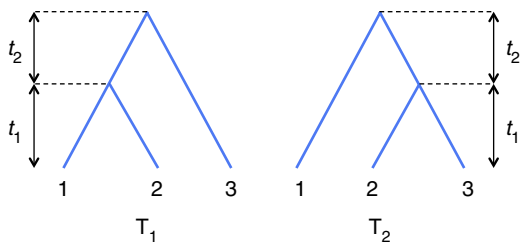

Figure 3 Three-leaf binary trees T_1 and T_2 satisfying molecular clock.

Splits and Flattenings

Phylogenetic invariants arising from flattenings of probability distributions are the most relevant and important among invariants. In this section we provide an overview of invariants that arise from flattenings induced by the single edge of the tree. Our choice for introducing these group of invariants (induced by an edge) lies in the fact that they play crucial role in the arguments concerning identifiability and estimation of the tree topology, and several algorithms have been implemented based on these invariants. For a comprehensive review and extensions to flattenings and invariants induced by a vertex we encourage the reader to consult Allman and Rhodes (2003, 2007, 2006, 2008a).

Let T be an n-leaf binary unrooted tree with leaves labeled by $L = \{1,2,\ldots,n\}$ and let $L_1|L_2$ be a split (bipartition) of L into two nonempty subsets L_1 and L_2. A split $L_1|L_2$ is 'valid' if the subtrees containing the taxa in L_1 and in L_2 do not intersect. We will say that a split is 'edge induced' if it is obtained by removing an edge of the tree T. Notice that a split is valid exactly when it is induced by an edge.

Example 2: Consider a four-taxon tree as in Figure 4 (top panel). This tree has a valid split 12|34 induced by an edge e_3. Splits 13|24 and 14|23 are not valid. One can see in this figure (bottom right image) that trees induced by the partition 13|24 intersect at the edge e_3 making this partition not valid.

Splits of a set of taxa provide a natural way to flatten (rearrange) an n-dimensional $\kappa \times \cdots \times \kappa$ probability distribution P into a matrix. Let $L_1|L_2$ be any split of a set of taxa L and denote

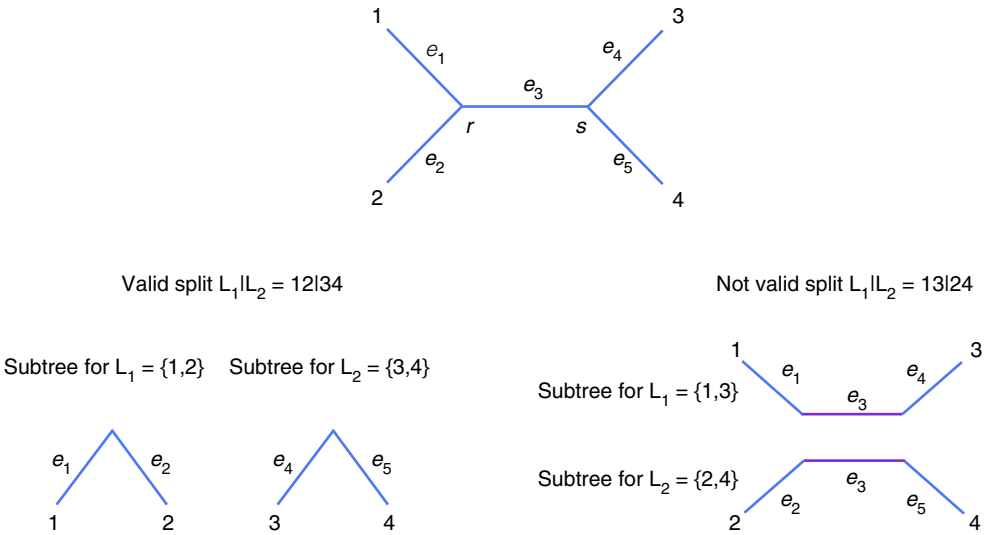

Figure 4 Four-leaf tree with an example of two partitions 12|34 and 13|24 and corresponding subtrees.

the cardinality of a set L_i (i.e., the number of elements) by $|L_i|$. A 'flattening' of the n-dimensional $\kappa \times \ldots \times \kappa$ array P, $\text{Flat}_{L_1|L_2}(P)$ is a $\kappa^{|L_1|} \times \kappa^{|L_2|}$ matrix, whose rows are indexed by possible states for the leaves in L_1 and columns by possible states in L_2. The entries of $\text{Flat}_{L_1|L_2}(P)$ correspond to the probability of the site pattern specified by the row and column indices.

Example 3: For a DNA Markov model $GM(4)$ on four bases $\{A, G, C, T\}$, let the four-taxon tree T be as in Figure 4 (top panel). Then the two flattenings of P for the splits 12|34 and 13|24 are the 16×16 matrices:

$$\text{Flat}_{12|34} = \begin{bmatrix} p_{AAAA} & p_{AAAG} & p_{AAAC} & p_{AAAT} & p_{AAGA} & \cdots & p_{AATT} \\ p_{AGAA} & p_{AGAG} & p_{AGAC} & p_{AGAT} & p_{AGGA} & \cdots & p_{AGTT} \\ p_{ACAA} & p_{ACAG} & p_{ACAC} & p_{ACAT} & p_{ACGA} & \cdots & p_{ACTT} \\ p_{ATAA} & p_{ATAG} & p_{ATAC} & p_{ATAT} & p_{ATGA} & \cdots & p_{ATTT} \\ p_{GAAA} & p_{GAAG} & p_{GAAC} & p_{GAAT} & p_{GAGA} & \cdots & p_{GATT} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ p_{TTAA} & p_{TTAG} & p_{TTAC} & p_{TTAT} & p_{TTGA} & \cdots & p_{TTTT} \end{bmatrix}$$

$$\text{Flat}_{13|24} = \begin{bmatrix} p_{AAAA} & p_{AAAG} & p_{AAAC} & p_{AAAT} & p_{AGAA} & \cdots & p_{ATAT} \\ p_{AAGA} & p_{AAGG} & p_{AAGC} & p_{AAGT} & p_{AGGA} & \cdots & p_{ATGT} \\ p_{AACA} & p_{AACG} & p_{AACC} & p_{AACT} & p_{AGCA} & \cdots & p_{ATCT} \\ p_{AATA} & p_{AATG} & p_{AATC} & p_{AATT} & p_{AGTA} & \cdots & p_{ATTT} \\ p_{GAAA} & p_{GAAG} & p_{GAAC} & p_{GAAT} & p_{GGAA} & \cdots & p_{GTAT} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ p_{TATA} & p_{TATG} & p_{TATC} & p_{TATT} & p_{TGTA} & \cdots & p_{TTTT} \end{bmatrix}$$

Edge invariants

To describe edge invariants for the models discussed in Phylogenetic Models on Gene and Species Trees, we first informally introduce a few necessary concepts from linear algebra. Consider three vectors $x_1 = (3,6,6)$, $x_2 = (1,0,2)$, and $x_3 = (1,3,2)$. Then $x_1 = x_2 + 2x_3 \rightarrow (3,6,6) = (1,0,2) + 2(1,3,2) = (1,0,2) + (2,6,4) = (1+2, 0+6, 2+4)$. Since we can write one of the vectors as a linear combination of the other vectors, we say that they are 'linearly dependent.' If none of the vectors is a linear combination of the others, then we say the set of vectors is 'linearly independent.' We can also talk about linear dependence (independence) if we replace vectors consisting of numbers with real-valued functions, polynomials, or site pattern probabilities.

Example 4: Let $\text{Flat}_{12|34}$ be as in Example 3 for the general Markov DNA model on a four-taxon tree T in Figure 4. Suppose that edges labeled by e_4 and e_5 are equal. Then, for example, for observation $AAAG$ we will get

$$p_{AAAG} = p_{AAGA}$$

Notice that p_{AAAG} is located in column 2 first entry and p_{AAGA} in column 5 first entry of the matrix $\text{Flat}_{12|34}$. The same will be true about second entry of columns 2 and 5, i.e.,

$$p_{AGAG} = p_{AGGA}$$

In particular, columns 2 and 5 of the matrix $\text{Flat}_{12|34}$ are equal and thus these two columns are linearly dependent. Note, there are other pairs of columns that are equal (the reader is encouraged to find them all).

One of the fundamental properties of a matrix is its rank. It is defined as the maximum number of linearly independent columns (rows) and is called column (row) rank. One of the basic facts is that row rank equals column rank, and thus we simply call it rank. Another important concept is that of a determinant of a square matrix, which is a value that can be computed from the entries of the matrix. Here we omit specific expressions for computing the determinant. An important fact about this value is that if columns/rows of a square matrix are linearly dependent then the determinant will be zero. Lastly, we would like to emphasize that if we have a square $m \times m$ matrix such that rows/columns of this matrix are linearly dependent then rank of the matrix will be strictly less than m, call this rank r. This means that any submatrix obtained from the original matrix by picking $r+1$ columns and $r+1$ rows will have determinant equal to zero. The determinant of such

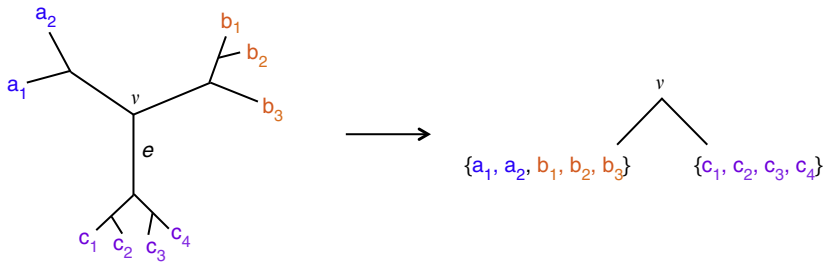

Figure 5 Flattening a model on an edge e.

submatrix is called $(r+1)\times(r+1)$ minor. We will denote the determinant of any matrix A by $det(A)$.

Flattenings based on valid splits, i.e., splits induced by an internal edge of the tree, have special properties. For the DNA Markov model $GM(4)$ on four bases $\{A, G, C, T\}$, let 9-taxon gene tree T be as labeled in Figure 5 (left panel). Then the internal edge e in this figure induces a split of the taxa $L_1|L_2$, where $L_1=\{a_1, a_2, b_1, b_2, b_3\}$ and $L_2=\{c_1, c_2, c_3, c_4\}$. Now we can think of a flattening of P as a probability distribution for a less complicated but related graphical model. In particular, by choosing the root to be one of the vertices of e, we view a new graphical model as the one that has one hidden random variable at the root with $\kappa=4$ states, and two descendent observed random variables with $\kappa^{|L_1|}=4^5$ and $\kappa^{|L_2|}=4^4$ states, respectively (see Figure 5 for a graphical depiction).

By interpreting a model in this way it can be shown that rank of the flattening $\text{Flat}_{L_1|L_2}(P)$ is at most 4. This implies from our discussion above that all 5×5 minors of $\text{Flat}_{L_1|L_2}(P)$ are zero, that is, they are phylogenetic invariants for the $GM(4)$ model on this tree T. Since these invariants are induced by the internal edge of the tree, they are called 'edge invariants.' We would like to note that edge invariants do not depend on the location of the root. These ideas can be extended to any κ-state general Markov model for any n-taxon gene tree T, and it can be shown that rank of the flattening for a valid split induced by any internal edge of the tree is at most κ. For a comprehensive overview of the above ideas see Allman and Rhodes (2007, 2006).

Example 5: Consider $\text{Flat}_{12|34}(P)$ from Example 3 for the $GM(4)$ model. This flattening is based on a valid split and thus this matrix has rank at most 4. This means that the determinant of any submatrix with 5 rows and 5 columns will be zero, i.e., edge invariant. As an example choose the first 5 rows and the first 5 columns from the matrix $\text{Flat}_{12|34}(P)$. The determinant of this submatrix is zero.

$$\det\begin{pmatrix}\begin{bmatrix} p_{AAAA} & p_{AAAG} & p_{AAAC} & p_{AAAT} & p_{AAGA}\\ p_{AGAA} & p_{AGAG} & p_{AGAC} & p_{AGAT} & p_{AGGA}\\ p_{ACAA} & p_{ACAG} & p_{ACAC} & p_{ACAT} & p_{ACGA}\\ p_{ATAA} & p_{ATAG} & p_{ATAC} & p_{ATAT} & p_{ATGA}\\ p_{GAAA} & p_{GAAG} & p_{GAAC} & p_{GAAT} & p_{GAGA}\end{bmatrix}\end{pmatrix}=0$$

We omit the expansion of this determinant (due to its length), which is just a polynomial in site pattern probabilities.

Now let S be a four-taxon binary species tree and let $P_{(S,\tau)}$ denote the probability distribution for the κ-state model under the coalescent as described in Section Site Pattern Probabilities for Species Trees under the Coalescent. It can be shown that for a valid split $L_1|L_2$ rank of $\text{Flat}_{L_1|L_2}(P_{(S,\tau)})$ is at most $\binom{\kappa+1}{2}$ (see Chifman and Kubatko (2015)). In the case of the DNA model under the coalescent, this rank is at most $\binom{4+1}{2}=\binom{5}{2}=10$ and thus 11×11 minors are all zero and are edge invariants. We would like to point out that rank condition exists for any n-taxon gene tree for $GM(\kappa)$ model, whereas for species tree under the coalescent model rank has been proven only for the four-taxon species tree.

Using Phylogenetic Invariants

This section provides a brief introduction to two important topics: identifiability of parameters and tree estimation from observed site pattern probabilities. There are other potential practical uses for invariants. For example, invariants can be used as a basis for a statistical test to differentiate between trees or to detect and quantify the extent of hybridization. Invariants and their structure are extremely appealing to many scientists and most likely they will find their way to be more useful for data analysis.

Identifiability

Many phylogenetic inference methods assume that the tree topology and other parameters can be identified from DNA sequence data at the leaves of the tree. Thus establishing as to what can be inferred under ideal conditions and proving that methods are statistically consistent and valid is of great importance.

The classical definition of identifiability can be formulated as follows: suppose that $\mathcal{M}(\Theta)=\{P_\theta:\theta\in\Theta\}$ defines a family of probability distributions with parameters θ. The model $\mathcal{M}(\Theta)$ is said to be 'identifiable' if the mapping $\theta\mapsto P_\theta$ is injective, that is, if for any $\theta_1\neq\theta_2\in\Theta$ we get that $P_{\theta_1}\neq P_{\theta_2}$. Unfortunately, for many models this map will not be injective. However, identifiability of parameters for finite space models is established by demonstrating that the set of parameters on which the model is non-identifiable is of measure zero within the parameter space. In this case we say that model parameters are 'generically identifiable.'

Techniques from algebraic geometry and invariants play an important role throughout proofs about identifiability. In the case of analytic models (e.g., covarion model or models under the coalescent), one can still use perspectives from algebraic geometry to prove generic identifiability (Chifman and Kubatko, 2015; Allman and Rhodes, 2006, 2009). Generic

identifiability for many evolutionary models on gene trees is well-studied and established. For a comprehensive introduction to identifiability using algebraic techniques we suggest a series of papers by Allman and Rhodes (2006, 2008a,b, 2009), Allman *et al.* (2008, 2011), and Rhodes and Sullivant (2012).

Species and Gene Tree Inference

Generally, identifiability of the tree topology is of prime interest. In this case edge invariants are used and are sufficient to identify the tree topology for generic parameters. Results in most cases are established using rank conditions on flattenings of the probability distribution. Moreover, it has been proved in Casanellas and Fernández-Sánchez (2011) that edge invariants are enough to reconstruct the phylogenetic tree for any number of species.

Using edge invariants for the estimation of the gene tree topology was initially proposed by Eriksson (2005). Eriksson's approach is similar to neighbor-joining; the tree is built by considering splits of varying sizes and iteratively joining taxa corresponding to the best split. Evaluating edge invariants for each flattening for various splits of taxa would be somewhat impractical, thus the main idea of the method is to compute a distance between each flattening and the nearest rank 4 matrix. However, the original method did not perform as well as neighbor-joining or maximum-likelihood and had a problem with short alignments and long branches.

Recently, the method has been revisited by Fernández-Sánchez and Casanellas (2014) for gene trees where they provide a procedure that supplies weights, which then can be used as inputs for quartet-based methods. For species trees under the coalescent, Chifman and Kubatko (2014) have also developed a method to infer relationships among quartets, and then use the quartets to estimate the overall tree. These methods performed well and showed high levels of accuracy. Below we provide a brief overview of the method for species tree estimation.

Suppose we have a set of n species and that there are D sites in the observed DNA sequences. First, we sample a set of four species $\{a, b, c, d\}$ from the n species and consider the three possible splits: $ab|cd$, $ac|bd$, and $ad|bc$. For each of these splits the flattening matrix $\text{Flat}_{L_1|L_2}(\hat{P})$ is estimated by replacing each entry with the observed site pattern frequency in the data. Next we assess which of these flattenings is closest to a rank 10 matrix. The number that we compute for each split is called an SVD score. The split yielding the smallest score is inferred to be the true split for taxa a, b, c, and d. Repeating this procedure for all sampled quartets leads to a collection of inferred splits for a set of quartets sampled from the overall set of n species. These quartet relationships can be used together to form an estimate of the overall tree. This is the well-studied problem of quartet assembly, for which numerous algorithms have been proposed (Strimmer and von Haeseler, 1996; Snir and Rao, 2012; Strimmer *et al.*, 1997). A species tree inference method under the coalescent model based on the results of Chifman and Kubatko (2014, 2015) has been implemented in the popular phylogenetic inference package PAUP* developed by Swofford (1998).

Conclusion

Introduction of phylogenetic invariants in 1987 led to a very reach area of research and many advances have been made since that time. Methods for the estimation of the tree topology based on phylogenetic invariants are now recognized as competitive and robust. Moreover, they have proved to be useful when addressing theoretical issues such as identifiability of the tree topology and other parameters. Invariants are definitely worth our attention and we hope that this overview, though very brief, will encourage many readers to continue their own investigations and possibly find new ways to use invariants for practical problems.

Phylogenetic Networks

L Nakhleh, Rice University, Houston, TX, USA
DA Morrison, Uppsala University, Uppsala, Sweden

Glossary

Bipartition Division of the complete set of taxa into two nonoverlapping groups (sometimes also called a split).
Character A characteristic or trait being measured on a set of taxa for use in a phylogenetic analysis, which displays at least two mutually exclusive character states (e.g., present vs. absent).
Gene duplication The duplication of a block of genetic material, often involving a complete gene or even a whole chromosome.
Gene tree A generic term for a phylogenetic tree derived from data for a single non-recombining sequence block (sometimes loosely referred to as a locus).
Graph In phylogenetics, the model used is a graph consisting of nodes (representing taxa) connected by edges (representing their inferred relationships).
Horizontal gene transfer Movement of a small piece of a genetic material between unrelated organisms by means other than sexual reproduction.
Hybridization The merging of distinct population lineages to produce a new hybrid lineage, achieved by combining the genomes within each organism.
Incomplete lineage sorting Retention of allelic polymorphisms through one or more speciation events, followed by selective loss of some of the alleles (sometimes also called deep coalescence, or ancestral polymorphism).
Introgression Movement of a small piece of a genetic material between related organisms by means of sexual reproduction.
Most recent common ancestor The ancestor most recently shared between two or more taxa.
Recombination The formation of composite genetic material within an individual by the mixing of parental genes via processes such as crossing-over or re-assortment.
Sequence alignment An arrangement of DNA or protein sequences to indicate which nucleotides or amino acids are related by inheritance from a common ancestor, usually with the sequences running horizontally and the related molecules aligned vertically.
Taxon (plural taxa) A generic term for any level of the biological hierarchy (e.g., individual, population, species, genus, etc.)

Phylogenetic networks are graphical representations used to explore and model complex evolutionary relationships, most notably ones that contain reticulations, such as those caused by horizontal gene transfer (HGT) or hybridization (Huson *et al.*, 2011; Morrison, 2011). In this article, we describe the different classes of phylogenetic networks, their inference, and how they are to be interpreted.

Phylogenetic networks differ from the networks most commonly encountered in biology, in which the nodes represent observed entities (individuals, populations, and species) and their connecting edges represent observed relationships (e.g., food webs and protein interaction networks). Phylogenetic networks, on the other hand, connect nodes representing observed taxa via edges representing inferred historical relationships and extra nodes representing inferred ancestors.

The article is organized as follows. We begin by giving a brief overview of phylogenetic trees and their interpretation. We then discuss processes that motivate the need for phylogenetic networks. In the third part, we describe the types of data that are commonly used to reconstruct phylogenetic networks. In the last two parts, we describe data-display and evolutionary networks, with special emphasis on their interpretation.

Phylogenetic Trees First

A phylogenetic tree on a set of taxa is a tree whose leaves are labeled bijectively (i.e., every taxon labels exactly one leaf in the tree, and no leaf is unlabeled) by the taxa. There are two types of phylogenetic trees: unrooted trees (**Figure 1(a)**) and rooted trees (**Figure 1(b)**).

An unrooted phylogenetic tree provides a graphical representation of bipartitions, also known as splits, of the taxa that are pairwise compatible such that they could be uniquely combined into a single tree. That is, if the partitions are nested then the graph will be treelike, but if they overlap then the graph will show complex reticulation patterns.

For example, the unrooted phylogenetic tree in **Figure 1(a)** represents the bipartition where A and B form one partition and C and D form the other part. Given an unrooted tree, the set of all bipartitions that it represents can be obtained by 'cutting' the tree edges one at a time and, for each, recording the bipartition formed by the two sets of taxa separated by the removal of the edge. Indeed, inspecting the bipartitions displayed by an unrooted phylogenetic tree constitutes its main exploratory use by practitioners (i.e., it shows which bipartitions are best supported by the data).

A rooted phylogenetic tree provides a single hypothesis of the evolutionary history of a set of taxa from their most recent common ancestor. The interpretation of such a tree is based on the ancestor–descendant relationships that it captures. For example, the tree in **Figure 1(b)** captures three such relationships: A and B descended from a most recent common ancestor, say X; X and C descended from a most recent common ancestor, say Y; and, Y and D descended from the most recent common ancestor of all four taxa, which is the root node of

 doi:10.1016/B978-0-12-800049-6.00221-3

the entire tree. Interpreting the tree the other way, the common ancestor splits into two descendants, one of which further splits into two descendants, and one of these splits again.

There is a straightforward relationship between unrooted and rooted phylogenetic trees. An unrooted tree can be rooted at any edge by introducing a new node into the edge and rooting the tree at the new node. A rooted tree can be turned into an unrooted tree by 'ignoring' the root node. These two operations are illustrated in Figure 2.

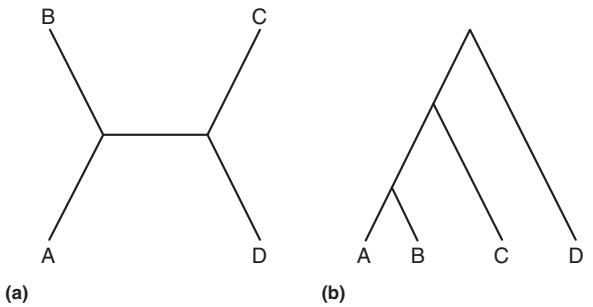

Figure 1 Phylogenetic trees. (a) An unrooted phylogenetic tree on four taxa: A, B, C, and D. This tree does not model ancestor–descendant relationships; rather, it provides a graphical representation of possible grouping of the taxa based on the data. In this case, A and B are grouped together, and C and D are grouped together. (b) A rooted phylogenetic tree on four taxa: A, B, C, and D. This tree models ancestor–descendant relationships: A and B descended from a common ancestor that, along with C, descended from a common ancestor that, along with D, descended from the most recent common ancestor of all four taxa.

Beyond a Single Tree

A phylogenetic tree is most commonly inferred, directly or indirectly, from a collection of characters and their states, most commonly a molecular sequence alignment, collected from the taxa under consideration. A main assumption underlying the inference of a phylogenetic tree is that all of the characters in the alignment have evolved down a single tree. When the sequence alignment consists of a single character, this assumption always holds. However, when an alignment contains two or more characters, different characters might have evolved down different trees (Nakhleh, 2010). It is important to note here that the different trees do not necessarily have to disagree topologically: Two different characters could have evolved down two trees whose topologies are identical, yet whose branch lengths are different. In situations where at least two characters have evolved down two different trees, a single phylogenetic tree is not sufficient to capture the evolutionary history of the whole sequence alignment.

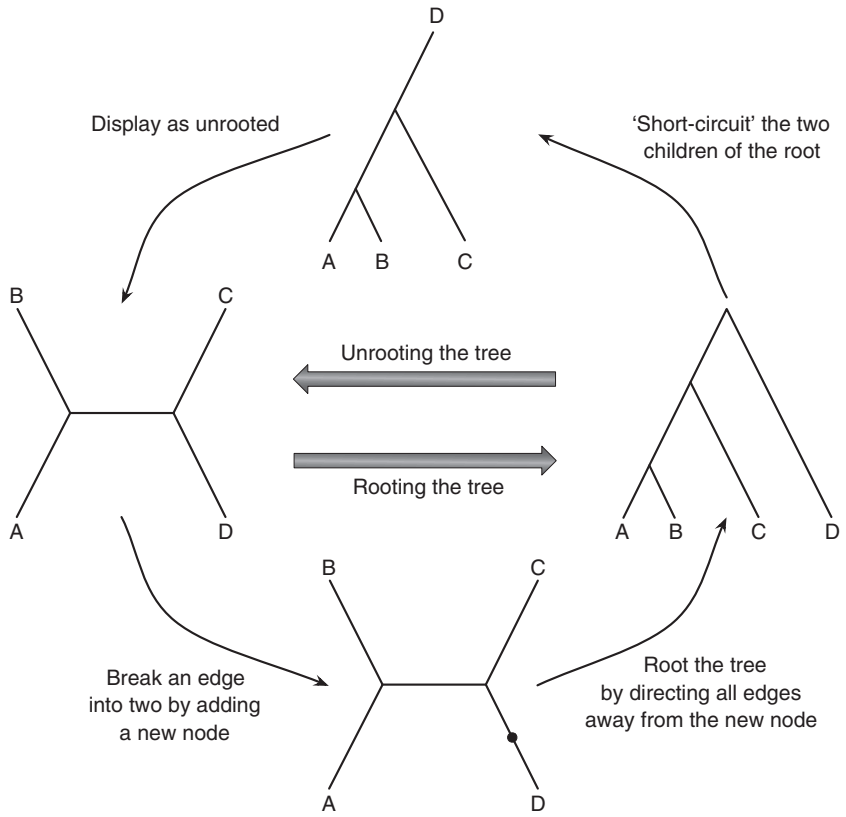

Figure 2 The relationship between unrooted and rooted phylogenetic trees. An unrooted tree can be rooted in many ways (one possible root for each edge). Here, the edge incident with the leaf labeled by taxon D is broken into two edges by the addition of a new node and then the tree is rooted at the new node by directing all edges away from it. A rooted tree is turned into an unrooted one in one way: the root node is removed, the two children of the root are connected, and all edge directions are ignored.

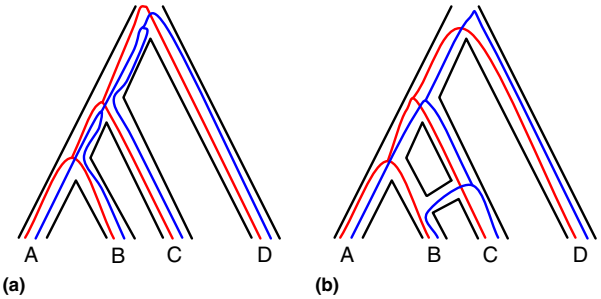

Figure 3 Beyond a single tree. (a) A 'trees within a tree' scenario. Here, different characters in the sequence alignment might have different evolutionary trees, while the evolutionary history of the whole alignment is still a tree. Processes that result in such a scenario include incomplete lineage sorting, heterogeneity in mutation rates across characters, and gene duplication and loss. (b) A 'trees within a network' scenario. Here, different characters in the sequence alignment might have different evolutionary trees, while the evolutionary history of the whole alignment is a phylogenetic network. Processes that result in such a scenario include recombination, horizontal gene transfer, and hybridization (including introgression).

Biological processes that result in scenarios where the evolutionary history of a sequence alignment cannot be captured by a single tree can be divided into two categories: treelike discord processes and reticulation processes. Treelike discord processes correspond to 'trees within a tree' scenarios (Figure 3(a)), in which the gene histories are different even though the species history is treelike. Processes such as incomplete lineage sorting (ILS), heterogeneity in mutation rates across characters, and gene duplication/loss belong to this category. Modeling evolutionary histories in the presence of these processes does not require networks, though these processes could be explored using data-display networks, as we discuss below.

Reticulation processes correspond to 'trees within a network' scenarios (Figure 3(b)), in which the species history itself is not treelike. Processes such as (meiotic) recombination, re-assortment, HGT, introgression, and hybridization belong to this category. When such processes occur, the evolutionary history of the sequence alignment takes the form of a phylogenetic network. Here, both the data-display and evolutionary networks could be used to explore and model the data (Morrison, 2005; Huson and Bryant, 2006).

It is important to note that phylogenetic networks can model both categories of processes, where phylogenetic trees cannot model reticulation processes. Therefore, 'network thinking' is a more encompassing and powerful paradigm than is 'tree thinking' (Bapteste *et al.*, 2013).

The Data

Various types of data have been used by the different methods to infer phylogenetic networks. These data types include:

- A single sequence alignment: In this case, each taxon is represented by a sequence of character states.
- Several sequence alignments: In this case, there is one sequence alignment per locus of interest, which are combined to infer the phylogenetic network.
- A set of distances: Differences are calculated pairwise between all of the taxa, based on one or more alignments, which provides a summary of their evolutionary relationships. It is these distances that are used to infer the phylogenetic network.
- A set of gene trees: Here, the data consist of a collection of gene trees inferred from individual sequence alignments of different loci. It is important to note that the use of 'gene tree' does not mean that the tree is necessarily inferred from the sequence alignment of a protein-coding gene. Rather, this naming is historical, and in the post-genomic era, these gene trees often include trees inferred from noncoding regions as well. Further, it is worth mentioning here that some methods make use of special types of trees, such as rooted triplets (rooted trees with three leaves each) or quartets (unrooted trees with four taxa each).
- A set of splits: Here, the data consist of splits, or bipartitions, of the set of taxa. Often, this set is obtained from sequence-alignment or gene-tree data. For example, given a collection of gene trees, the set of all their splits is computed (as described above), and this set is then used in the procedure for inferring the phylogenetic network.

Data-Display Networks

As we discussed above, the data for phylogenetic inference and analysis often consist of sequence alignments (when inferring networks from gene trees, these gene trees are estimated from the alignment data). Visual inspection of the sequence alignment provides a valuable way to understand the phylogenetic data. However, as the datasets become bigger, either in the number of sequences or number of characters or both, visual inspections of large tables of character states across sequences and characters become infeasible. Instead, a graph representation of the relationships that the sequence data encode among the taxa is a more natural and powerful tool (Morrison, 2010). Graphs where a subset of the nodes (leaves) are labeled by taxa are data-display networks; for example, Figure 4(a).

Consider two binary characters whose states for four taxa A, B, C, and D are

	Character 1	*Character 2*
A	0	0
B	0	1
C	1	1
D	1	0

This alignment gives two conflicting relationships among the taxa that cannot be represented simultaneously using a single tree. Character 1 groups taxa A and B together and taxa C and D together. Character 2, on the other hand, groups taxa A and D together and taxa B and C together. These binary relationships are incompatible from a tree perspective; that is, they do not fit a single tree. A data-display network provides a natural way to represent these relationships in a way that is amenable to visual inspection and exploration. Indeed, Figure 4(a) provides such a representation and describes how the relationships are embedded into and can be obtained from the network.

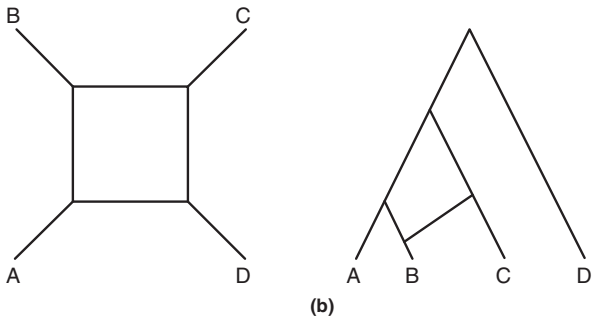

Figure 4 Phylogenetic networks. (a) A data-display network on four taxa: A, B, C, and D. Cutting the two horizontal parallel lines of the box displays the relationship '(A,B) vs. (C,D),' whereas cutting the two vertical parallel lines of the box displays the relationship '(A,D) vs. (B,C).' These two relationships cannot be simultaneously embedded in a single tree (using phylogenetics terminology, these two relationships are incompatible). (b) An evolutionary network on four taxa: A, B, C, and D. This network is interpreted as a rooted (the topmost node), directed (all edges are directed away from the root), acyclic (no directed cycle) graph that models ancestor–descendant relationships in the presence of reticulation. Here, parts of the genetic material of taxon B trace their ancestry to the most recent common ancestor of A and B, whereas other parts of B's genetic material trace their ancestry to the most recent common ancestor of B and C.

It is important to note here that the two characters in the example could very well have evolved down a single tree. For example, if each character represents a different site in the genomes of the four taxa, where 0 is A and 1 is C, then, the evolution of the sequence data can be explained by invoking multiple mutations at one or both of the characters. This is a central issue that underlies the construction, analysis, and interpretation of this type of network. The fact that the graph is not treelike does not mean reticulation has occurred during the evolution of the taxa; rather, the non-treelike components of the network call for a closer inspection of those parts to understand the conflicts in the data.

Algorithms are well developed for data-display networks, and computer programs are widely available. The most commonly used data-display networks are variants of what are known as splits graphs, which are explicitly designed to display bipartitions (Morrison, 2014). The variants differ in how they 'decide' which bipartitions to display under those circumstances where they cannot all be displayed simultaneously. Currently, the most commonly used variant for distance data is NeighborNet (Bryant and Moulton, 2002), and for character data it is the Median Network (Bandelt *et al.*, 2000). For gene trees there are Consensus Networks (Holland and Moulton, 2003) and SuperNetworks (Holland *et al.*, 2007). In population genetics, it is common to encounter the Reduced-median Network (Bandelt *et al.*, 1995) and the Median-joining Network (Bandelt *et al.*, 1999).

Evolutionary Networks

An evolutionary network (e.g., Nakhleh, 2010) gives an explicit model of the reticulate evolutionary history of the taxa under consideration. Formally, the topology of an evolutionary network is a leaf-labeled rooted, directed, acyclic graph with four types of nodes:

- The root node: This is a unique node that corresponds to the most recent common ancestor of all of the taxa. All edges in the networks are directed away from this node.
- The leaf nodes: These are the nodes that are bijectively labeled by the taxa. A leaf is characterized by having a single parent and no children.
- The tree nodes: These are those nodes each of which has at most one parent. Tree nodes are directly analogous to the nodes in a phylogenetic tree in that they represent events such as speciation and gene replication. The root is a tree node. Further, each leaf node that has a single parent is a tree node.
- The reticulation nodes: These are those nodes each of which has more than one parent. A leaf node that has more than one parent is a reticulation node. A reticulation node corresponds to a reticulation event involving the parents of the nodes, such as hybridization between two species or HGT from one organism to another.

Figure 4(b) shows an evolutionary network that has a single root node (the topmost node), four leaves (labeled by the taxa A, B, C, and D), eight tree nodes, and one reticulation node (the parent of the leaf labeled B).

While 'reticulation' is an umbrella term for all non-treelike evolutionary processes (e.g., recombination, HGT, and hybridization), evolutionary networks have appeared in the literature in many flavors, each emphasizing the biological process assumed to underlie the reticulation. Examples include hybridization networks and ancestral recombination graphs (ARGs). This classification notwithstanding, it is important to note that assigning a biological process to the inferred reticulation events in the network is best done a posteriori using knowledge of the data and organisms. In other words, from a mathematical and algorithmic perspective, methods that infer evolutionary networks cannot reliably distinguish meiotic recombination from hybridization, for example.

The three main flavors of evolutionary networks in the literature are:

- ARGs. This type of evolutionary network is mostly used for analyzing a sample of sequences obtained from a single population in the presence of mutation and recombination events. The reticulation nodes in ARGs correspond to recombination events, and are annotated with numbers that denote the physical location of (inferred) recombination

breakpoints. Under certain models of evolution, such as the infinite sites model, the edges of the ARG are annotated with the sites that mutate along those edges. The data used in ARG inference consist of either a sequence alignment or a set of single nucleotide polymorphisms. The evolutionary history of each non-recombining region in the sequence alignment is a tree embedded inside the ARG, which is obtained in a straightforward manner using the coordinates of the non-recombining region and the annotation of the reticulation nodes in the ARG. Gusfield (2014) is an excellent book that surveys the history as well as recent mathematical and algorithmic advances of ARG inference and use.

- HGT networks. This type of evolutionary network consists of a designated underlying tree and a set of horizontal edges connecting pairs of the tree edges. That is, HGT networks are used whenever the practitioner wants to emphasize the notion that the evolutionary history is mostly treelike, yet with some horizontally transferred elements. In most cases, the designated underlying tree is referred to as either the species tree or organismal tree. In terms of inference, HGT networks are inferred by reconciling the evolutionary histories of a set of genes with the designated underlying tree (which is assumed to be known). The genes can be given either by their sequences (e.g., Jin *et al.*, 2006, 2007) or their trees (surveyed in Doyon *et al.*, 2011). The evolutionary history of each gene is either identical to the designated underlying tree, in which case the gene's evolutionary history involves no HGT, or it is one of those trees inside the network that is obtained by using some or all of the horizontal edges (**Figure 5**).
- Hybridization networks. Unlike HGT networks, hybridization networks do not designate any underlying tree as the species or organismal tree. The data used in the inference of these networks consist of a set of genes given by their sequence alignments or gene-tree estimates. The inferred hybridization network can be viewed as an embedding of the gene evolutionary histories in a network under some criterion (**Figure 5**). That is, the network 'displays' a set of trees, obtained by cutting one of the parent edges of each reticulation node, and these trees represent the different gene histories involved in the hybridization. Introgression is included here as being a form of (partial) hybridization.

Methods for inference of evolutionary networks can be categorized based on the criterion they employ, as well as based on the processes they model (Nakhleh, 2013). In terms of criteria, most inference methods are based on the maximum parsimony principle: An evolutionary network with the fewest number of 'gene-level events,' including reticulations, is sought to model the evolutionary history of the data. For example, while an evolutionary network with three reticulation events could be constructed to embed the two trees in **Figure 5**, the network in **Figure 4(b)** is the desired one under the maximum parsimony criterion since it has the fewest number of reticulations needed to embed both trees (i.e., one). If more than solely reticulation is accounted for (e.g., reticulation plus gene duplication), then a weighted sum of the numbers of these events is minimized as the inference criterion. It is also possible to minimize related measures of reticulation complexity, such as the network level. More recently, methods for statistical inference of evolutionary networks have been introduced, based on likelihood. These methods make use of probabilistic models that incorporate reticulate evolutionary events (e.g., hybridization) in addition to vertical evolutionary events.

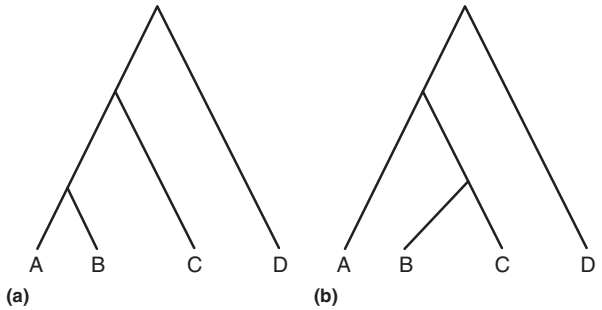

Figure 5 The two trees displayed by the phylogenetic network of **Figure 4(b)**. (a) The tree displayed by the phylogenetic network when the right edge coming into the reticulation node is removed. (b) The tree displayed by the phylogenetic network when the left edge coming into the reticulation node is removed. Assuming that the evolutionary history of a set of genes is the phylogenetic network of **Figure 4(b)**, and barring any processes such as gene duplication and incomplete lineage sorting, then every gene has an evolutionary history that is captured by one of these two trees.

While the majority of evolutionary network inference methods currently assume that reticulation is exclusively the cause of heterogeneity in evolutionary histories across genes, recently developed methods are beginning to incorporate more processes, and consequently should provide more accurate estimates of evolutionary histories. For example, Yu *et al.* (2013, 2014) provided maximum parsimony and maximum likelihood methods, respectively, for inference of hybridization networks in the presence of both reticulation and ILS.

Summary

Phylogenetic networks provide a powerful tool for exploring evolutionary relationships among taxa. While the use of tree methodologies in evolutionary analyses precludes, a priori, the potential for modeling reticulation, network methodologies allow simultaneously for treelike and non-treelike evolutionary relationships. Thus, networks go beyond what trees offer in terms of modeling power and expressiveness.

The input data for the network inference algorithms can be alignments, distances, or trees. In the latter case, the trees represent the assumed treelike evolutionary history of loci or non-recombining sequence blocks. The inferred networks can be solely multivariate summaries of the data (data-display networks) or they can represent hypotheses of phylogenetic history (evolutionary networks). In the former case, the objective is to display as many as possible of the bipartitions represented in the data. In the latter case, the optimization criteria are the same as for phylogenetic trees (parsimony- and likelihood-based).

As networks generalize the tree model, they fit the data at least as well as trees. This is why extra caution must be used when interpreting phylogenetic networks. A complex cobweb-like structure of an inferred data-display network is not necessarily an indication of many reticulations; rather, it indicates conflicting signals in the data about the relationships among the taxa, which merits closer inspection by the practitioner. Similarly, an evolutionary network with reticulation nodes indicates that the data do not fit a single tree well, and reticulations are inferred as potential hypotheses that should be pursued further.

Phylogenetic Tree

AD Scott and DA Baum, University of Wisconsin, Madison, WI, USA

Glossary

Branch The portion of a phylogenetic tree that connects two nodes (internal branch) or one node and a tip (external branch).
Clade A monophyletic group. Part of a rooted tree that can be separated from the rest of the tree (which includes the root) by cutting a single branch.
Cladogenesis See lineage splitting.
Cladogram A tree diagram that communicates only the topology (branching pattern). A cladogram provides all the information relevant to determine the degree of relatedness between taxa.
Crown node The node that represents the last common ancestor of a clade of interest.
Hybrid speciation When members of two distinct lineages interbreed and form a new evolutionary lineage distinct from the parental lineages. See also lineage fusion.
Introgression When individuals from two distinct lineages produce hybrid offspring that subsequently interbreed with one of the parental lineages, causing genes from one lineage to be introduced into the other.
Lineage fusion When two distinct evolutionary lineages merge into a single, hybrid descendant lineage. See also hybrid speciation.
Lineage splitting The division of an ancestral lineage into two or more descendant lineages.
Monophyletic Composed of all the descendants of a particular ancestor. In phylogenetic trees, monopohyletic groups are clades.
Node A branching point in a phylogenetic tree.
Outgroup Taxa that are assumed a priori not to be within the ingroup and may therefore be used to root a phylogenetic tree.
Phylogeny The treelike evolutionary history of a group of organisms.
Plesiomorphy An ancestral character state.
Population lineage A group of populations united by gene flow.
Relatedness The recency of common ancestry, with more closely related organisms being those that share more recent common ancestors.
Reticulation Having a netlike population history with both lineage splitting and fusion.
Root The earliest node in a tree, representing the last common ancestor of all the tips.
Sib taxa Two taxa descended from a common ancestor.
Stem lineage The branch that subtends a clade of interest.
Stem node The node that represents the last common ancestor shared by a taxon of interest and any other organisms.
Synapomorphy A shared derived character state.
Taxon (plural = taxa) A formally named group of organisms. The groups of organisms represented by the tips of a phylogenetic tree.
Tip (= leaf) The entities (e.g., taxa, genes) whose relationships are depicted using a tree diagram.
Topology The history of lineage splitting depicted by a tree; a rooted tree's topology being defined by the list of all its clades.
Trait A heritable feature of a lineage; a character or character state.
Tree thinking The ability to read and interpret phylogenetic trees and use trees to accurately represent the evolutionary process.
Unrooted tree A tree without a root and, thus, without a specified time axis.

Introduction

Evolution is a central concept that enriches our understanding of the natural world and has very real societal impacts. For example, evolutionary principles have been harnessed for agricultural improvement and to develop protocols for the appropriate use of antibiotics. Given its broad significance, individuals at all levels of biological expertise, from the general public to the research biologist, need to be able to think clearly about evolution. Key among the topics that need to be mastered is the ability to correctly interpret evolutionary trees and use them as a substrate for visualizing evolutionary history.

Describing the relationships among organisms has been a challenge since well before the origin of evolutionary theory. In antiquity, biological diversity was classified and placed on the Great Chain of Being or Ladder of Life, the *Scala Naturae*. This perspective held that organisms could be arranged as the rungs on a ladder, with rocks and minerals at the bottom moving up through plants and 'simple' animals, with humans close to the pinnacle. However, we now understand that the organisms alive today did not evolve from other living species, but from shared ancestors. Furthermore, a ladder is a misleading metaphor because it implies that evolution is progressive and directed toward a particular endpoint, which it is not. Instead, evolution is more accurately described as an exploration, a freewheeling road trip in an all-terrain vehicle, perhaps. There is no predetermined destination, no prescribed route, and no need to stick to predictable roads. Unlike a road trip, however, evolution doesn't stop. Modern day species are not at destinations, but wherever they happened to be when we humans decided to map things out. But while we cannot know their future, we can (in principle) figure out the path that each species took to its current locale. This broad-scale

 doi:10.1016/B978-0-12-800049-6.00203-1

history of evolutionary relationships is known as 'phylogeny.' So, if a ladder is not an appropriate metaphor, how can we picture phylogeny? No less a scientist than Charles Darwin provided an answer:

> The affinities of all the beings of the same class have sometimes been represented by a great tree. I believe this simile largely speaks the truth … the great Tree of Life … covers the earth with ever-branching and beautiful ramifications. (Darwin, 1859, pp. 131–32)

In the one hundred and fifty years since this passage was written, tree diagrams have come to be an indispensable tool for summarizing what is known about evolutionary history and guiding research in several fields, such as epidemiology, community ecology, and genomics. High school and university students also encounter phylogenetic trees in textbooks and in lectures as a means to organize knowledge of biological diversity. And trees are even found in popular media and museum displays, where they are designed to bring evolutionary discoveries to a general audience. As trees are so widespread and provide such a useful tool for representing evolutionary relationships, it is critical that we know how to read them and understand what they can and cannot tell us, a skill now commonly known as 'tree thinking' (O'Hara, 1992; Baum *et al.*, 2005; Baum and Smith, 2012).

Tree Terminology

Phylogenetic trees, by analogy to botanical trees, are made of leaves, nodes, and branches (Figure 1). Let us consider a tree from the canopy down to the trunk, or from the modern day to the past.

The leaves of a tree, also called tips, can be species, populations, individuals, or even genes. If the tips represent a formally named group, they are called taxa (singular: taxon). A 'taxon' is a group of organisms at any hierarchical rank, such as a family, genus, or species. The tips of a phylogenetic tree are most commonly living, but may also represent the ends of extinct lineages or fossils.

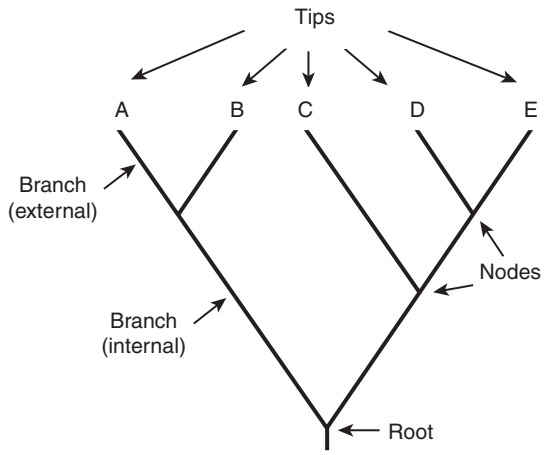

Figure 1 Components of a phylogenetic tree.

As in the trees you are already familiar with, tips or leaves are subtended by branches. A branch, which represents the persistence of a lineage through time, may subtend one or many leaves. Branches connect to other branches at nodes, which represents the last common ancestors of organisms at the tips of the descendant lineages. A branch connecting a tip to a node is called an external branch, whereas one connecting two nodes is called an internal branch (Figure 1).

Reading a tree from the past toward the present, a node indicates a point where an ancestral lineage (the branch below the node) split to give rise to two or more descendant lineages (the branches above the node). Branching on an evolutionary tree is also called 'cladogenesis' or 'lineage splitting.' After a lineage splits into two, evolution happens independently in these newly formed descendant lineages. The sequence of lineage splits in a tree creates its structure or 'topology.' Tree topology shows us the branching of lineages through time that gave rise to the tips.

'Clades' are groupings on a tree that include a node and all of the lineages descended from that node. The set of all the tips in a clade is defined as being 'monophyletic,' referring to the fact that it includes all the descendants of an ancestral lineage. In Figure 2, we could say that the tree supports monophyly of taxa C, D, and E or, put another way, C, D, and E together form a clade. Clades can be hierarchically nested within one another, as shown in Figure 2. A tree's topology can now be defined more precisely as the set of clades that the tree contains.

What a Tree Represents

Phylogenetic trees are a convenient way to represent millions or billions of years of evolution and the shared history of diverse organisms. So what are the branches and nodes really showing us?

Evolutionary trees are essentially about ancestors and descendants. You are probably familiar with pedigrees, which may be used to trace the ancestry of purebred dogs, tulip varieties, or royal families. Consider for a moment your own ancestry. Your line of ancestry includes your two parents, your four grandparents, and so on. You could map out your own ancestry in a family tree, and trace back your line of descent,

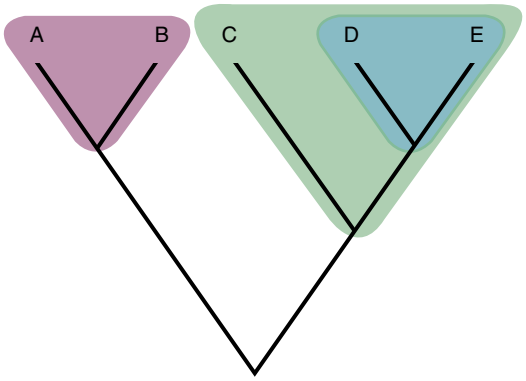

Figure 2 Clades are highlighted in a phylogenetic tree. Note clades can be hierarchically nested.

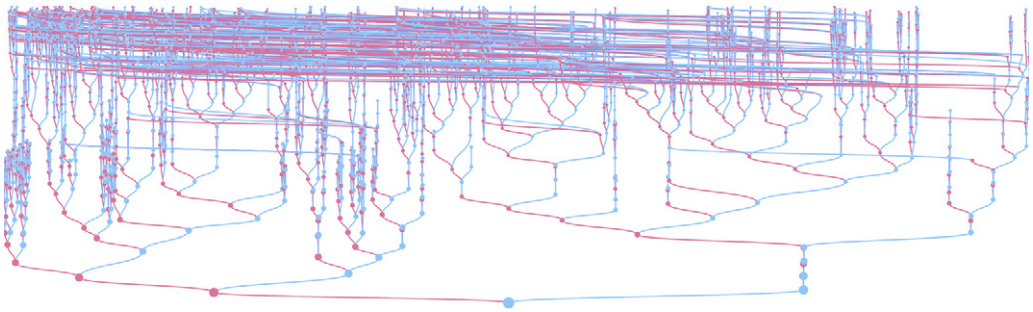

Figure 3 Image showing the ancestry of one person (Winston Churchill). Visualization tool by Bradford F. Lyon located at https://learnforeverlearn.com/ancestors/.

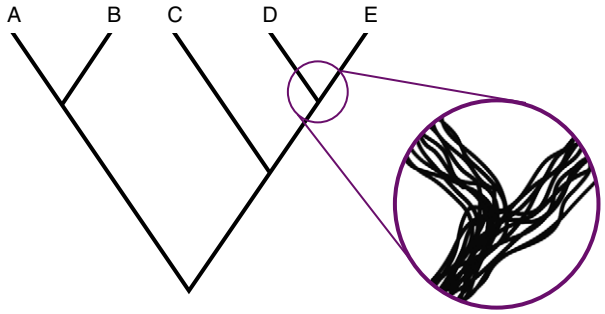

Figure 4 Close-up of lineage splitting on a tree. Lines of descent look sloppy up close, but are represented as clean lines when considered in evolutionary time.

but as you go farther back time, the number of individuals tends to balloon, at least initially (Figure 3). If you go far enough back in time or include many individuals besides yourself from the current generation it rapidly becomes difficult to map out all of the lines of descent neatly without crisscrossing. Now imagine expanding the pedigree to include every other member of our species. That would be messy and certainly not treelike! The problem is that we are thinking at the wrong timescale.

Evolution may be changed over time, but just how much time can be hard to grasp. In a short time frame, such as a human lifespan, the relationship among most organisms within a species is not treelike at all. However from a 'zoomed-out' view, we can consider the members of a species to be part of the same 'population lineage.' That is to say that members of a species share genes frequently enough that they evolve more or less as a single unit. The branches of a phylogenetic tree represent these population lineages, which are composed of many individuals over many generations (Figure 4). Every so often in evolution, a single population lineage splits into two (or more) descendant lineages. This happens when a species is split into two subsets, whose individuals do not exchange genes. When this occurs, the descendant lineages become free to accumulate differences and, if they don't come back together and fuse, will eventually give rise to very different organisms. A node represents such a lineage splitting event – the breaking of genetic connections that allowed the descendant lineages to accumulate differences and eventually give rise to distinct descendant clades.

It is worth noting that even from a zoomed-out perspective, there are cases where a phylogeny does not appear strictly treelike. Branches on the tree of life can sometimes grow together. Such a rendezvous between formerly distinct lineages is called 'reticulation.' Reticulation can be attributed to a few different biological processes (Figure 5). 'Introgression' happens when hybrids form between two distinct lineages and, through subsequent crossing, novel genetic material comes to be transferred from one species to another. In some cases, lineages can hybridize to form a new lineage that is distinct from either parental lineage – a process known as 'hybrid speciation.' Introgression of very few genes (whether by sexual reproduction or some other mechanism), called horizontal gene transfer, is usually best visualized as a treelike population history with a few genes having a discordant history. Indeed, so long as introgression and hybrid speciation are rare or limited to closely related tips, it is appropriate to represent evolutionary relationships using the tree metaphor. However, in extreme cases the tree metaphor may break down, meaning that evolutionary relationships are best represented as a network.

If evolution can be summarized as descent with modification, it makes sense that when we talk about evolution, we often do so in terms of those modifications (i.e., traits). 'Traits' are heritable characteristics of organisms. For example, flowers are a trait shared by all angiosperms, backbones are a trait shared by all vertebrates, and chitin cell walls are a trait shared by all fungi. Molecular characteristics, such as having the amino acid leucine at a certain position in a protein, should also be considered as traits. It is important to understand how traits evolve on trees, since traits serve as the basis of tree inference (see other articles within the Phylogenetic Methods section for theory and methods of phylogenetic inference).

Traits arise due to evolutionary changes within population lineages (see other articles within the Population Genetics section). Once a new trait arises and becomes fixed in a population lineage all descendant lineages are expected to have that trait, though due to subsequent evolution it might look quite different. All land vertebrates ('tetrapods'), for example, are descended from an ancestor with four limbs, though the form of their limbs differs greatly among species. Some land vertebrates did evolve a lack of limbs, but this occurred by further modifying the trait out of existence rather than by evolutionarily back-tracking to the precursor condition of having fins (Figure 6).

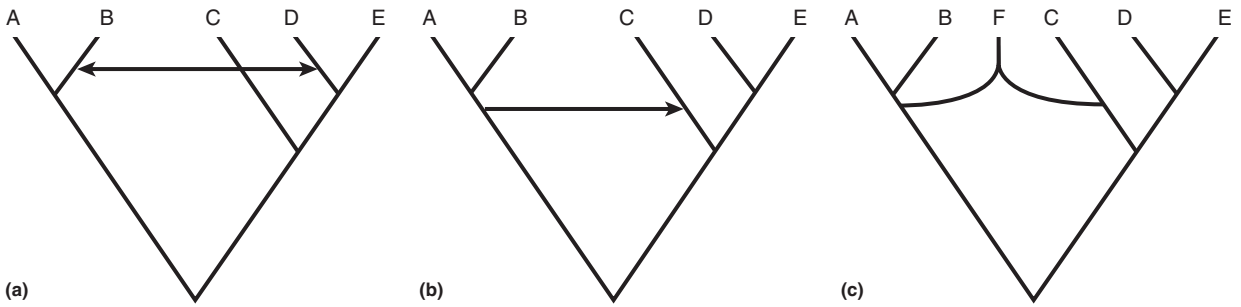

Figure 5 Processes leading to reticulation. (a) Bidirectional introgression into two parental lineages. (b) Unidirectional introgression. (c) Hybrid speciation.

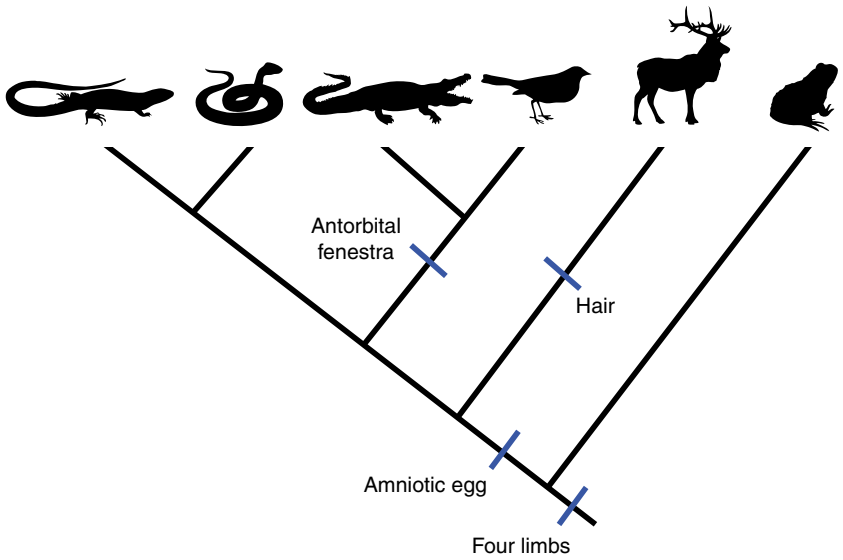

Figure 6 Cladogram of tetrapods showing trait evolution.

Lineage splitting is often mistakenly confused with trait evolution. A lineage splitting event is not necessarily accompanied by trait divergence (and even if it did, it might involve traits that we don't even know about). It is after lineage splitting that descendant lineages accumulate independent mutations, which over time may lead to novel traits. For this reason, as in Figure 6, traits are not usually depicted as evolving on nodes but on branches. If a certain clade has a unique trait, then we can infer that the last common ancestor of this clade, represented by the 'crown node,' had the trait. We can also assume that the last ancestor shared between this clade and its closest relative (its 'sib taxon') represented by the 'stem node' did not have the trait. This follows because, if stem node individuals had already evolved the trait, then the sister clade should have it too. Therefore, the correct mapping of the unique trait is on the 'stem lineage' of the clade, the branch linking its stem and crown nodes (Figure 7).

So far we have focused on trait evolution along a tree, which may imply that the products of evolution are always visible. It is important to note that evolutionary kinship is not always apparent just by looking at organisms. For example, the tree in Figure 6 shows that crocodiles are more closely related to birds than they are to lizards, even though superficially you might think lizards and crocodiles seem more similar. Relatedness does not equal similarity.

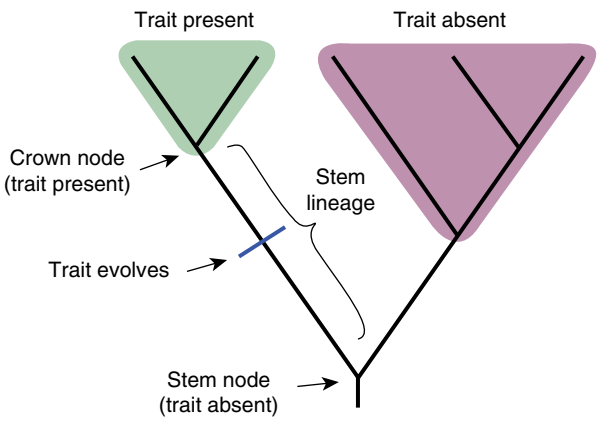

Figure 7 Trait evolution and crown/stem terminology.

There is a specialized group of terms used to describe traits, based on their distribution and origin. 'Synapomorphic' traits are ones that are unique to a particular clade. In Figure 6, snakes, lizards, crocodiles, birds, and mammals share the

synapomorphy of the amnion, which evolved after the divergence of amphibians; animals-with-amnions corresponds to a monophyletic group. 'Plesiomorphic' traits, in contrast, are those shared by a group of taxa that were inherited from an ancestor, where some other lineages lost this trait. For example, 'four limbs' is a plesiomorphic trait of tetrapods (Figure 6); vertebrates-with-four-limbs does not correspond to a monophyletic group because some tetrapods, such as snakes, legless lizards, caecilian, and whales, lack external limbs. If two independent lineages evolve a similar trait, they are said to share a homoplasious trait. Homoplasy arises when distinct lineages acquire similar traits.

Do Trees Show Advancement and Progress?

Despite the abandonment of overt ladder thinking there is still an unfortunate tendency to read a tree as though it supports a narrative in which some tips are more advanced or primitive than others. This is often apparent in the words biologists use to describe a tree. For example, vascular plants are sometimes referred to as 'higher plants' and vertebrates as 'higher animals.' But this is misleading since 'higher plants/animals' have had just as long to evolve from their common ancestors as 'lower plants/animals.' Likewise, some taxa with visible traits that make them resemble ancestors, such as lungfish, monotremes, liverworts, and bacteria, are called 'primitive' even though these lineages are all alive today and have many invisible differences from the ancestors they resemble. And species-poor lineages closely related to diverse clades are frequently labeled 'basal' or 'early-diverging' even though they diverged from their sib taxon at the same time that the sib taxon diverged from them. There isn't room here to discuss all of the potentially misleading labels and why they are wrong, but we advocate being mindful of these vestiges of ladder thinking. For more on this topic, see Krell and Cranston (2004), Crisp and Cook (2005), and Rigato and Minelli (2013).

Relatedness

When we say that taxa are closely related, what do we mean? 'Relatedness' refers to the amount of time since a group of organisms shared a common ancestor. For example, we say chimpanzees are the closest relatives of humans, because we share a common ancestor with chimps more recently than we do with any other organism (Figure 8). Using a tree diagram, it is simple to tease apart relatedness among taxa. Are chimps or humans more closely related to gorillas? Set aside your intuitions for a moment and look at Figure 8. Trace your way from one of the tips back through the tree to the node representing the common ancestor of chimps, humans, and gorillas (node *x*). Whether you start with the human tip or the chimpanzee tip, you reach the same ancestral node, which means that, given this tree, gorillas are equally closely related to humans and chimpanzees.

Two tips that are each other's closest relative are called sib taxa. In Figure 8, humans and chimpanzees are sib taxa. Gorillas are sibs to the human–chimpanzee clade.

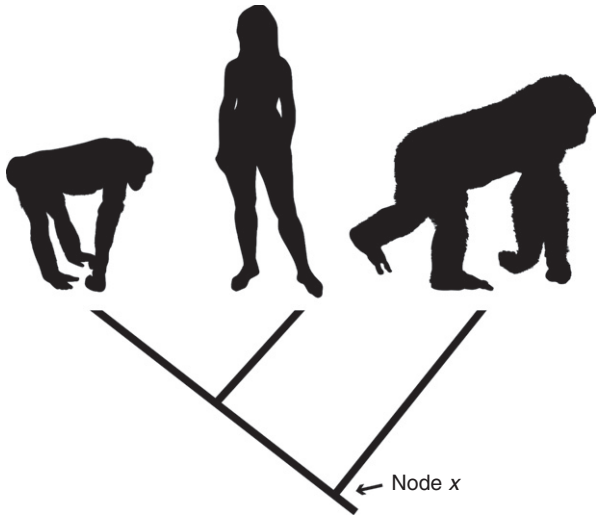

Figure 8 Cladogram showing relationships among primates.

Since tree topology refers to the list of clades that a tree includes and since all tips within a clade are more closely related to one another than to tips outside the clade, tree topology can be seen as a summary of evolutionary relatedness among all its tips. This is why tree topology is such an important evolutionary concept.

Trees can be depicted and modified in a number of different ways without changing their topology or the relatedness among organisms they represent. Regardless of whether a tree is orientated left to right, top to bottom, outward from the middle in a circle, or along a diagonal, the key information remains the same. For example, all the trees in Figure 9 show the same topology and imply the same set of evolutionary relationships. You can tell this because in all cases the list of clades is identical. Thus the orientation and style of a tree does not change the relationships it represents.

Along the same lines, the nodes of a tree can be rotated without modifying the topology (Figure 10). Looking at the two trees in Figure 10 you might think that they imply something different about evolutionary history. For example, you might think that the first tree implies that species E is the most advanced or evolutionarily derived, while the second tree implies something different. However, it turns out that these two trees have an identical topology, as you will see if you make a list of all the clades shown on each tree. This may serve to drum home the idea that trees do not show evolutionary progress even when drawn in a form that implies that some tips have changed less since the root.

Branch Length

Phylogenetic trees come in different flavors, depending on additional information they might contain. Trees may just show tree topology, in which case they may be called 'cladograms.' Sometimes, in trees called chronograms, branches are scaled to represent the opportunity for evolutionary change by drawing branch lengths proportional to time. If we assume that evolutionary changes occur at a fairly constant rate (sometimes called clocklike evolution), the length of a branch

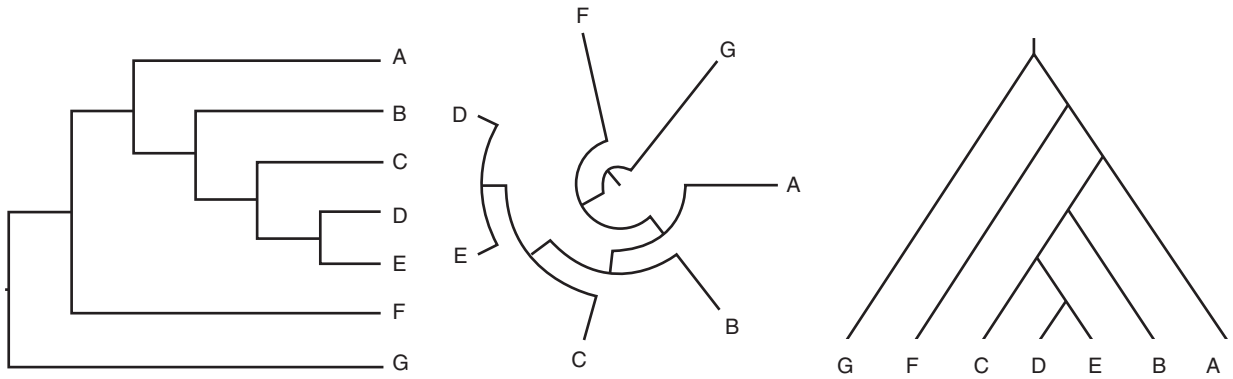

Figure 9 Trees can have different shapes and still retain the same topology.

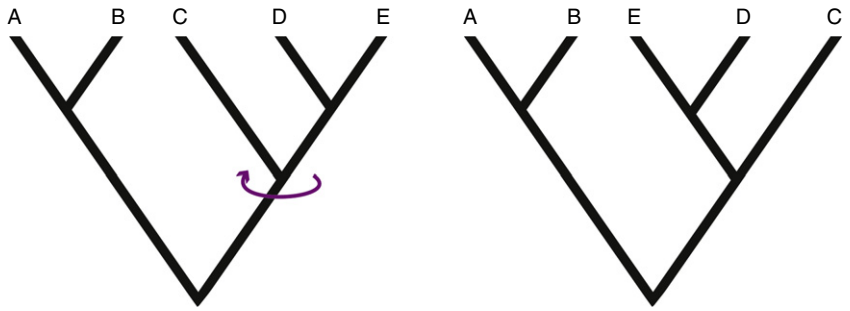

Figure 10 A tree can be rotated around any node without changing the relationships it depicts.

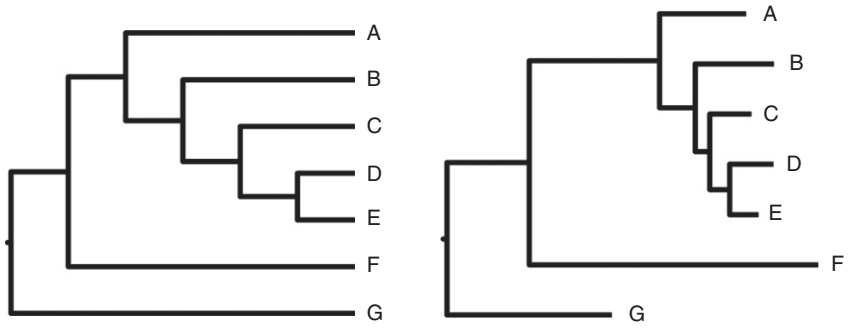

Figure 11 Cladogram (left) versus phylogram. Cladograms only communicate topology, while phylograms have branch lengths proportional to the expected amount of trait evolution.

on a chronogram tells us the relative probability that a particular trait evolved on this branch. However, this will not be true when the rate of evolution is not clocklike. In that case we can show instead a 'phylogram,' a tree whose branch lengths are drawn proportional to the expected amount of trait evolution. On a phylogram long branches indicate places where most of the changes occurred.

In a chronogram where all tips are living, all tips are equidistant from the root, since the branches represent the absolute time since divergence from a common ancestor. In a phylogram, in contrast, different tips may be different distances from the root, indicating the expectation that some tips may have accumulated more derived traits than others. Even when shown as a phylogram, however, it would be misleading to view tips or clades subtended by long branches (e.g., taxon F in Figure 11) as being more 'advanced' than ones with short branches. While they might have changed more from the common ancestor, they have had the same amount of time to evolve and may be just as well, or better, adapted to their specific ecological niche. Thinking clearly about evolution is best accomplished by completely dropping the concept of advanced and primitive taxa.

Unrooted Trees

So far, the tree diagrams we have shown are rooted trees. If a tree is rooted, all of the tips can be traced back through branches to a common ancestor. The 'root' of a tree therefore implies a chronological direction, starting in the past at the

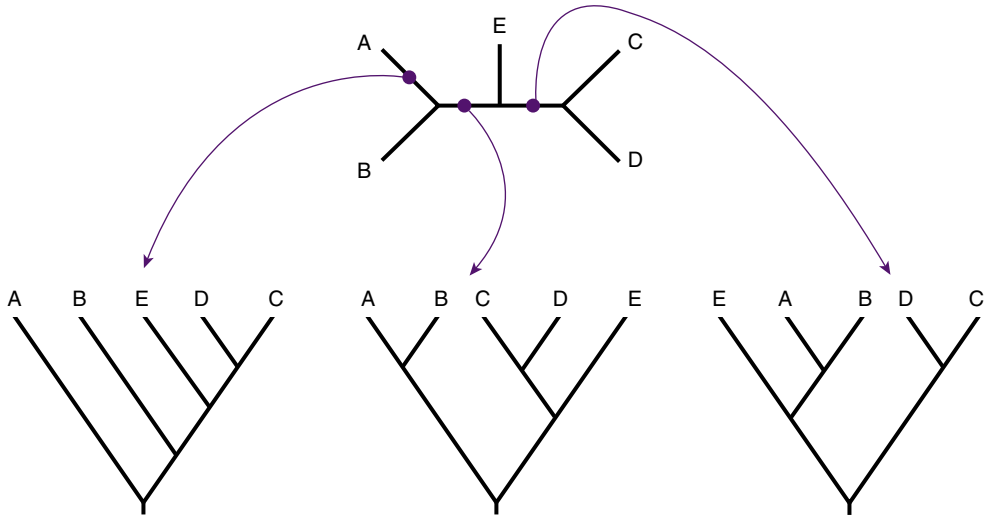

Figure 12 Different ways to root the same tree. Each of the three root positions changes the tree topology.

base of the tree and moving toward the present at the tips. However, as discussed in the following entries on tree estimation, methods for inferring phylogenetic trees often yield unrooted trees. An unrooted tree provides little information about the direction of trait evolution or the degree of relatedness of tips. This is because when a set of tips lie on one side of an internal branch we do not know if they will represent a clade on the correctly rooted tree. As a way to become more comfortable with phylogenetic trees, it is helpful to learn how an unrooted tree can be rooted (Figure 12).

The most common rooting method is outgroup rooting. To do this, we make sure that at least one tip included in a study (the outgroup) is distantly related to the other taxa in the tree (the ingroup). This requires some prior knowledge of phylogeny, since using an inappropriate outgroup can greatly change the rooted tree. As Figure 12 shows, where the root is placed can change the relationships, meaning it is important to root trees appropriately. Other rooting methods include molecular clock rooting, which assumes that all tips have had roughly the same opportunity for change since the root node, and duplicate gene rooting, which takes advantage of ancient gene duplication events.

Trees as Substrate

Understanding the relationships among organisms is just a small portion of what we can learn using trees. Once we build a phylogenetic tree, we can use it as a foundation for other analyses.

For a start, taxonomic decisions are informed by phylogenetic trees. For example, finding that one species in a genus is more closely related to members of a different genus might lead to it to be reassigned to that genus. Indeed, taxonomy now strives to only give formal names to monophyletic groups because all members of a clade are more closely related to each other than to any organisms outside the clade. A monophyletic group can thus be seen as occupying a single location on the tree of life, something that is not true for non-monophyletic groups.

Another major role for phylogenetic trees is in ancestral state reconstruction: with a tree and a trait that varies among tips, we can determine the likely characteristics of ancestral nodes in the tree. Analogous methods can also be applied to geographical distribution allowing us to infer an ancestor's historical range.

As discussed in other sections, trees have many other uses including making inferences about causes of character evolution and studying the movement of species in geographic space (see other articles within the Evolutionary Biogeography section). Indeed, scanning through the many sections of this encyclopedia you will see many phylogenetic trees – as clear an indication as any other that being able to think clearly about the process and pattern of evolution rests upon a solid foundation of phylogenetic trees and 'tree thinking.'

Phylogenetic Tree Comparison

MT Holder and EJ McTavish, University of Kansas, Lawrence, KS, USA

Glossary

Adjusted Bootstrap Proportion (aBP) A corrected bootstrap proportion of phylogenetic hypotheses which produces more accurate approximations of p-values when using the $p \approx 1-BP$. The aBP accounts for the complex boundaries between phylogenetic hypotheses.

Bootstrap It is a resampling procedure used to approximate the variance of a distribution. Many pseudoreplicate data sets are created by resampling the original data. An estimate is calculated for each pseudoreplicate. The standard error of the estimate on the actual data can be approximated by examining the variability across the collection of estimates from the pseudoreplicate data.

Bootstrap Proportion (BP) In the phylogenetic bootstrap, the BP is the proportion of bootstrap replicates that include a given clade. It is a measure of how well supported the clade is.

Kishino–Hasegawa test (KH test) A test of two competing topological hypotheses which is appropriate if both hypotheses are determined a priori.

Likelihood Ratio test statistic The test statistic is twice the difference in log-likelihoods between two hypotheses. Note that the ratio of likelihoods of different hypotheses becomes a difference when log-transformed.

Maximum likelihood (ML) A framework for statistical inference. The 'likelihood' of a hypothesis is the probability of generating a dataset identical to the observed data if that hypothesis were true. ML prefers the hypothesis that yields the highest likelihood.

Resampling of estimated log-likelihoods (RELL) A fast approximation of bootstrapping to assess variability in likelihood ratio test statistics. Instead of resampling characters and conducting a full phylogenetic analysis, in RELL we simply resample the site-likelihoods from the original analysis.

Shimodaira–Hasegawa test (SH test) SH test is an extension of the KH test which can be used to test one specific tree against another tree that was found by searching for the best tree among a large set of candidate trees.

Estimating the genealogical relationships between species is a computationally and statistically challenging endeavor. Whenever the tree that we estimate differs from the tree that we were expecting, a natural question is, 'Can we explain the discrepancy between our estimate and a previous hypothesis solely on the basis of sampling error?' If we have a small amount of character data or our data set has a large amount of internal conflict, we should be wary of our estimate. In such cases we may want to publish our best estimate, but not reject previous hypotheses about the phylogenetic relationships. We can treat our previous expectations for the topology as an null hypothesis for statistical testing.

The standard recipe for approaching this type of question in the frequentist approach to statistics is to:

1. choose a test statistic that describes how the data deviates from expectations under the null hypothesis;
2. describe the distribution of values that we would expect for this statistic if the null hypothesis were true – this is the null distribution of the test statistic;
3. compare the value of the test statistic to the null distribution to find out the probability of seeing a result that is at least this surprising if the null were true – this probability is the p-value; and
4. reject the null hypothesis if the p-value is small.

Likelihood Ratio Is (Almost Always) the Best Test Statistic

The choice of which test statistic to use in this form of testing is very open-ended. It may be tempting to use a test statistic that measures how different our estimated tree is from the trees that are a part of the null hypothesis. However, using only a tree-to-tree distance is suboptimal because it does not capture the strength of support for different groupings. Fortunately, the 'law of likelihood' assures us that the ratio of the likelihoods for competing hypotheses captures all of the evidence in the data for one hypothesis over another. So, we can focus our testing on a procedure that uses the popular 'delta' statistic:

$$\delta(T_1, T_0|X) = 2[\ln L(T_1|X) - \ln L(T_0|X)]$$

where T_1 and T_0 are the two trees that we are comparing, X represents the data, and L represents the likelihood of a tree for a data set. Note that δ is twice the difference in log-likelihoods for our two hypotheses. It is a measure of how much more support one hypothesis has than the other. We often call this the likelihood ratio test statistic. Note that the statistic is calculated on the log-scale. So, the logarithm of the ratio of two likelihoods becomes a difference between the log-likelihoods.

So what is the likelihood of a tree? The likelihood, $L(T_1|X)$, is simply the probability that we would generate a data set identical to our data (X) if tree 1 is an accurate depiction of the phylogenetic relationships. You can think of the likelihood as a measurement of how well our model (the tree) matches our data. Trees that would cause us to expect the patterns of data that we actually observe have higher likelihoods.

Because the likelihood is the probability of the entire data set, it uses all of the information in the data. Test statistics that are not functions of the likelihood are less powerful because they do not capture all of this information. While DNA sequence data is commonly used to reconstruct phylogenies,

these approaches can be applied to any data for which the likelihood of a tree can be calculated.

Null Hypotheses

Depending on the question at hand, our null hypothesis may be one of several types. The null may be that multiple topologies are equally good explanations, that one topology corresponds to the true set of relationships, or that one specific grouping is not a part of the true tree. Different tests described below are formulated with different null hypotheses. In addition, our hypotheses generally are statements about 'topologies' – the relationships among taxa. However, we calculate likelihoods on trees – topologies with branch lengths optimized according to the model of evolution to maximize the likelihood of the data. Thus, the testing procedures must include some method of handling the estimation of branch lengths, despite the fact that the hypotheses being tested rarely refer to branch lengths explicitly.

Calculating the δ Statistic in Phylogenetics

To conduct a test, we also need an alternative tree to contrast with the null hypothesis. As we will see later, we run into problems if the alternative tree that we want to test is not known when we start the study. This often occurs if we initiate a study to test a hypothesis. We may suspect that a particular grouping (the null) is not true, but we do not have a specific alternative. An appealing approach is to estimate the best tree for our data and then perform a test to see if we can reject the null. If we use the data to select the alternative tree to test, then we must alter the threshold that we use for deciding when we reject the null hypothesis (see Section 'Selection Bias Problems').

However, if we start our study interested in comparing two specific trees, then calculating δ is easy: we simply choose the most appropriate models of character evolution for our data and then calculate the log-likelihood of each tree. Calculating δ is easy in this case, but to conduct a test we also need to know the null distribution of the δ test statistic.

The Null Distribution of the Likelihood Ration Is Not Trivial to Obtain

The Null Hypothesis That Expected Likelihood Is the Same for Multiple Trees

To think about the null distribution, we have to think clearly about what hypothesis we are testing. Consider the null hypothesis that trees with or without a particular group are expected to be equally good explanations of the data. This may seem like an odd null hypothesis – after all when we are about to perform a test we do not actually expect all of the trees to be tied.

Imagine, for example, hypotheses for the relationships between humans, chimps, and gorillas, with orangutans as an outgroup (Figure 1). If our null was that in the true tree humans are the sister group to gorillas (Figure 1(a)), the most challenging form of this null would occur if the lineage that was the last common ancestor of only humans and gorillas persisted for an infinitesimal amount of time before speciating (Figure 1(d)). By 'most challenging' null, we mean the null hypothesis that will be hardest to reject. In that case, where the true tree has a zero-length internal branch, we would expect no character changes in the data set to support the grouping of humans and gorillas. Thus, we should expect each of alternative trees (e.g., trees with humans sister to the chimps (Figure 1(b)), or trees with chimps sister to gorillas (Figure 1(c)) to explain the data just as well as the true topology (Figure 1(a)). Frequentist hypothesis-testing tries to give the null hypothesis the benefit of the doubt at every step of hypothesis testing by focusing on these most challenging cases. Because of this focus on the most challenging case, the testing procedure will let us make very general statements such as 'either the null hypothesis is false or some rare form of sampling error occurred; we would only expect this extreme effect of sampling error in $P \times 100\%$ of tests.

Using Per-Character δ's to Generate a Null Distribution

Using the difference in log-likelihoods between the alternative and null hypothesis is appealing in terms of statistical power

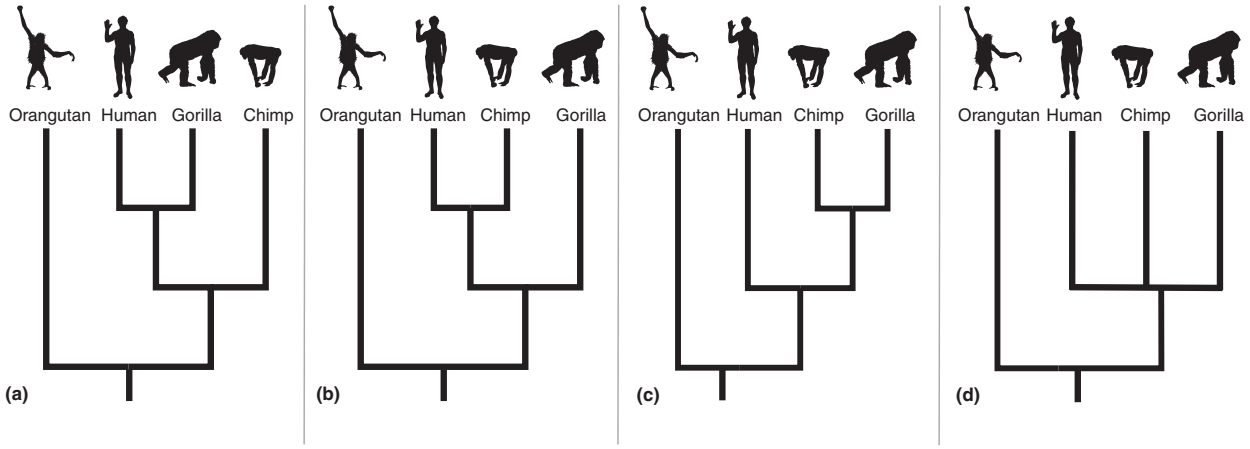

Figure 1 Three example trees demonstrating alternative potential topologies for the relationships between humans, chimps, and gorillas, with orangutans as an outgroup. (a), (b), and (c) are potential hypotheses, and (d) represents the border between these hypotheses. All branches which differ between (a), (b), and (c) are collapsed in (d). Silhouettes are reproduced from phylopic.org, credit Mike Keesey and Gareth Monger CC BY 3.0.

and making the best use of our data. Unfortunately, we do not have any clear, simple theoretical description of the null distribution of this statistic. In other words, if the null were true, we do not know how large the δ statistic might get solely as the result of sampling errors. Having a null distribution is crucial because it lets us convert an observed value of the test statistic to a p-value.

With no theoretical descriptions of the null distribution of the δ statistic, we seem to be incapable of conducting a hypothesis test. Fortunately, we can look at the phylogenetic signal within each character in our data set. This allows us to get a sense of whether the difference in log-likelihoods is coming from a few or many characters and whether or not there is much internal conflict. In almost all models used to describe character evolution in phylogenetics, different characters are assumed to evolve independently of one another. Thus the likelihood is calculated by taking a product over characters. On the log-scale the value of the δ statistic is simply the sum of the per-site versions of the δ statistic. So, looking at the distribution of the per-site differences in log-likelihoods gives us a rich view of the per-datum quantities that make up our test statistic.

Imagine that we have 50 characters in our data set and a total log-likelihood difference of 5.0 between our null hypothesis and an alternative tree. Is this degree of support statistically significant? The answer actually depends on the variance in the support from character to character.

Our null hypothesis states that trees with or without the clade of interest (e.g., Humans and Gorillas) are expected to explain the data equally well. If our tree inference method is not biased, we could imagine that every informative character has a 50% chance of favoring the null tree, and a 50% chance of supporting the alternative tree (as we will see below, this assumption is too simplistic because it ignores the number of trees that correspond to each hypothesis, but this simple case is a good starting point).

Consider the scenarios shown in Figure 2. In the case Figure 2(a), all 50 characters prefer the alternative tree by 0.1 log-likelihood units. In this case, the phylogenetic signal in the data is very repeatable and internally consistent. If the magnitude of character preference were only 0.1 and a tree with the clade was equally likely explain the data as a tree without the clade, what is the probability that we would see an overall difference in log-likelihoods of 5.0 from a data set of

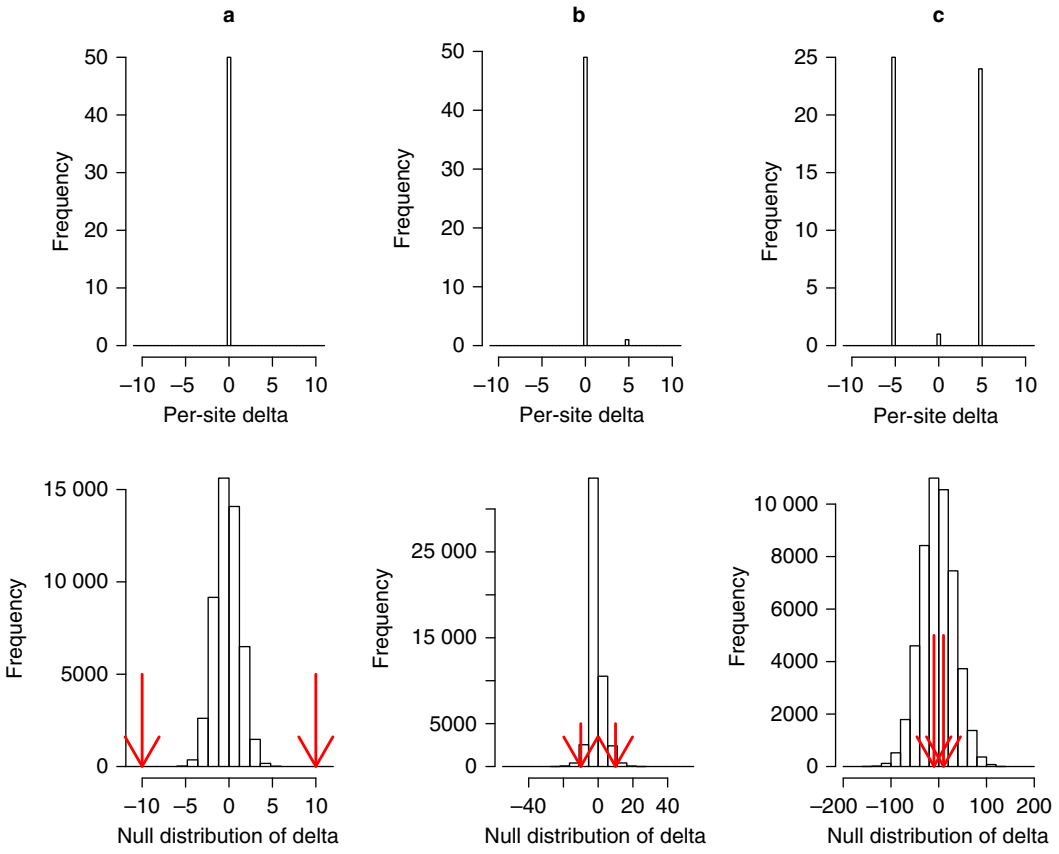

Figure 2 Null distributions under three different scenarios describing the distribution of per-site Likelihood Ratio statistics. Each column shows the per site delta distribution (top) and an approximation of the null distribution of the δ statistic (bottom). Note that the x-axis differs for each of the null distribution plots; red arrows on each plot indicate the test statistic value of 10.0 and –10.0 (the p-value is the probability of falling in the tails of the distribution more extreme than these arrows). In case (a), all 50 characters prefer the tree by 0.1 log-likelihood units (per site $\delta = 0.2$). In (b), 49 of the characters have no preference ($\delta_i = 0$) between the trees, and one character prefers the alternative tree by 5.0 log-likelihood units. In (c), we see a case of strong internal conflict in the data. One character has no preference between the hypotheses; 25 characters prefer the alternative tree; and 24 characters prefer the null tree. Among the 49 characters which have a preference for one tree over another, the magnitude of the preference is strong – centered around 5.0 log-likelihood units.

50 characters? To get a log-likelihood difference of 5, each of the 50 randomly selected sites would have to favor the same tree. The probability is tiny – it is the equivalent of flipping a fair coin 50 times and always seeing the same face of the coin (the probability is 0.5^{49} if you conduct a typical, two-sided hypothesis test). Seeing a total log-likelihood difference of 5.0 out of 50 characters each of which has a preference of around 0.1, is an extremely unlikely event if the null hypothesis is true. So we have reason to reject the null.

Figures 2(b) and **2(c)** depict two other possible outcomes of looking at the per-character log-likelihood differences. Note that the alternative tree is favored by 5.0 log-likelihood units in each of the **Figures 2(a)**, **2(b)**, and **2(c)**. In **Figure 2(b)**, 49 of the characters have no preference between the trees, and one character prefers the alternative tree by 5.0 log-likelihood units. In other words all of our signal is coming from one of our 50 data points. Unsurprisingly, this should not lead to a significant test result. If our character data is sampled from a universe with these sort of properties (probability of 0.02 of getting an informative site, and informative sites are strongly informative), then we would expect to see quite a bit of data set-to-data set variability in which tree is preferred. In fact there is a very strong chance ($\approx$0.63) that one of the trees will be preferred by at least 5.0 log-likelihood units even under the null hypothesis. Hence we do not have enough support in the real data set to make us reject the null hypothesis.

In **Figure 2(c)**, we see a case of strong internal conflict in the data. One character has no preference between the hypotheses; 25 characters prefer the alternative tree; and 24 characters prefer the null tree. Among the 49 characters which have a preference for one tree over another, the magnitude of the preference is strong – centered around 5.0 log-likelihood units. If this distribution described the signal in our data, then we should not be surprised at all to see a preference of about 5 log-likelihood units. Due to sampling error, we would almost always see this much of a difference.

Kishino–Hasegawa Test

The previous section tried to provide some intuition for why the distribution of differences in log-likelihoods per site has a strong effect on whether or not we consider a result such as $\delta = 10$ to be enough evidence for us to reject the null hypothesis (recall that the δ is twice the difference in log-likelihoods; so in the previous example a difference in log-likelihoods of 5 implies $\delta = 10$). To derive the null distribution requires more care than our intuitive exercise. Early efforts (Cavender, 1978; Templeton, 1983) had considered calculating a *p*-value from the total difference in scores using data that had integer scores only (or which scoring systems in which a character could just be defined as supporting or conflicting with a tree). Kishino and Hasegawa (1989) tackled this problem in a way that fully used the magnitude of the difference in log-likelihoods.

Kishino and Hasegawa (1989) reasoned that, because the difference in log-likelihoods between trees is simply the sum of many per-site differences, the statistic should (according to the Central Limit Theorem) follow a normal distribution if the data set is large. They used the empirically estimated per site log-likelihoods to estimate a variance of the normal distribution. They note that the sampled distribution of differences in log-likelihoods is not identical to the null distribution. However, the sampled distribution should have a similar variance to the null distribution. Under the null hypothesis, both trees should explain the data equally well. So, the null distribution should be centered at 0. Combining the mean of 0 with the sampled variance provides a normal distribution which approximates the null distribution.

Kishino and Hasegawa (1989) also noted that we can avoid the explicit assumption of normality by simply resampling the per-site differences in log-likelihoods many times to generate a distribution of δ statistics. This distribution will not be centered around 0, because whatever tree is favored by our real data will tend to be favored in the resampling procedure. We can correct for this bias very simply – by subtracting from each sampled δ value the mean over all of the simulation replicates. This enforces the null hypothesis expectation that the two trees would explain the data equally well. This procedure of resampling the per site-likelihoods is referred to as the 'resampling of estimated log-likelihoods' (RELL) bootstrap, and testing the significance of the difference between trees in this way is the 'Kishino–Hasegawa test (KH test),' after Kishino and Hasegawa (1989).

Susko (2014) questioned the assumption that the difference in log-likelihoods should follow a normal distribution. He has found the KH test using the normal as the null distribution and the RELL approximation to be too conservative. He introduced two new approaches for generating the null distribution for the KH test: a procedure that uses simulation from normal distributions to approximate the shape of the log-likelihood surface on phylogenetic trees, and a procedure using a null distribution created by mixing χ^2 (chi-squared) distributions. The mixture of χ^2 distributions is suitable for testing two trees that are very topologically similar to each other; Susko also introduced some conservative approximations that can be used in more general cases.

Selection Bias Problems

The largest impediment to the widespread use of the KH test is that it assumes that both the null hypothesis tree and the alternative are known a priori. In phylogenetics it is much more common for the null hypothesis to correspond to a set of trees and for the alternative hypothesis to be implicitly defined as 'all trees that do not fit the null.' This introduces a multiple testing problem: if you select the ML tree to use as your alternative, then you are implicitly wading through a huge number of possible alternative trees and selecting the one that is most likely to lead to rejection of the null. Selecting the most promising alternative tree makes sense in terms of constructing the most powerful test, but this selection of an alternative has a large effect on the null distribution of the test statistic. Failing to account for the multiple testing aspect of phylogenetic topology testing can lead to gross exaggerations of the strength of support against the null – this problem can be referred to as selection bias.

These considerations are even stronger in the case of another common pattern in phylogenetic data analysis: a researcher estimates a tree, and then would like to highlight the groupings that are significantly supported. In this case neither the null nor the alternative is specified a priori.

The Shimodaira–Hasegawa test (SH test) was the first phylogenetic testing procedure to deal with the problems related to selection bias.

Shimodaira–Hasegawa Test

Like the KH test, the SH test uses the likelihood ratio test statistic, and it uses a resampling procedure to generate the null distribution. In order to account for selection bias, the researcher must inform the testing machinery of the candidate set of trees that were considered plausible before the data set was examined. The SH test will test each of these trees in a way that acknowledges the fact that the researcher has searched through this set of trees to find the one with the highest score.

Recall that when performing the KH test we used the null hypothesized expectation of 0 for the difference in log-likelihoods. Because we are using the best of many trees as the alternative tree in the SH test, we can no longer assume that the δ statistic will be centered around 0. Clearly, the maximum likelihood (ML) tree will have a δ statistic that favors it when we compare it to any other tree – otherwise it would not be the ML estimate of the tree. In the SH test we allow each of the candidate trees to influence our null distribution for the delta statistic. Then we calculate a *p*-value for each tree individually to ascertain if its difference from the ML tree's score can be explained under the null hypothesis.

We can enforce the null hypothesis that a tree is no better than other members of the candidate set by:

1. resampling the sites to generate a estimate of the sampling distributions of log-likelihoods for each tree in the candidate set,
2. calculating the mean log-likelihood for each tree across all resampled replicates, and
3. subtracting that mean log-likelihood for a tree from each of its resampled log-likelihood values.

This centers the distribution of log-likelihoods for each tree across resampling replicates around 0.

To mimic the selection bias, for each replicate we find the highest *centered* log-likelihood over all of the trees. We use that value to stand in for the maximized likelihood. For each bootstrap replicate, each candidate tree's centered likelihood is compared to the highest centered log-likelihood for that replicate. This generates a sample of the null δ statistic for each tree.

For each topology in each bootstrap replicate we have generated a δ value under the expectation that on average that tree is no better or worse than the ML tree. For any candidate topology, we can then compare the observed δ to this distribution. The *p*-value for each tree is the fraction of the RELL bootstrap in which the resampled δ statistic for that tree is more extreme than that tree's δ statistic calculated on the real data set. In this way we are able to capture not only the effects of the number of candidate trees we are considering on the expectation of δ, but also the variance structure of the log-likelihoods for individual trees.

The SH test makes the pessimistic assumption that we should treat every member of the candidate set as equally likely a priori and that each contributes in an independent manner to the multiple testing problem. Because a few sites may strongly disfavor a large number of candidate trees, centering each tree's set of scores around 0 is probably too generous an assumption with respect to the worst trees in the candidate set. The result of making this cautious assumption is that the test tends to be too conservative.

A more pressing empirical problem with the test is that the researcher has to specify the candidate set of trees honestly. Omitting a tree from the candidate set will tend to exaggerate the significance of the trees tested. For even a moderate number of tips in a tree, there are a very large number of possible, and a priori plausible trees. Thus, the test can be infeasible to apply because it would requre storing and resampling the likelihood for too many trees.

Tests Based on Parametric Bootstrapping

The methods described above leverage the variation in the likelihoods across sites in observed data to generate distributions of expected δ values. This gives us the ability to estimate *p*-values. Alternatively, we can use our understanding of evolutionary process to generate expected distributions of data sets under a topology of interest. First, a substitution model is selected for the data. When we estimate a phylogeny using likelihood or Bayesian methods, we also estimate a model of evolution under which our sequences have evolved. For example, if we estimate a phylogeny using a general time reversible model for DNA sequences, we estimate the rate of change between each class of nucleotides. The choice of substitution model is often determined by a likelihood ratio tests or an information criterion. The parameter values for the chosen model, θ, are estimated for the null hypothesis topology.

Next a series of data sets are simulated on that topology under the parameters (θ) of that inferred model of evolution. A search for the ML tree is performed on each of these simulated data sets. In addition, the the likelihood of the optimized null topology is calculated for each simulated data set. The difference in likelihood score, δ, between the ML topology and the topology generating the data, is calculated for each simulated data set. This procedure produces a distribution of δ values that would be expected if the null tree were the correct topology. By comparing the observed δ to the distribution of simulated δ you can calculate the probability that the observed difference in likelihood between the ML tree and the null would have been observed if the null were the true tree. Testing phylogenies in this manner is often called the SOWH test, after Swofford, Olson, Waddell, and Hillis who first described using parametric bootstrapping to test topologies (Swoford *et al.*, 1996; Goldman *et al.*, 2000).

There are several advantages to using parametric bootstrapping for topology testing. Because this test uses the inferred model of evolution, the SOWH test has much higher power than the nonparametric approaches described above (Goldman *et al.*, 2000; Buckley, 2002). Also, conveniently, the SOWH test doesn't rely on topologies having been determined a priori. As the data sets are generated with respect to a specific topology, in comparison to the observed ML tree, these tests may be performed on the ML tree without the necessity of attempting to encompass all potentially plausibly trees, as is appropriate for the SH test. There may be millions of plausible trees, so this is a valuable advantage.

However, there are several important disadvantages to a parametric bootstrapping approach as well. Firstly, there is a large computational burden of estimating the ML phylogeny for hundreds of simulated data sets. If the individual ML searches do not find the best topologies, δ values in the null distribution will be underestimated; this can lead the test to reject too frequently. Although there are some shortcuts which can decrease the computational time, these may affect rejection rates in undetermined ways (Goldman *et al.*, 2000). Nonetheless, with increases in computational power, and the application of large computing clusters the technical issue of searching for ML trees can be overcome. More troubling is the issue that available models of sequence evolution under which we are able to simulate rarely capture the complexity of observed empirical data (Buckley, 2002). This oversimplification of simulated data likely results in phylogenetic inference on these data sets having an easier time inferring the correct tree. This will result in smaller values of δ statistics in the null distribution, and make it easer to reject the null topology as the generating tree. Researchers should be aware that if they reject a null hypothesis based on parametric bootstrapping, the appropriate conclusion is that the degree of support observed is too large to be easily explained by chance assuming that the simulated model of sequence evolution adequately mimics the level of conflicting signal in the true generating process. Indeed, in many comparisons of SH and KH tests to SOWH tests, parametric bootstrapping strongly rejects the null in cases where those nonparametric tests are unable to do so (Goldman *et al.*, 2000). This may be due to some differences in how the null and alternative hypotheses are generated under these different tests (rejecting one alternative tree vs. rejecting all other trees) and the general result that parametric tests have more statistical power. The more worrisome possibility is that SOWH may have excessive type I error when the model of evolution used is too simplistic (Buckley, 2002).

Susko (2014) has made some suggestions to improve the SOWH test and decrease the prevalence of type I error. If instead of using a fully resolved topology for the null distribution, a constrained topology in which branches differentiating the two hypotheses are collapsed (e.g., **Figure 1(d)**), the test would better capture the borderline between support for one topology or the other. By comparing this borderline topology, this modification gives a fairer chance to the null hypothesis and lowers the excessive rejection rates of the SOWH test (Susko, 2014).

Quick and Dirty Methods

Finding the likelihood ratio between the ML tree and the best tree that lacks a particular grouping can be computationally expensive. Often a nearest neighbor of the ML tree which has all of the groups with the exception of the clade of interest will be the 'next best' tree. A few testing methods have exploited this to produce quick statements of support for a branch in the ML tree by only considering the neighboring trees that lack that branch. This makes the δ test statistic quick to calculate. If a mixture of χ^2 distributions is used as a null distribution, this approach is referred to as an 'approximate Likelihood Ratio Test' (aLRT) (Anisimova and Gascuel, 2006). Anisimova *et al.* (2011) found that the aLRT rejects the null too frequently, and they recommend another fast approximate statement of support, the aBayes statistic. To calculate the aBayes score for a branch in the ML tree, one divides the likelihood of the tree containing the branch by the sum of the likelihood of that tree and the two trees that are nearest neighbors of the tree but lack the branch in question (see **Figure 3**). Simulations by Anisimova *et al.* (2011) indicate that using a 0.95 threshold for aBayes does not reject the null too often, but there are no theoretical results to indicate that this conclusion is general.

Pure Resampling Approaches

The methods discussed above all use the likelihood ratio test statistic – they only differ in how they generate the null distribution for that test statistic. It is also possible to take a fully resampling based approach in many cases. Felsenstein (1985) introduced the general statistical technique of bootstrapping to the field of phylogenetics as a method for determining confidence for different groupings in the tree. In the bootstrapping procedure, you create an artificial data set the same size as your data by resampling the characters (randomly and with replacement) from your original data set. You can estimate a tree on this bootstrap-pseudoreplicate data set. This process can be repeated many times to produces a collection of bootstrap trees. Clades that show up in all or almost all of the bootstrap trees must have substantial support. Even in the face of the sampling error of the bootstrapping procedure, these clades are almost always recovered. Thus, the amount of support for these clades in your data must be larger than the amount of noise that is typically produced by sampling error. If a clade appears across many different replicate subsamples of your data, you can have some confidence that the clade is not just an artifact of sampling error.

For some statistical problems, one can even approximate a p-value using 1.0 minus the bootstrap proportion (BP). So, if a result was found in 96% of the bootstrap replicates, its p-value would be approximately 0.04. Unfortunately, this simple approach does not apply to phylogenetic problems. The connection between the p-value and $1-BP$ is complicated (see Alfaro *et al.*, 2003; Newton, 1996, and references therein). Correction for the $1-BP$ approach have been developed based on theories about the geometry of tree space. This body of theory underlies the approximately unbiased test for phylogenies Shimodaira (2002) and the multi-level bootstrap method of Efron *et al.* (1996).

Adjusted Bootstrap Proportion

Susko (2010, 2014) developed improved phylogeny testing procedures that pay particular attention to the boundaries between hypotheses where the branches that differ between the trees all have branch lengths of 0. At that point, the different topologies make exactly the same prediction of what data we would expect to see – so it is impossible to distinguish data arising from one topology from data that arose from other trees. If we are treating one of the trees as the null, this point should be the hardest point of the null hypothesis to

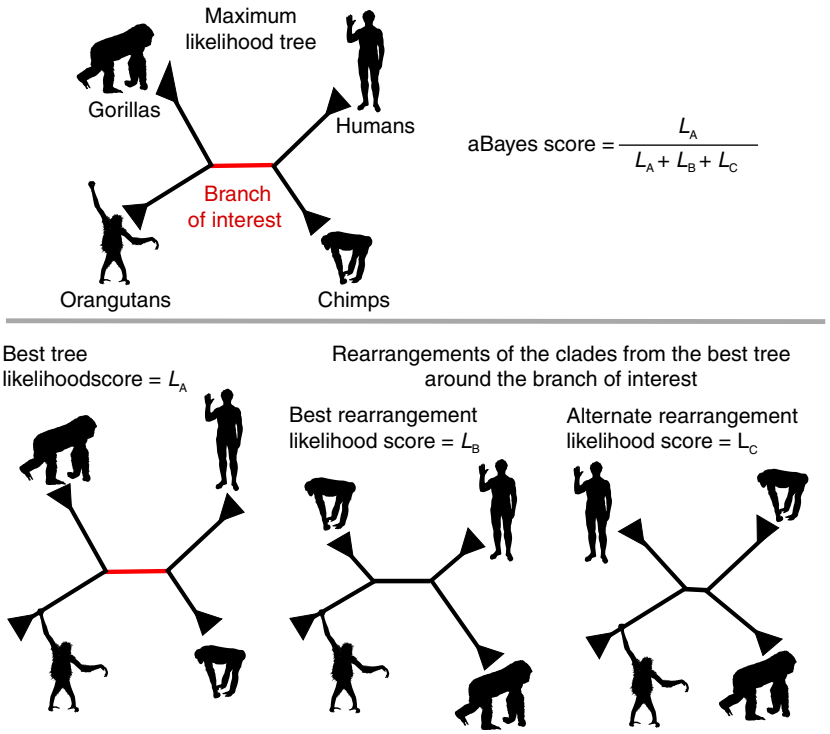

Figure 3 To calculate the aBayes score for a branch in the maximum likelihood (ML) tree, one divides its likelihood by the sum of the likelihood of that tree and the two trees that are nearest neighbors of the tree but lack the branch in question. Silhouettes are reproduced from phylopic.org, credit Mike Keesey and Gareth Monger CC BY 3.0.

reject. Not only are the boundaries between hypotheses curved, but more than two trees' boundaries come together at this point of zero branch lengths. Susko's approaches evaluate the curvature of the likelihood function for different trees at this point. After fitting normal distributions to mimic the shape of the likelihood surface, his 'adjusted bootstrap proportion' (a*BP*) can correct for the complexities of the hypothesis testing problem. Thus 1–a*BP* provides a better estimate of the *p*-value than the simple $1 - BP$ approach.

Further Considerations

This article has outlined methods for considering sampling error when phylogenetic hypotheses are tested. There are many other sources of error that a practitioner must be aware of that are completely ignored by the tests presented here. For instance:

- If the method of tree inference is not sophisticated enough to interpret the data, then the tree inference may be subject to systematic bias. For example, for some sets of branch lengths parsimony is guaranteed to estimate the wrong tree if given enough data. For you to have confidence in your estimated tree, you must be confident that it is not the result of either sampling error or systematic error.
- If you have data from one or a few loci, you may have confidence in your estimates of the gene trees. However, you should be aware that the species tree may differ from the gene tree due to hybridization, lateral gene transfer, problems of paralogy, or simply the failure of polymorphisms to fix during the duration of an ancestral species lineage. The topology tests described above do not accommodate these effects.
- Errors in the construction of the data set are ignored by the methods above. For example, the true alignment is not known and phylogenetic biases of alignment algorithms can affect the strength of support. See Karin *et al.* (2014) for recommendations about incorporating alignment uncertainty in parametric bootstrapping.

Phylogenetic Tree Distances

G Weyenberg and R Yoshida, University of Kentucky, Lexington, KY, USA

Introduction

The relatively recent development of cheap biological sequencing technologies has led to a sustained period of exponential growth in the amount of dat00a available to systematists. The analysis of this data presents some unique challenges that have attracted the attention of many researchers in the fields of mathematics, statistics, and computer science.

One object of particular interest is the phylogenetic tree. Phylogenetic trees summarize the most recent common ancestor relationships between a given set of taxa in the form of a mathematical graph. Figure 1 depicts a pair of unrooted trees on five taxa. These trees both specify branch lengths, which typically represent an expected number of substitution events per sequence locus, although other quantities may also appear (It is also common to encounter trees without branch lengths, as some methods only concern themselves with the relative relationships, and ignore the magnitudes of the differences.). These trees T_1 and T_2 will be used to demonstrate the calculations for all methods. If a distance measure does not require branch length information, then they may be ignored.

When observing real variables, there is little debate about how one ought to quantify the distance between two observed points, subtraction being the nearly universal choice. However, when the objects being observed are not real numbers, one must consider more carefully the question of how to define distance. There are numerous ways to define distances on the space of possible phylogenetic trees; some of these methods have convenient analytic or computational properties, while others have more natural biological interpretations.

In the subsequent descriptions, we use n to denote the number of terminal taxa (or leaves) in the tree. The space of all possible trees on n taxa is called $\mathcal{T}_n$. This space may or may not incorporate branch length information, and the trees may or may not be rooted, depending on the context. We use $\|x\|$ to represent the usual Euclidean length of a vector $x=(x_1,x_2,\ldots,x_d)\in\mathbb{R}^d$, that is defined as

$$\|x\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2} \qquad [1]$$

and $|\cdot|$ to indicate the cardinality of a set, that is, a measure of the number of elements in the set. A tree distance is a function, $d:\mathcal{T}_n\times\mathcal{T}_n\to\mathbb{R}^+$ that has, at a minimum, the properties $d(r,s)=d(s,r)$ and $d(t,t)=0$. Many of the methods also require a vectorization function, $v:\mathcal{T}_n\to\mathbb{R}^p$, for some p, which maps phylogenetic trees into Euclidean space. The symmetric difference between two sets is defined as $A\ominus B:=(A\backslash B)\cup(B\backslash A)$.

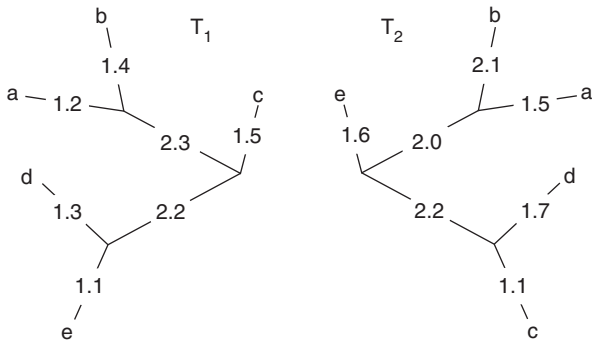

Figure 1 Example phylogenetic trees: T_1 and T_2. The trees represent proposed most recent common ancestor relationships between five taxa, labeled *a* through *e*. These trees have branch lengths specified, but not all trees need have such information.

Squared Euclidean Distances

A tree distance $d(\cdot,\cdot)$ is 'squared Euclidean' if there is a vectorization function v and a positive constant c, such that

$$d(r,s) = c\cdot\|v(r)-v(s)\|^2 \qquad [2]$$

Several popular tree distances are squared Euclidean distances as will be demonstrated below.

Robinson–Foulds Distance

A 'split' is a bipartition of the set of leaves of a tree. For example, $\{abc|de\}$ (sometimes shortened to simply *abc* when the context is clear) is one possible split of the taxa found in the example trees. This split is found in T_1, since by removing the branch with length 2.2 we can form two trees with the correct partitioning of leaves. However, this split is not found in $T2$; there is no way to remove a branch and obtain the desired partition.

Let $S(T)$ be the set of splits found in a tree T. The normalized Robinson–Foulds (RF) distance is defined as half of the size of the symmetric difference between the set of splits for each tree,

$$d_{RF}(T,T') := \tfrac{1}{2}|S(T)\ominus S(T')| \qquad [3]$$

The RF distance is a squared Euclidean distance, since we may define a vectorization function $v_{RF}:\mathcal{T}_n\to\mathbb{R}^{2n-1}-1$ where the components of v_{RF} form an enumeration of the indicator functions on all possible tree splits. In other words, for each possible split of the leaves, $A|A^c$, there is an element of $v_{RF}(T)$ which is 1 if $A|A^c\in S(T)$, and zero otherwise. We leave it as an exercise to the reader to demonstrate the connection between this vectorization scheme and the definition in terms of the symmetric difference, and to show that eqn [2] is satisfied, with $c=1/2$.

If the coordinates of v_{RF} are associated with splits in the following way,

$$(a,\ b,\ c,\ d,\ e,\ ab,\ bc,\ ac,\ cd,\ bd,\ ad,\ de,\ cd,\ bd,\ ae)$$

then the trees T_1 and T_2 from Figure 1 are vectorized as

$$\begin{aligned} v_{RF}(T_1) &= (1,1,1,1,1,1,0,0,0,0,0,0,0,0,1) \\ v_{RF}(T_2) &= (1,1,1,1,1,1,0,0,0,0,0,0,1,0,0) \end{aligned} \quad [4]$$

With these vectors, it is simple to calculate the normalized RF distance by applying eqn [2] and we find $d_{RF}(T_1,T_2)=1$.

Note that it is somewhat common for authors or programs (e.g., PHYLIP) to define the RF distance as the size of the symmetric difference without the normalizing constant $\frac{1}{2}$. When comparing RF values from different sources it is important to determine if the conventions used are compatible.

Quartet Distance

Given any tree with more than four leaves, it is possible to form a number of subtrees by pruning the tree down in various ways until it contains only four leaves. Such a subtree is called a 'quartet' of the original tree. Each quartet contains a single nontrivial split, obtained by removing the single interior branch. Since there are three possible unrooted topologies for each quartet, the splits which they define carry information about the topology of the complete tree.

We say that a tree T contains the quartet $ab|cd$, if the quartet comprising the listed nodes contains the given split. For example, T_1 contains the quartets $ab|de$ and $ab|cd$, but not the quartet $cd|be$. T_2, however, contains all three quartets.

Let $Q(T)$ be the set of quartets in a tree T. The quartet distance (Estabrook *et al.*, 1985) is defined as half of the size of the symmetric difference of quartets,

$$d_Q(T,T') := \tfrac{1}{2}|Q(T) \ominus Q(T')| \quad [5]$$

As in the case of the RF distance, d_Q can be written as a squared Euclidean distance such that using a vectorization function $v_Q : \mathcal{T}_n \to \mathbb{R}^{3\binom{n}{4}}$. This function maps tree T to the 0/1 vector $v_Q(T)$ whose entries are indicator functions of all possible quartet splits in T. For example, if the coordinates of v_Q are ordered in the following way,

$$\begin{aligned} &(ab|cd,\ ac|bd,\ ad|bc,\ bc|de,\ bd|ce, \\ &be|cd,\ ab|ce,\ ac|be,\ ae|bc,\ ac|de, \\ &ad|ce,\ ae|cd,\ ab|de,\ ad|be,\ ae|bd) \end{aligned} \quad [6]$$

then our example trees T_1 and T_2 from Figure 1 are vectorized as

$$\begin{aligned} v_Q(T_1) &= (1,0,0,1,0,0,1,0,0,1,0,0,1,0,0) \\ v_Q(T_2) &= (1,0,0,0,0,1,1,0,0,0,0,1,1,0,0) \end{aligned} \quad [7]$$

The distance between T_1 and T_2 is easily computed to be

$$d_Q(T_1,T_2) = \tfrac{1}{2}\|v_Q(T_1) - v_Q(T_2)\|^2 = 2 \quad [8]$$

Dissimilarity Map Distance

Given any tree T of n leaves with branch length information, one may produce a corresponding 'distance matrix,' $D(T)$. The distance matrix is a $n \times n$ symmetric matrix of nonnegative real numbers, with elements corresponding to the sum of the branch lengths between pairs of leaves in the tree. To calculate $D_{(ij)}(T)$, one simply determines which edges of the tree form the path from leaf i to leaf j, and then sums the lengths of these branches.

Since $D(T)$ is symmetric and has zeros on the diagonal, the upper-triangular portion of the matrix contains all of the unique information found in the matrix. We can vectorize T by enumerating this unique portion of the distance matrix,

$$v_D(T) := (D_{12}(T), D_{13}(T), \ldots, D_{23}(T), \ldots, D_{n-i,n}(T)) \quad [9]$$

The 'squared dissimilarity map distance' is defined to be

$$d_D(T',T) := \|v_D(T) - v_D(T')\|^2 \quad [10]$$

A discussion of the dissimilarity map distance can be found in Buneman (1971).

If we order the columns and rows of the distance matrix alphabetically, then the example trees are vectorized as

$$\begin{aligned} v_D(T_1) &= (2.6,\ 5.0,\ 7.0,\ 6.8,\ 5.2,\ 7.2,\ 7.0,\ 5.0,\ 4.8,\ 2.4) \\ v_D(T_2) &= (3.6,\ 5.1,\ 7.4,\ 6.8,\ 5.7,\ 8.0,\ 7.4,\ 5.5,\ 4.9,\ 2.8) \end{aligned} \quad [11]$$

From this point, computing the distance between the trees is simple,

$$d_D(T_1,T_2) = \|v_D(T_1) - v_D(T_2)\|^2 \approx 2.64 \quad [12]$$

Path Difference

The RF and Quartet distances are completely determined by the topologies of the trees, ignoring any edge lengths that may be present. Conversely, the dissimilarity map distance requires that the edge lengths be defined. The 'path difference' distance d_P is a distance analogous to the dissimilarity map, but which does not require edge length information.

The calculation of the path difference is identical to the dissimilarity map, except that elements in the distance matrix $D(T)$ are determined by counting the number of edges between the leaves, rather than summing the edge lengths (This is equivalent to the dissimilarity map distance with all edge lengths in the tree set equal to 1.). The path difference is studied and compared with the RF distances by Steel and Penny (1993).

Using the same vector ordering as in the dissimilarity map example, we find that the path difference vectorizations of our example trees are

$$\begin{aligned} v_p(T_1) &= (2,\ 3,\ 4,\ 4,\ 3,\ 4,\ 4,\ 3,\ 3,\ 2) \\ v_p(T_2) &= (2,\ 4,\ 4,\ 3,\ 4,\ 4,\ 3,\ 2,\ 3,\ 3) \end{aligned} \quad [13]$$

The path difference is therefore,

$$d_p(T_1,T_2) = ||v_p(T_1) - v_p(T_2)||^2 = 6 \quad [14]$$

Tree Rearrangement Distances

All of the tree distances discussed so far can be understood in terms of vector magnitudes in some Euclidean space. The

distances discussed in this section are defined in a different way: given a certain class of tree rearrangement operations, the distance between two trees is the minimum number of steps needed to transform one tree into another. These distances are all topological distances; they ignore any edge length information the trees may contain.

Nearest-Neighbor Interchange Distance

For each internal branch in a tree, there are three possible configurations for the connected subtrees, as shown in Figure 2. A nearest-neighbor interchange (NNI) operation (also known as a tree rotation) makes a small change to the topology of the tree by exchanging two adjacent subtrees, forming one of the alternative topologies (Robinson, 1971). The NNI distance between two trees is the minimum number of such moves required to transform one tree into the other. Although conceptually simple, computing the NNI distance is an NP-hard problem (Dasgupta *et al.*, 1997).

For instance, each of the example trees can be rotated about the length 2.2 branch, exchanging the leaves *c* and *e*, to form the other tree. Thus, the trees are separated by an NNI distance of 1.

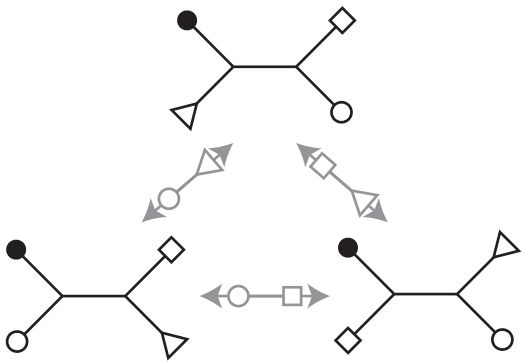

Figure 2 A nearest-neighbor interchange (NNI) move begins by selecting an internal branch from the tree. The selected internal branch defines four subtrees, which are represented in simplified form by different shapes. These four subtrees may be arranged in one of the three possible topologies. The NNI move is completed by exchanging two of the subtrees, forming one of the alternative topologies.

Subtree-Prune-and-Regraft Distance

Like the NNI distance, the 'Subtree-Prune-and-Regraft (SPR)' distance is defined by a minimum number of operations required to transform one tree into another. The steps of an SPR move are depicted in Figure 3. Succinctly, a subtree is pruned from the main tree, and then reattached to the middle of an edge elsewhere in the tree. An NNI move is a special case of an SPR move, where the detached subtree can only be moved to one of two possible locations.

Unfortunately, computing the SPR distance also is an NP-hard problem (Hickey *et al.*, 2008). However, since an NNI move is also an SPR move, we know that the example trees are also separated by SPR distance 1.

Tree-Bisection-and-Regrafting Distance

A further generalization of SPR, 'tree bisection and regrafting (TBR)' operations on trees can also be used to define tree distances (Semple and Steel, 2003). In a TBR operation, the pruned subtree can be reattached to the main tree in a more general fashion than in an SPR move. An example of a TBR move is depicted in Figure 4. Like the other distances in this section, the TBR distance is defined as the minimum number of such moves required to transform one tree into another.

Computation of the TBR distance is also NP-hard (Allen and Steel, 2001). However, in the case of our example trees, the distance is 1, since TBR is a generalization of both SPR and NNI.

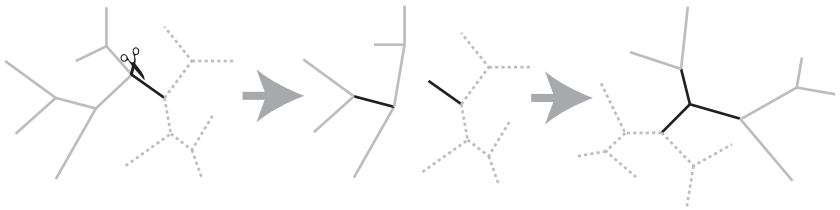

Figure 3 A subtree-prune-and-regraft (SPR) move: (Left) A subtree is selected and pruned from the main tree. (Middle) A branch is chosen from the main tree to receive the subtree. (Right) The subtree is regrafted onto the main tree.

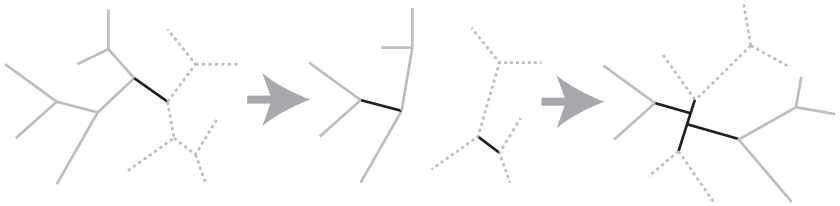

Figure 4 A tree-bisection-and-regraft (TBR) move: (Left) The tree is bisected by removing an internal branch. (Middle) Two branches are chosen from the resulting subtrees. (Right) The two branches are regrafted together in one of the three possible topologies.

Disagree Distance

Steel and Penny (1993) also described the 'disagree distance.' This distance is defined by the minimum number of taxa that must be removed from the phylogeny before the trees become congruent. For example, in our example, trees are separated by a disagree distance of 1, because removing any one of the taxa *c*, *d*, or *e* results in the trees being topologically congruent. Puigbó *et al.* (2007) discussed an algorithm for computing the disagree distance.

Billera–Holmes–Vogtmann Geodesic Distance

Billera *et al.* (2001) introduced a continuous space which models the set of rooted phylogenetic trees with edge lengths on a fixed set of leaves (Unrooted trees can be accommodated by using either the Ferras transform, or by designating an arbitrary leaf node as the root.). The Billera–Holmes–Vogtmann (BHV) tree space is not Euclidean, but it is non-positively curved, and thus has the property that any two points are connected by a unique shortest path through the space, called a 'geodesic.' The distance between two trees is defined as the length of the geodesic connecting them.

Consider a rooted tree with n leaves. Such a tree has at most $2n-2$ edges; there are n terminal edges, which are connected to leaves, and as many as $n-2$ internal edges. The maximum number of edges is achieved when the tree is binary, but the number of edges can be lower if the tree contains any polytomies. With each distinct tree topology, we associate a Euclidean 'orthant,' of dimension equal to the number of edges that the topology possesses (here, we may regard an orthant to be the subset of $\mathbb{R}^d$ with all coordinates nonnegative). For each topology, the orthant coordinates correspond to edge lengths in the tree.

Since all tree topologies have the same set of n terminal leaves, and each of these leaves is associated with a single terminal edge, the orthant coordinates associated with the terminal edges are of less interest than those of internal nodes. As a result, we will simplify our discussion by ignoring the terminal edge lengths, and concern ourselves primarily with the portion of each orthant which describes the internal edges. (Recall that this space has at most $n-2$ dimensions.)

Since each of the coordinates in our simplified orthant corresponds to an internal edge length, the orthant boundaries (where at least one coordinate is zero) represent trees with collapsed internal edges. These points can be thought of as trees with slightly different – but closely related – topologies. The BHV space is constructed by noting that the boundary trees from two different orthants may describe the same polytomic topology. With this insight, we may set about constructing the space by grafting orthant boundaries together when the trees they represent coincide.

Figure 5 depicts a portion of the BHV space on rooted trees with four leaves. The depicted portion of the space includes five orthants (topologies) and the structure of the connections between them. Since rooted binary trees on four leaves have two internal nodes, the space consists of two-dimensional orthants. Each point within an orthant corresponds to the tree with its associated topology and given internal edge lengths. The origin of each orthant corresponds to the tree with no internal edges (the 'star tree'), and the boundary rays correspond to trees where one edge is collapsed, forming a single internal node with three children.

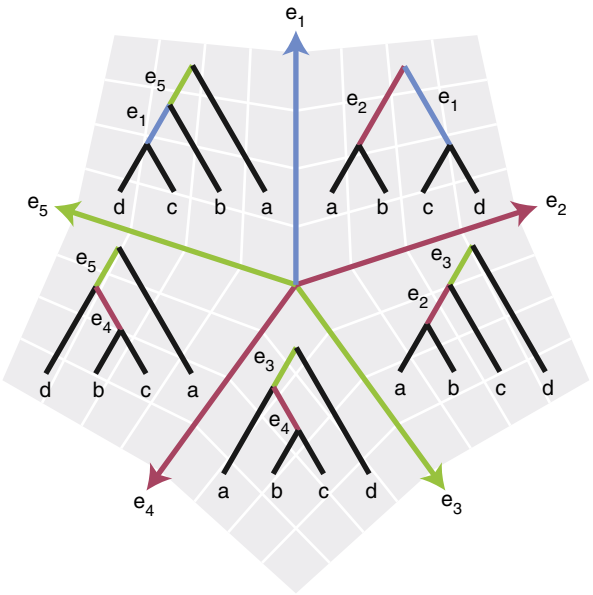

Figure 5 A portion of the space of rooted trees with four leaves. The space is formed by grafting together orthants, each corresponding to a particular topology. The full space contains several additional orthants, and is depicted schematically in Figure 6.

It is possible to represent the structure of the grafting, using the graph in Figure 6. In this graph, each edge represents a continuous path through a single orthant, from one boundary ray to the other. Conceptually, this path is formed by exchanging length between the internal edges of the tree. If two edges are joined by a node, then there are trees along the boundaries of the orthants which share a common (polytomic) topology. These boundaries are grafted together, making it possible to form a continuous path between the two orthants.

If two trees are within the same orthant, then we define the distance between them using the Euclidean distance between the corresponding points. However, if the trees have different topologies, then things become more difficult. In Figure 7 we have plotted the example trees (by arbitrarily designating node *e* as the root) onto the portion of the space from Figure 5. One possible continuous path between any two trees can be formed by shrinking the internal nodes of one tree down to zero (forming the star tree), and then expanding the tree again in the correct topology. This path is called the 'cone path' and is depicted by the dotted line.

However, there is a shorter path connecting the trees, in which only one internal edge is collapsed and the resulting polytomy can be resolved directly into the topology of the other tree. This path is depicted by the solid line. Considering only these two options, it is clear that cone path is longer. However, we have yet to establish that we have, in fact, found the shortest among all possible paths.

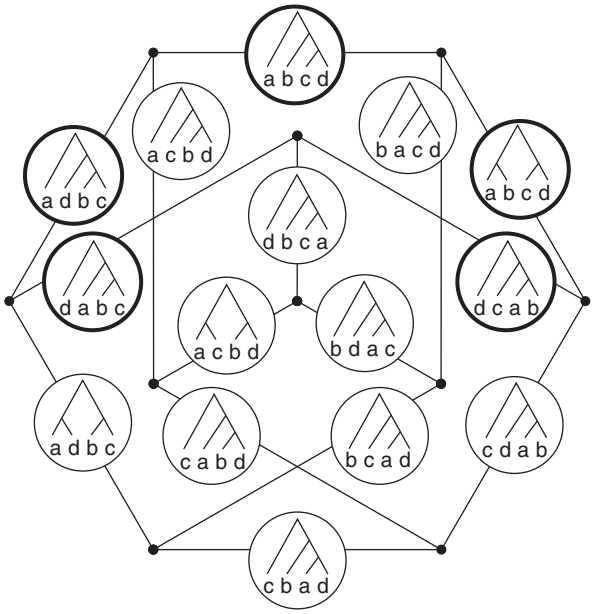

Figure 6 A schematic representation of the full space of trees on four leaves, forming a Petersen graph. Each edge represents a rooted binary tree topology, and each node represents the grafting together of orthant boundaries from the connected topologies. The portion of the graph depicted in **Figure 5** is bolded.

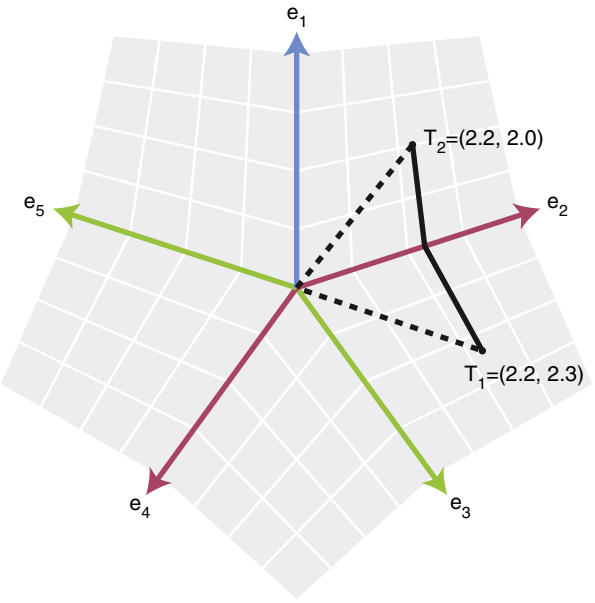

Figure 7 If we relabel leaf *e* as the root, then we can plot our example trees in the reduced tree space. (The orthants shown correspond to the same topologies as in **Figure 5**.) The cone path between the trees is shown as the dotted line. The shortest path connecting the trees is called a geodesic, and is plotted as the solid black path.

Since each orthant is locally a Euclidean space, the shortest path between two points within a single orthant is a straight line. The difficulty comes in establishing which sequence of orthants joining the two topologies will contain the geodesic. In the case of four leaves, we could do this through a brute-force search, but we cannot hope to do so with larger trees. Owen and Provan (2011) present a quartic-time algorithm (in the number of leaves) for finding the geodesic path between any two points in the space, but unfortunately the details are far beyond the scope of this article. However, once the geodesic is known, computing its length – and thus the distance between the trees – is a simple matter.

Other Tree Distances

This section contains a few other notable tree distances which do not fall into any of the previous categories.

Matching Splits Distance

A recently introduced distance is the 'matching splits distance,' developed by Bogdanowicz and Giaro (2011). Roughly speaking, the matching splits distance refines the RF distance by allowing splits to partially match each other when a portion of the split is shared by both trees.

Maximum Parsimony Distance

Fischer and Kelk (2015) introduced a notion of the 'Maximum Parsimony (MP) distance' between phylogenetic trees. The MP distance between trees is the difference between the MP scores of the given trees. The MP is a nonparametric phylogenetic tree reconstruction method and a score of taxa is computed how similar to each other among them based on a score matrix. Then the MP tree score is computed by picking the best score of all possible scores. One can find an example of the MP distance on the 'ParametricBootstrappingLab' wiki web page of Special Topics Courses: Workshop on Molecular Evolution (Hillis *et al.*, 2013).

Phylogeography

KA Marske, Center for Macroecology, Evolution and Climate, University of Copenhagen, Copenhagen, Denmark

Glossary

Alpha-diversity Species richness, or the number of species present at a location; a measure of biological diversity (biodiversity).

Beta-diversity Species turnover between locations, or the number of species present at one location which are not present at the second; a measure of biological diversity (biodiversity).

Coalescent The population genetic theory by which all alleles present in an extant population trace their genealogy back to a shared ancestor at some point in time.

Genetic drift The random change in frequency of alleles within a population.

Glacial refugia A contraction in a species' geographic range during glacial conditions, often resulting in a genetic bottleneck; that part of the range in which suitable environmental conditions allow a species to persist until conditions improve.

Macroecology The discipline which investigates ecological patterns and processes across multiple study systems or at large spatial scales, to identify general rules governing the distribution of biological diversity.

Macroevolution Evolutionary patterns and processes detectable at the species level or above, or the study thereof.

Microevolution Evolutionary patterns and processes detectable within species, or the study thereof.

Phylogeography The discipline which investigates how genetic diversity within species is related to geography and geological events.

Integrating Across Disciplines

Avise *et al.* (1987) originally envisioned phylogeography – the study of the geographical context for genetic variation within species – as a bridge between the processes acting on populations (e.g., genetic drift and selection) and supra-specific evolutionary patterns (see **Figure 1**). Since its inception, phylogeography has rapidly grown in popularity, resulting in a vast quantity of data from a myriad of taxa and environments, a blossoming of methods to analyze those data, and conceptual links with disciplines across evolution, ecology, and earth and climate sciences, making phylogeography "one of the most integrative disciplines in all of biology" (Hickerson *et al.*, 2010). Phylogeographic studies have facilitated a deeper understanding of the prevalence of gene flow among spatially structured populations (Knowles and Carstens, 2007); the prevalence of cryptic diversification within species (Martin and McKay, 2004); the complex roles of refugia, persistence, and dispersal in shaping species' geographic ranges after the last glacial period (Moritz *et al.*, 2009; Dasmahapatra *et al.*, 2010); and invaluable perspectives on genetic evolution (Singhal and Moritz, 2012). Multi-taxon comparative phylogeography studies have indicated the pervasiveness of idiosyncratic responses to past events among even co-distributed species with apparently similar ecologies, providing important insights into dispersal, adaptation, and other factors which mediate these differences (Taberlet *et al.*, 1998; Bell *et al.*, 2012; Marske *et al.*, 2012). Like all popular disciplines, phylogeography has also been the subject of pointed critique, particularly directed at the initially descriptive way in which phylogenies were related to historical events (Soltis *et al.*, 2006). This criticism – while largely warranted – sparked an explosion of analytical development and synthesis with nongenetic methods which have left phylogeography well placed to remain highly relevant to our understanding of questions as varied as speciation and evolution to ecosystem stability and species responses to climate change.

History and Development

Avise *et al.* (1987) coined the term 'intraspecific phylogeography' after observing that genetic discontinuities for multiple North American fishes corresponded with long-term geographic barriers, and described intraspecific phylogeographic structure as a function of geographic isolation and species' dispersal ability. As well as launching the nascent discipline of phylogeography, their foundational paper elucidated two guiding principles which formed the basis for subsequent study: First, Avise *et al.* (1987) recognized that phylogeography represented the theoretical evolutionary link necessary to infer species' histories across timescales, from population genetic patterns to phylogenetic systematics, and proposed that these microevolutionary processes reflected – and could predict – macroevolutionary phenomena. Second, phylogeography was presented from the very beginning as a comparative endeavor, namely, that "strong geographic barriers should mold the genetic structure of independently evolving species in concordant fashion" (Avise *et al.*, 1987). A decade after its inception, Bermingham and Moritz (1998) implicitly underscored these two principles when they predicted that continued progress within comparative phylogeography would allow 'investigation of the fundamental links between population processes and regional patterns of diversity and biogeography.'

A third feature which has characterized many phylogeographic studies from the beginning is a focus on Pleistocene processes and glacial refugia (reviewed by Hewitt, 1996; Taberlet *et al.*, 1998). Avise *et al.* (1987) never characterized their phylogeographic patterns in terms of glaciation – they described "long-term, extrinsic (i.e., zoographic) boundaries to

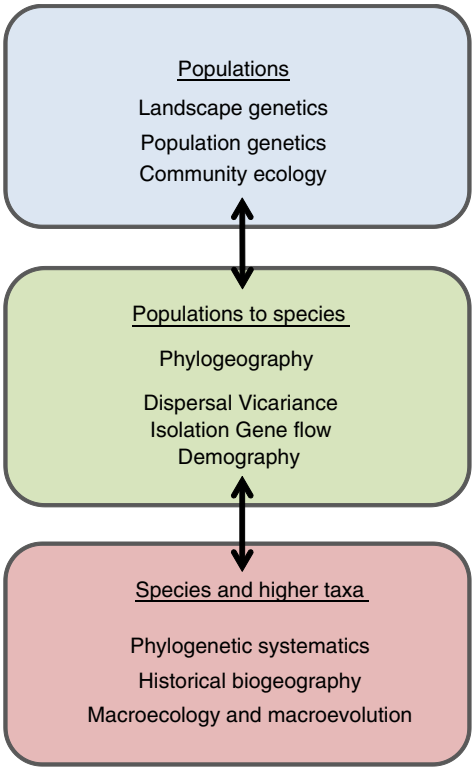

Figure 1 Phylogeography was originally envisioned as the conceptual bridge connecting processes acting on populations with evolutionary patterns detectable among species or higher taxa (Avise *et al.*, 1987). Implicit within this conceptualization is a temporal and spatial component, with population-level processes acting over shorter periods and smaller spaces but scaling up to historical biogeographic and macroecological patterns, which reflect deeper evolutionary history acting at a broader spatial scale. Thus, the population-level patterns detected using phylogeography are at the center of a continuum of ecological and evolutionary processes (Marske *et al.*, 2013). Adapted from Avise, J.C., 2009. Phylogeography: Retrospect and prospect. Journal of Biogeography 36, 3–15.

gene flow"; rather, this focus evolved as a natural result of the temporal span encompassed by intraspecific variation in mitochondrial DNA (mtDNA), upon which phylogeography was initially based (Avise *et al.*, 1987; Bermingham and Moritz, 1998). In their comparative syntheses of the effects of Quaternary glaciation on genetic diversity within Europe, Hewitt (1996, 2000) and Taberlet *et al.* (1998) emphasized both the idiosyncratic histories of individual species, and similar patterns of range expansion out of the peninsular refugia (the "southern richness, northern purity" pattern; Hewitt, 2000) with predictable suture zones where expanding lineages met. Based on these patterns, Taberlet *et al.* (1998) hypothesized that while phylogeographic congruence might occasionally occur within restricted areas, it was highly unlikely across large spatial scales, such as continents. Subsequent studies confirmed these patterns: Sullivan *et al.* (2000), in one of the first studies which explicitly tested a priori phylogeographic hypotheses, found that phylogeographic histories of two rodent taxa in a geologically complex region were neither entirely unique nor identical, but somewhere in between. In a later synthetic analysis of multiple North American taxa, Soltis *et al.* (2006) warned of the risk of pseudocongruence, where similar spatial patterns are driven by causal factors across different timescales. They also suggested that pseudocongruence might stem, in part, from the tendency among researchers to visually interpret and categorize phylogeographic patterns across species (Soltis *et al.*, 2006; but see Pyron and Burbrink, 2010), echoing a growing number of critics demanding a higher level of rigor in the testing of phylogeographic scenarios (Edwards and Beerli, 2000; Knowles and Maddison, 2002; Carstens *et al.*, 2005; Kidd and Ritchie, 2006).

One response to this criticism was the adoption of statistical phylogeographic methods, such as ancestral state reconstruction, which directly estimates the geographic locations of ancestral populations (Lemmon and Lemmon, 2008; Lemey *et al.*, 2009; Nylinder *et al.*, 2014), or model selection methods, which provide statistical support for explicit phylogeographic hypotheses (e.g., Carstens *et al.*, 2005; Hickerson *et al.*, 2006; Chan *et al.*, 2014; Pelletier and Carstens, 2014), mostly using an approximate Bayesian computational framework (Beaumont *et al.*, 2002). A key motivating factor driving the development of these methods and their implementation within a coalescent framework (e.g., Rosenberg and Nordborg, 2002) was the realization that stochastic, as well as deterministic, processes had left their mark on species' genealogies and hence, phylogeographic patterns (Edwards and Beerli, 2000; Arbogast *et al.*, 2002; Knowles and Maddison, 2002; Carstens *et al.*, 2005). These stochastic processes can result in discordant diversification among genetic loci, resulting in gene trees which do not reflect the species tree (Arbogast *et al.*, 2002). Statistical phylogeography has thus promoted both the widespread adoption and further development of coalescent tools and the increasing prevalence of multi-locus datasets within phylogeography (Knowles, 2009).

A second response to criticism was to explicitly or implicitly associate genetic data with other information sources, such as species distribution models (SDMs), to validate phylogeographic patterns (Kidd and Ritchie, 2006; Richards *et al.*, 2007; Kozak *et al.*, 2008). SDMs, which predict species' geographic distributions by relating collection localities to environmental data (Hugall *et al.*, 2002; Richards *et al.*, 2007), were first combined with phylogeography to test whether glacial refugia identified by genetic data coincided with areas of long-term climatic stability (Hugall *et al.*, 2002). SDMs are now hugely popular within phylogeography as a means of providing independent support for phylogeographic scenarios (Waltari *et al.*, 2007; Alvarado-Serrano and Knowles, 2014). Further, the two avenues of statistical phylogeography and independent verification with SDMs very quickly converged, with SDMs generating explicit spatial hypotheses (Richards *et al.*, 2007; Carnaval *et al.*, 2009), testing for potential environmental divergence underlying genetic differentiation (McCormack *et al.*, 2010), or setting the baseline conditions for direct simulations of species' histories under different dispersal scenarios (Brown and Knowles, 2012).

Current Status

Phylogeography provides a hypothetical framework with which to test the processes underlying diversification,

providing invaluable insights into how biodiversity is generated and maintained. As such, the questions currently addressed by phylogeography cover the full spectrum of ecology and evolution. A tremendous body of data across a variety of taxa and systems, from relatively easily sampled regions such as North America (Soltis *et al.*, 2006) to the farthest reaches of the globe, including Antarctica and the sub-Antarctic islands (Fraser *et al.*, 2012), suggest a myriad of responses to past climate change and other geological events. Notably, the late Quaternary history of many species was characterized by persistence in relatively small, isolated refugia (e.g., Carnaval *et al.*, 2009; Moritz *et al.*, 2009), many of which preserved evidence of much deeper divergence than just the last glacial period (Marske *et al.*, 2011; Bell *et al.*, 2012). Many studies have also yielded a much deeper understanding of dispersal, ranging from persistence in dynamic landscapes which function as temporally shifting habitat mosaics (Brown and Knowles, 2012), to movement through intermittent or leaky dispersal barriers (Burridge *et al.*, 2008; Marske *et al.*, 2009) to how dispersal potential relates to life history traits (Dawson, 2014). In spite of these dramatic changes in environment and species' geographic ranges, phylogeographic studies have largely discounted Late Pleistocene events as significant for initiating speciation (Bermingham and Moritz, 1998), but have illuminated other, older drivers of the speciation process, in conjunction with a variety of phylogenetic methods (Kozak *et al.*, 2005, 2006).

Phylogeography has also yielded insights into the origin and maintenance of regional to global biodiversity patterns, such as the distribution and drivers of alpha- and beta-diversity and the extent to which genetic diversity reflects these species-level patterns. For example, Martin and McKay (2004) proposed that if the global latitudinal diversity gradient results from higher rates of species origination at lower latitudes, genetic divergence among populations within species should be greater at the lower latitude portion of species' ranges. They synthesized data for 60 vertebrates from regions across the globe, and found that lower latitude populations do experience greater evolutionary independence, even when controlling for geographic distance and recent glacial activity (Martin and McKay, 2004). Dexter *et al.* (2012) sampled community composition and population genetic data for a genus of tropical trees along a transect in Amazonian Peru, and found that an ecological pattern of distance decay in compositional similarity masked a zone of heightened turnover where species expanding from separate refugia came into secondary contact, signifying the necessity of accounting for both contemporary and historical processes when examining the mechanisms behind biodiversity patterns. Finally, Emerson *et al.* (2011) have proposed using bulk genetic extraction techniques to simultaneously infer comparative phylogeography, historical biogeography, and phylogenetic beta-diversity among communities of soil invertebrates, using DNA barcodes to directly sample community composition for each soil sample rather than trying to demarcate community boundaries a priori.

Numerous phylogeographic studies have also sought to elucidate the processes shaping species' contemporary geographical ranges. In particular, the central-marginal or abundant center hypothesis states that species should achieve highest abundance at the range core where conditions are most optimal, with populations growing smaller and more isolated toward the range margins (Hengeveld and Haeck, 1982; Brown, 1984; Brussard, 1984). Therefore, genetic diversity and gene flow should be highest at the center of a species' range, with peripheral populations exhibiting less diversity but higher differentiation from each other and from the core (Eckert *et al.*, 2008). In a synthetic study incorporating population genetic data spanning the ranges of 115 taxa (animals and plants), Eckert *et al.* (2008) detected this pattern, but found that the difference in genetic diversity was relatively small. Notably, relatively few of the studies they included incorporated a phylogeographic perspective or invoked historical mechanisms, which Eckert *et al.* (2008) suggested might underlie the relatively weak support for the central-marginal hypothesis. Johansson *et al.* (2013) revisited the central-marginal hypothesis in a phylogeographic study of five European damselfly species, and found no general adherence to the patterns described above; rather, they found that genetic patterns were better explained by historical and contemporary ecological factors. Moritz *et al.* (2012) went a step further and explored whether variation in environmental conditions across the ranges of three skink species had resulted in different selection regimes between central and marginal populations. They found that the marginal populations were both physiologically differentiated from the core populations, and possessed thermal adaptations which might make them more likely than the core populations to adapt to and persist under contemporary climate change (Moritz *et al.*, 2012).

Other studies have centered on the formation of range margins, with a particular focus on where phylogeographic breaks, or points of spatial turnover between phylogeographic lineages, are shared across species. For example, Rissler and Smith (2010) tested whether phylogeographic breaks clustered together at contact zones between species as predicted by Taberlet *et al.* (1998) and Hewitt (2000), using available data for North American amphibians. They found significant clustering of phylogeographic breaks and contact zones in regions of known amphibian species richness, and highlighted these areas as important natural laboratories for further investigating the speciation process (Rissler and Smith, 2010). Moritz *et al.* (2009) focused on the Australia Wet Tropics, a narrow habitat corridor which forms a natural transect connecting regions of long-term climatic stability, to test the roles of historical versus contemporary climate conditions in driving diversification among lineages. They found that the majority of phylogeographic breaks occurred within a suture zone between two glacial refugia, but within this zone, individual phylogeographic breaks occurred in areas of relatively low contemporary environmental suitability (Moritz *et al.*, 2009). In contrast, Dasmahapatra *et al.* (2010) detected suture zones which, while shared across multiple Amazonian butterflies, failed to correspond to expectations based on several biogeographic hypotheses. They suggested that these zones might instead reflect contemporary ecological conditions, with multiple phylogeographic breaks shifting independently and becoming stuck on a common 'ecological hiatus' (Dasmahapatra *et al.*, 2010).

Phylogeographic studies have also generated a wealth of insight on modes of diversification and speciation. Allopatric divergence is regarded as one of the most common modes of

speciation (Coyne and Orr, 2004), and Pyron and Burbrink (2010) explored how allopatry around hard physical barriers versus environmental gradients has produced distinctly different phylogeographic patterns. They proposed that lineages should show strong concordance in the location of the phylogeographic break in cases of 'hard allopatry' around hard physical barriers, while break points might be more scattered where 'soft allopatry' reflects historical climatic disjunctions or environmental gradients. A synthetic study of genetic discontinuities around the Mississippi River Embayment and Cochise Filter Barrier in North America confirmed these predictions, as well as clarifying the temporal distribution of lineage breaks associated with each type of allopatry: under soft allopatry, divergence coincided with the timing of climate change, whereas under hard allopatry, divergence was dependent upon rare dispersal events across the barrier, and was therefore taxon specific rather than temporally clustered (Pyron and Burbrink, 2010). Jordal *et al.* (2006) utilized phylogeography to explore a putative case of sympatric speciation between two Canary Islands beetles. Rather than a sympatric origin, however, they found that the taxa likely diverged on separate islands before coming into secondary contact on La Palma, highlighting that contemporary sympatry does not rule out previous opportunities for allopatric phases of diversification (Jordal *et al.*, 2006). The mechanisms driving ecological speciation are more controversial than those for allopatric speciation, with disagreement over whether divergent natural selection leads to (Schluter, 2001) or follows (Wiens, 2004) speciation. McCormack *et al.* (2010) investigated whether allopatric lineages of *Aphelocoma* jays in the process of speciation were more different than expected based on a null model, and found little evidence for ecological divergence except in lineages which exist in partial sympatry. In contrast, Cooke *et al.* (2012) found that neutral and selected genetic divergence in Amazonian fish was more strongly driven by water color than either river system or biogeographic history. Further, they found that both selection and neutral population structure were heightened at the environmental interface between water types, providing strong evidence for environmental, rather than allopatric, divergence (Cooke *et al.*, 2012). These studies, and those detailed above, represent but a small sample of the diverse ecological and evolutionary insights stemming from phylogeographic studies, and these data still retain immense potential for broad-scale ecological and evolutionary synthesis (Bermingham and Moritz, 1998; Marske *et al.*, 2013).

Challenges and Future Directions

Numerous analytical challenges remain within phylogeography, such as the impact of parameter selection (e.g., Carstens *et al.*, 2013), model specification (e.g., Pelletier and Carstens, 2014), or underlying theoretical assumptions (e.g., Chikhi *et al.*, 2010; Heller *et al.*, 2013) on phylogeographic inference. One persistent analytical challenge is a dearth of methods which can directly deal with community-level data, and with the notable exception of hierarchical approximate Bayesian computation (Hickerson and Meyer, 2008), comparative phylogeography typically consists of inferring individual species histories and comparing them post-hoc (Andrew *et al.*, 2013). One reason is the computational challenge of dealing with large comparative datasets (Andrew *et al.*, 2013), but the more critical aspect is conceptual: an increasing number of studies indicate that co-distributed species often exhibit consistent – but not concordant – phylogeographic histories (Taberlet *et al.*, 1998; Sullivan *et al.*, 2000; Soltis *et al.*, 2006; Moritz *et al.*, 2009; Bell *et al.*, 2012; Marske *et al.*, 2012). This may be related to the methods with which species' histories are estimated: for example, detailed spatially explicit simulations of range expansion (e.g., Brown and Knowles, 2012) or estimated dispersal routes leading out from multiple refugia (e.g., Marske *et al.*, 2012); repeated across multiple taxa, may be more likely to highlight differences between species' histories, even where similarities exist. In contrast, methods which rely upon summary statistics to test specific hypotheses of population size changes (e.g., Chan *et al.*, 2014) can classify histories as similar or different, but lack the spatial component which might tie together divergence events on different timescales. These alternate views have implications for interpretation of community assembly and stability over time (i.e., Taberlet *et al.*, 1998); for example, most species likely have idiosyncratic histories, but the regional species pool may have behaved in a more predictable way (Zink, 2002; Marske *et al.*, 2013). A more nuanced analytical approach is needed to integrate these individual histories into a model of community evolution.

The data challenge – what types of data are most appropriate and how best to procure them – remains one of the longest-running conversations within the phylogeographic community. Avise *et al.* (1987) first envisioned phylogeography as the 'mtDNA bridge' between evolutionary disciplines, but relatively early on, Bermingham and Moritz (1998) highlighted the rich potential for large-scale, multi-locus comparative studies to tease apart evolution across timescales. Adoption of coalescent methods quickly identified a weakness inherent to many phylogeographic datasets, that mtDNA often lacked sufficient resolution for robust parameter estimation (Edwards and Beerli, 2000; Carstens and Knowles, 2007), but gave rise to a variety of methods which integrate information across multiple loci to estimate divergence history while accounting for stochastic genetic processes (Knowles, 2009). In that same vein, one of the greatest contemporary challenges in phylogeography – and one of the areas with greatest promise – is how to best make use of high-throughput sequencing technologies. To date, the major hurdles have included designing data capture in a way relevant for phylogeography, developing the informatics pipeline to process the data, and finding the right balance between spatial sampling and sequencing depth of individuals and populations (Carstens *et al.*, 2012; Lemmon and Lemmon, 2012; McCormack *et al.*, 2012; Andrew *et al.*, 2013; O'Neill *et al.*, 2013). Once these challenges are addressed, the pitfalls and promises are the same – how best to glean maximum evolutionary and ecological insight from the data available.

This new era in phylogeography, in which data acquisition is no longer a significant limiting factor on experimental design, offers unprecedented opportunity for creating new syntheses across disciplines and exploring creative new questions at the interface of ecology and evolution. Data-rich,

geographically comprehensive comparative studies within and between regions and taxonomic groups, currently the purview of macroecology and macroevolution, can tackle issues like diversification and community assembly and significantly contribute to our understanding of the organization of biodiversity. As new genomic sequencing methods erode the distinction between model and non-model organisms, the tantalizing possibility of associating neutral genetic diversification with selection at the functionally important genes underlying divergence draws closer to reality. Phylogeography's most important contribution to ecology and evolution may be that it is integrative and flexible, and unraveling the next set of interesting questions will likely require pairing phylogeography with novel types of external data and methods from other disciplines. However, moving toward a more complete and process-based understanding of evolution, adaptation, community assembly, and the generation of biodiversity patterns such as richness gradients requires a multifaceted approach, of which phylogeography is an integral part.

Plant–Pollinator Interactions and Flower Diversification

WS Armbruster, University of Portsmouth, Portsmouth, UK

Glossary

Bilaterally symmetrical flower (zygomorphic) Flowers with one axis of symmetry, usually a vertical one, such that the right and left sides are mirror images.
Clade A group of organisms with a common ancestor.
Character displacement Divergence of phenotypic traits in response to selection to reduce competition or reproductive interference between sympatric species.
Generalized pollination Ecological state of being pollinated by many species or functional groups of animals.
Nectar spurs Tubular structures containing nectar or other pollinator rewards.
Radially symmetrical flower (actinomorphic) Flowers with several to many axes of symmetry (as in a starfish, for example).
Reproductive isolation The tendency for members of two different species (or other groupings) not to mate or not to be interfertile; reproductively isolated populations do not exchange genes.
Reinforcement Reinforcement of reproductive isolation as a response to selection against mating or exchanging genes with members of other species (or other groupings) in secondary sympatry.
Specialized pollination Ecological state of being pollinated by few species or functional groups of animals.
Species richness The number of species (e.g., in a clade) is referred as species richness.
Sympatry/sympatric When organisms occur in the same region, near enough to one another potentially to mate or interact ecologically (opposite: allopatry).

Darwin (1859, 1877) was probably the first to recognize that specialized plant–pollinator interactions could influence both the evolution and the diversification of plants and interacting animals. Grant (1949, 1994) and most subsequent researchers (see review in Kay and Sargent, 2009) have focused primarily on the influence of floral specialization on speciation rates. However, a group's standing diversity (better termed 'clade species richness,' where a clade is a group of organisms with a common ancestor, and species richness is the number of species) is the difference between speciation and extinction rates over time since origin. It is thus important to consider the effects of pollination mechanisms on both differential extinction and speciation. Indeed, Stebbins (1950, 1951, 1974) focused on the possible influences of floral traits and trait combinations on 'adaptive success' (i.e., lower extinction rates), while suggesting a more limited influence of floral specialization on speciation rates.

The strongest clues that plant–pollinator interactions influence plant diversification rates come from analyses of the species richness of clades versus. aspects of their floral morphology or pollination ecology. For example, Dodd *et al.* (1999) found that clades of plants that are biotically pollinated are more diverse than their abiotically pollinated relatives (e.g., those with wind or water pollination). Hodges (1997) and Hodges and Arnold (1995) found greater diversification rates in plants bearing specialized flowers with nectar spurs (tubular structures containing nectar or other pollinator rewards) than in relatives with flowers not having nectar spurs. Schiestl and Schlueter (2009) found similar trends in orchids. Sargent (2004) found that clades containing plants with bilaterally symmetrical flowers were more diverse than sister clades with radially symmetrical flowers, where bilateral symmetry is assumed to increase specialization in, and/or precision of, pollination (see also Kay and Sargent, 2009). All these authors have generally interpreted the association between floral specialization and clade species richness as the result of floral specialization promoting the effectiveness of reproductive isolation between related sympatric species, and hence potentially increasing speciation rates. However, as noted above, one also needs to consider other possible causes of such correlations, such as the influence of floral specialization on extinction rates, as Stebbins (1951, 1974) and others have pointed out (see reviews in Armbruster and Muchhala 2009; Armbruster, 2014). Below I consider, in turn, speciation, extinction, and other factors that could individually, or together, contribute an association between specialized pollination and increased plant diversification (see **Figure 1**).

Effects of Floral Traits on Speciation Rates

Floral traits that limit the number of pollinator species visiting and pollinating flowers could enhance the likelihood of reproductive isolation developing between related sympatric species. The expected mechanism is that specialization in pollination ecology allows related species to use different pollinators (leading to 'ethological isolation;' Grant, 1949, 1994) or place pollen in, and pick up pollen from, different locations on the pollinators' bodies (leading to 'mechanical isolation;' Grant 1949, 1994). Both isolation mechanisms are assumed to enhance the potential for speciation either with initial divergence in sympatry (sympatric speciation) or on secondary contact (reinforcement of reproductive isolation).

Ethological Isolation

Some plants have flowers that attract only very specific pollinators (e.g., one species), and this specificity may generate ethological isolation from related species. Such pollinator

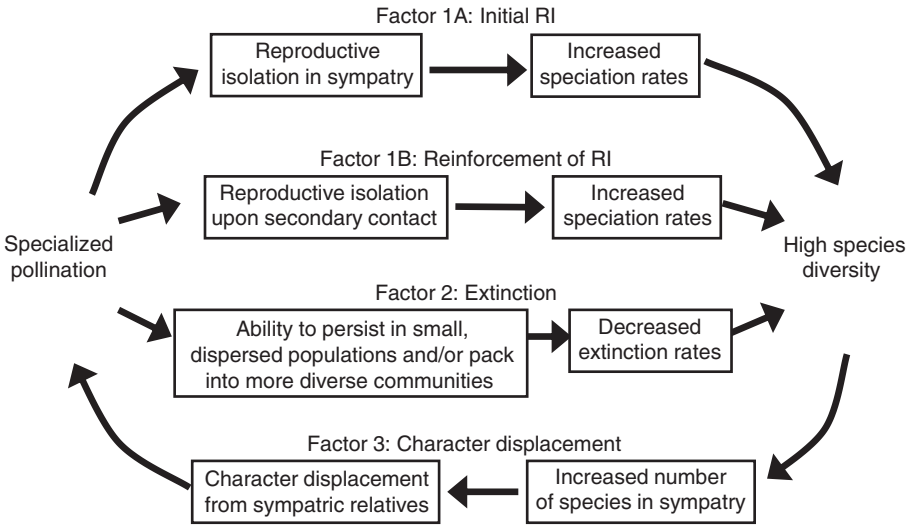

Figure 1 A graphical model of the mechanisms interlinking pollination ecology and species richness (diversity) of clades.

specificity is seen among nursery-reward species (where larval food is the motivating reward for the pollinator), such as figs and yuccas, as well as among some orchids and other plants with extreme flower morphologies, such as the Madagascar star orchid (*Angraecum sesquipedale*), with approximately 30 cm nectar spurs that restrict access to a species of sphinx moth with a similarly long proboscis (Wasserthal, 1997). Flowers pollinated by male euglossine bees (Apidae: Euglossini) may also be sufficiently specialized for ethological isolation to operate. For example, some orchids pollinated by male euglossine bees attract one or a few species of pollinators by having unusual compounds or complex mixtures of compounds in their fragrance attractants (Dodson, 1962; Dodson *et al.*, 1969; Dressler 1982; Ramirez *et al.*, 2011). Extremely similar, closely related orchid species may be virtually identical in all features but fragrance chemistry and yet remain reproductively isolated. Their speciation may have involved only small shifts in the chemistry of their floral fragrances (which are, importantly, rewards as well advertisements). That speciation can occur with little phenotypic or genetic change suggests isolation can evolve rapidity, and there should hence be increased rates of diversification in such lineages.

Outside of orchids and nursery-reward plants, however, extreme specialization and specificity of plant–pollinator relationships is generally thought to be rare, at least in most geographic regions (e.g., Waser *et al.*, 1996; cf. Johnson and Steiner, 2000; Armbruster, 2006; Schleuning *et al.*, 2012; Trojelsgaard and Olesen, 2013; Pauw and Stanway, 2015). This means that floral ethological isolation through pollinator specialization probably contributes only infrequently to diversification of plant lineages (see Armbruster (2014) for further discussion). Ethological isolation could also, in theory, be manifested through floral constancy, the tendency of individual bees to restrict foraging to one species of flower for extended periods of time (Grant, 1950; Waser, 1986). Despite being adaptive in reducing floral handling time, however, floral constancy is never absolute and is generally too incomplete to generate reproductive isolation between sympatric plant species (Chittka *et al.*, 1999; Armbruster, 2014). For example, bumble bees, which are often highly constant, still make many interspecific-flower transitions when they make periodic assessments of resource availability (Heinrich, 1976). Euglossine bees (Apidae: Euglossini) can be completely inconstant, at least when the mechanics of handling flowers is similar across plant species (Armbruster and Herzig, 1984).

Mechanical Isolation

Floral 'mechanical isolation' operates through differential pollen placement on pollinators (Grant 1949, 1994). As Stebbins (1950) pointed out, some of the strongest cases for this mechanism are seen in orchids that have pollen united into packets ('pollinia'). For example, sympatric orchids pollinated by male euglossine bees in the tropical Americas usually differ in the location of pollinarium attachment on pollinators (Dressler, 1968). This may be critical in the maintenance of reproductive isolation and play a role in speciation and diversification. Stebbins (1950) suggested that milkweeds (Apocynaceae), which also have their pollen united into pollinia, also have the potential for mechanical isolation and enhanced speciation rates, although fewer data support this contention. The critical element in these two examples is the organization of pollen into packets that can be placed precisely on pollinator and stay put until removed by other conspecific flowers. This is in contrast to most plants, which have granular pollen; granular pollen rarely lands and stays in a small enough space on the pollinator to preclude interspecific pollination (Armbruster and Muchhala 2009; Armbruster *et al.*, 2014). Indeed, recent research by Huang and Shi (2013) and Armbruster *et al.* (2014) on specialized *Pedicularis* (Orobanchaceae) flowers indicated that the granular pollen was distributed too widely on the pollinator to effect reproductive isolation between sympatric species, even when the modal sites of pollen deposition and stigma contact differed among species.

Thus, the original paradigm established by Grant (1949) and partially reinforced by Stebbins (1950), wherein

specialized pollination increases plant speciation rates by increasing the likelihood of ethological and mechanical isolation among closely related species, may be more the exception than the rule among flowering plants (but cf. Kay and Sargent, 2009). Stebbins (1974, pp. 11–13) himself suggested that ethological and mechanical isolation were unlikely to be sufficiently effective to affect rates of speciation in most plants.

Effects of Floral Traits on Extinction Rates

Another route to clade species richness is reduced extinction rates (**Figure 1**). Lowered extinction rates may occur in plant lineages that have particularly effective combinations of floral traits (Stebbins, 1951, 1974), which lead to effective attraction of, and mechanical fit with, pollinators (Armbruster, 2014). These may sometimes be associated with ecological specialization of flowers (i.e., flowers being pollinated by only a few animal species), although some models (e.g., Waser *et al.*, 1996) predict the opposite: greater reproductive success of plants with generalized pollination systems. The role that adaptive character combinations and adaptive specialization play in diversification has received very little empirical investigation. It is, unfortunately, very difficult to estimate extinction rates from phylogenetic data, so direct study of the relationship between specialization and extinction is difficult in the absence of a good fossil record. Needless to say, fossil evidence of plant–pollinator interactions is extremely limited.

One mechanism through which specialized pollination may reduce extinction rates is that more species can coexist in a plant community if they partition limiting pollinator resources. This is an axis of ecological differentiation, where limiting similarity in pollination may reduce the number of pollination generalists that can coexist in a community, relative to pollination specialists (Pauw, 2013; Benadi, 2015). Thus, as species become more specialized in their pollination, more can coexist in communities without reproductive exclusion occurring. This should lower the extinction rate in lineages with specialized pollination (Armbruster and Muchhala, 2009; Armbruster, 2014).

Effects of Diversity on the Evolution of Specialized Flowers

A third route to the association between specialized flowers and clade species richness has been pointed out only recently: members of species-rich clades may regularly experience sympatry with one or more relatives, and this selects for floral specialization (**Figure 1**; Armbruster and Muchhala, 2009; Armbruster, 2014). The logic is as follows. Closely related species are likely to share pollinators, at least when they initially come into sympatry. Members of large clades (e.g., genera) are more likely to occur sympatrically with close relatives than are members of small clades. When related species share pollinators, there will be strong selection for them to diverge in pollinator use (character displacement), such that one or both of them may become more specialized in their pollination. This is a largely untested idea, but it is consistent with the fairly common observation of floral character displacement occurring in flowering plants (e.g., Hopkins *et al.*, 2012; Beans, 2014).

Conclusions

Although there is little doubt that plant–pollinator interactions and plant-diversification rates are interrelated, the actual mechanisms involved, and their relative importance, remain to be fully elucidated. In some groups, such as orchids, specialized relationships with pollinators may increase the likelihood of reproductive isolation between similar plant taxa and thus increase speciation rates. More commonly, however, effective flower–pollinator relationships may contribute to plant diversification rates by enhancing the effectiveness of pollination and seed production, increasing population viability, and hence reducing rates of extinction. Finally, in some plant lineages, the association between specialized pollination and species diversity may reflect specialization in response to selection generated by pollinator sharing with closely related, sympatric species.

Plasmid Driven Evolution of Bacteria

BJ Ridenhour and EM Top, University of Idaho, Moscow, ID, USA

Glossary

Coevolution Evolutionary change that is reciprocated between two interacting groups (usually species). For example, evolutionary change in group A leads to evolutionary change in group B which in turn causes evolutionary change in group A and so forth.

Conjugation Transfer of genetic material directly from one bacterium to another via cell–cell contact, mediated by plasmids or integrative conjugative elements (ICEs).

Geographic mosaic theory (of coevolution) A framework set down by J. N. Thompson for examining the coevolutionary process and its outcomes. In particular the GMTC emphasizes that coevolutionary interactions are spatially and temporally variable, which has led to novel theoretical and empirical findings in coevolutionary systems.

Horizontal gene pool or mobilome The collection of mobile genetic elements that are available to a bacterium for uptake and contained in the local environment.

Mobile genetic element (MGE) DNA fragments that can be transferred from one organism to another via methods other than inheritance. In bacteria these methods are conjugation, transformation, and transduction. There are several types of MGEs including plasmids, insertion sequences, transposons, and ICEs (integrative and conjugative elements).

Plasmid host range The diversity of bacterial species in which a plasmid can replicate. Host ranges are often classified as being 'broad' for those plasmids that can replicate in many hosts across distantly related taxa (such as IncP-1 plasmids in multiple classes within the phylum Proteobacteria), or 'narrow' for those plasmids that are constrained to closely related taxa (such as IncF plasmids).

Plasmid incompatibility Two plasmids are considered incompatible if they cannot stably coexist in the same lineage over multiple generations. Incompatibility typically arises due to high similarity in replication or partitioning machinery.

Plasmid stability or persistence Highly stable plasmids are those that remain within a bacterial lineage for long periods of time, mostly due to efficient partitioning mechanisms and/or post-segregational killing systems (those plasmids that are always present in a species are considered 'native'). Conversely, plasmids that remain in a lineage for only a few generations are called unstable.

Transduction Transfer of DNA from one bacterium into another by a virus (bacterial viruses are called bacteriophages).

Transformation Transfer of genetic material directly from the abiotic environment (i.e., free-floating DNA) in a bacterium. Bacterial cells that are naturally able to take up free DNA are called competent. Transformation of cells using an electrical field (also known as electroporation) is commonly used in the laboratory to cause uptake of extracellular DNA.

The emergence and rapid spread of antibiotic resistance in bacterial species is one of the major challenges facing public health. According to a recent study in the United States (Magill *et al.*, 2014), it is estimated that there were more than 700 000 hospital-acquired (nosocomial) infections resulting in 75 000 deaths in 2011; however, others (Klevens *et al.*, 2007) have previously estimated the number to be as high as 1.7 million infections that accounted for nearly 100 000 deaths based on data available from 2002. A large percentage of these infections are caused by bacteria that have acquired multidrug resistance (MDR), such as the Gram-positive bacteria *Clostridium difficile* and *Staphylococcus aureus* and the Gram-negative bacteria *Acinetobacter baumannii* and *Klebsiella pneumoniae*, and are associated with severe health outcomes. For example, hospital patients infected with MDR *Acinetobacter* are more than two times as likely to have prolonged stays in both intensive care units (13.3 d vs. 6.7 d) and general care wards (27.5 d vs. 19.8 d); furthermore, mortality rates were 26% for MDR strains versus 17.6% for susceptible strains (Sunenshine *et al.*, 2007).

There are multiple methods by which bacteria become MDR but horizontal gene transfer (HGT) is thought to be one of the more common and problematic mechanisms. Numerous studies have indicated that HGT leads to rapid adaptation and evolution of bacteria (Gogarten and Townsend, 2005; Jain *et al.*, 2003; Ochman *et al.*, 2000). The rapid evolution is evidenced by the divergence of genome sequences among bacteria that are supposedly of the same species, with some reports of conspecifics sharing less than 50% of their genome (Abby and Daubin, 2007; Welch *et al.*, 2002). Furthermore, HGT between distantly related prokaryotic organisms is not a rare event (Bellanger *et al.*, 2014; Polz *et al.*, 2013; Frigaard *et al.*, 2006) and may even commonly occur between prokaryotes and eukaryotes (Bruto *et al.*, 2014). HGT therefore provides a method by which genes favored by natural selection – such as drug resistance – can rapidly be acquired from other members of the bacterial community. This has led to the terms 'horizontal gene pool' (Zechner and Bailey, 2004) and 'mobilome' (Frost *et al.*, 2005) which refer to the reservoir of mobile genetic elements (e.g., plasmids, insertion sequences,

transposons) available to bacteria for the production of a wide array phenotypes.

Plasmids and Horizontal Gene Transfer

One of the primary mechanisms for HGT is gene acquisition via the transfer of plasmids during bacterial conjugation. The term plasmid was first introduced by Lederberg (1952) and defined "as a generic term for any extrachromosomal hereditary determinant." However, more modern definitions of plasmids include the caveat that these extrachromosomal DNA determinants are self-replicating genetic elements. Several plasmids are self-transmissible in that they encode the necessary machinery for transferring a copy of their DNA to adjacent cells by means of conjugation. The genes carried by plasmids are typically not essential for normal cellular function but, as in the case of antibiotic resistance, could be vital to survival in certain environments. Most plasmids are circular dsDNA but linear plasmids also exist (Stewart *et al.*, 2005; Hinnebusch and Tilly, 1993); they typically consist of (1) a 'backbone,' which contains the genes necessary for self-replication, maintenance, control, and conjugative transfer and (2) various 'accessory' genes that provide other functions to the host bacterium. It is these plasmid-borne accessory genes that contribute, at least in part, to the rapid spread and emergence of traits across Archaea and Bacteria.

Numerous types/classes of traits are encoded for by the accessory genes of plasmids. As previously mentioned, antibiotic resistance is one of the most concerning of the traits. The transfer of antibiotic resistance by means of plasmids was first documented between members of the Enterobacteriaceae in the late 1950s and early 1960s (Leclercq, 2002; Watanabe and Fukasawa, 1960). However, as shown in **Figure 1**, increased resistance to many drugs, and in particular 'last line' drugs like vancomycin (Chang *et al.*, 2003; Weigel *et al.*, 2003), has been spreading rapidly in the last several decades and is also tied to plasmid encoded genes (Friães *et al.*, 2014). Resistance to toxic heavy metals (such as cadmium, cobalt, silver, lead, and mercury) is also often encoded by plasmids. For example, the plasmid pWR501 has been demonstrated to transfer genes for resistance to mercury in *Shigella* (Venkatesan *et al.*, 2001). Heavy metal resistance genes allow bacteria to exist and thrive in harsh, contaminated environments. Moreover, due to co-localization of metal and antibiotic resistance genes on the same plasmids, the presence of heavy metals may co-select antibiotic resistance, as suggested by recent alarming examples such as in the MRSA strain ST398 (Gómez-Sanz *et al.*, 2013). Plasmids also often transfer virulence factors between bacteria. A classic example of virulence encoded by plasmids occurs in

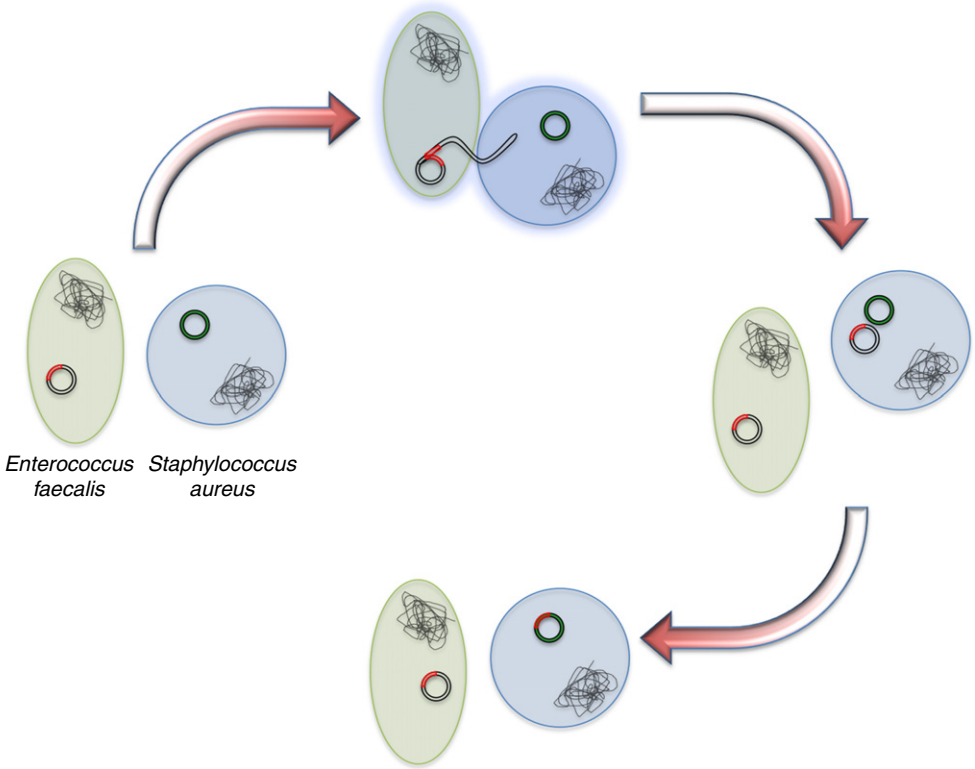

Figure 1 Hypothesized transfer of vancomycin resistance from *Enterococcus faecalis* (green) to a methicillin resistant *Staphylococcus aureus* (MRSA) (blue), resulting in a vancomycin resistant MRSA strain (VRSA), based on the findings of Weigel *et al.* (2003). Each bacterium carries its chromosomal DNA (black lines) and a plasmid (circles). The vancomycin resistance gene is carried on a transposon (red segment of *E. faecalis* plasmid; left). Although rare, conjugation can occur between *E. faecalis* and *S. aureus* when they come in contact. The *E. faecalis* plasmid is then transferred to *S. aureus*, resulting in *S. aureus* carrying both its normal plasmid and the plasmid carrying vancomycin resistance. Finally, the transposon encoding vancomycin resistance moves to the *S. aureus* MRSA plasmid via transposition. The *E. faecalis* plasmid is eventually lost from *S. aureus*, but now the *S. aureus* lineage carries the vancomycin resistance on its own plasmid, and is thus a VRSA (bottom).

the *Bacillus cereus* group of which the species *B. cereus*, *Bacillus thuringiensis*, and *Bacillus anthracis* are all highly genetically related members. However, *B. anthracis* is the etiological agent of the dreaded anthrax disease. The plasmids pXO1 and pXO2 carry the genes that encode for the exotoxin and acid capsule (both virulence factors) of *B. anthracis*, respectively (Kolstø *et al.*, 2009). Degradation of organic compounds is another function plasmids may provide bacteria. These catabolic plasmids are usually large (>50 kb) because degradation of organic compounds often requires numerous genes that are part of catabolic cascading pathways. Classical examples of this are naphthalene and toluene/xylene degradation by the plasmids NAH7 and pWWO in *Pseudomonas putida*, and the many catabolic plasmids of the broad-host-range plasmid group IncP-1 (Fernández *et al.*, 2012; Top and Springael, 2003). It should be noted that this is not an exhaustive list of the many phenotypes plasmids can encode in bacteria (Top *et al.*, 2000), just those that are often considered highly important.

Plasmids are typically classified in incompatibility groups. Incompatibility is defined as the inability of two plasmids to be vertically co-transmitted within a cell lineage for multiple generations (Couturier *et al.*, 1988). Traditionally, this was determined using selection for plasmids and then releasing the selection pressure and observing which plasmids remained in a lineage. More recently incompatibility types are being determined by DNA sequence information on the replication region of the plasmid (Sota and Top, 2008; Carattoli *et al.*, 2005). Plasmids of Gram-negative bacteria are typically classified into an alphabetical grouping (i.e., IncA through IncZ). Classification of plasmids from Gram-positive bacteria follows various methods, for example, the plasmids of *S. aureus* are broken into 15 families (Inc1 through Inc15). Needless to say, the classification of plasmids is confusing and overlap between classification systems exists (Couturier *et al.*, 1988), but the concept of plasmid coexistence within a bacterium is important to how groups of plasmids can shape evolution in bacteria.

In broader biological terms, the relationship between plasmids and bacteria can be thought of as an interaction between species where bacteria fulfill the role of the host. Thus a great deal of research has focused on the host range of plasmids, with the delineation of having either broad or narrow host range (BHR vs NHR). The host range of a plasmid is normally defined by the group of hosts in which a plasmid can successfully replicate. This does not necessarily indicate which bacteria a plasmid may be found in. Without selective pressure, replicating plasmids may be rapidly lost from some lineages but can also be efficiently retained in other strains, even within the same species (De Gelder *et al.*, 2007). Conjugative transfer of some plasmids can occur to bacteria or even eukaryotes in which the plasmid cannot replicate, resulting in a transfer range that is much wider than the replication range (Thomas and Smith, 1987). In terms of the evolution of unwanted phenotypes, like antibiotic resistance, BHR plasmids are the most problematic because of their ability to pass genes for such traits to numerous species of bacteria and may be the most important means of HGT between distantly related bacterial hosts (Mazodier and Davies, 1991). Thus, one of the central questions related to plasmid-mediated bacterial evolution is how host ranges and the stability of a plasmid within a host evolve.

Coevolution of Plasmids and Bacteria

The evolution of plasmid persistence and host range is dependent on the coevolution of plasmids and their bacterial hosts. Coevolution, using the broadly accepted definition of Janzen (1980), occurs when reciprocal evolutionary change occurs between interacting groups (typically species). Interactions between species can broadly be classified in several categories: competitions, mutualisms, antagonisms, commensalisms, and amensalisms. These classifications come from the fitness consequences of two species interacting together. If we let (+) indicate a fitness benefit, (−) indicate a fitness loss, and (0) indicate neutral fitness consequences, then a (−,−) species pair is a competition, a (+,+) species pair is a mutualism, a (+,−) species pair is an antagonism, a (+,0) species pair a commensalism, and a (0,−) species pair is amensalism ((0,0) is sometimes referred to as a neutralism, for completeness, but is typically considered a lack of interaction). Understanding these types of interactions and their consequences is central to understanding coevolutionary outcomes (Thompson, 1982). Thus, studying the fitness costs and benefits of plasmids interacting with their host is an important topic; Harrison and Brockhurst (2012) have gone so far as to claim that, "HGT via conjugation can only be fully understood in a coevolutionary framework."

On the surface, it often appears that the gain of a plasmid by a bacterium would be beneficial to its host. The host is often gaining a phenotype needed for its survival, such as antibiotic resistance. For the plasmid, the benefit would be the access to the hosts replication machinery which allows the plasmid to propagate. Therefore, at first pass, it might seem that plasmid–bacterium interactions fall into the category of mutualisms. A classic example of a mutualistic interaction between plasmids and bacteria is that of the pSym plasmids carried by *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium*. All three genera are Gram-negative soil bacteria. Rhizobia form root nodules where they provide nitrogen fixation services to their host plant in exchange for photosynthates. However, this plant–bacteria symbiosis requires the presence of pSym plasmids which encode genes necessary for rhizobia to actually perform nitrogen fixation (Mercado-Blanco, 1996). The pSym plasmids are nearly always present in rhizobia. Interestingly, non-symbiotic plasmids of rhizobia (non-pSym) also exists and are not required to form the symbiosis host plant. These non-pSym plasmids seem to be acquired opportunistically by rhizobia, particularly during periods of root colonization in which traits encoded on these plasmids may confer competitive advantages such as increased nodulation in beans (Martinez-Romero and Rosenblueth, 1990).

The mutualistic relationship between plasmids and their hosts can easily change. For example, once selective pressure for a trait encoded by a plasmid is removed, a bacterium is no longer benefiting from the plasmid. Worse yet, the plasmid is now acting as a parasite because it is utilizing the replication machinery and energy stores of its host in order to propagate itself. The fitness consequences of interacting with a bacterium can also change for a plasmid. For example, if the host is in an environment where conjugation often results in transfer to bacteria outside the plasmid's host range, or if transfer results in direct competition between the plasmid and other members

of its incompatibility group, then persisting within that particular host could have negative fitness consequences for the plasmid. Or worse, if that host's population size becomes severely reduced due to competition for resources or antagonistic interactions with other members of the microbial community, that host is no longer favorable and the plasmid is doomed if it cannot escape by horizontal transfer to fitter neighbors in time (Bergstrom *et al.*, 2000). Therefore, depending on context, the relationship between a plasmid and its host could shift to other forms of interactions.

One particularly fascinating question is why plasmids exist (Fox *et al.*, 2008; Lundquist and Levin, 1986; Levin and Stewart, 1980; Stewart and Levin, 1977; Bergstrom *et al.*, 2000). It has been demonstrated numerous times that, in the absence of selection for some accessory gene, plasmids impose a fitness cost on their host, due to use of DNA replication and maintenance machinery, the energetic cost of protein production, possible negative interference of expressed functions with host processes, etc. (Corchero and Villaverde, 1998). Evidence from *Escherichia coli* suggests that plasmids that code for either numerically more or more complex gene products impose the highest fitness costs on their hosts (note that this not necessarily the same as the base pair length of the plasmid). Given the fitness cost of maintaining a plasmid, it would be more sensible for bacteria to integrate advantageous genes from a plasmid and then discard the plasmid. Thus a conflict exists regarding what is best for the plasmid (to replicate within or across bacterial lineages) and what is best for its host (chromosomal integration of selectively advantageous genes). Coevolution has served as primary hypothesis behind why plasmids still exist (Harrison and Brockhurst, 2012). Several studies have investigated this hypothesis. For example, when comparing models of two potential bacterial mitigation strategies (either suppression of plasmid gene expression or simply resisting invasion by a plasmid), it was determined that host regulation of gene expression should be the favored strategy (Mc Ginty and Rankin, 2012). However, other models have suggested that simply modeling such strategies without including competition among plasmids can lead to incorrect conclusions, and that rescue by nonresident/immigrant plasmids could disrupt the coevolutionary process (Tazzyman and Bonhoeffer, 2014).

In some ways, it seems obvious that the relationship between plasmids and bacteria must be coevolutionary. Clearly, uptake of genes via HGT leads to the evolution of bacteria, but this is just one side of a 'reciprocal' coevolutionary relationship. The issue of plasmid persistence being increased due to the amelioration of costs via coevolution has long been considered a possibility (Duncan *et al.*, 1995), and several recent studies have provided evidence for this (De Gelder *et al.*, 2008; San Millan *et al.*, 2014; Sota *et al.*, 2010).

More concrete evidence has been accumulating however that bacteria also affect plasmid evolution. Recently, it has become evident that bacteria may use clustered, regularly interspaced short palindromic repeats (CRISPRs) as a form of 'adaptive immunity' to the invading genetic elements of viruses and plasmids (Marraffini and Sontheimer, 2010; Bhaya *et al.*, 2011). Along with CRISPRs come CRISPR-associated proteins (Cas) which together then constitute a CRISPR–Cas system. By incorporating DNA from plasmids into a CRISPR array, bacteria can recognize specific plasmid sequences as nonself. The Cas protein can then target these invading genetic elements, interfere with plasmid gene expression, and degrade foreign nucleic acids. Reciprocally, plasmids must evolve to elude the host's CRISPR recognition system in order to produce proteins necessary for their propagation. Models have shown that complex coevolutionary dynamics arise (which often lead to the proliferation of novel genotypes akin to the dynamics in many host–pathogen models) for plasmids and CRISPR–Cas systems (Berezovskaya *et al.*, 2014; Childs *et al.*, 2012; Levin, 2010). It has been suggested that the toxicity of anthrax is actually due to coevolutionary relationship where *B. anthracis* has lost its ability to regulate protein production in pXO1 and pXO2 due to a mutation in the P1cR regulatory gene (Kolstø *et al.*, 2009).

Another example of how incoming plasmid encoded genetic information can be affected by the host machinery is the transcriptional silencing of horizontally acquired plasmid genes by host H-NS, one of the nucleoid-associated proteins of bacteria (Dorman, 2014; Will *et al.*, 2004). A good example is the repression of conjugative transfer of the F plasmid by H-NS during entry into stationary growth phase in *E. coli* batch cultures (Will *et al.*, 2004). The finding that H-NS-like proteins are also encoded on some plasmids makes it even more intriguing (Suzuki *et al.*, 2014), and suggests that plasmids may be coevolving with each other as well.

Further evidence of the coevolution of plasmids and bacteria has been discovered by looking for shared genomic signatures (e.g., looking at frequency of particular dinucleotide repeats with the genome and comparing those between plasmids and hosts). Notably, it has been shown using genomic signatures that the backbone of the BHR plasmid IncP-1 adapts/evolves in accordance with the hosts to which it is exposed (Norberg *et al.*, 2011). Similarly, Suzuki *et al.* (2010) found that genomics signatures can actually be used to predict the host range of plasmid. For example, the signatures of IncP plasmids do indeed suggest they are BHR plasmids, while the IncF plasmid signatures are very similar to those of Enterobacteriaceae, their known hosts. Such evidence reinforces the idea that not only are plasmids shaping bacterial evolution, but that bacteria are reciprocally shaping plasmid genomes.

The support for ongoing coevolutionary interactions between plasmids and bacteria points to the need to study such interactions in the broader context of coevolution. The geographic mosaic theory of coevolution (GMTC) proposed by Thompson (1994, 2005) acts as a general framework for much of current coevolutionary thinking. This framework emphasizes sources of heterogeneity within the coevolutionary process. First, coevolutionary outcomes are expected to vary among populations due to differences in selection pressure and environments. This type of dynamic is exemplified by the differences observed in plasmid–bacteria interactions in spatially structured biofilms versus liquid cultures (Madsen *et al.*, 2012). For example, two plasmids (pMCBF1 and pMCBF6) isolated from the same marine biofilm have identical backbones, but have evolved to carry to different versions of their accessory genes (namely mutations in their mercury resistance transposons) (Norberg *et al.*, 2014); this indicates that diverse evolutionary outcomes are possible within spatially structured biofilms. Second, looking at a population (or a

metapopulation) at one point in time is an incomplete representation of a coevolutionary system because these interactions often display complex (e.g., cyclic) dynamics that are highly variable through time. Thus to truly understand coevolution, one must look at both spatial and temporal variability. The previously mentioned CRISPR–Cas systems predicted such highly complex, cyclical (perhaps even chaotic), temporally heterogeneous outcomes (Childs *et al.*, 2012; Berezovskaya *et al.*, 2014), but this remains to be tested empirically. The ongoing and future integration of plasmid studies with coevolutionary theory will greatly enhance our understanding of plasmid-bacteria interactions.

Conclusions

The role of plasmids in bacterial evolution can be thought of in two different lights: that of short-term, rapid evolution via HGT between bacterial lineages and that of the long-term coevolutionary relationships that dictate the host range boundaries for HGT. Gogarten and Townsend (2005) wrote: "Throughout the decades, mutualism and reticulation have often been considered the most important processes in species evolution." In bacteria, the reticulate evolution via HGT by plasmids and coevolutionary mutualisms with plasmids definitely fulfill this paradigm. The majority of research to date has focused on HGT and its implications for bacterial evolution. This focus is largely due to the observed rapid spread of phenotypes that are dangerous to human health – such as antibiotic resistance and virulence – via HGT. Research in this area has led to shocking discoveries about the (high) degree to which distantly related bacteria share genetic information, and plasmids have been implicated as a primary mechanism by which such distant transfers occur. From this, it is clear that plasmids are a driving factor in shaping the genomes of bacteria. This remains an area of intense research and new methods of analysis (such as network analysis) are being brought to bear on reticulate evolution within microbes (Dagan *et al.*, 2014; Conlan *et al.*, 2014).

Newer research is focusing on the ecological and coevolutionary relationships between plasmids and bacteria that dictate who-transmits-what-to-whom. Mounting evidence suggests that these relationships are indeed reciprocal and not simply plasmids driving the evolution of bacteria (as one might assume with HGT). The fitness benefits and consequences of conjugative transfer of plasmids, to both the plasmid and the host bacterium, must be studied in order to understand what makes one plasmid more stable within a lineage than another and why some plasmids have NHRs while others have BHRs. When considering the fitness outcomes of an interaction between a plasmid and its host, it becomes apparent that there is a large role for context dependence, as promoted by the GMTC. In particular, spatial and temporal heterogeneity in both the biotic and abiotic environment will lead to different coevolutionary outcomes. For example, such heterogeneity has been demonstrated to have an effect when plasmids and bacteria interact in spatially structured biofilms rather than homogeneous liquid cultures (Król *et al.*, 2011; Madsen *et al.*, 2012). However, there is currently a lack of studies that have focused on issues outside of HGT by plasmids, and thus the coevolution of bacteria and plasmids is far from well understood. For a truly synthetic understanding of the role of plasmids in bacterial evolution, much more research on the ecological and (co)evolutionary underpinnings is still needed. Such research will enable predicting and controlling the emergence and spread of unwanted phenotypes such as antimicrobial resistance.

Polyandry and Female Postcopulatory Choice

CR Friesen, University of Sydney, Sydney, NSW, Australia
M Olsson, University of Gothenburg, Gothenburg, Sweden

Glossary

Adaptation(s) A feature/trait that has become prevalent in a population because of the selective advantage of that feature in the improvement in function typically increasing the probability of offspring survival and viability.

Aedeagus The male copulatory, intromittent, or sperm-depositing organ of insects.

Anisogamy Sexual reproduction involving the fusion of gametes (haploid sex cells) that differ in size with males being defined as the sex with the smaller gametes and females with larger gametes. Contrast with isogamy, in which the gametes are the same size.

Antiaphrodisiacs A substance that reduces sexual receptivity or attractivity, often delivered by a male to female during mating to delay or reduce the likelihood that she will remate.

Artificially inseminate (AI) The deliberate introduction of sperm, by an investigator or doctor, into a female's reproductive tract for the purpose of fertilizing eggs by means other than sexual intercourse.

CM-PCR (competitive polymerase chain reactions) A method that amplifies small repeated segments of DNA (i.e., microsatellites) in a pool of cell samples from different individuals to assign a relative contribution of cells to the pool. This method was developed to assess the relative number of mixed sperm cells from different males within a female's reproductive tract.

Comparative method A procedure for inferring the adaptive function of a character by correlating its states in various taxa with one or more variables, such as ecological factors hypothesized to affect its evolution, while controlling for phylogeny (i.e., shared evolutionary history).

Conspecific Members of the same species. Contrast with heterospecific which means members of a different species.

Copulatory plugs (also known as mating plug, sperm plug, vaginal plug) This is gelatinous secretion or sometimes a piece of the male's intromittent organ that is deposited by a male into the female genital tract, such as the vagina, and that often later hardens into a plug or glues the tract closed. Commonly proposed functions of copulatory plugs are to reduce female remating rates by preventing further copulations, prevent sperm leakage or ejection, enhance sperm performance.

Counter-adaptation A coevolutionary response that generates an adaptive response to another adaptation. For example, in bedbugs the male's intromittent organ pierces the female's abdomen. This is an adaptation that increases the male's chances at reproductive success but it inflicts harm on the female. Females of this species have evolved a counter-adaptation to reduce the harm by thickening the cuticle in the area where males most commonly pierce them.

Cryptic female choice (CFC) A form of intersexual sexual selection whereby 'nonrandom paternity biases resulting from female morphology, physiology, or behavior that occur after coupling.'

Ejaculate (noun) Is a fluid issued by males that is composed of seminal fluid and sperm. The seminal fluid is a complex matrix containing many different molecules and compounds that are largely produced by sex accessory glands that nourishes sperm, can affect female physiology and form copulatory plugs.

Fisherian process (or runaway sexual selection) A model of sexual selection in which a male displays character and female preference for the character become correlated and reinforce one another so that both evolve to be more extreme.

Genetic incompatibility Reduction in the fitness of an offspring because of interaction between certain alleles in one parent with specific alleles at other loci in the other parent. This is most commonly seen in hybrid offspring produced in between population, subspecies or species crosses.

Genotype The set of genes possessed by an individual organism; often, its genetic composition at a specific locus or set of loci singled out for discussion.

Heritable variation The proportion of the variance in a trait among individuals that is attributable to differences in genotype and therefore can be passed on to a parent's offspring. In quantitative genetics it is expressed as the ratio of additive genetic variance to phenotypic variance.

Heterospecific A different species. Contrast with conspecific which means the same species.

Honest signal A signaling trait that accurately conveys the 'quality' of the sender to the receiver.

Immune response The process by which an organism recognizes and defends itself against substances that appear foreign and harmful, for example, bacteria and viruses.

In vitro A process performed or taking place in a test tube, culture dish, or elsewhere outside a living organism: contrast with *in vivo*, which are processes performed or taking place in a living organism.

Intersexual selection Selection that occurs due to interactions between the sexes, such as mate choice.

Intrasexual competition Selection that occurs due to the interactions between members of the same sex, usually in direct competition for mates or fertilization success.

Intromittent organ A general term for an external organ of a male that is specialized to deliver sperm during copulation such as the mammalian penis. But any organ that functions to delivery sperm can be an intromittent organ. For example, the tail of the tailed frog (*Ascaphus truei*) functions to deliver sperm into the female reproductive tract.

Knockout lines or RNA interference experiments to knock down gene expression These molecular methods allow researchers to experimentally manipulate trait expression to test the function of the target trait. Knockout lines are lineages of laboratory animals (typically mice or fruit flies) that have been bred to lack certain genes that determine the expression of the trait of interest. RNA interference introduces RNA molecules to inhibit gene expression (e.g., by damage of specific mRNA molecules), and thereby affecting the trait of interest.
Lag load dynamic The idea that if the selective environment changes such that the optimum genotype is always shifting, then there will be a 'lag' between average trait value in a population and the optimum trait value. This can lead to rapid evolution as there is always selection to move the trait value to its optimum.
Major histocompatibility complex (MHC) A set of cell surface molecules encoded by a large, highly diverse gene family which aids in the recognition pathogens by the immune system in all vertebrates.
Mate order effects The effect that the order of mating males (e.g., first male to mate with a female vs. second male to mate with the same female) has on the probability of fathering the offspring of female mates with more than one male.
Mate-guarding When a male remains close by a female, or prolongs copulation to prevent or reduce the likelihood that the female will mate again with a different male.
Non-transitive In terms of a competitive mating experiment (a given set of males are competing against each other to fertilize the eggs of a set of separate females), it means that the probability of a particular male being more or less successful at gaining fertilizations depends on the identity of the female and less on his competitors.
Ovarian fluid Fluid released from an ovarian follicle at ovulation. In externally fertilizing fish, females usually release large volumes of ovarian fluid along with their eggs. In some species, sperm of particular males exhibit greater motility and swimming speed in the ovarian fluid of particular females but less so in the ovarian fluid of other females.
Paternity Being the father of offspring (to father or sire offspring).
Paternity patterns The proportion of paternity that can regularly be ascribed to males under defined conditions. For example, in some species the last male to mate with a female usually fathers most of the offspring regardless of the identity of the female or competitors.
Phagocytosis The ingestion of a smaller cell, cell fragment, microorganism, or foreign particles by engulfing the object by the cell's membrane.
Phenotype The characteristics of an individual resulting from the interaction of its genotype with the environment.
Polyandry When females mate with multiple males.
Postcopulatory sexual selection When the processes of intrasexual competition and intersexual selection continues during and after copulation in the form of sperm competition and cryptic female choice.
Precopulatory sexual selection When the processes of intrasexual competition and intersexual selection occur in securing mates prior to copulation.
Promiscuous Demonstrating or implying an unselective approach to mate choice typically resulting in multiple matings.
Reproduction (sexual) Production of offspring whose genetic constitution is a mixture of those of two potentially genetically different gametes that unite at fertilization.
Sexual cascade The idea put forward by Geoff Parker that with the evolution of syngamy (sexual reproduction by the union of gametes) there is an inevitable evolution of copulation (internal fertilization) and sex roles (leading from anisogamy). Sexual conflict as an expected consequence of anisogamy and precopulatory sexual selection has a relatively late appearance in the evolution of the sexual cascade.
Sexual conflict When the evolutionary interests of males and females do not coincide.
Sexual selection Selection resulting from differential success in mate acquisition and fertilization.
Sexually antagonistic coevolution A dynamic and iterative process in which selection favors traits in males and females that increase their fitness at the expense of the opposite sex.
Sperm competition When the sperm of more than one male compete for the fertilization of a set of ova.
Sperm competition defense Traits that aid a male in preventing sperm competition from occurring and thus preserving his share of paternity, for example, mate guarding, copulatory plugs, prolonged or frequent, repeated copulations. Typically the first male to mate is in a defensive role.
Sperm competition offense Traits that aid a male in gaining paternity when mating with a previously mated female, for example, removing or displacing previous male's ejaculate.
Sperm storage Extended maintenance of sperm. This can be within the male prior to mating, and/or can be within the female after mating.

Polyandry is common and widespread across animal and plant taxa (Jennions and Petrie, 2000; Pizzari and Wedell, 2013; Taylor *et al.*, 2014). Therefore, the battle for reproductive success does not always end after intrasexual competition for mates (usually males) or intersexual selection of mates (usually by females) (Darwin, 1871; Andersson, 1994). Instead, sexual selection continues within the ovarian fluid plumes of external fertilizers and, in internal fertilizers, inside the reproductive tracts of promiscuous females, where the ejaculates of competing males vie for fertilization (Parker, 1970; Parker and Pizzari, 2010). There the ejaculates compete and female traits bias the contest for fertilization success (Thornhill, 1983;

Eberhard, 1996; Arnqvist, 2014). Many studies confirm the ubiquity and strength of both these forms of postcopulatory sexual selection (Smith, 1984; Birkhead and Møller, 1998; Birkhead and Pizzari, 2002; Andersson and Simmons, 2006; Pitnick and Hosken, 2009; Kvarnemo and Simmons, 2013; Arnqvist, 2014).

Although there are many ways that females benefit from polyandry (Arnqvist and Nilsson, 2000; Arnqvist and Kirkpatrick, 2005; Simmons, 2005; Snook, 2014), here we will focus on the fact that polyandry provides females with the opportunity to bias paternity toward male phenotypes that are superior and/or genetically compatible and away from incompatible or inferior male phenotypes and thus increase the fitness of her offspring (e.g., Tregenza and Wedell, 2000; Tregenza and Wedell, 2002; Pilastro *et al.*, 2004; Bretman *et al.*, 2009; reviewed in: Slatyer *et al*,. 2012). Given the limited space, our review of CFC cannot be exhaustive but instead we present a historical overview of research in this field, which we hope has heuristic value and then suggest where we think the field is headed.

Sexual selection can be conveniently divided into selection generated through intrasexual competition and intersexual mate choice (Andersson, 1994). Intrasexual competition occurs when males must compete directly with one another for access to females or control of resources females require (Emlen and Oring, 1977; Shuster and Wade, 2003). Traits that aid males in directly monopolizing these resources or the females will be under selection. Examples of these traits are sexual dimorphism in body size and defensive ornaments (e.g., antlers) (Andersson, 1994; Emlen, 2008). Intersexual mate choice occurs when a female exhibits a preference for a male with particular phenotypes. Classic examples of these traits are colorful plumage, displays, and elaborate tail feathers of male birds. Those traits that females find more attractive will be under selection and become exaggerated through evolutionary time through a Fisherian process or because these traits honestly signal male quality and are augmented by selection (Lande, 1981; Arnold and Wade, 1984; Andersson, 1994; Jones and Ratterman, 2009; Prum, 2010). In each of the examples listed above, selection occurs before copulation thus is termed precopulatory sexual selection. However, sexual selection does not end at copulation.

When females are promiscuous, that is, mating with multiple males during a single breeding season, the sperm from two or more males may overlap within the female's reproductive tract (or plume of ovarian fluid). The sperm from multiple males may then compete to reach ova and/or preferred fertilization sites closest to the ova. Parker (1970) coined the term 'sperm competition' to describe this situation. To the extent that females are promiscuous, sperm competition is predicted to generate selection for more, faster and/or longer-lived sperm (Parker and Pizzari, 2010). By analogy it follows that, if sperm competition is the postcopulatory equivalent to precopulatory male–male competition, then there is likely a postcopulatory equivalent to female mate choice. In 1983, Thornhill suggested that "in principle, female animals may choose males before, *during or after mating*." Although others had hinted at this idea (e.g., Lloyd, 1979; Halliday, 1983), Thornhill was the first to make an explicit claim that female choice could occur during or even after copulation (Eberhard, 1996); he called it cryptic female choice (CFC). Because of the inherent difficulty of segregating male and female effects within the female's reproductive tract, much has been written on methods and experimental designs that could definitively distinguish between sperm competition and CFC.

In 2000, four papers were published concurrently in *Evolution*, each of which aimed to more clearly define CFC, establish criteria and develop experimental methods for demonstrating CFC to the exclusion of sperm competition (Birkhead, 2000; Eberhard, 2000; Kempenaers *et al.*, 2000; Pitnick and Brown, 2000). As Eberhard (1996) suggested, and others have acknowledged since, to separately focus on male traits for sperm competition that have evolved to excel within the female reproductive tract from those very female traits that evolved to bias paternity toward 'superior' sperm competitors in some way misses the point of CFC (Eberhard, 1998; Pitnick and Hosken, 2009; Pitnick et al., 2009; Arnqvist, 2014). No doubt, the focus on delineating male and female processes was fueled by disbelief of the existence of cryptic female sperm choice and was analogous to the skepticism about female precopulatory mate choice in previous decades (Milam, 2010). However, we now recognize the inescapable fact that female traits influence male fertilization perhaps especially in internally fertilizing species (Olsson *et al.*, 1996; Birkhead *et al.*, 2009; Pitnick *et al.*, 2009; Arnqvist, 2014).

Defining Cryptic Female Choice

In an encyclopedic book treatment, Eberhard (1996) described 20 potential mechanisms of CFC (**Table 1**) and defined CFC as "a female-controlled process or structure that selectively favors paternity by conspecific males with a particular trait when the female has copulated with both types." Eberhard's book has been of great utility to evolutionary biologists for its numerous examples of potential cases of CFC and because it brought much needed attention to postcopulatory female processes (Holland and Rice, 1997). However, several authors criticized Eberhard's emphasis on supposed "female control" (e.g., Holland and Rice, 1997). Female control implies that females have direct and purposeful influence over sperm use (Birkhead, 2000; Pitnick and Brown, 2000). To illustrate the potential confusion introduced by Eberhard's use of the term "female control," consider *Calopteryx* damselflies (Pitnick and Brown, 2000). A male *Calopteryx* damselfly stimulates the female with horns at the tip of his aedeagus (intromittent organ) during copulation and the female responds by dumping sperm from her previous sexual partner. The amount of sperm she dumps from her previous partner is significantly correlated with the size of the male's aedeagus (Córdoba-Aguilar, 1999). Male copulatory stimulation can be interpreted as an example of CFC or as male manipulation of the female (i.e., sexual conflict, Arnqvist and Rowe, 2005; Córdoba-Aguilar, 2006; see sexual conflict below). Under Eberhard's definition, the evolutionary history of the trait must be known in order to answer this question (i.e., why the trait evolved) before we can claim it is CFC (Pitnick and Brown, 2000). It is possible to infer a trait's evolutionary history using modern comparative methods, although reconstructing the evolutionary history of a trait before assigning its function is a nearly

Table 1 List of the potential mechanisms by which a female may bias the relative fitness of her mates

Transport sperm of different males to different storage sites and then preferentially use sperm from particular storage sites based on male phenotype
Preferential ejection of sperm for one mate or another during or after copulation
Control of intromission, male genitalia, or copulation duration to increase or decrease ejaculate transfer
Affect deposition of copulatory plugs or allow (or resist) mate guarding
Produce or contribute to copulatory plug material or affect quick dissolution of the copulatory plug to allow subsequent matings
Behavioral, physiological, or morphological modifications that prevent or increase the likelihood of subsequent matings or ejaculate transfer of subsequent matings
Recruit more primary oocytes and/or ovulate more ova
Differential provisioning of eggs fertilized by particular males
Increase or decrease the rate of oviposition relative to male phenotype
Control transport of sperm such that they are closer or farther from prime fertilization sites relative to male phenotype
Transport sperm of different males to different storage sites and then preferentially use sperm from particular storage sites (i.e., from particular males)
Upregulate immune responses that may damage or remove sperm from the fertilization set (e.g., phagocytosis, absorption into epithelia cells, etc.) Gold medal research question: how are these sperm identified?
Differential nourishment of sperm in transport or of those in storage
Differential abortion of zygotes or embryos
Prepare uterus(i) for implantation or not
Differentially invest in offspring sired by preferred males or the converse (at any point in their ontogeny)

impossible and unnecessary burden (Arnqvist, 2014). We should only need to demonstrate that a female trait is maintained by CFC (Arnqvist, 2014). For example, researchers are not required to answer the analogous question regarding the origin of female precopulatory choice, only whether variation in male mating success is associated with the male trait (Andersson, 1994). Eberhard's definition also misplaced the focus solely on the female's active response to different males, while it neglected potential passive mechanisms that may bias paternity (Birkhead, 2000; Pitnick and Brown, 2000). In response to Eberhard's (1996) problematic definition, Pitnick and Brown (2000) proposed a more general definition: "nonrandom paternity biases resulting from female morphology, physiology, or behavior that occur after coupling." This definition includes both active and passive proximate mechanisms, and avoids confusion over the need to establish female intent, which would be nearly impossible in any experimental setting (Birkhead, 2000). Furthermore, this definition places the emphasis on traits which are much more tangible than patterns or processes of paternity (Arnqvist, 2014).

A female may actively respond differently to one male versus another male, either behaviorally or physiologically. After copulating with a subdominant male, a female jungle fowl is likely to eject his sperm (Pizzari and Birkhead, 2000) and female sperm dumping has been found in several other taxa as well (e.g., Dunnocks (*Prunella modularis*), Davies, 1983; Kittiwakes (*Rissa tridactyla*) to avoid old sperm, Wagner *et al.*, 2004; fruit flies (*Drosophila melanogaster*), Snook and Hosken, 2004; Spiders (*Silhouettella loricatula*), Burger, 2007; *Physocyclus globosus*, Peretti and Eberhard, 2010); female scorpionflies (*Harpobittacus nigriceps*) and field crickets (*Gryllus bimaculatus*) may remate with a preferred male using mate order effects (i.e., systematic biases in paternity due to the order in which a pair of males mate) to control paternity (e.g., *in sensu* Thornhill, 1983; Simmons, 1987); and female water frogs (*Rana lessonae–R. esculenta* complex) reduce clutch size when they are amplexed by undesired hybrid males (Reyer *et al.*, 1999). Importantly the timing of sperm ejection is heritable, and thus can evolve, in female fruit flies (*Drosophila melanogaster*) and this timing affects sperm usage of first versus second males (Lüpold *et al.*, 2013). These are active behavioral responses that conform to Eberhard's definition of CFC. It is less clear whether a female's physiological responses to different males should be considered 'active.' For example, a differential increase in immune response to different male's sperm may be considered either an active or passive action (Ziegler *et al.*, 2005; Poiani, 2006; Birkhead and Brillard, 2007; Pitnick *et al.*, 2009), as could differential nourishment, transport, and storage or displacement of sperm (e.g., Villavaso, 1975). The female immune response is activated by insemination in a diverse range of taxa from humans (Robertson, 2007) to fruit flies (Kapelnikov *et al.*, 2008; Pitnick *et al.*, 2009). Some predicted that females may exhibit different immunological responses to different males' sperm (Olsson et al, 1997), and although it still remains controversial, mechanisms for major histocompatibility complex (MHC) expression on sperm and female recognition of MHC within the reproductive tract have been proposed and supported (Olsson *et al.*, 1996, 1997; Ziegler *et al.*, 2002; Ziegler *et al.*, 2005; Alcaide *et al.*, 2012; Løvlie *et al.*, 2013).

In addition to active mechanisms, a female may passively affect sperm within her reproductive tract via differences in the size and shape of her sperm storage organs or their lumen pH (Pitnick and Brown, 2000; Poiani, 2006, respectively). In *Drosophila*, male fertilization success is determined by a correlation between the length of his sperm with the length of the individual female's sperm storage organ (Miller and Pitnick, 2002). Both active and passive selective mechanisms within the female's reproductive tract are important drivers of male fertilization success, and the mechanisms need not invoke a female's purposeful intent as Eberhard's definition does.

The Problem of Paternity Patterns in Investigating CFC

One of the central problems in demonstrating CFC that was comprehensively discussed in *Evolution* (2000) is that paternity patterns do not always identify and differentiate among

competing mechanisms (e.g., a male that has mated without siring offspring may have been both unsuccessful in sperm competition and/or been selected against by the female using CFC mechanisms; Birkhead, 2000; Eberhard, 2000; Kempenaers *et al.*, 2000; Pitnick and Brown, 2000; Olsson and Uller, 2009). The problem with paternity patterns is what misled Ward (1993) to credit CFC for the patterns of precedence he observed (large-male precedence: Simmons *et al.*, 1996; Simmons *et al.*, 1999). Thus, the problem with pattern of paternity is not exclusive to CFC but also complicates the interpretation of results in studies of sperm competition (Simmons, 2001). In sperm competition studies, mate order patterns are often due to either displacement of, or a decline in the number of the first male's sperm, i.e., sperm competition is won by a fair raffle; the male with the most sperm inside the female wins. However, in some extreme cases mate order effects may not be due to sperm competition. For a classic example, a male damselfly (*Calopteryx maculate*) removes the sperm from a female's previous mate with hooks on the end of his aedeagus (Waage, 1979). The second male receives close to 100% of the paternity, not because he is superior in sperm competition, nor because of some peculiarity of the female's reproductive tract; the second male gains paternity by avoiding sperm competition altogether (Waage, 1979). This example illustrates the problem inherent in assigning mechanistic cause via patterns alone. Studies of CFC have a similar problem in that observed biases in paternity toward or away from certain males are difficult to attribute solely to the female (Birkhead, 2000; Pitnick and Brown, 2000). One way forward to resolve this is the statistical partitioning of variance in paternity patterns.

Variance in the proportion of offspring sired by the second male to mate – P_2 (Simmons, 2001), can be attributed to different components, including: mate order, interval between matings, copulation duration (sperm numbers or volume of important ejaculate components), and time to oviposition or ovulation (Smith, 1984; Birkhead and Møller, 1998; Simmons, 2001). After controlling for these factors, different males (i.e., genotypes) may have different levels of success in sperm competition (Lewis and Austad, 1990; Simmons and Parker, 1992; e.g., Clark *et al.*, 1995; Fiumera *et al.*, 2005). In addition, female genotypes vary in their effect on P_2 (Wilson *et al.*, 1997; e.g., Clark and Begun, 1998; Mack *et al.*, 2002; Fedina and Lewis, 2008; Lüpold *et al.*, 2013). Thus, variance in patterns of paternity can be attributed to male effects, female effects, and if those effects are not independent of one another, the male × female interactions (e.g., Wilson *et al*, 1997; Clark *et al.*, 1999; Mack *et al.*, 2002). For example, male A may outperform male B when mated with female C, but their relative performance may reverse if they are mated with female D (Clark *et al.*, 2000; Birkhead *et al.*, 2004; Bjork *et al.*, 2007). Because paternity is dependent on the complex interactions of the individuals involved, these are said to be non-transitive outcomes. In short, if sperm choice is occurring at all, we may not expect all females within a population to prefer the same male's sperm; although this may be the case in some populations or species (Arnqvist, 2014; Kempenaers *et al.*, 2000; Pitnick and Brown, 2000). In fact, variation in precedence within a male pair that has inseminated a series of females would be evidence that female mechanisms are affecting the outcome. This is because the male pairing should produce similar patterns of paternity across all females if those patterns are due to sperm competition alone (Birkhead, 2000; Pitnick and Brown, 2000). Pitnick and Brown (2000) suggested that an experiment could be designed such that male and female variance components could be isolated, and that a significant male × female interaction term would be indicative of CFC. However, this experiment would not reveal CFC if all females biased paternity toward the same males (Pitnick and Brown, 2000; Arnqvist, 2014).

Pitnick and Brown's (2000) experimental design was based on the work of Clark *et al.* (1999). In *Drosophila*, there is significant variation in male fertilization success among experimental, inbred lines (Clark *et al.*, 1995). When pairs of males from these lines were crossed with females from these same lines ($6 \times 6 = 36$ crosses), there was a significant male × female interaction in paternity outcomes (Clark *et al.*, 1999). This result cannot be explained by genetic incompatibility between the lines (e.g., Zeh and Zeh, 1997), because in a separate experiment they found no significant differences in egg viability among the 36 crosses (Clark *et al.*, 1999). Therefore, the male × female interaction is strong evidence for female-mediated effects in this case. However, a weakness with this design is that copulation occurred naturally and the male × female interaction could be due to interactions during copulation; sperm choice was not unequivocally demonstrated. Domestic fowl (*Gallus gallus domesticus*) have also been shown to exhibit non-transitivity of paternity. Birkhead *et al.* (2004) used sperm from nine pairs of males to artificially inseminate (AI) 14 hens per male pair up to seven times at monthly intervals. Thus they had seven replicates within each individual female and across 14 females per male pair. With this design they were able to partition the variance as Pitnick and Brown (2000) described, and demonstrated a significant male × female interaction. One strength of this study was that they used AI. Using AI they eliminated all male effects due to interactions during copulation as well as controlled for sperm numbers. However, we note that there are pitfalls to AI, because stimulation during copulation or during postcopulatory courtship may be an important cue for females using CFC (Eberhard, 2009, 2010, 2011), as Løvlie *et al.* (2013) subsequently found in red jungle fowl (*Gallus gallus*). Unlike Clark *et al.* (1999), Birkhead *et al.* (2004) could not fully dismiss the potential effect of differential viability (genetic incompatibility) because of the limits of their study organism. However, they were dubious that there were, in fact, viability differences given their knowledge of domestic fowl reproduction (Birkhead *et al.*, 2004). In well-studied model organisms, such as *Drosophila*, when strong male × female interactions are characterized with crosses of established genetic lines, the reproductive genes of males and females can be screened for associations within the interacting lines (e.g., Reinhart *et al.*, 2015). Male × female interactions may also be prevalent in external fertilizing species. Sperm velocity is a primary determinant of fertilization success in externally fertilizing salmonid fish (*Oncorhynchus tshawytscha*, Evans *et al.*, 2013; *Salmo salar*, Gage *et al.*, 2004). A female releases her eggs along with ovarian fluid as male(s) deposit sperm in the plume of ovarian fluid. Studies conducted using pooled ovarian fluids from several females have shown that ovarian fluid increases motility and longevity of salmonid

sperm (e.g., Lahnsteiner, 2002; Turner and Montgomerie, 2002; Rosengrave *et al.*, 2009; Butts *et al.*, 2012; Evans *et al.*, 2013). In competitive *in vitro* fertilization trials between trout and salmon sperm; ovarian fluid mediated fertilization success of conspecific sperm over heterospecific sperm (Yeates *et al.*, 2013). In conspecific trials there was a significant male × female interaction on sperm velocity of different males in the ovarian fluid from single females (Chinnok salmon (*Oncorhynchus tshawytscha*), Rosengrave *et al.*, 2008; Arctic char (*Salvelinus alpinus*), Urbach *et al.*, 2005). Similar results were found in guppies (*Poecilia reticulata*), with internal fertilization, probably explaining similar biases in paternity (Gasparini and Pilastro, 2011), which are likely to be influenced by components of ovarian fluid (Gasparini *et al.*, 2012).

These examples clearly demonstrate that females have an effect on the fertilization success of particular males. In the first two examples, only paternity patterns were established. Clark *et al.* (1999) were able to rule out genetic incompatibility as a cause for the male × female interaction, while Birkhead *et al.* (2004) controlled for all male effects except those interactions between a male's sperm and a female's reproductive tract and ova. Apart from the practical advantages of working with an external fertilizer for sperm competition/CFC experiments, a strength of the last example using fish is that it provides us with a probable mechanism, ovarian fluid, whereby females can enhance the velocity of particular male's sperm, a trait that has been shown to increase fertilization success. There is no doubt that some species have inherent limitations for the study of CFC, but in general, the strengths of each of these experiments should be emulated. A conclusive demonstration of CFC by sperm choice would need to account for genetic incompatibilities, control for all male effects except for the effects of sperm × female reproductive tract interactions, and establish the mechanism that correlates with patterns of paternity (Birkhead, 2000; Arnqvist, 2014).

Differential Sperm Storage as Mechanism

The most important mechanism for CFC by sperm choice is likely to be differential sperm storage (Birkhead, 2000). In species with sperm storage where females mate with several partners, females may influence the fate of individual spermatozoa. Nearly nothing is known, for any taxon, about the mechanisms by which a female might bias paternity after copulation, for example, sperm choice (Pizzari and Birkhead, 2000; Andersson and Simmons, 2006; Bussiére *et al.*, 2006).

However, several recent studies have shown that different male's sperm are stored in different amounts in the female reproductive tract. Paul Ward's lab group utilized CM-PCR (competitive polymerase chain reactions) to quantify the amount of sperm of different males in the female reproductive tract in yellow dung flies (*Scathophaga stercoraria*) and field crickets (*Teleogryllus commodus*) (Bussiére *et al.*, 2010; Hall *et al.*, 2010). Bussiére *et al.* (2010) confirmed previous work by Simmons *et al.* (1999), which suggested that sperm displacement explains second male precedence in yellow dung flies (Bussiére *et al.*, 2010). Bretman *et al.* (2009) showed that when female field crickets (*Gryllus bimaculatus*) mated with their brothers and an unrelated male, they stored fewer sperm from their brother, and that this difference was reflected in paternity. This result indicates that the costs associated with genetic incompatibility can be avoided by CFC mechanisms that result in differential storage of sperm from a preferred male. Populations of sand lizards (*Lacerta agilis*) with low genetic diversity may facilitate the evolution of detection mechanisms that identify the sperm for elimination (Olsson and Madsen, 2001), which is CFC by differential sperm storage or 'sperm choice' (Olsson *et al.*, 1996). As suggested above, differential sperm storage may result from differential immune responses and selective targeting of sperm from related or outbred individuals for phagocytosis, based on sperm surface proteins and/or components of the ejaculate (Pitnick *et al.*, 2009). This area needs much more attention, if we are to fully work out the mechanisms and thus the traits under selection by CFC.

Female morphology can also potentially exert a strong influence on male fertilization success. Male traits, such as sperm and genital morphology, covary with female sperm storage organs that drive their evolution (Miller and Pitnick, 2002; Simmons and Kotiaho, 2007; Simmons and Garcia-Gonzalez, 2011; e.g., Higginson *et al.*, 2012), this provides strong support for sexual selection of sperm traits by reproductive tract traits (i.e., male postcopulatory phenotypes selected by female postcopulatory phenotypes – or CFC). Expanding on the groundbreaking work of Clark *et al.* (1998, 1999, 2000), the perhaps most sophisticated study of female-mediated differential sperm storage are those that actually visualize different fluorescently labeled sperm within the female reproductive tract in real time to model the factors that determine paternity in a competitive context (Manier *et al.*, 2010; Lüpold *et al.*, 2013; Manier *et al.*, 2013; Marie-Orleach *et al.*, 2014). For example, the experiments from Scott Pitnick's lab using transgenic lines of *Drosophila* show that heritable variation in the timing of female sperm ejection influences the relative proportions of first and second males' sperm, which in turn influences which male sires a female's offspring (Lüpold *et al.*, 2013). The female tract morphology and anatomy controlling sperm ejection is a potential CFC trait, as is the size differences of the sperm and spermatheca (Miller and Pitnick, 2003). Male morphological traits involved in copulatory and postcopulatory courtship are known to influence female sperm usage and thus may have evolved via CFC (Eberhard, 1996, 2009, 2010b, 2011). Female genitalia can also function to influence paternity. Although couched in terms of sexual conflict – where the evolutionary interests of the sexes do not coincide (Parker, 1979; Arnqvist and Rowe, 2005) – the convoluted reproductive tract in some species of waterfowl (family Anatidae), with blind tubes into which the phallus, and therefore, the sperm of coercive males are directed. Thus the complex female anatomy is a morphological mechanism by which females can bias paternity (Brennan *et al.*, 2010). The female reproductive tract and phalluses also show signature of male–female coevolution indicative of both sexual conflict and sexual selection via CFC (Brennan *et al.*, 2007; Brennan and Prum, 2014). A more subtle example of potential CFC and sexual conflict occurs in garter snakes (*Thamnophis sirtalis*) where copulation duration affects paternity and the female's muscularized vaginal pouch and body-rolling behavior shortens the duration of copulation and reduces the size of the male's copulatory plug (Friesen *et al.*, 2014a,b,c). Female

resistance may be evidence of CFC in response to male harassment (Shine *et al.*, 2005; King *et al.*, 2009; Friesen *et al.*, 2014c). Indeed, distinguishing between the effect of postcopulatory sexual selection and sexual conflict on the evolution of reproductive traits has recently become a central focus of evolutionary and behavioral ecology (Arnqvist, 2014; Brennan and Prum, 2014; Simmons, 2014).

Sexual Conflict and CFC

The example of female–male genital interactions highlight the difficulty of delineating between postcopulatory processes and sexual conflict (reviewed in Arnqvist, 2014; Brennan and Prum, 2014; Simmons, 2014). Increasingly, researchers recognize that sexual conflict is a nearly inescapable consequence of anisogamy and the resulting 'sexual cascade' (Parker, 2014) culminating in the advent of sexual selection (see the following reviews for in-depth treatment of the relationship between sexual selection and sexual conflict: Parker, 1979; Arnqvist, 2014; Brennan and Prum, 2014; Kokko and Jennions, 2014; Perry and Rowe, 2014). Polyandry not only leads to the evolution of male adaptations that aid males in both sperm competition offense (e.g., better performing, more sperm and seminal fluids (Parker and Pizzari, 2010; Fitzpatrick and Lüpold, 2014)) it also leads to evolution of defense mechanisms (e.g., mate-guarding, antiaphrodisiacs, and copulatory plugs (Knowlton and Greenwell, 1984; Stockley, 1997; Parker and Pizzari, 2010)). These defense mechanisms can inflict direct harm on females, preventing them from mating at their optimal rate and/or preclude female choice (Knowlton and Greenwell, 1984; Arnqvist and Rowe, 2005). Likewise, although generally overlooked (Arnqvist, 2014), CFC traits such as sperm ejection, spermicides, and bet hedging via extreme promiscuity may reduce male fitness. Under these circumstances there is the opportunity for sexually antagonistic coevolution where each sex evolves adaptations and counter-adaptations to control the outcome of copulation in a lag load dynamic as each sex alternately gains the upper hand at the expense of the other sex through evolutionary time (Rice *et al.*, 2006; Kokko and Jennions, 2014).

Conclusion

CFC has a history of controversy. Like any nascent field of scientific study, controversy yields discussion, clearer definitions, and explicit recommendations for research programs. Taking a reductionist approach of dissecting functional interactions between male and female traits via experimental manipulation or utilizing natural phenotypic variation associated with paternity bias should identify traits involved in CFC (e.g., Eberhard, 2010; Eberhard, 2011). With recent technological advances such as CM-PCR or fluorescently labeled sperm, patterns of sperm storage can be deduced or directly visualized (e.g., Manier *et al.*, 2010; Marie-Orleach *et al.*, 2014). By correlating patterns with processes (e.g., sperm storage and survival), investigators disentangle which male traits may have evolved because of the 'environmental conditions' imposed by the multivariate traits of the female reproductive tract (e.g., Lüpold *et al.*, 2013). Controlled crosses after a number of generations of experimental evolution at different densities can be used to identify traits and genes that respond to selection on male phenotypes relative to female phenotypes, and determining whether increased female fitness associated with these traits can reveal CFC or sexual conflict (e.g., Simmons and Garcia-Gonzalez, 2011). In addition, when reproductive genes associated with strong male × female interaction effects on paternity are identified (e.g., Reinhart *et al.*, 2015), the functional significance of these candidate genes can be assessed in knockout lines or RNA interference experiments to knock down gene expression (e.g., Bretman *et al.*, 2010; Findlay *et al.*, 2014). However, the tractability of these methods in non-model species in natural populations is a serious limitation. Greater focus on the naturally standing heritable variation in fitness associated with both male and female traits suspected to be involved in CFC 'in the wild' is crucial to understanding which modes of selection (natural selection, sperm competition, sexual conflict, and CFC) predominate their evolution (Arnqvist, 2014; Snook, 2014). These studies could be augmented by experiments concentrated on the functional significance and fitness consequences of female traits that interact with particular male phenotypes, but understanding their consequences in the 'real world' should be a focus if we want to understand the costs and benefits of adaptive traits.

Polyploid Speciation

CJ Rothfels, University of British Columbia, Vancouver, BC, Canada; and University of California, Berkeley, CA, USA
SP Otto, University of British Columbia, Vancouver, BC, Canada

Glossary

Allopolyploid A polyploid formed by the combination of genomes from two different species.
Autopolyploid A polyploid formed by the combination of genomes from within a single species (from the same or different parental individuals).
Diploid Having two sets of each chromosome. For example, humans are diploid (the majority of our cells have two sets of chromosome, one from each of our parents).
Diversification rate The net rate at which a group of species grows in number. The diversification rate equals the speciation rate minus the extinction rate.
Haploid Having one set of each chromosome (as found in the eggs and sperm of mammals). For example, the leafy green parts of most mosses are haploid.
Homolog/homeolog Chromosome pairs inherited from one's mother and father are known as 'homologs' (e.g., the two X chromosomes in a daughter are homologs). Chromosomes that are similar to each other because they both descend from a polyploidization event are known as 'homeologs.'
Minority cytotype exclusion The idea that when there is a mixture of ploidy levels within a population, the rarer type would tend to disappear because it more often mates with another ploidy level, producing offspring of intermediate ploidy and lower fitness (i.e., it suffers from a triploid block).
Neopolyploidy A polyploidization event that occurred in the recent past.
Paleoploidy A polyploidization event that occurred in the distant past. It is typically reserved for events that happened long enough ago that they have to be inferred from data other than chromosome counts alone.
Ploidy The number of complete chromosome sets a cell contains. For example, a human egg cell contains one set whereas the cells of an adult human have two sets.
Polyploid Having more than two sets of each chromosome in the majority of cells of an organism (3 sets = triploid, 4 sets = tetraploid, 5 sets = pentaploid, 6 sets = hexaploid, etc.).
Polyploidization The process by which an organism (or cell) has more genome copies than did its progenitors.
Triploid block The idea that triploids prevent the establishment of polyploids because of their low viability and fertility. In particular, if newly formed tetraploids are rare they might predominantly mate with diploid relatives and produce only low-fitness (or sterile) triploids.
Triploid bridge The idea that triploids may provide an important stepping stone to the establishment of tetraploids because they can produce some haploid, diploid, or triploid gametes that can combine with the gametes from other individuals in a population to generate additional polyploid individuals. The triploid bridge also increases gene flow between ploidy levels and introduces genetic variation to the polyploids.
Unreduced gametes The production of gametes that have not undergone the normal process of reductive division, such that the gamete has the same number of chromosomes as the parent instead of half the number.

Introduction

> Particularly remarkable is it that tetraploids while crossing with each other, yield a sufficient quantity of seeds, but in crosses with [the progenitor diploids] almost no formation of seeds occurs, i.e. the tetraploid hybrids prove already singled out from the parental species.
>
> (Karpechenko, 1928, p. 62)

The structure and size of genomes are fluid, changing over evolutionary time via a variety of mechanisms including gene duplications, translocations, inversions, and, most strikingly, polyploidization. The 'ploidy' level of an organism refers to the number of copies of each chromosome it contains: haploid for one (think of a human egg or sperm cell), diploid for two (e.g., a human adult), and polyploid for any larger number (triploid: three, tetraploid: four, pentaploid: five, etc.). Differences in ploidy are frequently observed among species, particularly in plants, with some of the most famous polyploids illustrated in Figure 1. Furthermore, individuals of different ploidy levels are often reproductively isolated from one another, leading biologists to consider 'polyploid speciation' to be one of the most direct routes to the formation of new species.

Karpechenko (1928) was one of the first to describe the experimental formation of a new polyploid species, obtained by crossing cabbage (*Brassica oleracea*) and radish (*Raphanus sativus*). Both parent species are diploids with $n = 9$ ('n' refers to the gametic number of chromosomes – the number after meiosis and before fertilization). The vast majority of the hybrid seeds failed to produce fertile plants, but a few were fertile and produced remarkably vigorous offspring. Counting their chromosomes, Karpechenko discovered that they had double the number of chromosomes ($n = 18$) and featured a mix of traits of both parents. Furthermore, these new hybrid polyploid plants were able to mate with one another but were infertile when crossed to either parent. Karpechenko had created a new species!

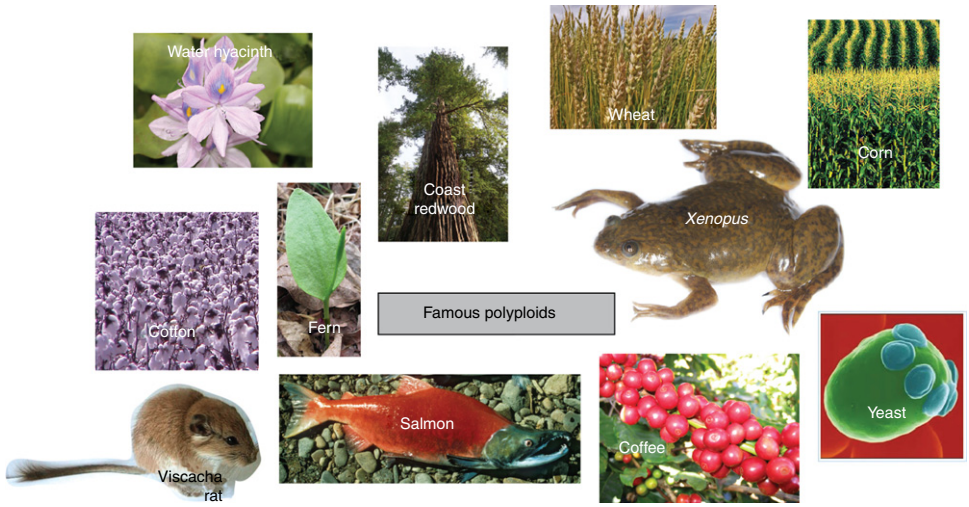

Figure 1 Illustrated are some of the most famous polyploid species, from the beautiful but highly invasive water hyacinth to the red viscacha rat, one of two known polyploid mammals. Also shown is the fern *Ophioglossum reticulatum*, the record holder for most chromosomes ($n = 720$) with about 100 copies per homologue.

This newly formed species, now called 'radicole' and used as a crop for animal fodder, represents an 'allopolyploid,' as coined by Kihara and Ono (1926) – it is a polyploid formed by the union of genomes from different species. Not all polyploids form in this way. An alternative possibility, 'autopolyploidy,' refers to the increase in ploidy level within a species. These categories are not absolutes, however, because polyploids formed from crosses between subspecies or distant populations may have characteristics intermediate between the two.

Polyploids are common in nature, especially in plants, and many of our most economically important plants – including both crop species and destructive weeds – are polyploids (**Figure 1**). For example, recent estimates suggest that 35% of vascular plants are recent polyploids ('neopolyploids'), having doubled in genome size since their genus arose (Wood *et al.*, 2009). Moreover, if one goes back far enough, all seed plants (Jiao *et al.*, 2011) and tetrapods (i.e., four-limbed vertebrates; Postlethwait *et al.*, 1998) have descended from polyploid ancestors.

Polyploidy is thought to play a major role in speciation for two reasons. The first is that chromosome doubling causes polyploids to be incompatible with their diploid parents, with crosses between them leading to low-fitness offspring (e.g., triploids). Consequently, polyploidy could be a rapid route to reproductive isolation, reducing gene flow between newly formed polyploids and their parental populations, and hence taking a key step toward speciation. The second reason is that polyploids often differ phenotypically from their diploid parents. These differences can be the immediate consequence of a doubled genome size (see next section) or be a consequence of the polyploids combining adaptations from different parents, allowing the polyploid to outperform both parents, at least in some environments. Polyploid hybrids are particularly interesting because they can maintain both parental genomes for long periods of time (illustrated as red and blue chromosomes in **Figure 2(d)**), perpetuating the advantages displayed by some hybrids ('hybrid vigor'). Furthermore, polyploids often avoid the sterility problems that can plague diploid hybrids by balancing the contributions of each genome and providing each chromosome with a closely related partner (a homolog) for pairing.

Given the prevalence and apparent success of numerous polyploid species and the ease with which changes in ploidy can contribute to reproductive isolation, it is natural to assume that polyploidy has played an important role in speciation. In this article, we discuss the current evidence for polyploid speciation and its consequences. We address two distinct but related questions. What role do ploidy *changes* play in speciation (i.e., in the instantaneous formation of new species)? And what influence does polyploidy have on subsequent speciation events (i.e., do polyploid species, *once formed*, have a greater or lesser tendency to speciate themselves)?

Polyploid Speciation I: The Formation of New Species by Polyploidization

Mechanisms of Polyploidization

Before discussing the impact of polyploidy on speciation, we briefly review the mechanisms by which polyploids form. An increase in ploidy level ('polyploidization') occurs via three primary mechanisms: somatic doubling, polyspermy, and unreduced gamete formation.

Somatic doubling occurs when DNA replication is not followed by a cell division. If this doubling occurs early in development, the entire (otherwise diploid) animal or plant can become tetraploid. If later in development, only part of the organism will be tetraploid. Although such tetraploid cells are often associated with cancer, they also arise normally during development in several tissues, including the heart, bone marrow, and liver in humans and other mammals (Zimmet and Ravid, 2000; Ganem *et al.*, 2007). However, for the doubled genome to be inherited – for there to be a chance of a new species forming – the doubling must occur in the germline. There is evidence that some polyploids do form in this way, including one of the first described allopolyploids,

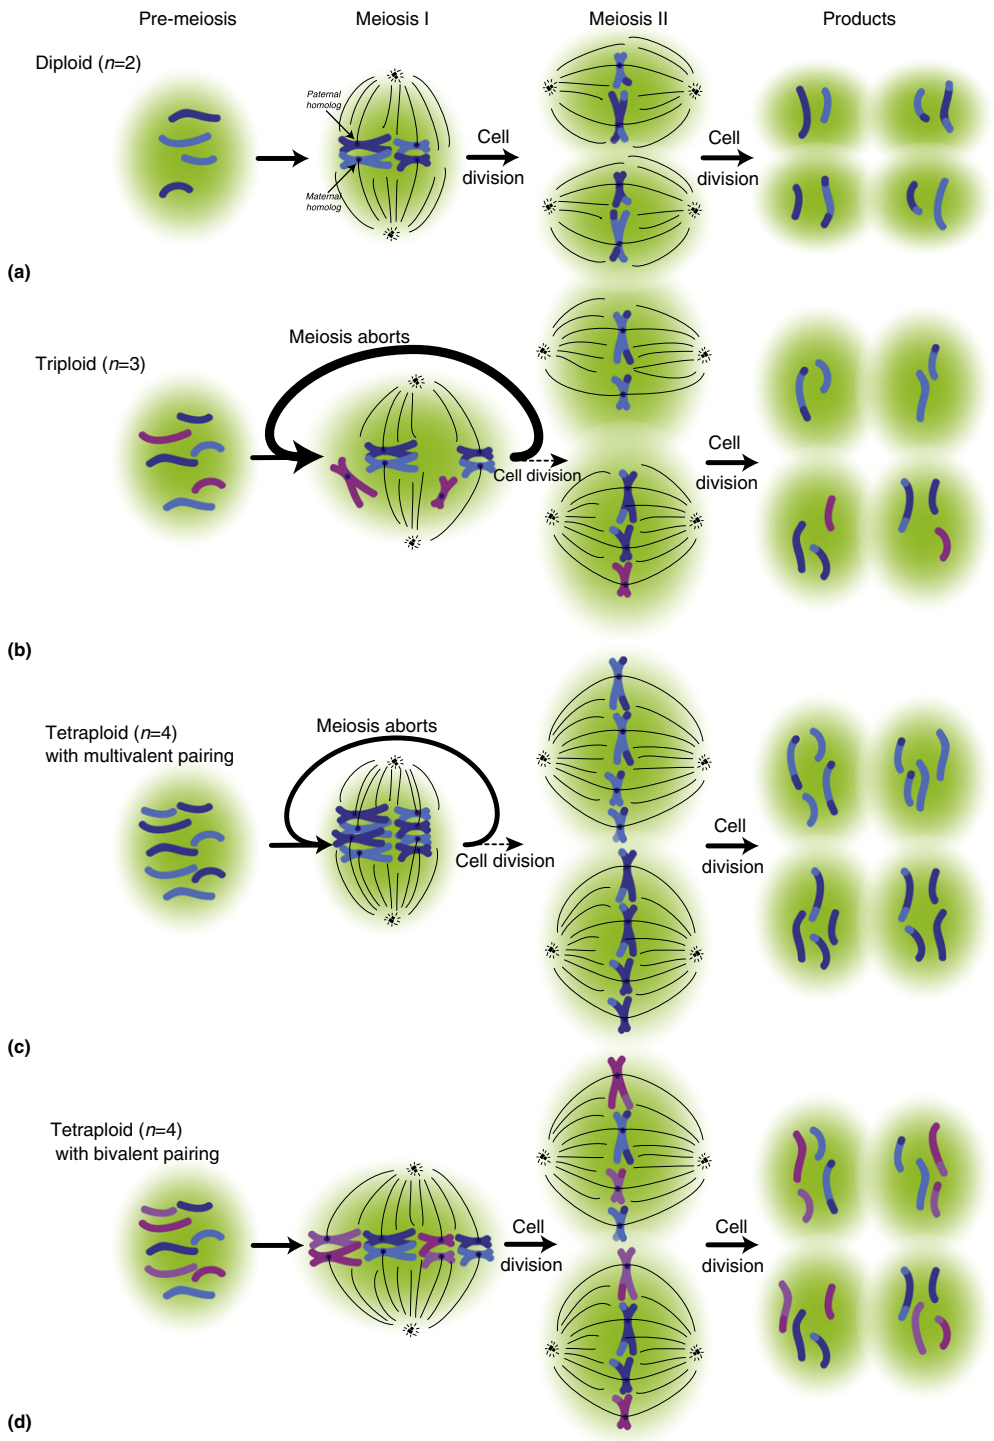

Figure 2 The segregation of chromosomes in diploids (a), triploids (b), and tetraploids (c, d). In triploids, unpaired chromosomes typically float in the cytoplasm during meiosis rather than being drawn to the metaphase plate, resulting in the abortion of meiosis or the production of highly unbalanced gametes, although occasionally balanced gametes are produced. Tetraploid segregation patterns are shown both for the case where all four sets of chromosomes come together at metaphase ('multivalent formation' (c)) and where only two sets come together ('bivalent formation' (d)). While meiosis is more likely to proceed normally via bivalent formation in allopolyploids, autopolyploids also frequently exhibit bivalent meiosis (Ramsey and Schemske, 2002).

Primula kewensis (Newton and Pellew, 1929). Somatic doubling is, however, thought to be a relatively uncommon route to polyploidy (Ramsey and Schemske, 1998).

Another route to polyploidization is *polyspermy*, the fertilization of an egg by more than one sperm. This mechanism is also thought to be rare in plants (Ramsey and Schemske, 1998),

but it may be more common in animals. For example, in humans, polyspermy is a frequent cause of polyploid conceptions (60%); these polyploid conceptions generally do not come to term and account for a relatively large fraction (10%) of spontaneous abortions (Zaragoza *et al.*, 2000).

Finally, the production of *unreduced gametes* through a failure in meiosis is the predominant route to polyploidy in plants (Ramsey and Schemske, 1998; De Storme and Mason, 2014) and the second most common route to polyploidy in humans (Zaragoza *et al.*, 2000). Unreduced gametes can arise by a failure to divide during meiosis I or meiosis II (referred to as 'first division restitution' and 'second division restitution,' respectively; Hermsen, 1984); these two forms can be distinguished based on the pattern of segregation of markers near and far from the centromere (**Figure 3**). Unreduced gametes can also arise when there is an endomitosis – an extra doubling of a cell's genome – prior to meiosis I ('Döpp–Manton sporogenesis'; Döpp, 1932; Manton, 1950).

Through any of these mechanisms, a triploid offspring would be expected in the next generation (assuming that unreduced gametes are rare and most likely to combine with reduced gametes). There are, however, circumstances under which the production of unreduced gametes is sufficiently common that two unreduced gametes might fuse, leading directly to tetraploidy. One such circumstance is cold shock (Fankhauser, 1945; Bogart *et al.*, 1989; Ramsey and Schemske, 1998), which might account for the association between polyploidy and high altitude and high latitude populations. Interestingly, unreduced gametes are also more common among hybrids (Harlan and deWet, 1975; Kobel, 1996; Ramsey and Schemske, 1998), occurring at 50-fold higher rates in hybrid plants than in non-hybrids

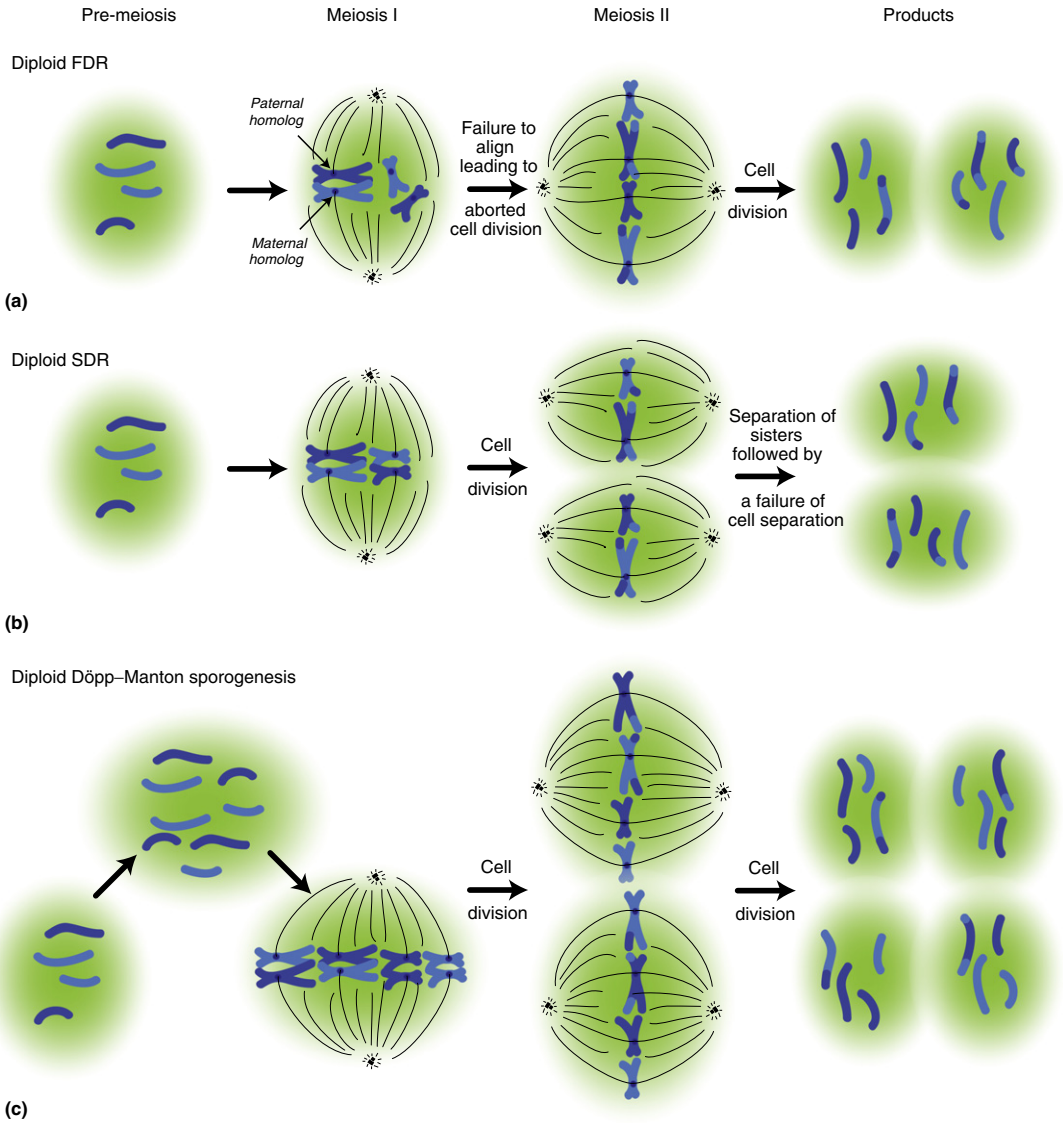

Figure 3 Abnormal segregation patterns leading to unreduced gametes. The three panels illustrate the three main routes to unreduced gametes (Köhler *et al.*, 2010): failure to divide the cell during meiosis I ('first division restitution' (a)), failure to divide the cell during meiosis II ('second division restitution' (b)), or an extra doubling of the genome prior to meiosis ('Döpp-Manton sporogenesis' (c)).

(Ramsey and Schemske, 1998). Unreduced gamete formation among hybrids is thought to be particularly important for allopolyploid formation, whereby, as in the radicole example, a mostly sterile diploid hybrid is able to produce some unreduced gametes, which when crossed with each other, restore fertility.

The Nature of New Polyploids

The pathway by which polyploidization occurs can have a major impact on the genetic variation observed among the newly formed polyploids. For example, tetraploids formed from two unreduced gametes from the same parent (selfing) bear a maximum of two alleles across their four gene copies, whereas four alleles can be captured if the unreduced gametes come from different parents. In addition, more genetic variation is captured when several polyploids are formed independently within a population ('multiple origins'). Although observing multiple polyploidization events may seem highly unlikely, circumstances that make it more likely for one polyploid to form (e.g., cold shock, hybridization, or genotypes predisposed to produce unreduced gametes) also make it more likely for multiple polyploids to form, as has been observed in several recent studies (Soltis and Soltis, 1999; Kaur *et al.*, 2014; Sigel *et al.*, 2014). Genetic diversity can be further augmented by matings between polyploids and diploid relatives. While such crosses often lead to partially sterile triploids, the few unreduced gametes produced by these triploids may contribute substantially to the number of tetraploids as well as their genetic diversity (the 'triploid bridge' mechanism, Ramsey and Schemske, 1998). For all of these reasons, young polyploid populations may not be as genetically depauperate as one might initially expect.

Phenotypically, newly formed polyploids often differ from their diploid progenitors. The most reliable phenotypic difference is increased cell size (Cavalier-Smith, 1978). Larger cell size can lead to larger body size in multicellular organisms, an association common in invertebrates, sometimes observed in plants, but rarely found in vertebrates (Otto and Whitton, 2000). In addition, polyploidization can affect development time, with polyploids often taking longer to develop (Ramsey and Schemske, 1998; Otto and Whitton, 2000). In plants, newly formed polyploids often differ from their diploid progenitors in morphology (e.g., thicker leaves), reproductive characters (e.g., larger flowers and later flowering times), and physiology (e.g., altered water transpiration and photosynthesis; Ramsey and Schemske, 1998). Ecologically, diploids and polyploids often differ in resistance to pests, sensitivity to nutrient stress, susceptibility to drought, and tolerance of extreme abiotic conditions (heat, cold, etc.; Levin, 1983). Many of these differences are idiosyncratic (e.g., with some tetraploids being more cold tolerant and some less so), making it impossible to predict the exact phenotypic shift likely to emerge in a new polyploid.

What is important is that polyploids are, immediately upon their formation, phenotypically different in ways that may make them better suited to some environments and less suited to others, shifting the ecological niche or the 'adaptive gestalt' of a population (Levin, 1983).

Moreover, some phenotypic shifts may additionally contribute immediately to reproductive isolation between polyploids and their diploid progenitors. For example, changes in flowering time associated with polyploidy can immediately isolate (at least partially) the new polyploids from their diploid progenitors (Husband and Schemske, 2000). Similarly, frogs in the genus *Hyla* both sing at lower frequencies (the males) and prefer lower frequency songs (the females) following increases in ploidy level, likely caused by increased cell sizes (Tucker and Gerhardt, 2012). By contributing both to ecological divergence and to reduced gene flow, polyploidization in such cases may represent a particularly easy route to speciation (a so-called magic trait; Coyne and Orr, 2004).

The Rate at Which New Polyploids Establish

Shifts between ploidy levels are inferred by two main signatures. The first is genomic: evidence that whole tracts of genes have been duplicated at the same point in time. This signature can last for hundreds of millions of years and is typically the information used to infer ancient polyploidization events (e.g., Bowers *et al.*, 2003; Jiao *et al.*, 2011). The second signature is a wholesale shift in the number of chromosomes within a lineage. For example, if most species in a genus have seven chromosomes after meiosis, but one recently derived species has 14, the latter is likely polyploid. In addition, because genome doubling always yields an even number of chromosomes, excesses of even over odd gametic chromosome numbers can be used to infer rates of polyploidization. This pattern is common in plants (63.2% of ferns have even numbers, 59.4% of monocots, and 54.9% of dicots, Otto and Whitton, 2000), which, assuming a conservative estimate of how often chromosome numbers change, yields an estimate of the rate of polyploidization relative to the rate of speciation of 2–4% in angiosperms and 7% in ferns (Otto and Whitton, 2000). A more refined approach maps chromosome number shifts along the phylogeny of a group of species. Using this approach, Wood *et al.* (2009) estimated that the rate of polyploidization was, on average, 15% that of the rate of speciation across a set of 123 angiosperm genera and 31% across 20 fern genera.

The above estimates do not account for differences in the rate of speciation and extinction between diploids and polyploids. Studies that have done so far have yielded much higher estimated rates of ploidy change. In one recent study, Scarpino *et al.* (2014) fitted a model to data from 60 genera of angiosperms. Their model estimated how much speciation and polyploidization is needed for each genus to have evolved from one species to the known number of species of each ploidy level that exist today, allowing diploids and polyploids to speciate at different rates (but ignoring extinction). This study inferred that, on average, diploids undergo polyploidization at a rate that is 39.9% the rate of speciation. Performing a phylogenetic analysis that allowed for differences in speciation and extinction; Mayrose *et al.* (2011) also obtained high estimates for the rate of polyploidization. Angiosperms polyploidized at a rate that was 29.6% that of the speciation rate, a number that rose to 41.0% for non-seed

plants, averaged across 50 angiosperm and 13 non-seed plant phylogenies, mostly at the genus level (Mayrose *et al.*, 2011). These numbers were inferred using a model that assumed polyploidization occurs over time, during the evolution of a lineage. An alternative model that allowed polyploidization to occur only at speciation events yielded similar estimates (29.7% for angiosperms, and 38.7% for non-seed plants). Thus, our best inferences at the moment suggest that plant species become polyploid at roughly one-third the overall speciation rate.

Importantly, these analyses only provide estimates of the relative rates at which polyploidization and speciation occur; they do not address how often they occur together. As a consequence, the extent of synchronization between changes in ploidy and the formation of species remains unclear. Furthermore, these analyses use data from within genera, and thus only estimate rates from the relatively recent past and do not account for polyploidization rate variation over time. Indeed, it has been argued that times of environmental stress may greatly increase the rate of polyploidization, with evidence of an excess of polyploidization events dating back to the Cretaceous–Paleogene boundary, a time of massive environmental upheaval and widespread extinction (Vanneste *et al.*, 2014).

Another open question is how often these polyploidization events involve hybridization between species versus arise within a species (i.e., allo- versus autopolyploidy). Of the above studies, only Scarpino *et al.* (2014) attempted to tease apart the nature of the polyploids (by assuming that some ploidy levels, e.g., hexaploids, would only be formed by hybridization between species); they found that allopolyploidy was roughly four times more common than autopolyploidy. This inference conforms to the traditional view that autopolyploid species should form less frequently because they suffer reduced fertility due to multivalent formation during meiosis (**Figure 2(c)**; Clausen *et al.*, 1945; Stebbins, 1971). It is also consistent with phylogenetic studies of groups with lots of polyploids, which tend to find a preponderance of allo- versus autopolyploids (e.g., Doyle *et al.*, 2003; Brysting *et al.*, 2007; Rothfels *et al.*, 2014). On the other hand, estimates of autopolyploid speciation may be biased downwards because autopolyploids are frequently overlooked as unique species due to their morphological similarity to diploid progenitors, even if they satisfy the conditions of most species concepts (Soltis *et al.*, 2007). Indeed, recent studies suggest that autopolyploids may form and establish at high rates (Ramsey and Schemske, 1998; Ramsey and Schemske, 2002), and autopolyploid speciation may be more common than previously thought (Parisod *et al.*, 2010b). Future studies are needed to quantify more precisely the contribution of allopolyploidy and autopolyploidy to polyploid speciation.

The Role of Polyploidization in the Formation of Species

In the previous subsection, we discussed estimates of the rate at which polyploid species arise. Here, we tackle the more difficult question: to what extent is the change in ploidy, itself, responsible for the formation of new species?

Because newly formed polyploids can be reproductively isolated from their diploid progenitor species, as exemplified by radicole, and because many closely related species differ in ploidy level (Wood *et al.*, 2009), it is often assumed that polyploidization drove speciation for all species pairs that differ in ploidy. For example, in the fern genus *Pteris* (Pteridaceae), a recent study found that 40 out of 106 studied species were polyploid and concluded that these were the result of polyploid speciation (Chao *et al.*, 2012). An alternative, however, is that new species form via mechanisms that are not associated with ploidy shifts (e.g., the accumulation of genetic incompatibilities in isolated populations), with the ploidy shifts occurring independently over evolutionary time.

Ideally, we would learn about the role of polyploidization in the generation of new species by directly observing the process of speciation. Unfortunately, we typically only have snapshots at different stages in different taxa. There have, however, been studies that explore very closely related taxa and measure the contributions of various features, including ploidy differences, to reproductive isolation. One study of diploid and tetraploid subspecies of fireweed, *Chamerion angustifolium*, found that the reproductive isolation between them was almost entirely (98%) due to mechanisms like pollinator differences and preferences for high versus low elevation habitats: little of the observed reproductive isolation was due to the hybrid sterility typically assumed to prevent gene flow between diploids and polyploids (Husband and Sabara, 2004; Martin and Husband, 2013).

This example illustrates many of the problems facing scientists investigating polyploid speciation. For one, it is difficult to know what mechanisms acting to separate species today were important in driving or facilitating their initial divergence. Did fireweed divide into high and low elevation habitats, and subsequently there happened to be a polyploidization event whose descendants came to dominate the lower elevation population, or did polyploidization facilitate the initial divergence?

A second problem is that, even if polyploidization was the first step toward speciation, it is hard to know which features of the new polyploids mattered most. It could be that the critical feature was an altered morphology or ecological tolerance of the polyploid, not its genetic incompatibility with the diploids. If polyploids form often enough (estimated at a frequency of 0.24% in fireweed; Husband and Sabara, 2004) and if they have an advantage over the diploids in certain habitats (e.g., at low elevations in the fireweed example), then eventually a self-sustaining population of polyploids may colonize sites beyond the range – and niche – of the diploid. Here, for example, polyploids may have established because they can better survive at lower elevations; the sterility of crosses between polyploids and diploids may have been largely irrelevant.

The view that polyploidy provides an 'instantaneous' reproductive barrier between species is based largely on the assumption that crosses between diploids and tetraploids will generate infertile triploids (the 'triploid block'). Having three sets of chromosomes reduces fertility, because meiosis either fails in the absence of paired chromosomes or proceeds but leads to gametes without a full set of chromosomes ('aneuploidy'; **Figure 2(b)**). Nevertheless, this view is now considered too absolute: inter-ploidy hybrids need not be completely sterile, and even if they are, other routes can allow

gene flow between populations of different ploidy levels (Soltis and Soltis, 1989).

In fact, rather than causing a block, triploids may provide an important genetic connection between different ploidy levels – a 'triploid bridge' – particularly in the early phases when a new tetraploid population is first establishing (Bever and Felber, 1992; Husband, 2004; Rieseberg and Willis, 2007). Triploids can facilitate tetraploid establishment by occasionally producing unreduced (triploid) gametes that fertilize a normal haploid gamete to produce a new tetraploid individual or by producing partially reduced (e.g., diploid) gametes that can combine with a diploid gamete produced by a tetraploid – in either case, genetic material can flow to the tetraploid population, reducing its reproductive isolation. An increasing number of empirical studies have documented gene flow between ploidy levels, including gene flow from diploids to both auto- and allopolyploids (Slotte *et al.*, 2008; Parisod *et al.*, 2010b).

Of course, even if reproductive isolation is initially incomplete, selection on new polyploid populations will favor stronger reproductive barriers to avoid the production of sterile (or partially sterile) triploid offspring. This process – selection favoring the evolution of greater degrees of reproductive isolation to avoid wasting gametes on low-fitness hybrids – is referred to as reinforcement and is expected to be particularly relevant to the establishment of new polyploids, which might otherwise breed repeatedly with their diploid progenitor until they go extinct ('minority cytotype exclusion'; Levin, 1975; Butlin, 1987).

While the above discussion considers reproductive isolation between a polyploid and its diploid progenitors, another consideration is how polyploids – specifically allopolyploids – affect gene flow between the two parental diploid species. The triploid bridge, for example, might allow introgression (via the polyploid) of genes between two parental species that are otherwise genetically isolated. The opposite is also possible, however, if polyploid hybrids replace inter-fertile diploid hybrids at points of contact between two species and reduce gene flow between them (e.g., through increased meiotic break down in triploid progeny). Both of these outcomes are theoretically possible, but whether allopolyploids tend to facilitate or hinder divergence between parental diploid species is an interesting open question.

Polyploid Speciation II: The Speciation of Polyploids

The Influence of Ploidy on Diversification Rates

Another way that polyploidy can impact speciation, aside from the formation of new species by ploidy changes, is by altering the rate of speciation (and extinction). In other words, do polyploid species themselves form new species more or less often than their non-polyploid relatives? This is a question with a rich and contentious history. Early evolutionary biologists tended to believe that, while polyploids may form frequently, they rarely themselves speciated and instead tended to go extinct: they were 'evolutionary dead-ends' (Stebbins, 1950; Wagner, 1970). This opinion was informed, in part, by the belief that the 'extra' genomes of polyploids would mask mutations from selection (because most mutations are recessive), reducing the efficacy of selection and ultimately making polyploids less adaptable (Stebbins, 1950). However, there are also theoretical arguments in favor of polyploids speciating more frequently or going extinct more slowly. For example, by uniting multiple genomes, polyploids often exhibit greater enzymatic variability (Roose and Gottlieb, 1976) and maintain higher levels of heterozygosity, which has the potential to increase evolutionary flexibility (Mable and Roberts, 1997; Petit and Thompson, 1999; Parisod *et al.*, 2010a,b) and promote diversification (Stebbins, 1985; Ricklefs and Renner, 1994). Polyploids may also benefit from the redundancy inherent in polyploidization in that they have 'back-up' copies of each gene if ever one is damaged (and thus they may go extinct more slowly) and because these 'extra' gene copies, even if initially identical, are available to be molded by selection for different uses (Ohno, 1970; Zhang, 2003; Des Marais and Rausher, 2008), potentially increasing speciation rates. For example, Hofberger *et al.* (2013) argue that polyploidy allowed the evolution of a key group of defensive compounds in the mustard plant family, and Málaga-Trillo and Meyer (2001) similarly link the extensive body plan variation in fish to rounds of ancestral polyploidy.

Polyploidy may also increase diversification rates directly by increasing the rate that reproductive isolation arises between populations. Because most mutations that affect fitness are deleterious, the probable fate of a duplicate gene pair is the silencing of one of its members. If different copies of an important gene are silenced in different populations, offspring of a cross between populations will have reduced fitness because some of their progeny will not inherit any functional copies. Because this 'reciprocal silencing' or 'divergent resolution' can happen at multiple loci, isolated polyploid populations may rapidly lose the ability to produce fertile hybrids (Werth and Windham, 1991; Taylor *et al.*, 2001).

These theoretical links between polyploidy and elevated diversification rates are seemingly supported by four main empirical observations. First, clades with a higher percentage of polyploids tend to contain more species (Petit and Thompson, 1999; Otto and Whitton, 2000; Vamosi and Dickinson, 2006), although this may simply reflect the fact that small young clades have not had time to accumulate polyploids or that diploids may produce polyploid daughter species at high rates in some clades (without these polyploids diversifying at high rates). Second, extant polyploids can be highly ecologically successful relative to their diploid relatives (Hahn *et al.*, 2012; Te Beest *et al.*, 2012), while their related diploids are rare, undiscovered, or extinct (e.g., Grusz *et al.*, 2009; Beck *et al.*, 2010). Third, studies of both paleontological and genomic data have inferred multiple 'paleopolyploidy' events in the history of most major lineages (e.g., Masterson, 1994; Sidow, 1996; Wolfe and Shields, 1997; Soltis, 2005). Some of these paleopolyploidy events appear to have occurred at the base of major radiations (for example, at the base of the angiosperms and the base of teleost fishes), suggesting that polyploidization may have elevated speciation rates in these lineages (Hoegg *et al.*, 2004; De Bodt *et al.*, 2005; Barker *et al.*, 2008; Santini *et al.*, 2009; Tank *et al.*, 2015).

However, additional investigations, mostly in the past decade, have cast doubt on the arguments that polyploids should have increased diversification rates. At a theoretical level, the model of Muir and Hahn (2015) shows that the conditions under which reciprocal silencing leads to speciation are very restrictive, requiring nearly complete geographical isolation. The empirical arguments, likewise, are not as compelling as they first appear. For example, while clades with polyploids do tend to have more species than clades composed entirely of diploids, that pattern appears to be driven by the diploids in the mixed clades speciating more (both by forming new diploids and by creating polyploids, Mayrose *et al.*, 2011); polyploid-only clades are no richer than their diploid-only relatives (Vamosi and Dickinson, 2006). And the few studies to systematically examine the ecological 'success' of polyploids (i.e., their ecological or geographic breadth in comparison with related diploids) fail to find any advantages for the polyploids (Petit and Thompson, 1999; Martin and Husband, 2009).

The paleopolyploidy arguments likewise are less convincing than they first appear. While there are numerous examples of paleopolyploidy, relatively few analyses have asked whether there are more such cases than expected given the high rate at which polyploidization occurs. Because diploids give rise to polyploids, but not vice versa, there is a ratchet-like process to increase ploidy levels, which can explain the prevalence of polyploidy and of paleopolyploidy events, without any need for polyploids to speciate more than diploids (Meyers and Levin, 2006). Indeed, a recent simulation study using empirical estimates of speciation, extinction, and polyploidy rates assuming that polyploids and diploids diversify at the same rates found that there should be approximately 4.6 to 8.9 paleopolyploidy events in the history of any given angiosperm species (Mayrose *et al.*, 2011), instead of the 1 to 4 such events thought to have occurred (Jiao *et al.*, 2011). Thus, if anything, the number of paleopolyploidization events in plants suggests that polyploids have diversified less than diploids.

The related argument – that polyploidy events tend to occur at the base of major clades – suffers from problems related to the effects of incomplete sampling and extinction. Jiao *et al.* (2011), for example, reconstruct a paleopolyploidy event at the base of the seed plants, but the dating is imprecise, with the event occurring sometime during the approximately 100 million years between the divergence of the lycophytes from the rest of vascular plants and the divergence of the ancestor of extant gymnosperms from that of the angiosperms (Smith *et al.*, 2010). Furthermore, if a polyploidization event leads to a number of dead-end species that go extinct before a subsequent event leads to a species-rich clade, polyploidy will appear to be at the base of the diverse clade, even though polyploidy did not cause higher speciation rates (Donoghue and Purnell, 2005). Overall, there is no strong evidence that paleopolyploidy events directly caused increased diversification.

Recent analyses, typically using phylogenetic approaches, reinforce the emerging picture that, on average, polyploid lineages diversify more slowly than their diploid relatives (at least in plants; Mayrose *et al.*, 2011; Husband *et al.*, 2013). This diversification trend is driven by polyploids having both reduced speciation rates and elevated rates of extinction (Mayrose *et al.*, 2011), which results in evolutionary trees where polyploids frequently arise but commonly go extinct, such that the majority of polyploids observed in the present are relatively young species that have yet to go extinct (e.g., see Beck *et al.*, 2011; Escudero *et al.*, 2014). Within this broad tendency, exceptions exist – for example, the Hawaiian silversword alliance, the New World cottons, and several species-rich clades of bamboos all appear to have radiated at the polyploid level (Carr *et al.*, 1996; Adams and Wendel, 2004; Triplett *et al.*, 2014). Furthermore, there is some evidence that polyploid fish may diversify more rapidly than their diploid relatives (Zhan *et al.*, 2014), in keeping with an increase in diversification associated with the genome duplication event at the base of the telost fishes (Santini *et al.*, 2009). In addition, much of the speciation advantage experienced by diploids may, ironically, be due to their greater ability to produce polyploid daughter species; by comparison, polyploids are relatively bad at polyploid speciation (Mayrose *et al.*, 2011; Scarpino *et al.*, 2014)!

Conclusions

Polyploidy has contributed to the rich diversity of life, with ancient polyploidization events (paleopolyploidization) inferred to have occurred early in the evolution of angiosperms, teleost fishes, vertebrates, and yeast, along with numerous recent events (neopolyploidization) in many groups of plants and in some animals. However, the prevalence of polyploids reflects the combination of two processes: the establishment of new polyploid populations and the diversification of these populations, corresponding to the two main sections of this article. The interaction of these processes can be thought of as a balance, whereby new polyploid individuals are constantly added to populations, due largely to errors in meiosis or fertilization. Many of these ploidy mutants are, however, unfit and fail to leave descendants. Occasionally newly formed polyploids are successful and establish new populations. Once established, many of these new polyploid populations form their own species, but these new species are also generally unfit (at least in plants); only rarely are they able to avoid extinction and themselves speciate. That the ultimate fate of most polyploid individuals and populations is extinction does not preclude the potential for rare advantageous polyploids to have important long-term evolutionary consequences, including establishing major branches of the tree of life (Mayrose *et al.*, 2014; Arrigo and Barker, 2012).

Much remains to be learned about the impact of polyploidization on speciation, at both these levels. At the first level, it is clear that polyploids often differ phenotypically from their parent species in ecologically important ways as well as having a degree of chromosome-based reproductive isolation, potentially providing them with an easy route to speciation (Coyne and Orr, 2004). Accumulating data suggest that this route, however, is often not 'instantaneous.' Indeed, the prevailing view is that a period of gene flow between diploids and recently formed polyploids assists in polyploid establishment, both by increasing genetic variation in the polyploids and by increasing the number of potential mates

for the polyploid individuals. Even in those cases where isolation is strong and rapid, it is unclear whether it is the typically invoked chromosomal incompatibilities or other phenotypic differences that are most responsible for the isolation between the new polyploid and its progenitors.

While there is a strengthening consensus that polyploid plant species tend to diversify more slowly than their diploid relatives (Mayrose *et al.*, 2011; Arrigo and Barker, 2012; Escudero *et al.*, 2014; Mayrose *et al.*, 2014; Scarpino *et al.*, 2014; but see Tank *et al.*, 2015), it is unclear how widely applicable these results are to other taxonomic groups; the opposite pattern, for example, is suggested for polyploid fish (Santini *et al.*, 2009; Zhan *et al.*, 2014). In addition, why some polyploid lineages can persist and even proliferate, while others are lost, remains unknown.

Future research promises to clarify the role that hybridization (allopolyploidy) and environmental perturbation (Vanneste *et al.*, 2014) play in the success or failure of polyploid lineages. Another promising area of research is to confirm the tantalizing finding that previous rounds of polyploidization inhibit subsequent rounds (Mayrose *et al.*, 2011; Scarpino *et al.*, 2014). Is this because rising chromosome numbers cause increasingly severe meiotic problems or because the advantages of genome doubling are stronger in small genomes, which may be more constrained with fewer genes to take on new functions? Finally, as this review emphasizes, future research is needed to determine whether polyploid transitions are concentrated in time at speciation events, and if so, whether polyploidization plays an early and/or major role in the development of reproductive isolation.

Population Structure and Gene Flow

JP Wares, University of Georgia, Athens, GA, USA

Glossary

Anadromous It describes fish species that lay eggs that hatch in fresh water, but after hatching the fish migrates to the sea to feed and grow to reproductive maturity.

Philopatry The process of an adult returning to the region or habitat of its birth for mating and reproduction.

A frequently used term in biology is 'structure' – the organization and relation of parts. It may refer to communities, it may refer to morphology; in evolutionary biology, it is often used to refer to population structure. This type of structure ;is invoked when individuals of a study species comprise more than one population, defined by the diversity within each. A population evolves primarily through the reproductive success of its members, and (for most eukaryotic organisms) who they mate with. When, for whatever reason, there are groups of individuals that are less likely to mate with other groups of individuals, we set them apart because these distinct populations, harboring distinct diversity, may be responding to different environments (Slatkin, 1987).

The primary information about diversity in a population involves the number of genetic variants from a region of the genome, or alleles, found in a sample of individuals. First, we may just count the number of types sampled and assess the frequency of each, and a simple frame of reference comes from the Hardy–Weinberg (HW) model. This model is generally used as a null hypothesis in evolutionary studies, so that rejection of this model leads us to understand what mechanism(s) of evolution (change in genetic diversity) may be acting on that population (Hartl, 2000). The basis for testing this hypothesis involves the frequencies of alleles, and the frequencies of diploid genotypes comprised of these alleles, assuming independent assortment and no evolutionary mechanisms acting. Of course, we expect the diversity of almost any population to be influenced by immigration, finite population size, mutation, selection, or nonrandom mating. Only when we reject this simple model can we begin to identify which are acting, and whether they lead to identifiable structure.

So, the next consideration is space: where were the samples taken from? As a set of genetic samples includes more locations, we can ask whether the allele and genotype frequencies for the sample at any location are consistent (statistically probable) with the allele and genotype frequencies at another location being the same. If not, we may start to see that these frequencies have diverged across locations, and a first question to ask is whether this is the result of nonrandom mating. Here this simply means that individuals at one location are more likely to have mated with another individual from the same location than an individual from the other location. This is one way to define population structure – that the sampled individuals from distinct locations are not often mating with one another. There may be reasons why individuals at the same location mate nonrandomly as well (**Figure 1**).

This nonrandom mating is a form of inbreeding, as it involves reproduction between individuals that tend to be somewhat more closely related to one another. This in turn leads to an excess of genotype homozygosity relative to all other spatial samples, in the terms of the HW model, and is a means of statistically testing for population structure. Some of these statistical tests are detailed below.

It might also seem as though the DNA sequence divergence of particular alleles would tell us about population structure; two individuals that carry mitochondrial haplotypes that are different at 5 out of every 100 nucleotides seem more likely to be from different populations, in an evolutionary sense, than if their haplotypes are nearly identical. However, even alleles that are quite divergent may be found in the same population if individuals still mate with one another. Famously, alleles at the major histocompatibility complex in mammals may be much older than the species they are found in (Hughes and Nei, 1992)! Any single locus can have an unusual history or dynamics that lead it to carry ancient diversity. To understand this diversity we require the context of other loci, to see if

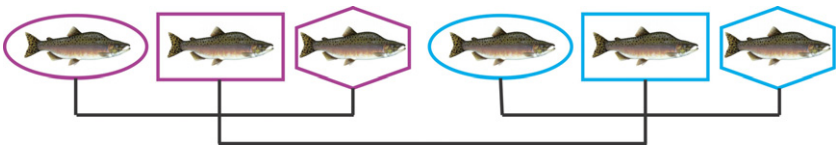

Figure 1 Visualizing population structure. There are two types of population genetic structure in pink salmon (*Oncorhynchus gorbuscha*). Branching of highly simplified genealogy identifies relatedness of individuals from population samples. Regional samples (represented as distinct shapes) exhibit high within-sample relatedness because of philopatry, and could help identify adaptation to distinct environments. However, the same spatial samples are split temporally because of the 2-year maturation cycle of this anadromous fish (Beacham *et al.*, 2012): the 'odd' years (pink) have evolved distinct allele and genotype frequencies from the 'even' years (blue), and have different patterns of abundance and demography. Thus, structure results from both spatial limits on gene flow, as well as the temporal effect of alternating maturation cycles.

individuals are clearly distinct at multiple loci, suggesting again that they are not mating with one another. The cause of reproductive isolation may be extrinsic – a barrier between populations – or intrinsic, when the populations do not recognize one another as good mates or when there are fitness consequences for crosses between the populations (Bewick and Dyer, 2014).

Leaving the biological, intrinsic mechanisms alone for now, we can see that an important way in which populations form is from simple limits on individuals encountering one another. So, organisms that move very little in their lifetime would be expected to only encounter a mate locally; organisms that have at least some stage in their life of high motility will expand the spatial range of possible mates (Slatkin, 1987). If an individual moves from one area to another, and successfully mates, we now have gene flow – literally, the movement of alleles from one location to another. If this happens often, it is likely that the locations are part of the same population (we cannot statistically differentiate the individuals from different locations), and if it is rare then we begin to posit 'structure.'

It is important to note that this is a quantitative and continuous designation. It may seem odd, but rejecting a hypothesis of a single population does not necessarily mean there are two, or more, populations. A phenomenon known as 'isolation by distance' refers to situations in which the level of gene flow is sufficient that neighboring locations may appear to be consistent with one population, but as the domain is expanded to include more geographically or ecologically distinct samples, the probability of sufficient dispersal and gene flow diminishes, and allele frequencies, genotype frequencies, or pattern of substitutions become consistent with populations that are demographically isolated from one another (Wright, 1943). So, the number of populations inferred may depend on the scale and sampling for the analysis.

Inference of Structure

Analytically, our understanding of structure follows the logic identified above. There are many ways to approach this problem; here we focus first on the diversity within and among sample locations – in other words, examples in which the location of the sampled individual influences the analysis – and then on approaches that assess the fit of the data to a series of models of population structure to determine the most probable description of structure given the data; these latter approaches do not require spatial information, and can help identify patterns arising through other mechanisms.

As noted above, when individuals are sampled from multiple locations, we can measure the genetic diversity both within locations as well as inclusive of multiple locations. Traditionally, the complete data set is considered as the 'total' diversity, and diversity from individual 'sites' are evaluated for how much of the total diversity they contain. By symbolizing the site-level diversity as S, and the total diversity as T, we can evaluate a family of statistics that quantify structure as X_{ST}, where S and T are as defined and X is a symbol that varies depending on assumptions about the data. Though this now sounds complicated, our most general model for quantifying population structure can be expressed in simple terms:

$$X_{ST} = \frac{(\text{total diversity}) - (\text{mean within-site diversity})}{(\text{total diversity})}$$

where diversity may be measured as heterozygosity or related measures of genetic diversity (where X is replaced by F or G), variance in microsatellite allele size (where we assume the stepwise mutation model, and use R_{ST}), nucleotide diversity (which may be evaluated using Φ_{ST}), and other 'flavors' of this approach (Excoffier *et al.*, 1992; Hartl and Clark, 1997). Typically, researchers will refer to F_{ST}, which was the first common 'fixation index' for such studies and can be estimated using a variety of computational approaches (Whitlock, 2011).

Often these indices are calculated in a hierarchical 'analysis of molecular variance,' mirroring a standard ANOVA statistical framework. If there is no structure – no correlation of allele frequencies by site, no increase in genotypic similarity by site – then there is as much diversity at the 'site' level of diversity as the 'total' level and the statistic X_{ST} is close to zero. At the extreme where every single site sampled harbors low diversity, but allelic diversity is distinct from all other sites (high divergence among regional groups of alleles), the statistic approaches 1 (**Figure 2**).

In recent years, effort has gone toward recognizing the limits of this class of statistics that are caused by how much variation is found at the site level, limiting the comparability of these indices among taxa. Improved (but slightly more complicated) statistics may be appropriate for some considerations, and may greatly improve our capacity to explore structure at multiple hierarchies of biodiversity (Jost, 2008; Whitlock, 2011; Smouse *et al.*, 2015). In almost all cases, this family of statistics is assessed for statistical significance through permutation testing, where genotypes are randomly assigned to a spatial site to generate a null distribution of divergence.

The other way in which population structure is often assessed is explicitly through finding the best fit of genotype data from individuals to inferred populations, where it is assumed that a true population will have minimal deviations from Hardy–Weinberg expectations on allele and genotype frequencies. As discussed above, to the extent two locations are connected by immigrants, the allele and genotype frequencies will not be divergent from one another; if gene flow is limiting, then by the stochastic process of variation in reproductive success (drift) these frequencies diverge from one another at different locations. When there are populations with heterogeneous allele and genotype frequencies, whether the location of the samples are considered or not, the overall fit to Hardy–Weinberg expectations will be poor.

A way to identify populations and which individuals belong to each is implemented in programs like structure (Pritchard *et al.*, 2000). A type of 'clustering analysis,' this approach identifies how well data fit Hardy–Weinberg expectations when 1, 2, 3, or more evolutionary populations are assumed – in each case, the likelihood of this analysis comes from the fit (lack of deviation) of genotype data in each cluster to HW expectations and thus the number of populations can be inferred in some circumstances (**Figure 3**). Other clustering approaches (Gao *et al.*, 2007) may be used when this

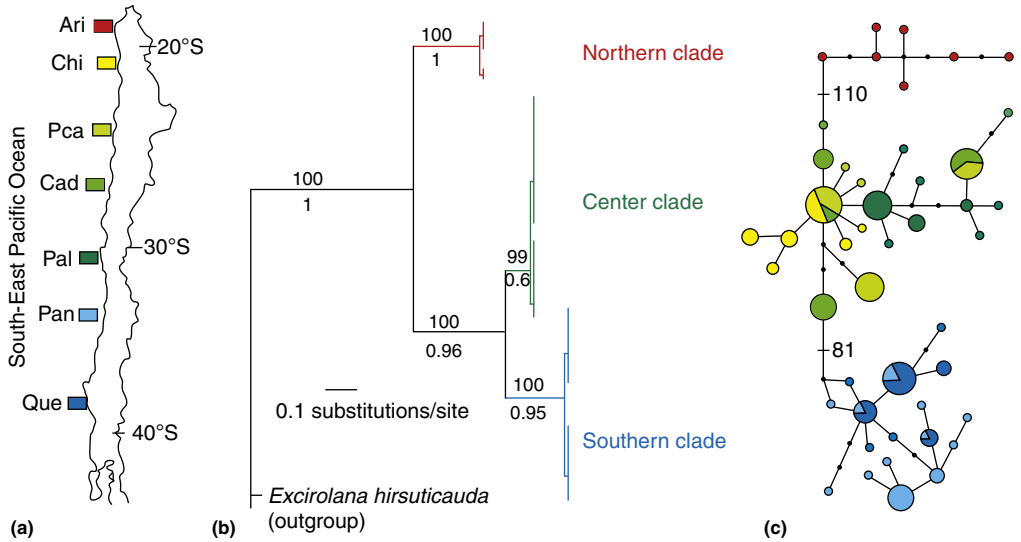

Figure 2 Illustrating hierarchical population structure. Mitochondrial haplotypes were sequenced from the isopod *Excirolana braziliensis* (Varela and Haye, 2012), from sites indicated in part (a). In (b), a phylogram illustrates the relationships among these haplotypes; the genetic relationship between particular haplotypes as well as the locations at which they were collected are then summarized in (c). From this network it can clearly be seen that the total amount of sequence variation in Excirolana is large (the numbers along the haplotype network indicate the number of nucleotide substitutions between clades), and at particular sites (or within sub-regions) the variation is less (e.g., only 7 distinct haplotypes in the Northern Clade). For sequence data, it is typical to calculate Φ_{ST} which uses the sum of squared differences among DNA sequences as a metric within an ANOVA framework. Φ_{ST} values among locations in the Center Clade, for example, range from 0.158 to 0.444, while values between sites in the Center Clade and other regions consistently present Φ_{ST} greater than 0.95.

Figure 3 Clustering analyses. A genealogy illustrates the temporal relationship among alleles in two sites with limited gene flow. Simulated diploid microsatellite genotypes at a single locus present data that, when a single population is assumed, exhibit homozygote excess relative to the allele frequencies and the relationships of the HW model. When two populations (blue and green) are assumed, the fit of genotypes to HW is much better. This is a model-fitting approach to inference of population structure.

underlying genetic model is likely to be violated (e.g., in selfing plants where assumptions of HW are known to be false).

Of course, while it is known that migration and gene flow are the forces that will homogenize allele and genotype frequencies among locations, it is important to recognize that migration is not always (or often) omni-directional and symmetric among sites. From fundamental papers in population genetics to more contemporary efforts, we know that in these instances the upstream, or source, population diversity will end up driving the diversity in the recipient sites (Nagylaki, 1978; Wares and Pringle, 2008). This has numerous

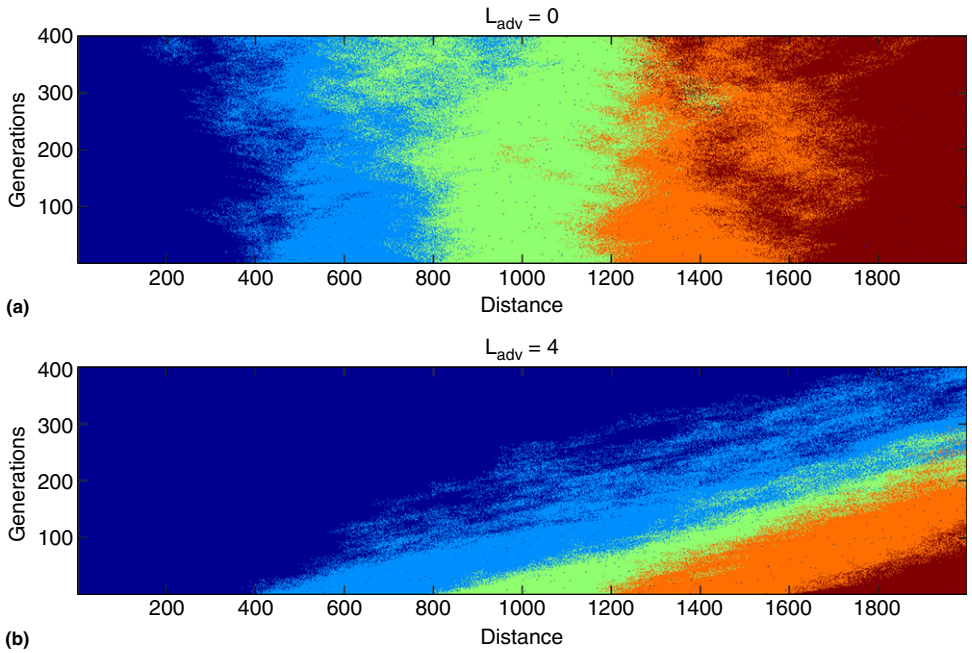

Figure 4 Effects of asymmetric gene flow. When dispersal is biased by wind, currents, or other environmental features, the genetic diversity of a system may be homogenized with the diversity of the 'upstream' region (source region) dominating the entire system. In both panel (a) and panel (b), a simulation model is carried out where the domain is initialized with haploid individuals and 5 distinct alleles, each geographically isolated to 1/5 of the domain. The model is run for 400 generations. In (a), there is no advection (asymmetric gene flow) and diffusion is the primary mechanism of dispersal. In (b), advection is approximately 40% as strong as random diffusion of offspring, and the offspring preferentially disperse toward the right. The upstream allele (indicated in blue) quickly dominates the entire domain. Reproduced from Wares, J.P. and Pringle, J.M., 2008. Drift by drift: Effective population size is limited by advection. *BMC Evolutionary Biology*, **8**, 235.

effects on the maintenance of diversity throughout the domain of a species (Figure 4). The most direct way to identify source–sink demographic systems, where the composition of the 'sink' populations may be entirely reflective of the composition of the 'source' is to use multi-locus genetic data to identify parentage of recruits by site (Peery *et al.*, 2008).

The Context of Population Structure

At some level the structure of a 'species' into 'populations' may seem academic, but 'species' are not responding to environmental change – the populations they are comprised of are. Repeatedly, researchers have found that individuals sampled from distinct sites – and ultimately shown to be in distinct populations – have distinct environmental tolerances, reaction norms, and levels of additive genetic diversity allowing response to change (Sanford and Kelly, 2011; Crozier and Hutchings, 2014; Evans *et al.*, 2015). Understanding population structure gives us great insight into the frequency and mechanisms of movement between sites, as well as the variation in the environment – some of it abiotic, some biotic – that maintains population structure. Much of what we know of trait variation – even the trait of reproductive isolation – is not necessarily at the level of species; instead, the values of traits may differ by geographic location and the genetic composition of those populations (Cutter, 2012; Mandeville *et al.*, 2015). The extent to which even subtle traits – coloration and other quantitative measures – vary among populations *could* be driven by local adaptation at associated genes, but is often undirected change associated with genetic structure or population structure of the focal organism instead. The context of structure is thus necessary for interpreting how evolution is changing natural patterns of diversity. Population genetics was founded on a statistical necessity; it is now necessary for exploring diversity at finer scales than can be named.

Predation and Parasitism

THQ Powell and KM Prior, University of Florida, Gainesville, FL, USA

Introduction

Predator–prey and parasite–host interactions are nearly ubiquitous in ecological communities. These two interaction types comprise a subset of the broader victim–exploiter interaction in which one consumer species benefits at the cost of its partner through a direct trophic (consumptive) interaction. Predation and parasitism differ from one another in the lethality of the interaction for the victim species and the number of individuals involved on either side of the interaction. In a predatory interaction, the consumer species kills individuals of the prey species. Typically, this involves an individual predator consuming multiple prey individuals over the course of its life cycle. In a parasitic interaction, the parasite's consumption of the host is not necessarily lethal and often involves a reversal of the relative number of individuals participating on either side of the interaction: many parasites consuming a single host. A single individual parasite may interact with a single host individual, while hosts are likely to interact with many individual parasites.

A third class of consumers, parasitoids, shares a mix of traits between predators and parasites. Parasitoids function like parasites in that they usually interact with a single victim over the course of their lives. But like predators, the parasitoid's victim dies as a result of the interaction. Parasitoid–host systems can often be extremely specialized. Here, we will treat parasitoid–host interactions as a particularly intimate form of predator–prey interactions. Some of the traits involved in these systems, such as manipulation of host gene expression by parasitoids and the host's immune response are certainly more reminiscent of a gut parasite's interaction with its host than a lion killing an impala. However, the lethality that defines parasitoid life histories is an important distinction (Figure 1).

The outcomes of either predation or parasitism can have crucial fitness consequences for both interacting species. Natural selection is expected to act on variation in the ability of predators and parasites to efficiently consume their victims as well as on variation in the ability of victim species to either avoid or fend off aggressors. The intrinsic differences between predation and parasitism lead to different predictions regarding coevolutionary dynamics in these systems. However, the central premise is similar for both types of interactions. A simple Lotka–Volterra model of predator–prey dynamics is useful for illustrating the general premise of predator–prey coevolution (Abrams, 2001). This model predicts rates of change in a prey population of size V and a predator population of size P over a period of time t, and may be written as:

$$\frac{dV}{dt} = V(r - cP)$$

$$\frac{dP}{dt} = P(bcV - d)$$

where r is the intrinsic growth rate of the prey population, d is the mortality rate of the predator population, c is the capture rate for the average predator, and b is the conversion rate of captured victims into predator offspring. Although this is a somewhat simplistic model, more complex extrapolations that incorporate density-dependence, more realistic functional responses, and discrete generation time still incorporate the basic components of the Lotka–Volterra framework involved in coevolution.

The value of c (capture rate) is determined by traits in both predator and prey populations, and highlights how trait evolution in one species can have an immediate effect on the fitness landscape of the other species. Given intraspecific genetic variation, prey species are expected to evolve trait values which decrease the magnitude of c, while natural selection should favor predator traits that increase c (Abrams, 2001). The strength of this antagonistic coevolution around c

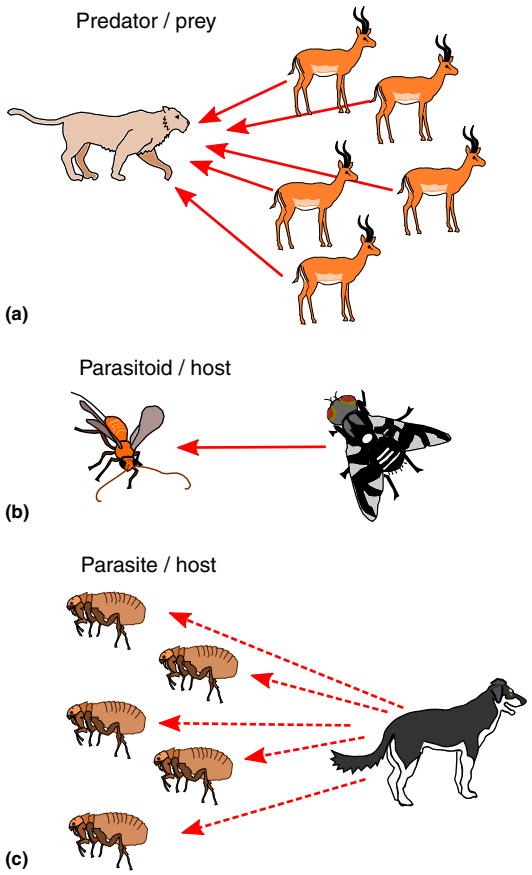

Figure 1 Diagram of basic demographic and lethality relationships for three types of exploiter/victim ecological relationships: (a) a single predator killing and consuming multiple prey individuals over its lifetime, (b) a single parasitoid killing and consuming a single host individual over its lifetime, and (c) many parasite individuals consuming (but not killing) a single host individual.

 doi:10.1016/B978-0-12-800049-6.00188-8

is necessarily limited by the tradeoffs evolving traits may impose on other components of fitness. For instance, a defensive trait that may reduce c for a prey species may be energetically costly, decreasing r (fecundity). Similarly, in parasite–host systems natural selection should act on traits of both species affecting the rate of transmission of parasites between hosts, the parasite's ability to draw resources from the host, and the host's resistance to the parasite.

Footprints of coevolutionary dynamics in predator–prey and parasite–host systems may be seen in two different patterns in nature: coevolutionary arms races and codiversification. A third pattern restricted to parasite–host coevolution is the mitigation of virulence. Each of these is discussed in the following sections.

Coevolutionary Arms Races

Alongside tightly specialized mutualisms, evolutionary arms races are probably the phenomena most commonly associated with the term coevolution. The concept of two species locked in a never-ending struggle to gain the evolutionary upper hand is a powerful one, and it fits well with the widely held notion of nature as 'red in tooth and claw.' This scenario, in which an evolutionary advantage gained in one species is met with a compensatory change in the other, is both straightforward and plausible. This sort of constant coevolutionary struggle has even been implicated as a major reason behind the advantage of sex. However, empirical evidence for arms races can be difficult to find in nature, given that our view of current ecological communities is often limited to only their present state, revealing only a single time point in a dynamic process. The best evidence for on-going arms races comes from predator–prey or parasite–host populations whose traits differ in a correlated manner over geographic space (Thompson, 2005). The geographic mosaic theory of coevolution predicts variation in the strength and specifics of the coevolutionary process among different local populations of interacting species. Thus, predator or parasite populations that are well matched to the traits of their local victim populations, and vice versa, provide strong evidence for on-going coevolutionary arms races.

Perhaps the best studied example of this is the classic case of rough-skinned newts and garter snakes in the western United States (Brodie, 2011). In the 1960s, otherwise harmless rough-skinned newts (*Taricha granulosa*) in Pacific Northwest were found to be highly toxic. The newts produce a compound called tetrodotoxin, which binds to and blocks sodium channels in neurons. The level of toxicity produced by these animals was surprising; with individual newts weighing only a few grams producing doses capable of killing 25 000 mice. Moreover, at the time there were few known predators of these newts, and in particular no large vertebrate predators that would require such a formidable defense. Further ecological surveys of the newts identified a reason for the toxicity: high levels of predation by the common garter snake (*Thamnophis sirtalis*), which is resistant to the newt's toxins. Decades of work in this system, led by Edmund Brodie Jr. and Edmund Brodie III, has succeeded in painting a clear picture of the coevolutionary arms race between newts and garter snakes.

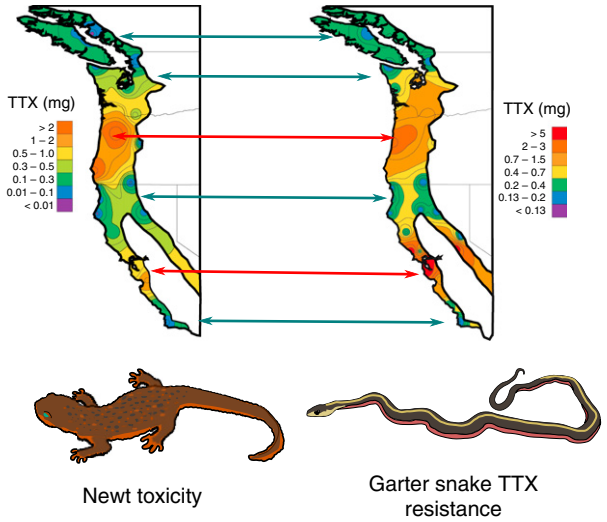

Figure 2 Depiction of the geographic mosaic in the newt/garter snake coevolutionary arms race. The map on the left shows how newt toxicity (amount of TTX produced) varies over space. The map on the right shows the geographic variation in snake resistance (dose of TTX needed to hinder snake performance). The broad correspondence of geographic variation in the traits of these two species are highlighted with the red (high toxicity and resistance) and blue-green (low toxicity and resistance) arrows. Adapted from Hanifin, C.T., Brodie Jr., E.D., Brodie III, E.D., 2008. Phenotypic mismatches reveal escape from arms-race coevolution. PLoS Biology 6, 0471–0482. Originally published under the Creative Commons Attribution license.

Considerable variation exists in both newt toxicity and snake resistance in different geographic locations. Congruent with the geographic mosaic model of coevolution, there is also strong geographic correlation in trait values of newt and snake populations, with more toxic newts generally found within areas with more resistant snakes (**Figure 2**; Brodie *et al.*, 2002; Hanifin *et al.*, 2008). The molecular basis for both newt toxin production and snake resistance is also now well understood. Newts increase production of tetrodotoxin, while resistant garter snakes possess mutations which change the conformation of sodium channel proteins, which decreases the binding affinity between the toxin and the channels (Geffeney *et al.*, 2002). Experiments have also demonstrated a clear fitness tradeoff in resistance for the snakes. The sodium channel mutations that reduce the toxicity of tetrodotoxin on the snakes also have a negative effect on snake locomotor capacity. Resistant snakes are slower and clumsier than nonresistant snakes (Brodie and Brodie, 1999). This helps explain why the highly resistant alleles have not spread through all the snake populations; the locomotor costs are not worth the benefit when the local newts are less poisonous. This classic garter snake/newt system represents an elegant case study highlighting the potential power of coevolutionary arms races in predator–prey systems in driving trait evolution.

In addition to directional escalation of trait values, frequency dependent selection dynamics during coevolutionary arms races may lead to long-term maintenance of genetic diversity in populations. Selection should favor parasite phenotypes that are best suited to attacking the most common phenotype in the host population. As those parasite phenotypes

increase in number, the fitness of the most common host phenotype will decline, and fitness increases for previously rare host phenotypes that can avoid or fend off the now-common parasite phenotypes. The outcome of these dynamics may be to favor host populations that are heterogeneous with respect to defensive traits. In our own immune systems, the tremendous diversity of our MHC genes may partly be explained by our coevolutionary history with parasites.

Codiversification

Another potential outcome of coevolution in predator or parasite systems is codiversification. Instead of the back-and-forth struggle of trait evolution in an arms race, reciprocal selection pressures imposed by predators or parasites and their prey or hosts may lead to reciprocal diversification in both trophic levels. One method of reducing predation or parasitism pressure may be for a prey or host species to escape from their enemies by adopting new habitats. Divergent adaptation to novel habitats or niches is the basic premise underlying ecological speciation. The relatively enemy-free habitat of the derived population may not last long, however, as new enemies may move in to take advantage of the flourishing new resource. These new enemies may be derived from the previous enemy population, now undergoing divergent adaptation in lock-step with its old coevolutionary partner or an entirely new set of enemies may move in.

Just as selection may favor shifts of prey species into new habitats, selection may favor predators and parasites that can find new victims. If a prey species gains a strong upper hand in defense, there may not be sufficient genetic variation in the predator population for an adequate coevolutionary counter move. The resulting fitness landscape may favor predator populations improving their capture rate (parameter c in the model above) by exploiting different, more susceptible prey species. In systems involving a high degree of specialization, like parasitoid insects, these shifts may also trigger ecological speciation events. Lock-step codiversification is expected to produce matching phylogenies in the species of both trophic levels. However, more complex patterns of host shifting may result in discordant phylogenetic patterns that are nonetheless driven by coevolution. For example, even if a novel enemy species came from outside the ancestral system, evolutionary changes in one species are still having a direct effect on the fitness landscape of the other.

One prime example of codiversification in action is the case of the apple maggot fly, *Rhagoletis pomonella*, and the specialist parasitoid wasps that attack it. The apple maggot fly was originally a specialist attacking the fruit of hawthorn trees (*Crataegus* sp.) throughout much of North America. Domestic apples were introduced to North America from Eurasia in the seventeenth century. About 150 years after this introduction, a population of these flies shifted and began attacking apples instead of hawthorn fruit (Bush, 1969). Genetic and phenotypic evidence has confirmed that these two populations are now strongly reproductively isolated and are on the path to becoming separate species. The apple and hawthorn flies differ in their chemosensory response to host fruit volatiles and in their life history timing (coinciding with differences in the timing of fruit ripening of their respective hosts). Four parasitoid wasp species specialize in attacking the apple maggot fly, and predation by these wasps may have been a key factor in the selective advantage of the shift to apples. Parasitoid rates in the hawthorn race can be quite high (sometimes in excess of 50%). Apples are considerably larger than hawthorns, with much more room for fly larvae to hide from the ovipositors of wasps on the fruit surface. This enemy-free space is thought to be a major reason behind the shift to apples (Feder, 1995).

However, the apple-infesting populations of *R. pomonella* are not entirely free of parasitoid enemies. The incipient speciation of the apple flies has led to incipient speciation in the wasps as well. The most prevalent of the four parasitoids, *Diachasma alloeum*, shows strikingly similar patterns of ecological divergence and reproductive isolation (Forbes *et al.*, 2009). These wasps lay eggs into late instar fly larvae tunneling through the fruit. The wasps infesting different races of flies have differentiated in the same key ecological traits that separate the flies: response to fruit olfactory cues, the first crucial step in finding their larval quarry and life history timing specifically in synch with the life cycle of apple flies. Interestingly, genetic evidence suggests that this is not a simple case of lock-step codiversification. Rather, the proximate ancestor of the apple fly-infesting wasps appears to be *D. alloeum* populations specialized to attacking the blueberry maggot fly, *Rhagoletis mendax*. Thus, the coevolutionary consequences of divergent adaptation in one species are not restricted to the original interaction partner but can ripple further out into the ecological community.

Parasite Transmission and the Attenuation of Virulence

In many parasite–host systems, effective transmission of parasite offspring to new hosts is a critical component of parasite success. It is likely that tradeoffs between efficient use of host resources (conferring greater fitness costs to the host) and transmission among hosts are common. Parasite transmission may require close contact between host individuals. Parasites that grow and reproduce quickly by efficiently pillaging the host's body may render their hosts too ill to pass their progeny on to new hosts. An aggressive parasite could make a host too weak to move widely and interact with conspecifics, or could kill the host before any opportunity for transmission.

One solution to this dilemma is for parasites to alter their host's phenotypes specifically to maximize transmission. This has important consequences for human disease. Many of the symptoms induced by parasites directly impact the success of parasite transmission. It is likely no coincidence that the main symptoms of infections by waterborne parasites such as *Vibrio cholera* (the pathogen responsible for cholera) or *Giardia lamblia* involve severe digestive distress, a surefire way to quickly reinfest water used by hosts. Similarly, the violent behavioral symptoms of rabies infections maximize the transmission of the rabies virus through saliva.

Instead of entirely hijacking host phenotypes, some parasites may increase transmission success by minimizing the costs imposed on their hosts. Healthier hosts may live longer,

move further, and interact with more conspecifics, ultimately leading to greater transmission and dispersal for the parasite. Thus, in situations where transmission is limiting, natural selection may favor reduced virulence in the parasite populations. A famous example of this phenomenon occurred during an attempt at biocontrol of invasive rabbits in Australia (Fenner, 1983). European rabbits (*Oryctolagus cuniculus*) were introduced to Australia during the mid-nineteenth century. The combination of their rapid reproduction rate and a relatively depauperate predator community in Australia led to an explosion of the rabbit population, causing widespread environmental and economic damage. A solution to the rabbit invasion appeared when an extremely virulent Myxoma virus was discovered in a population of captive rabbits in South America. The virus was intentionally introduced to the Australian rabbit population in 1950. The plan appeared to be a great success in the first couple of years. The virus was nearly always lethal, and the rabbit population declined by more than 75%. However, as the density of the rabbit population plummeted, transmission became an important selective force for the virus. Aggressively virulent strains of the virus caused rabbits (and the viruses they harbored) to die before they were likely to come into contact with other rabbits, while less virulent strains were more likely to be transmitted and survive. By 1952, less virulent strains of the virus began to proliferate and the rabbit population rebounded. The coevolutionary combination of attenuated virulence by the virus and genetic resistance to infection by the rabbits has led to the long-term persistence of Myxoma-infected rabbit populations in Australia.

The above example illustrated how parasitic interactions may evolve to become less costly to host species. The difference between parasitism, commensalism, and mutualism is determined by the net result of the costs and benefits to the symbiont partners. Thus, a sufficient decrease in virulence could tip the entire balance of the interaction into a commensal or even mutualistic relationship. Such shifts in the net result of species interactions may occur in both directions. In a mutualism, if one species starts to cheat by failing to provide a benefit to its partner, the interaction may immediately become parasitic in nature. Similarly, if selection on transmission success by parasites leads to minimizing fitness costs for hosts, it is not difficult to imagine a scenario where the net fitness costs to the host are minimized by the parasite providing some offsetting benefit, which could tip the balance into mutualist territory. A striking example of this phenomenon occurred serendipitously in the laboratory of Dr. Kwang Jeon of the University of Tennessee (**Figure 3**; Jeon, 1972). Jeon was conducting cyto-nuclear transplant experiments with lab lines of the amoeba *Amoeba discoides*. In 1966, some of the amoeba cultures became infected with very high numbers of an intracellular bacterial parasite. The bacteria appeared to be highly virulent; most newly infected cells died. Those that survived showed markedly slower generation time, smaller size, and greater susceptibility to starvation and mechanical stress. Because of the amount of work that had gone into this project, the amoeba lines were kept alive and nursed along for 5 years. During that time, the infection persisted, but the negative effects completely disappeared. But this was not a straightforward case of attenuation of virulence. In that 5-year span, Jeon's amoebae not only became resistant to the effects of the bacteria but they also became dependent on them. Nuclei from the now resistant infected lines performed very poorly when transferred to cells from uninfected lines. These infected-into-uninfected transfers resulted in a greater than 10-fold reduction in survivorship compared to transfers within infected or uninfected cells. Similarly, the bacteria could not be cultured outside of the amoebae, indicating that like many endoparasites, they were obligatorily dependent on their hosts. Thus, in only 5 years ($\sim$1000 amoeba generations) a clearly parasitic interaction evolved toward a nearly obligatory mutualism.

Coevolution and Ecological Dynamics

Coevolutionary responses have important implications for community dynamics in predator–prey and parasite–host systems. Population dynamics and evolutionary change act at the same time scale: generational time. It was once common for biologists to make a clear distinction between biological processes operating in 'ecological time' or 'evolutionary time.' However, this old dichotomy is neither correct nor useful. Both population demographics and evolutionary change constantly inform and affect one another. The fitness effects of particular alleles depend on the specific ecological and demographic contexts of the population. Likewise, shifts in allele frequencies between generations can alter the outcome of ecological interactions. In the simple Lotka–Volterra model presented above, selective deaths of both predator and prey species may instantaneously change the trait values that control the capture rate parameter (c). Explicity considering this additional dimension of change in models of species interactions demonstrates that on-going coevolution may strongly affect the overall dynamics of predator–prey systems (Abrams, 2001).

Interestingly, coevolutionary responses have the potential to stabilize otherwise unstable systems or destabilize otherwise stable systems (Abrams, 2001). One of the important determinants of this appears to be whether the traits involved in prey defense are limited in the potential directionality of their evolutionary response (Abrams and Matsuda, 1997; Gavrilets, 1997). That is, are prey traits likely to evolve in a single direction or can advantageous mismatches be achieved by moving bidirectionally along the trait axis? Unidirectional defensive trait evolution tends to make systems more stable, while bidirectional defensive trait evolution tends to induce cycles in previously stable systems or increase the amplitude of existing cycles.

Coevolution may alter population dynamics, but population dynamics may also influence the outcome of coevolution. Whether arms races continue to escalate may be determined by the particular mathematical relationship between predator and prey populations. For instance, the functional response of predators to greater prey population densities is a key consideration (Abrams, 1986). Stronger prey defense may result in a lower capture rate (c) for predators, but the resulting higher prey densities may compensate for this change. This suggests that selection imposed by prey defensive traits on predator traits may generally be weaker than the

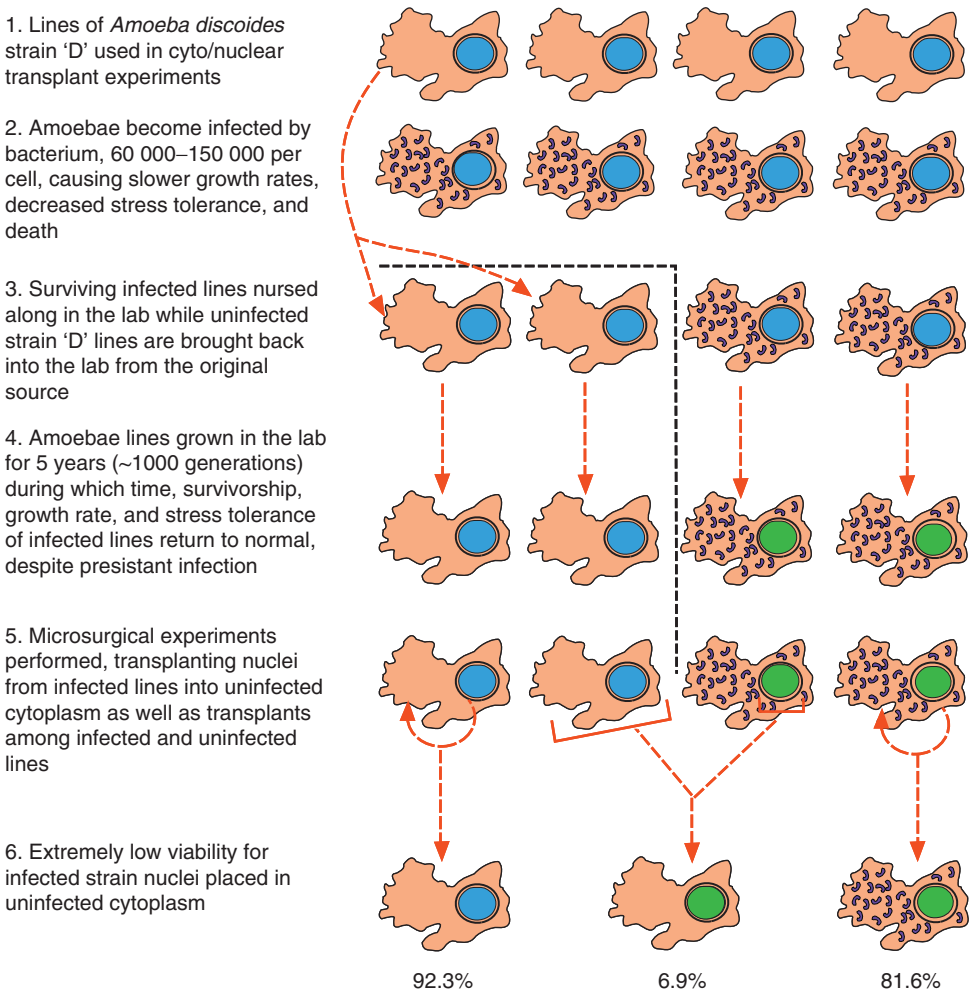

Figure 3 Schematic of coevolutionary shift from parasitism to mutualism between *Amoeba discoides* and a bacterial endosymbiont in the lab of Dr. Kwang Jeon at the University of Tennessee in the late 1960s. Diagram based on description of events, methods, and results by Jeon, K., 1972. Development of cellular dependence on infective organisms: Micurgical studies in amoebas. Science 176, 1122–1123.

reverse, with stronger predator attack traits resulting in both higher per capita capture rates and higher predator densities. This reciprocal feedback between coevolution and community demographic dynamics in predation and parasitism systems calls attention to the continued need for greater integration between evolutionary biology and ecology.

Macroevolutionary Patterns

The examples above demonstrate the various ways that coevolution affects predator–prey and parasite–host systems. While they may be difficult to study empirically, the fingerprints of coevolution are ubiquitous in ecological communities. But what effect has coevolution between predators and prey and parasites and hosts had on broad scale patterns of biodiversity over geological time? Do we see a clear signature of persistent arms races or codiversification in the fossil record? The answer may be that coevolution does indeed drive macroevolutionary patterns, but perhaps in a diffuse and limited fashion. It is nearly impossible to study pairwise specialist interactions in the fossil record; organisms rarely leave behind precise records of who they ate and who ate them. However, paleontologists have been able to take the approach of studying patterns within ecological guilds that were likely to be broadly interacting.

Paleontologist Robert Bakker analyzed coevolutionary trends in morphology between cursorial (chasing) mammalian predators and their primary prey, ungulates, across the entire history of their shared existence from the beginning of the Cenozoic period until the present day (Bakker, 1983). This is a case where the primary trait affecting the parameter c is basically the same for both predator and prey: speed. With few exceptions, ungulate species rely on speed during the early stages of a chase to escape predators, and it is this fleetness of foot of both predator and prey that determines the outcome of most hunts. The basic expectation of coevolution between these guilds would be increased running speed through time. Directional change in skeletal morphology for both ungulates and predators indicates that both groups have become

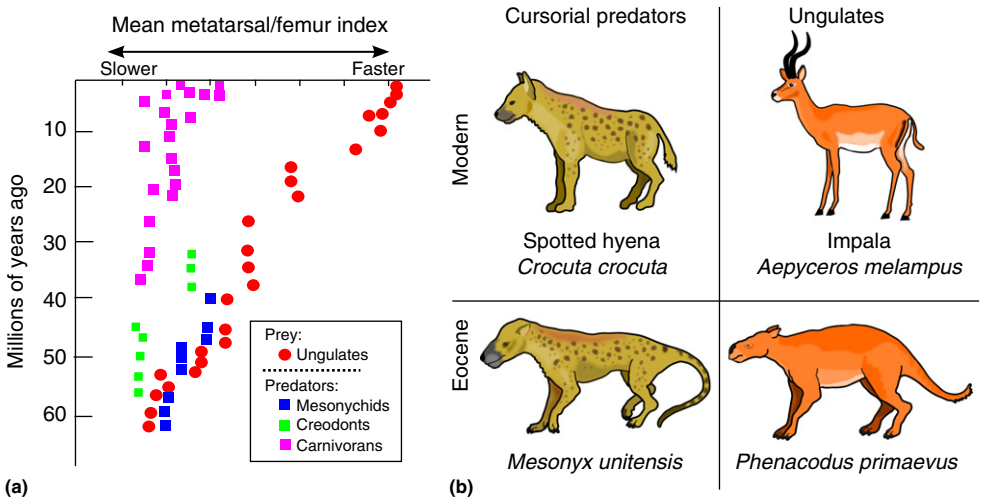

Figure 4 (a) Plot of inferred running speed (based on limb ratios) over time for ungulates (red circles), and three lineages of cursorial mammalian carnivores, mesonychids (blue squares), creodonts (green squares), and carnivorans (pink squares). These data highlight the continuous directional evolution of running speed in hoofed mammals, but not their predators, at the macroevolutionary scale. Based on data presented in Bakker, R.T., 1983. The deer flees, the wolf pursues: Incongruencies in predator–prey coevolution. In: Futuyma, D.J., Slatkin, M. (Eds.), Coevolution. Sunderland, MA: Sinauer. (b) Example cursorial predators (left) and ungulates (right) from two time along the graph, the Holocene (modern times) (top) and the late Eocene (~50 million years ago). These examples highlight the greater change in limb morphology for hoofed herbivores vs. running predators over the past 50 million years.

increasingly swifter. Several traits associated with greater speed including less acute limb angles, more constrained movement in ball joints, the reduction of side digits, and shorter phalanges show clear progressions in both groups. However, the pace of speed-related skeletal adaptation in ungulates far outpaces that of predators. Ungulates have consistently been getting faster, while cursorial predators have been unable to keep up (pun intended) (Figure 4). Bakker argues that basic trophic structure may be responsible for the widening gap in this arms race. The necessarily greater population size of the prey species makes them less prone to extinction and more likely to stumble upon evolutionary innovations for speed. Alternatively, this could be a case of stronger tradeoffs for the predator species; many carnivores use their hands and claws for digging, fighting, or manipulating prey, and such diverse functional requirements may prevent carnivores from evolving super-specialized running tools. In either case, the fossil record suggests that predator–prey coevolution can indeed drive important long-term evolutionary trends but that there are likely considerable limits to perpetual escalation in arms races.

Glossary

Aggregation Proteins are said to 'aggregate' if they specifically or nonspecifically stick to other proteins and form large protein complexes without biological function.
Complex A macromolecular assembly of two or more proteins. When multiple proteins bind to each other, they are said to form a 'complex.'
Conformation The specific, three-dimensional arrangement of all atoms in a protein.
Enzyme A protein that catalyzes a chemical reaction.
Epistasis Interaction between two or more mutations in a protein, such that the fitness effect of one mutation is altered by the presence or absence of the other mutations. (Note that this definition differs from the standard genetical definition which considers functional or fitness interactions among loci rather than individual sites in a protein.)
Folded state A protein is said to be in its 'folded state' when it is folded into its native conformation.
Hydrophobic The biophysical property of molecules to segregate themselves from water. Hydrophobic amino acids tend to be found in the core of proteins, where they are protected from water. When hydrophobic amino acids are exposed on the protein surface, such proteins tend to 'aggregate.'
Misfolding Proteins are said to be 'misfolded' when they have taken on a conformation other than their native conformation. A misfolded protein is similar to an unfolded protein; the main difference is that the term 'misfolded' specifically carries the connotation of a negative effect. Misfolded proteins are expected to have deleterious effects on organism fitness, while unfolded proteins may or may not have such effects.
Native conformation The lowest energy conformation of a protein, also often referred to as 'ground state.' Most proteins carry out their biological function when they are folded into their native conformation.
Solvent accessibility The extent to which an amino acid in a protein is exposed to solvent (i.e., water). Amino acids on the surface of a protein tend to have high solvent accessibility, and amino acids in the core tend to have low solvent accessibility.
Stability The extent to which a protein can be found in its native conformation. The more stable a protein is, the more likely it is to assume and remain in its native conformation. Formally, stability is the difference in free energy between the native conformation and the ensemble of all unfolded states.
Unfolded state The opposite of folded state. A protein is said to be in its 'unfolded state' when it is not folded into its native conformation.

Introduction

Proteins are among the most fundamental components of living organisms. Proteins can act both as structural building blocks, for example, to build tissues such as hair, skin, nail, muscle, connective tissue, or bones, and as functional building blocks, where they serve as biochemical machines that carry out specific functions, such as digestion, sensing (e.g., of light, taste, or smell), synthesis or degradation of metabolites, and many others. The evolution of protein-coding genes is shaped by the biophysical and biochemical effects mutations have on the expressed proteins. In particular, mutations that negatively affect a protein's ability to carry out its native function will, in general, be deleterious and selected against. By contrast, mutations that have no measurable effect on the structure and function of a protein will generally be neutral. Such mutations will accumulate in genomes in proportion to the rate at which they are generated. Finally, mutations that alter a protein's function can occasionally be beneficial to the organism. An example could be a viral protein that acquires a mutation that reduces the virus's susceptibility to an antiviral drug. Such beneficial mutations can often accumulate quite rapidly, in particular in organisms that experience high mutation rates.

In the next section, we will describe the main mechanisms shaping protein biophysics. The subsequent section connects these mechanisms to the effects of individual mutations. The final section elaborates on how these mechanisms may interact to shape sequence evolution. For a more in-depth treatment of these and related topics, see e.g., Liberles *et al.* (2012), Sikosek and Chan (2014).

Biophysical Mechanisms

There are three broad categories of mechanisms that connect protein biophysics to organism fitness: First, proteins need to fold stably into their native structure. Second, proteins need to carry out their specific function. Third, proteins must not be toxic, i.e., they must not harm the organism expressing them.

Protein Folding and Protein Stability

Protein folding and protein stability are governed by basic thermodynamics. A protein is a polymer (a long molecule composed of many repeated subunits) that can take on many different conformations. It is useful to think of a protein as a

string of beads, where the beads represent the individual amino-acid residues. There are myriad ways in which such a string of beads can be arranged in space, and we refer to each individual arrangement as a 'conformation.' In the case of proteins, the beads (residues) have different chemical properties: some attract each other, some repel each other, and some try to avoid water (are hydrophobic). As a result, different conformations have different energies. For example, if two residues repel each other, then conformations in which the residues are in physical contact will tend to have higher energies. In contrast, if two residues attract each other, then conformations in which the residues are in physical contact will tend to have lower energies. Note, however, that because the residues are connected in a fixed polymer chain, there may not be a conformation that forms every favorable contact and avoids every unfavorable one – however, there will always be some conformations that have more favorable and less unfavorable contacts (and so lower energies) than others.

Given the simple energetic picture of a protein as a string of beads, one might think that proteins simply collapse into the conformation that minimizes their energy and then stay there. However, things are not quite that simple, because proteins generally exist in environments that have a temperature greater than absolute zero, meaning that the atoms and residues in a protein are always in motion. As a consequence, a protein doesn't just remain fixed in one low-energy conformation; instead, over time it takes on many different conformations.

Thermodynamics allow us to calculate the likelihood that a protein will be found in a given conformation. Assume we could enumerate all possible conformations a protein can assume and wanted to know the probability that we will find the protein in conformation i. At equilibrium, that probability is given by the Boltzmann distribution

$$P_i = e^{-E_i/kT}/Z$$

where E_i is the energy of the conformation i, T is the temperature, k is the Boltzmann constant (a numerical constant converting temperature into energy), and Z is the partition function

$$Z = \sum_j e^{-E_j/kT}$$

As the equation for P_i clearly shows, the lower (more negative) the energy of a conformation the more likely it is that the protein will assume that conformation. However, this effect is counteracted by temperature. The higher the temperature, the more often we will find a protein in a higher-energy conformation.

In practice, enumerating all possible conformations that a protein can assume is not very useful. First, there are a vast number of possible conformations. Second, many of these conformations are quite similar to each other, and therefore it is preferable to group them into more broadly defined conformational categories. Third, many of the theoretically possible conformations are highly unlikely to ever occur due to their high energy, and therefore can be disregarded. In fact, in practice we are often only interested in two broad classes of conformations. The first, which we usually call the 'native conformation' or 'folded state,' corresponds to the set of (usually very similar) conformations the protein will typically be found in under physiologic conditions in an organism. In general, a protein has to be in its folded state to carry out its biological function. The second, which we usually call the 'unfolded' or 'misfolded' state, comprises all other possible conformations.

It turns out that the Boltzmann formula applies to these broad categories of conformations, as long as we replace the energy E in the formula with the Gibbs free energy G. Thus, we can write

$$\frac{P_{\text{folded}}}{P_{\text{unfolded}}} = \frac{e^{-G_{\text{folded}}/kT}}{e^{-G_{\text{unfolded}}/kT}} = e^{-\Delta G/kT}$$

where $\Delta G = G_{\text{folded}} - G_{\text{unfolded}}$ is the difference in free energy between the folded and the unfolded state. ΔG is commonly referred to simply as the 'stability' of the protein. The lower (more negative) the ΔG, the more likely the protein is going to be found in its native conformation. In fact, since we defined the unfolded state as all possible conformations that do not belong to the folded state, we have $P_{\text{folded}} = 1 - P_{\text{unfolded}}$, and hence we find that

$$P_{\text{folded}} = \frac{1}{1 + e^{\Delta G/kT}}$$

This simple formula shows us that a protein with $\Delta G = 0$ has a probability of being folded of 0.5, i.e., it can be found in its native conformation exactly half of the time. More negative ΔG values imply the protein is more likely to be folded than unfolded, and positive ΔG values imply the protein is more likely to be unfolded than folded (see also **Figure 1**).

Typical ΔG values for functional proteins tend to be on the order of -5 to -15 kcal mol^{-1}. These values tell us that at room temperature ($T \approx 294$ K), proteins are typically unfolded less than 0.02% of the time, and the more stable proteins are

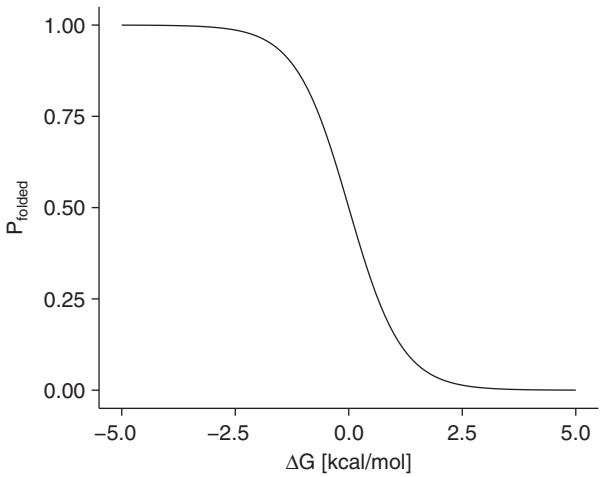

Figure 1 Probability of finding a protein in its native conformation at room temperature ($T = 294$ K), as a function of the protein's stability ΔG. At typical stabilities of $\Delta G = -5$ to -15 kcal mol^{-1}, proteins are virtually always properly folded. However, as ΔG increases, the proportion of time that a protein spends in its native conformation declines rapidly, reaching 50% at $\Delta G = 0$ kcal mol^{-1} and declining to nearly 0% around $\Delta G = 2.5$ kcal mol^{-1}. This figure assumes the protein conformations are at equilibrium.

virtually never unfolded. (The Boltzmann constant is $k = 0.001\ 987$ kcal mol^{-1} K^{-1}.)

Protein Function: Catalytic Sites, Protein–Protein Interactions, Ligand Binding

In addition to folding into a sufficiently stable native conformation, proteins often perform specific biochemical functions such as catalyzing chemical reactions, engaging in protein–protein interactions, or binding to ligands.

Catalysis usually requires two ingredients: (1) The protein's native conformation needs to form an active site with a size and shape suitable to accommodate the target substrate. (2) In the active site, there need to be a few key amino-acid side chains that catalyze the actual enzymatic reaction. Often a protein containing hundreds of residues may have only a handful of amino acids that are directly involved in catalysis.

Protein–protein interactions and/or ligand binding generally require suitable patches on the surface of the 3D structure where the protein partner or ligand can bind. There is no simple rule to what these patches may look like; their properties are largely determined by the biophysical properties of the binding partner.

Toxic Functions and Protein Misfolding

One might think that the worst that can happen to a protein, in terms of organism fitness, is the loss of its function. However, sometimes proteins do worse than just losing their function. Sometimes they actually become toxic, and exert deleterious effects that exceed those expected from the simple waste of resources on a nonfunctional protein.

The most common form of protein toxicity arises through misfolding. Misfolded proteins frequently expose hydrophobic residues on their surface, and these residues can bind to other proteins. As a result, the misfolded proteins aggregate, and these aggregates interfere with proper functioning of the cellular machinery. In humans, many diseases, in particular neurodegenerative diseases such as Alzheimer's and Huntington's, are associated with aggregated misfolded proteins. However, it seems that this is not just an issue for humans. In fact, evidence of selection against protein misfolding can be found throughout the tree of life (Drummond and Wilke, 2009, 2008).

Biophysical Effects of Mutations

The previous section has introduced several of the key mechanisms needed to understand protein biophysics. We now discuss how these mechanisms relate to mutations.

Mutations and Stability Changes

The stability ΔG of a protein is a property of the protein's specific amino-acid sequence. If we make a mutation somewhere in the protein, then ΔG will change. For this reason, we frequently are interested in the 'stability changes' associated with individual mutations. For example, assume the wild-type

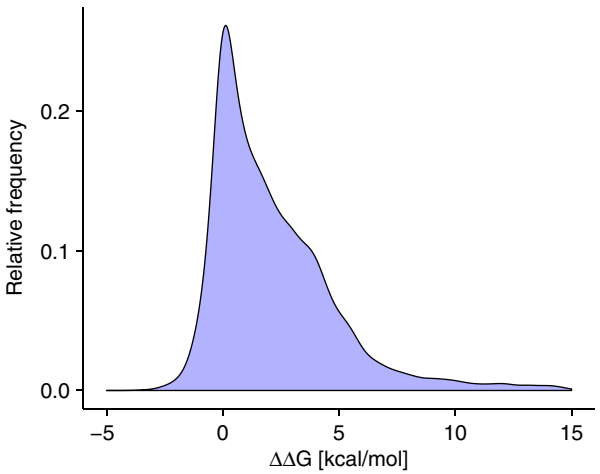

Figure 2 Predicted distribution of $\Delta\Delta G$ values for all single-point mutations in a protein. We see several characteristic features: (1) The majority of the mutations are destabilizing (have $\Delta\Delta G > 0$). (2) The mode of the distribution is near zero, so that a substantial fraction of mutations have only minor effects on stability. (3) Some mutations have destabilizing effects of 5 kcal mol^{-1} or more. Such mutations can, individually, cause a protein to entirely lose the ability to remain stably folded (see **Figure 1** for reference). The data presented are for the protein methionyl tRNA synthetase (PDB ID: 1a8h), as calculated by Echave *et al.* (2015). The $\Delta\Delta G$ values were computationally predicted using the FoldX method (Guerois *et al.*, 2002).

stability of a protein is ΔG_{wt} and the stability of a mutant is ΔG_{mutant}. Then we can define the stability change

$$\Delta\Delta G = \Delta G_{wt} - \Delta G_{mutant}$$

If $\Delta\Delta G < 0$, then the mutation is 'stabilizing,' i.e., it increases the stability of the protein. If $\Delta\Delta G > 0$ on the other hand, then the mutation is 'destabilizing,' i.e., it decreases the stability of the protein. Typical $\Delta\Delta G$ values fall between -5 and $+15$ kcal mol^{-1}, but $\Delta\Delta G$s are more likely to be positive than negative (**Figure 2**). Thus, the majority of mutations reduce the stability of a protein, and many mutations can destabilize a protein to an extent that it loses its ability to fold to its native conformation.

Epistasis

When multiple mutations occur in a protein, they can interact with each other, a situation termed 'epistasis.' Concrete examples would be a mutation that is beneficial in the presence of another mutation and deleterious otherwise, or two deleterious mutations that jointly become beneficial to the organism (**Figure 3**).

Epistasis arises naturally in the context of protein stability. For example, consider a pair of mutations A and B where A alone destabilizes the protein and renders it nonfunctional, but in the presence of B the protein can tolerate mutation A. This situation can arise, for example, if the stability change associated with A, $\Delta\Delta G_A$, is of a magnitude comparable to or exceeding the ΔG_{wt} of the wild-type protein while the stability change associated with B, $\Delta\Delta G_B$, is negative. Thus, in the

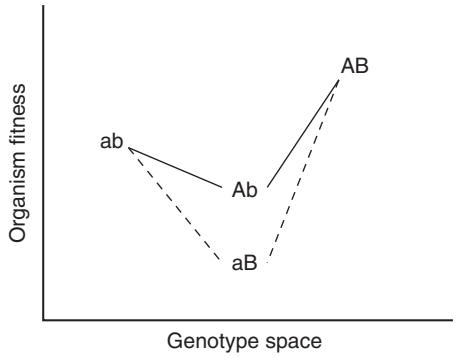

Figure 3 Illustration of interaction between two mutations (epistasis). An organism carrying the wild-type protein (labeled 'ab') has a given fitness. Two individual amino-acid substitutions both create protein variants with lower fitness (labeled 'Ab' and 'aB'). However, in combination, the two substitutions cause the organism to have higher fitness than it had with the wild-type protein. Adapted from Figure 2B of Covert, A.W., Lenski, R.E., Wilke, C.O., Ofria, C., 2013. Experiments on the role of deleterious mutations as stepping stones in adaptive evolution. Proceedings of the National Academy of Sciences of the United States of America 110, E3171–E3178. doi:10.1073/pnas.1313424110.

absence of B, the mutated protein will have stability $\Delta G_{\text{mutant A}=\Delta G\text{wt}} + \Delta\Delta G_A > 0$, but in the presence of B, the mutated protein will have stability $\Delta G_{\text{mutant A}+\text{B}} \approx \Delta G_{\text{wt}} + \Delta\Delta G_A + \Delta\Delta G_B < 0$. In the latter equation, we have used the approximately equals sign ($\approx$) because it is not necessarily the case that the stability changes of two mutations are perfectly additive. In principle, the occurrence of mutation A could alter the magnitude of $\Delta\Delta G_B$ and vice versa. However, in practice, it has been found that stability changes are frequently additive, or at least approximately additive, and substantial, useful insight into protein evolution can be obtained from models that assume $\Delta\Delta G$s are additive (Bloom *et al.*, 2005).

Epistasis can additionally arise through direct interactions between two amino-acid side chains in direct contact with each other in the protein structure. If one of the two amino acids is mutated, the second one may require a compensating mutation. For example, assume amino acid A is large and amino acid B is small. If A gets mutated to a small amino acid, then B may have to be mutated to a large amino acid so that the A–B pair continues to take up the same amount of space in the structure. In the absence of this compensating mutation, the mutation at A may disrupt the protein fold and hence be quite deleterious. These kinds of compensating interactions between contacting amino acids are so common that it is possible to infer 3D contacts in a protein structure from patterns of covariation between sites observed in evolving sequences (Jones *et al.*, 2012).

Protein Stability and Mutations that Generate Novel Function

There are a few general mechanisms of how a mutation may generate a novel function. First, a mutation to a catalytic amino acid in an enzyme may change the type of substrate that is generated by an enzyme-catalyzed reaction. Similarly, mutations in or near the active site may change the active site's shape or size and hence allow for different substrates to enter. Finally, a mutation in a surface patch involved in ligand or protein binding may change the specificity of that patch, and either bind a specific partner more or less tightly than previously, or alternatively may allow the patch to bind a new partner.

In all these cases, besides whatever effect a given mutation has on protein function, the mutation will also change protein stability. And since there is no particular reason why a functionally relevant mutation may have a specific stability effect $\Delta\Delta G$, we can assume that the mutations $\Delta\Delta G$ is simply chosen at random from the $\Delta\Delta G$ distribution. As Figure 2 shows, a randomly chosen $\Delta\Delta G$ will likely be destabilizing. Therefore, we can expect that most mutations that create novel function will also destabilize the protein. In line with this hypothesis, it has been observed that proteins are more likely to evolve novel function if they have previously experienced a stabilizing mutation (Bloom *et al.*, 2006; Gong *et al.*, 2013).

How Protein Biophysics Shapes Sequence Evolution

In this final section, we discuss some examples of larger-scale evolutionary trends that emerge from the biophysical mechanisms governing protein folding and function.

Purifying Selection in the Core of Proteins and in Protein–Protein Interfaces

Typical proteins are several hundred amino acids long. However, only a small fraction of these amino acids are directly involved in the function of the protein, by being catalytic residues or belonging to protein–protein interfaces. The other residues serve primarily as scaffolding, to place the key functional residues into the correct locations in space. Therefore, a majority of sites in a protein experience purifying selection; mutations at these sites are allowed as long as they do not disrupt the protein's stability or alter its native conformation. However, not all sites in a protein are equally important for the protein's stability or conformation. In particular, mutations at surface sites are on average less likely to disrupt the protein than mutations in the core of the protein (Franzosa and Xia, 2009). The simple explanation for this observation is that surface sites participate in fewer residue–residue interactions than core sites, and hence are less likely to be constrained in the types of amino acids they can tolerate.

Similarly, one finds that surface sites in protein–protein interfaces are more conserved than surface sites outside such interfaces. Interface sites experience additional purifying selection to maintain the protein–protein interaction (Franzosa and Xia, 2009). A mutation in a protein–protein interface is deleterious if it destabilizes its protein, if it destabilizes the protein–protein interaction, or both. By contrast, a mutation outside an interface region is deleterious only if it directly affects the stability or fold of its protein.

Positive Selection in Viral Immune Escape

Positive selection, i.e., selection for proteins with modified or novel function, can be observed most readily in viral evolution. Many viruses experience significant selection

pressure to escape their host's immune system, or to be able to cause infections despite vaccination or antiviral treatments.

As an example of immune escape, consider the case of influenza virus. The influenza virus causes annual, seasonal outbreaks in humans. People who successfully fight of an influenza infection acquire immunity to the influenza strain with which they were infected. Similarly, people who get vaccinated tend to be protected against the specific strains against which the vaccine was targeted. However, in both cases, immunity tends to wear off within a few years, and people become again susceptible to the circulating influenza strains. This waning of immunity occurs because every year, the virus accumulates a few additional mutations that make it look different to the human immune system.

Biophysically, this immune escape evolution is similar to the evolution of protein–protein interfaces, only that now selection prefers mutations that eliminate – rather than maintain – binding. The human immune system's primary defense against influenza infections are antibodies that bind proteins exposed on the viral surface, and in particular the protein hemagglutinin (the H in influenza strain classifications such as H1N1 or H3N2). If hemagglutinin experiences a mutation that makes it less of a target to antibodies currently present in the human population, then the virus carrying that mutation will have a selective advantage over viruses not carrying that mutation, and hence the mutation spreads through the viral population. In fact, the most variable regions in influenza hemagglutinin are the regions of the proteins at which antibodies commonly bind (Bush *et al.*, 1999).

Protist Diversification

AGB Simpson and Y Eglit, Dalhousie University, Halifax, NS, Canada

Glossary

Algae Term of convenience for protists that are photosynthetic (or are very closely related to photosynthetic protists).

Amoeba (plural Amoebae) A cell that lacks flagella and produces some kind of pseudopodia, almost always used for locomotion, or feeding, or both.

Bacterivory The ability to feed on prokaryotic cells, almost invariably via phagotrophy.

BYA Billion Years Ago.

Complex plastids Plastids surrounded by more than two membranes, resulting from a higher-order endosymbiosis (e.g., secondary endosymbiosis or tertiary endosymbiosis).

Endosymbiosis Symbiosis where one of the partners (the symbiont) resides inside the cells of the other (the host). The origins of mitochondria and plastids involved a symbiosis of this kind. Also referred to as 'endocytobiosis.'

Flagellate A eukaryotic cell with flagella.

LECA Last eukaryotic common ancestor. The most recent-living population/species from which all extant (i.e., living) eukaryotes are descended.

Macroalgae Term of convenience for algae that are macroscopic and multicellular, or at least have a large, differentiated thallus, for example, 'seaweeds.' Contrast with 'microalgae.'

Microalgae Term of convenience for algae that are unicellular or colonial. Contrast with 'macroalgae.'

Mixotrophy As used here, the ability of an organism to perform both photosynthesis and heterotrophy, specifically via phagotrophy. Note that this term is often used slightly differently in the bacteriological and botanical literature, there referring to photosynthesis combined with heterotrophy of any kind.

MYA Million Years Ago.

Nucleomorph The highly reduced nucleus of the eukaryotic symbiont that gave rise to a complex plastid, still retained within the plastid (in the periplastid compartment). Only a few groups with complex plastids have retained nucleomorphs (cryptophytes and chlorarachniophytes, in particular), whereas the symbiont nucleus has been completely lost in most complex plastids.

Periplastid compartment Also known as 'periplastidial compartment,' or 'PPC.' In complex plastids, the space between the inner two membranes on one side, and outer 1–2 membranes on the other. Represents the cytoplasmic compartment of the eukaryotic symbiont that gave rise to the plastid. Contains the nucleomorph, as well as eukaryotic-type ribosomes, in nucleomorph-bearing plastids.

Phagotrophy The ability of a cell to feed by ingesting large particles, usually other cells.

Plastid General term for the photosynthetic organelles of eukaryotes (e.g., the chloroplasts of green algae) and related non-photosynthetic organelles (e.g., the apicoplasts of many apicomplexan parasites).

Primary alga A protist with a plastid that descends directly from an event of primary endosymbiosis, in other words, with a plastid that is directly descended from a photosynthetic bacterium.

Primary endosymbiosis Endosymbiosis involving a prokaryotic symbiont, rather than eukaryotic symbiont. Used with reference to the origins of organelles of endosymbiotic origin, especially plastids.

Protists Eukaryotes that are not animals (Metazoa), land plants, or true fungi.

Protozoa Term of convenience for protists that are heterotrophic, but not fungus-like.

Secondary alga A protist with a (photosynthetic) plastid that directly descends from an event of secondary endosymbiosis, in other words, with a plastid that is most immediately descended from a primary alga, rather than from a photosynthetic bacterium.

Secondary endosymbiosis A term used with reference to the origins of 'complex' plastids. Refers to an endosymbiosis where the symbiont was a primary alga (i.e., had a plastid because of descent from an event of primary endosymbiosis).

Tertiary endosymbiosis A term used with reference to the origins of 'complex' plastids. Refers to an endosymbiosis where the symbiont was a secondary alga (i.e., had a plastid because of descent from an event of secondary endosymbiosis).

What are Protists? Evolutionary and Ecological Importance

Eukaryotic organisms are distinguished from prokaryotes by numerous of cellular and genomic traits, including the possession of distinct nuclei containing a genome that is distributed across multiple linear chromosomes, many-armed endomembrane systems, organelles that arose through endosymbiosis (e.g., mitochondria and, frequently, plastids), and more complex cytoskeletal systems. Eukaryotes are also remarkable because they include the large many-celled organisms that seem, at first glance, to dominate the Earth – principally animals (Metazoa), land plants, and fungi. However, animals, plants, and fungi are actually only three highly specialized and unusual lineages amongst the very broad diversity of eukaryotic life forms. The other eukaryotic organisms are collectively called protists. These are mostly unicellular and microscopic, with some important and spectacular exceptions.

 doi:10.1016/B978-0-12-800049-6.00247-X

The existence of protists is well known in the abstract, but their tremendous significance for understanding the evolution and biodiversity of eukaryotes is routinely underappreciated. They are also of great ecological importance and take on a huge variety of roles in natural systems.

According to the most widely used definition, protists are simply those eukaryotes that are not true animals, land plants, or true fungi. 'Protists' does not represent a phylogenetically cohesive grouping of closely related organisms, neither do protists share any biological features other than those that are common to all eukaryotes. Most subgroups of protists are loosely categorized as either algae or protozoa. Algae are 'plant-like' in that they are photosynthetic (or are closely related to photosynthetic forms). They range from small unicellular forms, many of which are motile, through to multicellular macroalgae that can rival large land plants in size and complexity. Unicellular and colonial algae are responsible for a large proportion of aquatic primary production, while macroalgae of various kinds are dominant components of ecosystems of regional significance, especially in coastal waters (examples include kelp forests and the algal components of tropical reefs). Protozoa are heterotrophic, and most are 'animal-like' in that they ingest solid food particles, using phagotrophy. The great majority of protozoa are unicellular or exist as simple many-celled forms (e.g., colonies of similar cells), and motility is a common trait. Many protozoa are free-living, and most of these prey on prokaryotes ('bacterivory') or other microbial eukaryotes. A substantial proportion of protozoa are instead parasites of animals, plants, or other protists. Diseases of humans caused by protozoa include malaria, amoebic dysentery, sleeping sickness, Chagas' disease, leishmaniasis, giardiasis ('beaver fever'), toxoplasmosis, and the sexually transmitted infection trichomoniasis.

Both algae and protozoa are rough terms of convenience that do not refer either to phylogenetically coherent groups, or to clear-cut ecological types. For example, many unicellular photosynthetic algae are 'mixotrophs' that will prey upon other microorganisms (McKie-Krisberg and Sanders, 2014; Sanders, 1991; Stoecker, 1999). Predation upon prokaryotes by mixotrophic algae can actually exceed bacterivory by heterotrophic protozoa in some systems (see Unrein *et al.*, 2007). There are also several heterotrophic protist groups that are unrelated to true fungi, but nonetheless resemble fungi in some aspect of their life cycle, for example, in existing primarily as a mycelium of hyphae and/or by producing a fruiting body as a reproductive or dispersal structure (examples include oomycetes and slime molds – see below). Such groups are often not considered 'protozoa,' and historically at least, have typically been studied by mycologists (see, e.g., Stephenson, 2011).

The Origin of Eukaryotes – A Brief Overview

It is more-or-less universally assumed that the first members of the eukaryote lineage were unicellular and that the last common ancestor of living eukaryotes (last eukaryotic common ancestor, or 'LECA') was also a single-celled organism, as are many of the eukaryotic lineages alive today (see below). In other words, it is clear that questions of how eukaryote cells evolved and diversified are, to a large extent, questions about protists, and that protists are a crucial source of the information required to answer them.

Ancient History of Eukaryotes

Most researchers who study eukaryote evolution (though not all) assume that eukaryotic cells evolved from prokaryotic ancestors. The closest relatives of eukaryotes among the prokaryotes are the Archaea. Recent sophisticated phylogenetic analyses support the hypothesis that eukaryotes actually evolved from within the diversity of living archaea (i.e., that archaea are paraphyletic), and this is further supported by the discovery of various mixtures of a few 'eukaryotic' genes in the genomes of the archaeal groups inferred to be most closely related to eukaryotes (Williams *et al.*, 2012, 2013; Spang *et al.*, 2015). This inference is depicted in cartoon form in **Figure 1(a)**. Nonetheless, irrespective of the exact relationship between the Archaea and eukaryotes, there is still a huge gulf in cellular organization between Archaea (or at least those that have been well studied to date – see Williams and Embley, 2015) and living protists. Comparative cell structure and genome analyses across eukaryotes, especially protists, has demonstrated that this distinction extends back to the common ancestors of living eukaryotes. In other words, LECA was already a eukaryotic cell of essentially 'fully developed' complexity (Koumandou *et al.*, 2013). The attempt to understand the actual evolution of the 'full eukaryotic cell' prior to LECA is an extremely vibrant, if contentious, discipline, but mostly beyond the scope of this article (though see comments on the mitochondrion, below). This topic is covered in detail in at least two excellent recent collections of review articles (Keeling and Koonin, 2014; Williams and Embley, 2015).

From the current understanding of the phylogenetic tree of living eukaryotes (see below), it is routinely inferred that LECA was a heterotrophic protozoan, most probably a single-celled flagellate (i.e., with eukaryotic flagella). Examinations of the cytoskeletons of living eukaryotes, combined with current phylogenetic estimates, suggest that LECA probably had two dissimilar flagella, and a complex microtubular cytoskeleton that defined the cell shape, including supporting a specialized region of the cell adapted for feeding by phagocytosis (Cavalier-Smith, 2013; Heiss *et al.*, 2011, 2013; Yubuki and Leander, 2013).

There are tremendous uncertainties concerning the timeline of eukaryote diversification. The fossil record of eukaryotes beyond ~750 MYA remains extremely sparse and limited in detail. The earliest fossils considered to potentially represent eukaryotic organisms reach back to more than 2 BYA (and possibly more than 3 BYA), but are identified on very limited criteria, primarily that their size and/or complexity is more characteristic of living eukaryotes than of living prokaryotes (Butterfield, 2015; Javaux *et al.*, 2010). The probable eukaryotes most solidly identified by these criteria date to ~1.6 BYA and younger, while fossils that can be assigned with high confidence to particular living eukaryote groups are all 1.2 BYA and younger (Butterfield, 2000, 2015; Butterfield *et al.*, 1990; Javaux *et al.*, 2004; Pang *et al.*, 2013; Porter and Knoll, 2000). Molecular dating approaches (based on multigene datasets assembled from living eukaryotes) that are calibrated using this latter part of the fossil record have also been

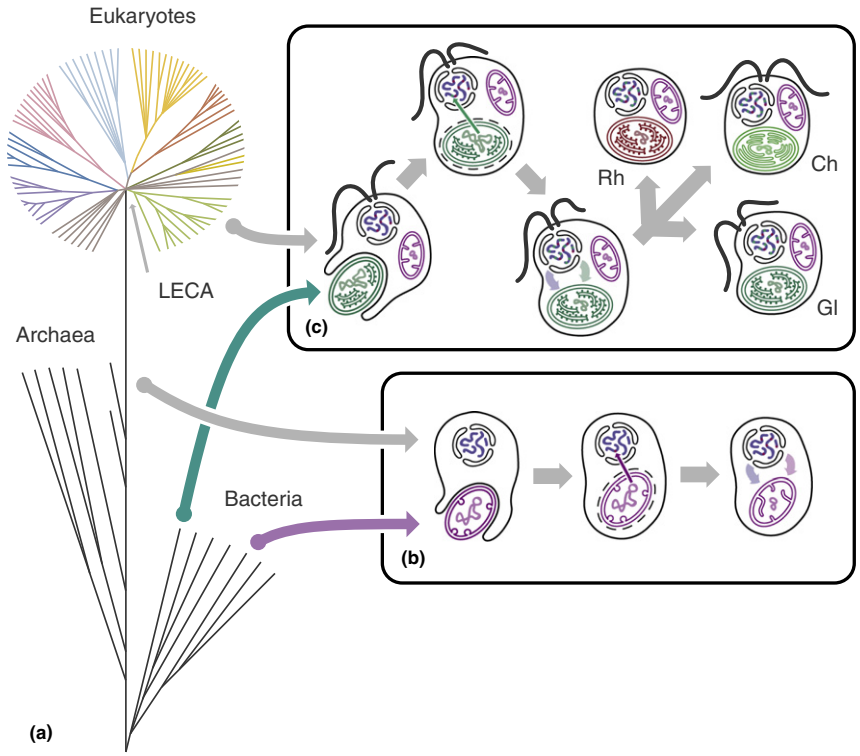

Figure 1 Early history of eukaryotic cells. (a) Simplified view of the Tree of Life, indicating the likely relationship between eukaryotes and a paraphyletic archaea group, and contextualizing the events of (primary) endosymbiosis leading to mitochondria and plastids in eukaryotic cells, respectively, before and after the last eukaryotic common ancestor (LECA). The colored branches within the eukaryote subtree represent major groupings, detailed in **Figure 3**. (b) Mitochondrial symbiosis between a member of the eukaryote lineage, and an alphaproteobacterium. Note that there is debate as to whether the nucleus was present in the eukaryote-lineage host prior to the mitochondrial symbiosis, and also whether the alphaproteobacterial symbiont was acquired by phagocytosis (see text); both are shown here for simplicity. The host vacuolar membrane surrounding the symbiont (if ever present) was lost, while both the cell membrane and outer membrane of the bacterium were retained. The evolutionary transformation of the bacterial symbiont into an organelle involved genome reduction, including endosymbiotic gene transfer to the nuclear/pre-nuclear genome (narrow purple arrow), and also the targeting to the mitochondrion of nucleus-encoded proteins, including some originally of endosymbiont origin (broad purple arrow) but also others originating from the nuclear lineage or elsewhere (broad blue arrow). Implied homology between alphaproteobacterial cell membrane invaginations and mitochondrial cristae follows Muñoz-Gómez *et al.* (2015). (c) Primary plastid endosymbiosis between a eukaryote ancestral to Archaeplastida and a cyanobacterium engulfed via phagocytosis. Early in the symbiosis, the host vacuolar membrane was lost, but both cyanobacterial membranes were retained. As with mitochondria, the evolutionary transformation of the symbiont into an organelle included genome reduction, endosymbiotic gene transfer to the nucleus (narrow green arrow), and the targeting to the plastid of nucleus-encoded proteins of cyanobacterial origin, and other origins (broad green and blue arrows). This primary plastid was inherited directly by the three archaeplastid groups: Rhodophyta (Rh), Chloroplastida (Ch), and Glaucophyta (Gl).

used to infer the ages of early eukaryotes. Such analyses show a lot of method-dependence and uncertainty, but have generally estimated ages for LECA between 1 and 2 BYA (with most estimates toward the lower end of this range), followed by a relatively rapid divergence of the major extant eukaryote groups discussed below (see Eme *et al.*, 2014). In summary, most researchers in this subdiscipline infer that eukaryote life had evolved by ~1.5 BYA (and possibly a long time before that), with LECA dating to some time before ~1 BYA.

Endosymbiosis; The Mitochondrion

The last eukaryotic common ancestor had mitochondria capable of aerobic respiration. The mitochondrion is one of the two major organelles of eukaryotes that are of endosymbiotic origin (plastids, such as chloroplasts, being the other). Both of these organelles were originally Gram-negative bacteria that became intracellular symbionts, and then lost their genetic independence over time (**Figures 1(b)** and **1(c)**). The great majority of the proteins required for the function of modern mitochondria and plastids are not encoded on their own genomes (though these genomes have almost always been retained, albeit in very reduced form), but are instead now encoded on the nuclear genome of the eukaryote 'host' (see Gray and Archibald, 2012). Transcripts specifying these proteins are translated on cytosolic ribosomes, and the polypeptides are then imported into the organelle by complex translocation machineries. In both mitochondria and plastids, some of these nucleus-encoded organelle-targeted proteins trace their origins back to the endosymbiont's genome, and the genes encoding them were moved to the nuclear genome through the process of 'endosymbiotic gene transfer,' however, a surprisingly large proportion seem to be derived from other

eukaryotic genes or other prokaryotic sources (Gray and Archibald, 2012).

The mitochondrion is descended from an alphaproteobacterium and was acquired once in eukaryotic history, prior to the time of LECA (Gray *et al.*, 1999; Gray and Archibald, 2012; **Figure 1(b)**). This organelle has been retained by all living eukaryote groups that have been studied in detail, even the many taxa (primarily of protists) that live in low oxygen environments and have no capacity for aerobic respiration (Müller *et al.*, 2012; Stairs *et al.*, 2015). There is a long-standing and ongoing debate as to whether the mitochondrial organelle was amongst the last eukaryotic innovations to be acquired (i.e., the original host was already a cell with a nucleus, complex endomembrane system, eukaryotic cytoskeleton, etc.), or whether it was one of the first (Gray and Archibald, 2012; Poole and Gribaldo, 2014). In particular, several hypotheses propose that a symbiosis between an archaeon (or Archaea-related prokaryote) and the bacterial ancestor of mitochondria was itself the seminal founding event of the eukaryotic lineage (see Embley and Martin, 2006; Martin *et al.*, 2015).

Primary Plastids

The history of the plastid endosymbiosis has important and complex impacts on our understanding of the biodiversity of living protistan eukaryotes. The original endosymbiotic event that ultimately lead to (almost) all of the organelles we call plastids occurred after the time of LECA, and clearly involved a fully developed eukaryotic cell as the host, and a cyanobacterium capable of oxygenic photosynthesis as the symbiont. The eventual outcome of this process of 'primary endosymbiosis' was a photosynthetic 'primary alga' with a plastid surrounded by two membranes that are derived from the cell membrane and outer membrane of the cyanobacterial symbiont (see Archibald, 2009, 2012; Gould *et al.*, 2008; Keeling, 2010; Reyes-Prieto *et al.*, 2007).

With the special exception of *Paulinella* (see 'Rhizaria' below), all of the living groups of primary algae appear to descend from a single primary endosymbiosis (**Figure 1(c)**). The evidence for this shared primary endosymbiosis includes phylogenies that show that plastid genes and genomes form a monophyletic group relative to cyanobacteria, unique (or at least unusual) shared features of plastid genome organization, and the fact that plastids share a common protein import machinery (Archibald, 2012; Keeling, 2010; McFadden and van Dooren, 2004; Price *et al.*, 2012; Reyes-Prieto *et al.*, 2007; Turner *et al.*, 1999). The large group of primary algae and land plants is called Archaeplastida, or sometimes simply 'Plantae,' although land plants themselves are a relatively recently derived subsection of this large and ancient lineage (see below).

Secondary Endosymbiosis

The real complexity in the history of plastid origins comes from the fact that multiple 'higher-order' endosymbioses have spread plastids to several lineages of protists outside of Archaeplastida. Secondary endosymbiosis refers to an event in which a eukaryotic cell (typically, but not necessarily, a heterotroph) acquires a primary alga as an endosymbiont, and over time the endosymbiont is reduced to a genetically dependent organelle that imports most of the proteins required for plastid function (**Figure 2(a)**). Plastids acquired through secondary endosymbiosis characteristically are surrounded by more bounding membranes than primary plastids, often four in total. The two inner membranes are the same two that surround a primary plastid. The outermost membrane hails from the host's endomembrane system, while the second-from-outermost is (generally inferred to be) descended from the cell membrane of the primary algal endosymbiont (Archibald, 2012; Keeling, 2010; though see Gould *et al.*, 2015). The usual presumption is that the primary alga that gave rise to the secondary plastid was originally retained intact and was enclosed in a vacuole, i.e., part of the host's endomembrane system. This accords with the observation that contemporary algal endosymbionts (which are relatively common in protists) typically reside inside host vacuoles (see Nowack and Melkonian, 2010). In several secondary algae the outer membrane of the plastid is actually physically continuous with the endoplasmic reticulum and nuclear envelope system of the host (Keeling, 2010: examples, haptophytes, cryptophytes, many stramenopiles – see below and **Figure 2(b)**). In a minority of cases (phototrophic euglenids, typical dinoflagellates), there are just three membranes surrounding the plastid, with the second-from-outside membrane (i.e., inferred descendant of the primary algal cell membrane) being lost, or perhaps never present (Keeling, 2010; **Figures 2(a)** and **2(b)**). These organelles with three or more membranes derived through serial endosymbiotic events, can be referred to collectively as complex plastids (e.g., Gould *et al.*, 2008; Archibald, 2015). The protein import systems of complex plastids are fascinating and complicated sets of interconnected mechanisms, but beyond the scope of this article (see Gould *et al.*, 2008; Keeling, 2010).

In most (presumed) secondary algae, there is very little left of the primary algal endosymbiont except the plastid itself, and (where still present) the membrane descended from the cell membrane of the primary alga. The equivalent of the algal symbiont's cytoplasm is the material immediately outside the inner two plastid membranes. This compartment, termed the periplastid compartment (or periplastidial compartment), has little volume, and usually lacks distinct organelles. However, there are two major algal lineages – cryptophytes and chlorarachniophytes (see below) – in which the nucleus of the primary algal endosymbiont is retained in the periplastid compartment in highly reduced form, lying between the inner pair and outer pair of membranes (see Gould *et al.*, 2008). In both groups this remnant nucleus, known as the nucleomorph, is surrounded by a nuclear envelope, and contains small linear chromosomes (always three, curiously) that possess fewer than 500 protein-coding genes in total (Douglas *et al.*, 2001; Gilson *et al.*, 2006; Moore and Archibald, 2009). Transcripts encoded by genes from the nucleomorph genome are translated on eukaryote-type ribosomes within the periplastid compartment. The existence of nucleomorphs provides very strong evidence of the reality of secondary endosymbiosis (Archibald, 2015), especially since phylogenies estimated for nucleomorph genes confirm that nucleomorphs are indeed most closely related to primary algae (e.g., Cavalier-Smith *et al.*, 1996).

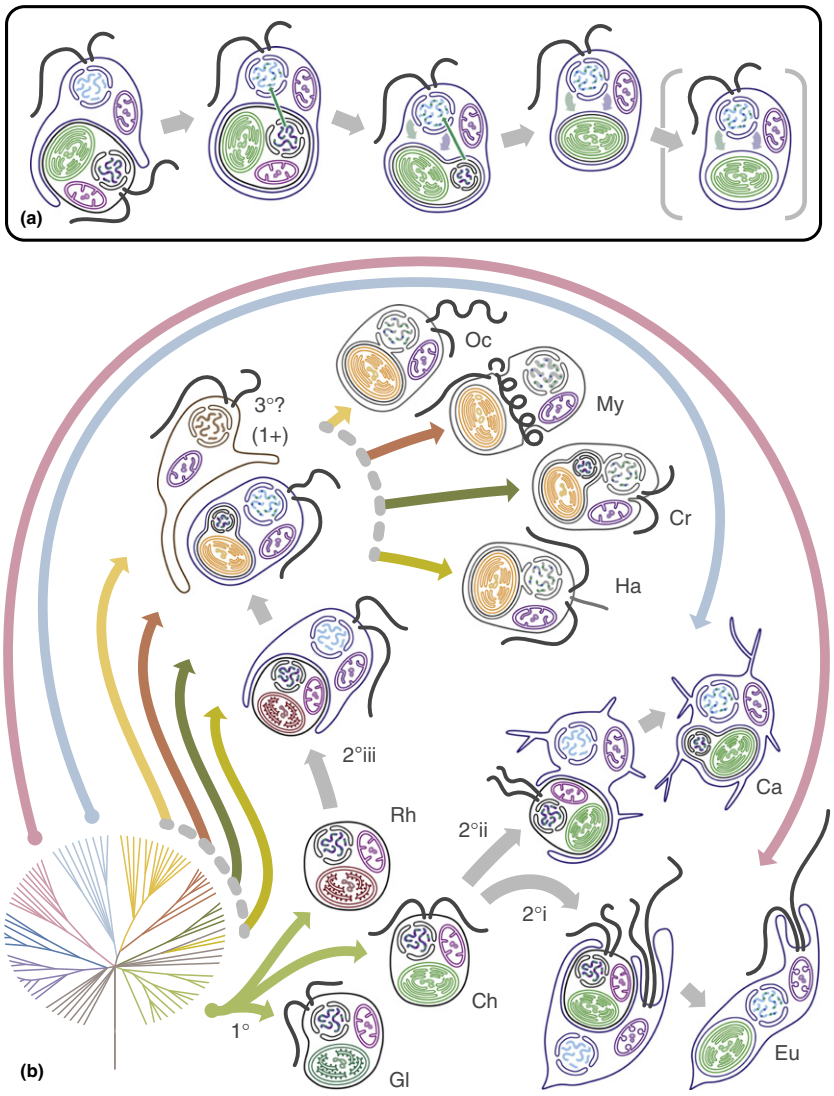

Figure 2 Higher-order endosymbioses and origins of the major groups of algae. (a) Diagrammatic representation of secondary endosymbiosis. The precise order of events shown is representative only; other sequences are plausible. A eukaryote, likely without its own plastid, phagocytosed a primary alga. Over evolutionary time there was a loss of genes from the nuclear genome of the algal symbiont, including endosymbiotic gene transfer to the nuclear genome of the host (narrow green arrow), and the symbiont cell itself became reduced, for example, by loss of its mitochondrion. As with primary endosymbiosis, the transformation of the symbiont into an organelle was cemented by the evolution of a translocation system for the import of proteins necessary for the maintenance of the symbiont, including its photosynthetic capabilities (broad green and blue arrows). In some cases, the organelle has continued to harbor a reduced form of the primary algal nucleus, the 'nucleomorph,' but this nucleus was completely lost in most cases, leaving what is essentially a plastid surrounded by four membranes. In a few cases, the second-from-the-outside of these four membranes was also lost, leaving a plastid with three membranes (right-most cell, in parentheses). (b) Phylogenetic context for the evolution of photosynthetic eukaryotes via multiple endosymbiotic events. The colored branches within the eukaryote subtree represent major groupings, detailed in **Figure 3**. Archaeplastida, the chief group of algae derived directly from primary endosymbiosis (1°), includes Rhodophyta (Rh), Chloroplastida (Ch) and Glaucophyta (Gl). Two separate events of secondary endosymbiosis involving chloroplastid symbionts (2°i; 2°ii) resulted in the advent of photosynthetic euglenids (euglenophytes; Eu), and chloroarachniophytes (Ca), which belong to Excavata and Rhizaria respectively. A third secondary endosymbiosis (2°iii), involving a rhodophyte as the symbiont, gave rise ultimately to the plastids of four groups of chlorophyll *c*-containing algae; Cryptophyta (Cr); Haptophyta (Ha), the myzozoan alveolates (My), the best-known algal representatives of which are dinoflagellates (depicted here), and the photosynthetic stramenopiles, also known as Ochrophytes (Oc). However, the dissemination of plastids to these groups probably also involved one or more events of tertiary endosymbiosis ('3°?'), involving secondary algae with rhodophyte-derived plastids as the symbionts. Possible quaternary endosymbiotic events have also been postulated (not shown).

Complex Plastids, Complex History

Secondary endosymbiosis then is a mechanism by which unrelated groups of eukaryotes can end up sharing the same basic trait of photosynthesis. Furthermore it is clear that secondary endosymbiosis has happened multiple times (**Figure 2(b)**). For example, there are two main groups of secondary algae – chlorarachniophytes and phototrophic euglenids – that have

chlorophylls *a* and *b*, like green algae and land plants (see below); however, phylogenies of plastid genome sequences show that chlorarachniophyte and euglenid plastids are related to the plastids of different subgroups of green algae (Rogers *et al.*, 2007; Turmel *et al.*, 2009). This demonstrates that chlorarachniophytes and euglenids acquired their plastids through separate events of secondary endosymbiosis.

The situation in other groups of algae with complex plastids is more complicated. Four important groups of algae – cryptophytes, haptophytes, photosynthetic dinoflagellates, and photosynthetic stramenopiles (also known as ochrophytes, or heterokont algae) – typically have complex plastids that contain a distinctive chlorophyll, chlorophyll *c*, in addition to chlorophyll *a* (see Andersen, 2004; Graham *et al.*, 2009). Phylogenies based on sequence data from the plastid genome show that these chlorophyll *c*-containing organelles are related to red algal plastids (Bachvaroff *et al.*, 2005; Janouskovec *et al.*, 2010; Yoon *et al.*, 2002), demonstrating that they have a separate endosymbiotic ancestry from the chloroplastid-derived complex plastids of chlorarachniophytes and euglenids discussed above. Furthermore, these plastid gene phylogenies also indicate that the plastids of chlorophyll *c*-containing groups stem ultimately from a single event of secondary endosymbiosis (Bachvaroff *et al.*, 2005; Yoon *et al.*, 2002). However, attempts to estimate the evolutionary trees of the algae themselves, using genes from their nuclear genomes, do not demonstrate that these organisms as closely related. For example, as discussed below, dinoflagellates are more closely related to ciliates (which never have their own plastids), than they are to stramenopiles, haptophytes, or cryptophytes (e.g., Burki *et al.*, 2012; Van de Peer and De Wachter, 1997).

There are two main scenarios that would resolve this apparent contradiction. One possibility is that all of these algae indeed stem directly from a single event of secondary endosymbiosis in a common ancestor, but this photosynthetic ability (and in most cases, the entire plastid) was subsequently lost by ancestors of several major groups of heterotrophs, at a minimum ciliates, Rhizaria, several groups of heterotrophic stramenopiles, and some obscure taxa related to plastid-bearing cryptophytes. The second possibility is that there was a single event of secondary endosymbiosis that gave rise to the chlorophyll *c*-containing plastid, but this plastid was subsequently acquired by one or more unrelated groups through additional symbiotic events (Bodyl *et al.*, 2009; Cavalier-Smith, 1999; Gould *et al.*, 2008; Keeling, 2013). These additional events could have involved a heterotrophic eukaryote acquiring a secondary alga as a symbiont, and over time, this symbiont becoming reduced to just a plastid, in other words 'tertiary endosymbiosis' (Archibald, 2009; Keeling 2013). Tertiary endosymbiosis is actually an independently documented phenomenon: There are some dinoflagellates that have plastids that seem to be derived relatively recently from different secondary algae. In the clearest case, the donor of the plastid was a haptophyte, as evident from both plastid pigments, and phylogenetic analysis of plastid genes (Tengs *et al.*, 2000).

Unfortunately, it is not straightforward to distinguish between secondary and tertiary endosymbioses that happened a long time in the past, and at present it is not clearly resolved which of the two scenarios outlined above best corresponds to the actual evolutionary history (see Archibald, 2015; Keeling, 2013; Gould *et al.*, 2015; Petersen *et al.*, 2014; **Figure 2(b)**). What is not disputed is that resolving the histories of red-alga-derived complex plastids, and of their host algae, remain amongst the most important questions in the study of the evolution of extant eukaryotes.

Uncovering Protist Diversity and Phylogeny

Our current understanding of the biodiversity and phylogenetics of protists is based on more than two centuries of research, but has undergone a profound evolution in the last couple of decades. Much of the known higher-lineage-level diversity of protists had been encountered by light microscopists by the end of the nineteenth century and some major groups that are recognized today were well circumscribed during this era, mostly larger forms and/or those with complex morphologies. By contrast, small heterotrophic flagellates and amoebae (in particular) tended to be grouped into high-level taxa by simple criteria, such as the number of flagella or the form of pseudopodia, that turned out not to define evolutionarily cohesive assemblages. The widespread application of high-quality electron microscopy since the early 1960s led to considerable improvement in our understanding of the diversity of form of protist cells (and related to this, there was eventually a greater tendency to consider protists as a whole, rather than treating 'plant-like' and 'animal-like' cells separately, e.g., Taylor, 1976; see Patterson, 1994). On one hand, this helped identify or highlight many artificial taxonomic groupings, and on the other, it demonstrated a number of previously unsuspected (or poorly supported) phylogenetic groupings (Patterson, 1999). The diverse-but-unified taxon now known as Euglenozoa (see below) is a classic example of a major grouping identified primarily using electron microscopy data (Cavalier-Smith, 1981; Kivic and Walne, 1984; Taylor, 1976).

As with prokaryotes, the application of molecular phylogenetics has transformed our understanding of the protist portion of the tree of life. Briefly, molecular phylogenetics of protists began in the 1970s, but the introduction of small subunit ribosomal RNA (SSU rRNA) as a molecular marker in the 1980s proved to be a crucial innovation (e.g., McCarroll *et al.*, 1983; Sogin *et al.*, 1986), especially after analysis methodologies and taxon sampling improved during the 1990s. Much of what we understand now about the higher-level relationships amongst eukaryotes was established or confirmed during the 1990s and 2000s, primarily through phylogenetic analyses of SSU rRNA sequences, and the common use of multigene phylogenies, mostly based on slowly evolving, protein-encoding nuclear genes (e.g., Baldauf *et al.*, 2000; Gajadhar *et al.*, 1991; Nikolaev *et al.*, 2004; Van de Peer and De Wachter, 1997; Wainright *et al.*, 1993; Parfrey *et al.*, 2010). In the early 2000s, the accumulation of whole genome sequences and surveys of mRNA sequences (EST surveys, later transcriptome sequencing) led to 'phylogenomic analyses' incorporating dozens-to-hundreds genes (Bapteste *et al.*, 2002; Rodriguez-Ezpeleta *et al.*, 2005; Philippe *et al.*, 2005; note that the term 'phylogenomics' is also applied to very different analyses in other contexts). Since ~2007,

phylogenomics has become the major tool for inferring the deepest-level structure of the eukaryote tree, and current 'supergroups' such as Sar and Obazoa were identified primarily on the basis of phylogenomic analyses (see below). At the same time, the application of environmental sequencing approaches over the last 15 years has greatly improved our understanding of the diversity of protists within major lineages (in particular), and in many cases has profoundly altered our knowledge about their distributions across habitats (e.g., Massana *et al.*, 2014).

Nonetheless, despite the massive availability of sequence data, the eukaryote tree of life remains incompletely resolved. Phylogenetic inference is complicated by methodological problems, the existence of lateral gene transfer, and the fact that taxon sampling (i.e., the number and variety of species for which there are sequence data available) is still very limited for many protist groups of particular phylogenetic importance (see Brown *et al.*, 2013; Burki *et al.*, 2012; Yabuki *et al.*, 2014; Zhao *et al.*, 2012). Technical difficulties are particularly hard-felt in the crucial question of the position of the 'root' of the eukaryote tree (i.e., identifying the earliest division amongst lineages represented by living eukaryotes), where the very large evolutionary distances between most prokaryotic sequences and their eukaryotic homologs make phylogenetic inference extremely challenging. Recent studies have estimated phylogenies for gene sets where these distances are unusually low, or considered other molecular data such as gene duplication and loss information, or the taxonomic distribution of important cellular machineries (e.g., Cavalier-Smith, 2010; Derelle and Lang, 2012; Derelle *et al.*, 2015; He *et al.*, 2014; Katz *et al.*, 2012; Wideman *et al.*, 2013); regardless, these have not yet given a consensus on the position of the root (Williams, 2014). Furthermore (and excitingly), new major lineages of protists are still being discovered and characterized at a high rate, both through isolation and cultivation methods, and the use of environmental molecular approaches (e.g., Glücksman *et al.*, 2011; Kim *et al.*, 2011; Not *et al.*, 2007; Seenivasan *et al.*, 2013; Yabuki *et al.*, 2010, 2011).

The Diversity of Living Eukaryotes

At present, the great majority of living eukaryotes can be assigned to one or other of four 'supergroups': Archaeplastida, Sar, Excavata, and Amorphea. Sar brings together three already impressively diverse groups; Stramenopiles, Alveolates, and Rhizaria, while Amorphea unites at least two major taxa; Amoebozoa and Obazoa (with the latter containing the better-known subgroup Opisthokonta). Each of these is likely to represent a monophyletic group, although proposals have been forwarded that the 'root' of the eukaryote tree (see above) might fall within Excavata or Amorphea. The best-known taxa that do not belong to one of these supergroups are the cryptophyte and haptophyte algae discussed briefly above. There is, however, a longer list of heterotrophic organisms that may also belong to phylogenetically distinct major lineages outside of the current supergroups (see 'other groups,' below). A summary tree depicting the major phylogenetic groups of eukaryotes in shown in **Figure 3**.

Archaeplastida

Archaeplastida ('ancient plastids') are the group containing essentially all of the primary algae (i.e., with plastids of primary endosymbiotic origin – see above), and the great majority of living species in this assemblage are photosynthetic. Their history likely dates back more than 1 billion years, based on scant early fossils (Butterfield *et al.*, 1990). Archaeplastida consists of three groups: Chloroplastida, Rhodophyta, and Glaucophyta.

Chloroplastida (also known as Viridiplantae or Chlorobionta) includes the various green algae, that is, all the primary algae with chlorophyll *b* in addition to chlorophyll *a*, and the land plants. Green algae range from numerous small unicellular flagellates, which likely represent the ancestral form of Chloroplastida (**Figure 4(a)**), through various colonial and filamentous types (**Figure 4(b)**), to complex, differentiated macroalgae. Large size and complexity has evolved independently within green algae on multiple occasions. For example, the major group of green seaweeds (Ulvophyceae) is not closely related to the major freshwater macroalgae or to land plants (Leliaert *et al.*, 2012). The land plants evolved from within the streptophyte/charophycean green algae, which are mostly freshwater forms. The precise relationships between land plants and the various streptophyte green algae are still incompletely resolved. Recent phylogenomic analyses of nuclear and plastid markers favor a close relationship with the unicellular or filamentous Zygnametales (Laurin-Lemay *et al.*, 2012; Leliaert *et al.*, 2012; Timme *et al.*, 2012; Wickett *et al.*, 2014; Zhong *et al.*, 2014; **Figure 4(b)**), rather than the previously preferred hypothesis of a closer affinity between the land plants and the complex macroalgae called Charales, or 'stoneworts' (see Lewis and McCourt, 2004).

Rhodophytes, or red algae, are mostly marine macroalgae (**Figure 1(c)**; see also **Figure 1(f)**), although there are also unicellular forms. Glaucophytes are a very obscure lineage of freshwater unicellular or colonial algae (**Figure 1(d)**). The plastids of both rhodophytes and glaucophytes lack the chlorophyll *b* that is the main accessory pigment of Chloroplastida, but instead retain the phycobilisome accessory pigment system present in the cyanobacterial ancestor of plastids (Graham *et al.*, 2009; Jackson *et al.*, 2015); the red color typical of red algae, for example, is primarily due to an abundance of the phycobilin phycoerythrin (Graham *et al.*, 2009). Remarkably, the plastids of glaucophytes also retain a vestige of the bacterial peptidoglycan cell wall between inner and outer plastid membranes (Löffelhardt and Bohnert, 1994; Jackson *et al.*, 2015).

Sar

The taxon Sar (also known as SAR, or Harosa) is a large and complex assemblage that draws together a wide variety of organisms that were not previously considered as specially related, but have been grouped by multigene phylogenetics or phylogenomic studies (Burki *et al.*, 2007; Hackett *et al.*, 2007; Rodriguez-Ezpeleta *et al.*, 2007). The name Sar/SAR was originally an acronym of its three subclades: Stramenopiles, Alveolata, and Rhizaria (Adl *et al.*, 2012; Burki *et al.*, 2007), each of which is already very diverse.

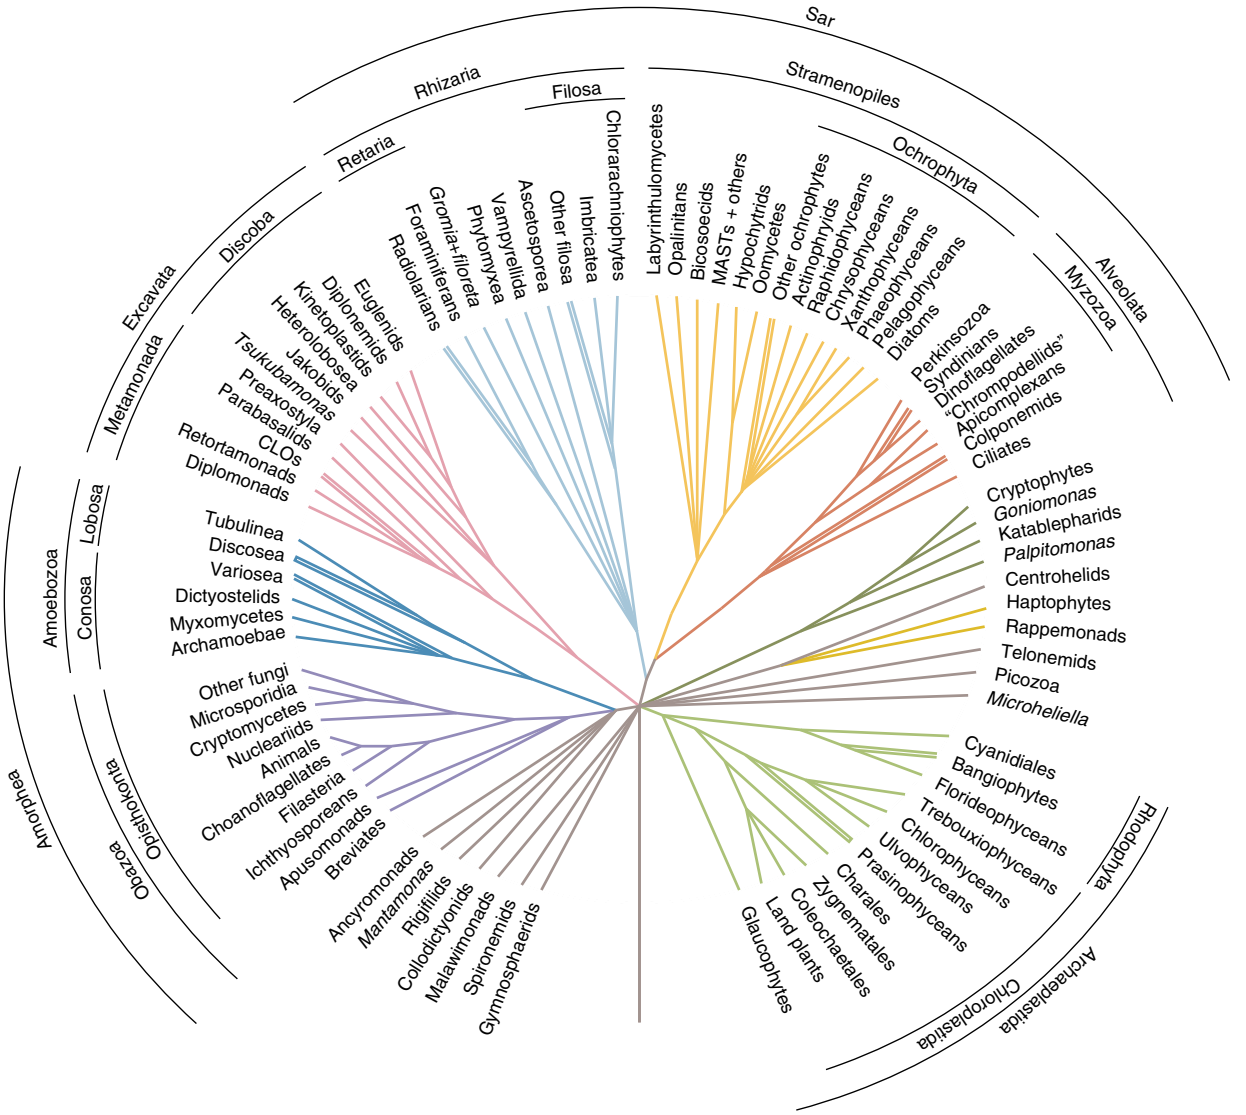

Figure 3 Summary tree of extant eukaryote groups. Branching order is based primarily on molecular phylogenetic and phylogenomic analyses. Some smaller taxa are not shown. Double lines indicate groupings that are likely paraphyletic rather than monophyletic. CLO – *Carpediemonas*-Like Organisms; MASTs – Marine Stramenopiles.

Stramenopiles

Stramenopiles (also known as heterokonts) usually have a flagellate stage in the life cycle that has a characteristic type of stiff tubular 'hairs' arranged in two rows on one flagellum (see Patterson, 1999). These flagellates swim in the direction the hair-bearing flagellum is pointing. Stramenopiles include a particularly wide variety of algae with chlorophyll *c*-containing complex plastids (see above), which are often now known as ochrophytes. These range from unicells and colonial microalgae, both flagellated and nonmotile (e.g., diatoms, Chrysophyceae, Pelagophyceae, Raphidophyceae, and many others; **Figures 4(e)** and **4(g)**) to large macroalgae, such as kelps and wracks (Andersen, 2004; Graham *et al.*, 2009; **Figure 4(f)**). A substantial proportion of microalgal stramenopiles produce elaborate cell coverings made of silica (diatoms and many chrysophyceans, e.g.). Ochrophytes of different kinds are frequently amongst the most important algae within a given aquatic system: for example, diatoms, together with dinoflagellates (see below), are the dominant larger microalgae in ocean waters. However, the stramenopile clade also contains numerous lineages of protozoa, most of which are small bacterivorous flagellates (see Patterson, 1999; Massana *et al.*, 2014; **Figure 4(h)**). These protozoan stramenopiles actually exceed the algal stramenopiles in molecular sequence diversity (Massana *et al.*, 2014; Shiratori *et al.*, 2015), but are more poorly studied: for example, some of the most abundant protozoa in the oceans are stramenopiles that belong to major groups which were discovered by environmental sequencing efforts within the last 15 years ('MASTs'; Massana *et al.*, 2004, 2014). There are also some important fungal-like groups among the heterotrophic stramenopiles. The most famous of these are the oomycetes, some of which are important

parasites of aquatic animals and land plants, including the causative agents of late blight in potatoes and sudden oak death (Thines, 2014).

Alveolata

The alveolates include the dinoflagellates, about half of which are algae with complex plastids, and two large and important groups of protozoa: the apicomplexan parasites, and the mostly free-living ciliates (**Figures 4(i)–4(m)**). Of these three groups, dinoflagellates and Apicomplexa are the most closely related; together with more obscure relatives these form a 'Myzozoa' grouping that appears to descend from a photosynthetic common ancestor (see below).

Dinoflagellates (**Figure 4(k)**) are one of the most abundant forms of larger microalgae, and the diversity of species in marine plankton is particularly high (Taylor *et al.*, 2008). They

are most famous for the formation of algal blooms, and the production of potent toxins that can harm or kill humans, usually through consumption of toxin-contaminated shellfish or finfish (though algae from several other groups can also be also bloom-forming and/or toxic). The non-algal dinoflagellates are mostly predators of other microorganisms, or parasites of animals or large protists. It has become increasingly clear that many, perhaps most, algal dinoflagellates are also predators of other microorganisms, and as such are textbook examples of mixotrophs (see above; Jeong *et al.*, 2010; Stoecker, 1999).

Apicomplexa are almost all parasites of animals, and the several thousand described species include the organisms that cause malaria, cryptosporidiosis, and toxoplasmosis in humans, as well as several major livestock diseases (**Figure 4(m)**). They typically have sexual life cycles that include multiple cell types, and that can involve multiple host species. Most are intracellular parasites that use a specialized 'apical complex,' which includes distinct kinds of secretory organelles, to actively invade host cells and subsequently modify them (Kemp *et al.*, 2013). Remarkably, most Apicomplexa also possess a complex plastid that is non-photosynthetic, but plays essential biosynthetic roles (see Gould *et al.*, 2008; Keeling, 2010). Apicomplexan parasites turn out to be most closely related to the 'chrompodellids' grouping (Janouskovec *et al.*, 2015) that includes both the colpodellid protozoa, which are predators or ectoparasites of other unicellular protists (**Figure 4(l)**), and a couple of recently discovered algae with photosynthetic complex plastids (*Chromera* and *Vitrella*; Moore *et al.*, 2008; Obornik *et al.*, 2011). Most of these, as well as deep-branching organisms from the dinoflagellate lineage (e.g., perkinsids), have structures that that are homologous to the apical complex, and are used in feeding or host invasion (Okamoto and Keeling, 2014).

The final major group of alveolates, the ciliates, usually have numerous cilia on the cell surface (Lynn, 2008; **Figures 4(i)** and **4(j)**). They are extremely diverse and abundant predators in many aquatic systems, often using closely packed arrays of specialized 'oral cilia' as a part of their feeding mechanism. They have an unusual genomic organization: each ciliate typically contains two types of nuclei. The 'somatic' macronuclei are the templates for essentially all transcription during the asexual phase of the life cycle, while the micronuclei participate in the sexual stage of the life cycle, and act as the germline (whereas macronuclei degenerate during and/or after the sexual process).

Rhizaria

Rhizaria (**Figures 5(a)–5(d)**), the final group within Sar, is a diverse collection primarily of free-living protozoan organisms, although the taxon also includes significant parasites of marine animals (e.g., ascetosporeans – haplosporidians and paramyxids), and of plants (many Phytomyxea, namely, plasmodiophorids; Burki and Keeling, 2014). Rhizaria also contains two small groups of photosynthetic organisms, one of which is the chlorarachniophyte secondary algae discussed above (**Figure 5(c)**), while the other is a tiny group of filose testate amoebae (see below) from the genus *Paulinella*, which have photosynthetic organelles that derived from cyanobacteria completely independently of the 'true' plastids discussed elsewhere in this article, and much more recently (Nowack, 2014). Many free-living Rhizaria produce thin, and often branching pseudopodia for feeding (e.g., **Figure 5(b)**). Some Rhizaria locomote using flagella (often using a gliding motility in preference to swimming; e.g., **Figure 5(d)**). Others are non-flagellated amoebae, which may use their pseudopodia for locomotion as well as feeding. The best-known rhizarians – Foraminifera (**Figure 5(a)**), the radiolarians, and the filose testate amoebae – are all amoebae of this kind, but in addition usually have self-mineralized shells (tests) or 'skeletons,' which are made of calcium carbonate, strontium sulfate or silica, depending on the group or subgroup (e.g., Febvre *et al.*, 2002). Foraminifera and radiolarians in particular are often very large cells (occasionally several millimeters or more in diameter), and are abundant in marine waters and sediments, and, in many cases, in the fossil record.

Excavata

Like Rhizaria, Excavata (**Figures 5(e)–5(j)**) are primarily a collection of protozoa, but also include a single group of secondary algae. The most recent common ancestor of excavates was a flagellate (probably a free-living bacterivore) with a characteristic broad feeding groove, and various extant free-living groups still have this basic cell form (Simpson, 2003; e.g., **Figure 5(f)**). Excavates are divided into two main subgroups, Metamonada and Discoba (Hampl *et al.*, 2009). Metamonads are descended from a common ancestor that had lost the ability to perform aerobic respiration, and consequently have highly modified mitochondria of various kinds that lack mitochondrial genomes (Cavalier-Smith, 2003; Stairs *et al.*, 2015). Many metamonads are free-living and inhabit oxygen-poor marine or freshwater environments (e.g., Kolisko *et al.*, 2010; **Figure 5(f)**), but several subgroups have become specialist parasites or symbionts of animals. The intestinal parasite *Giardia* and urogenital parasite *Trichomonas vaginalis* are highly prevalent human pathogens (e.g., Adam, 2001; Lehker and Alderete, 2000), however, there is also a spectacular diversity of symbiotic metamonads in the hindguts of many wood-eating termites (Brugerolle and Lee, 2002a,b; **Figure 5(e)**).

Most Discoba have aerobic mitochondria with organellar genomes, in fact, the small flagellate group Jakobida (e.g., *Reclinomonas* and *Andalucia*) have mitochondrial genomes that retain more unique genes, and more bacterial-like features, than those of any other eukaryote (Burger *et al.*, 2013; Lang *et al.*, 1997). Discoba also include Heterolobosea (**Figure 5(g)**), many of which have alternate amoeba and flagellate phases (the infamous 'brain-eating amoeba' *Naegleria fowleri* is a heterolobosean; see Visvesvara, 2013). The final major Discoba group, Euglenozoa, includes numerous protozoan flagellates that are abundant surface-associated bacterivores and predators of microbial eukaryotes (e.g., 'bodonid' kinetoplastids, and phagotrophic euglenids; Boenigk and Arndt, 2002; Larsen and Patterson, 1990; **Figure 5(j)**). It also includes the parasitic kinetoplastids that cause sleeping sickness, Chagas' disease, and leishmaniasis in humans (all caused by different trypanosomatids; **Figure 5(h)**), and several important diseases of animals and a few plants (Simpson *et al.*, 2006; Vickerman, 2002). Euglenozoa is

also the taxonomic home for the photosynthetic euglenids, which are secondary algae with a plastid of green algal origin (see above; **Figure 5(i)**).

Amorphea

The Amorphea supergroup (previously known as 'unikonts') unites Amoebozoa and Obazoa, two major taxa that are examined individually below (Adl *et al.*, 2012). A close relationship between Amoebozoa and Obazoa has been supported by many phylogenetic analyses (e.g., Baldauf *et al.*, 2000; Bapteste *et al.*, 2002; Hampl *et al.*, 2009; Derelle and Lang, 2012), albeit some analyses place the 'root' of the eukaryote tree within Amorphea (see above).

Amoebozoa

As the name suggests, most members of the taxon Amoebozoa are amoebae, and this is the group that includes famous large forms such as *Chaos*, and the genus *Amoeba* itself. Most produce lobose pseudopodia (**Figure 6(a)**), or lamellipodia, both of which are much broader than the fine pseudopodia typical of Rhizaria (see above; Smirnov *et al.*, 2011), however, there is also a substantial diversity of amoebozoa with fine, often reticulating pseudopodia (e.g., Berney *et al.*, 2015). Many amoebozoa are free-living amoebae (e.g., **Figure 6(a)**), although some are obligate or facultative parasites (e.g., *Acanthamoeba*; Visvesvara, 2013), and a few have a flagellate stage in their life cycle. They are especially common in freshwater and marine sediments. One clade, the lobose testate amoebae, inhabit shells (tests) with a single broad aperture to allow them to extend their pseudopodia (**Figure 6(b)**). Testates are common in freshwater and terrestrial habitats, including soil, where they can be present in very high abundances (Meisterfeld, 2002). Another unusual group within Amoebozoa, the archamoebae, are all anaerobes that have highly modified mitochondria (similar to the metamonads

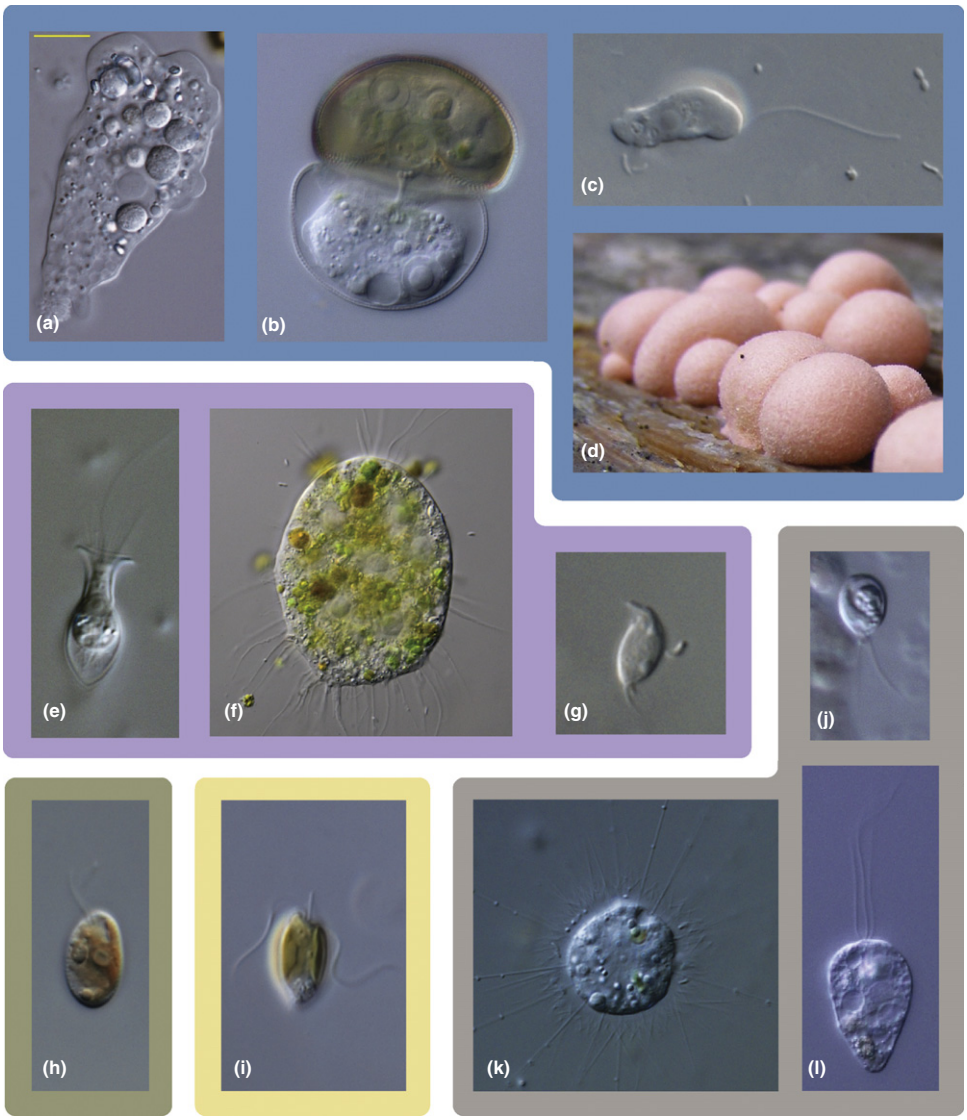

Figure 6 Amoebozoa, Obazoa, Cryptophyta, Haptophyta, and 'other taxa.' Background boxes delineate major groupings, colored as in **Figure 3**. discussed above; see Stairs *et al.*, 2015). Archamoebae includes free-living amoebae, flagellated amoeboid organisms (**Figure 6(c)**), and commensals/parasites such as the major human pathogen *Entamoeba histolytica* (Ptáčková *et al.*, 2013; Stanley, 2003). Several distinct subgroups within Amoebozoa are 'slime molds': terrestrial organisms that exist as amoebae for at least one part of the life cycle, but also produce a fruiting body (sorocarp) that releases spores (Shadwick *et al.*, 2009; **Figure 6(d)**). Dictyostelid slime molds produce the fruiting body through the cooperative aggregation of many individual amoebae (Romeralo *et al.*, 2012), while the fruiting bodies of Myxomycetes (myxogastrids; **Figure 6(d)**) are reproductive structures generated by outgrowth from a single individual, a large multinucleate 'plasmodium' (Stephenson, 2011).

Obazoa (including opisthokonta)

The final major grouping of eukaryotes is the recently discriminated taxon Obazoa (Brown *et al.*, 2013), almost all of which fall into a slightly less inclusive but better-known group called Opisthokonta. Opisthokonta includes both animals (Metazoa) and true Fungi, which evolved from protistan ancestors independently of each other (Cavalier-Smith, 1987; Wainright *et al.*, 1993). Molecular phylogenies have demonstrated that animals are closely related to the choanoflagellates, a group of small solitary or colonial flagellates with a microvillar feeding collar, which are important bacterivores in ocean plankton (Leadbeater, 2015; **Figure 6(e)**), as well as several more obscure groups, such as the Ichthyosporean parasites, which mostly infect aquatic animals

(Lang *et al.*, 2002; Mendoza *et al.*, 2002; Shalchian-Tabrizi *et al.*, 2008; Steenkamp *et al.*, 2006). Fungi are related instead to nucleariids, a small group of amoebae with fine 'filose' pseudopodia (Amaral Zettler *et al.*, 2001; Steenkamp *et al.*, 2006; **Figure 6(f)**), although research over the last decade has identified a diverse clade of mostly uncultivated aquatic organisms, now called Cryptomycota (or Rozelliida), that is either the closest sister group to Fungi, or the deepest branch within Fungi, depending on exactly how Fungi are to be defined (Jones *et al.*, 2011; Lara *et al.*, 2010). Cryptomycota appear to be parasites of other aquatic organisms. They may produce chitinous cell walls similar to those of true fungi during some stages of the life cycle (e.g., in the formation of structures that allow them to infect their hosts), however, the feeding structures are not enclosed by these cell walls, unlike the absorptive hyphae of most mycelial fungi (James and Berbee, 2012; Jones *et al.*, 2011). The microsporidia, small animal-infecting intracellular parasites long considered related to fungi in some way (Van de Peer *et al.*, 2000), may well in fact belong to Cryptomycota, or at least be closely related to them (James *et al.*, 2013).

The grouping Obazoa reflects the recent confirmation that Opisthokonta is related to two small taxa of surface-dwelling bacterivorous flagellates, apusomonads (**Figure 6(g)**), and breviates (Brown *et al.*, 2013; Cavalier-Smith and Chao, 2010; Kim *et al.*, 2006). As a consequence of their phylogenetic position, these two previously obscure protist lineages are now of heightened importance for tracing the evolution of multicellularity in animals and fungi (Brown *et al.*, 2013).

Other Groups

The groupings listed above encompass most, but not all of the diversity of living eukaryotes. Firstly, they do not include two well-known groups of algae, cryptophytes and haptophytes, and their relatives. Cryptophytes in the strict sense (e.g., **Figure 6(h)**) are a group of chlorophyll *c*-containing unicellular flagellates (mostly; some have non-photosynthetic plastids), which are notable for retaining a nucleomorph within the plastid (see above). They are most closely related to a nested series of more obscure heterotrophic forms including goniomonads, katablepharids, and probably the recently described *Palpitomonas* (Yabuki *et al.*, 2010, 2014; Hackett *et al.*, 2007; Okamoto and Inouye, 2005; Okamoto *et al.*, 2009), but beyond this their phylogenetic affinities are still unclear (see below).

Haptophytes (**Figure 6(i)**) are also chlorophyll *c*-containing unicellular algae (see above) that are found in diverse environments, but are particularly important in the ocean. Many are flagellated (at least in some life cycle stages), and some are known to be mixotrophs (Andersen, 2004). The most famous haptophytes are the exclusively marine coccolithophorids, which produce a casing of often-elaborate calcium carbonate scales called 'coccoliths' (Young *et al.*, 2005). Some phylogenomic analyses favor a relationship with the taxon Sar (Burki *et al.*, 2012; though see below). Haptophtyes may also be related to 'rappemonads,' a recently discovered group of unicellular algae that can be abundant in ocean plankton, but have never been cultured (Kim *et al.*, 2011), and possibly also to centrohelid heliozoa (see below). Previous phylogenetic evidence that haptophytes are closely related to cryptophytes and their kin (Burki *et al.*, 2008; Hackett *et al.*, 2007; Patron *et al.*, 2007) has usually been only weakly supported, or not supported at all, by recent analyses (Burki *et al.*, 2012; Katz and Grant, 2015).

In addition, there are a greater number purely heterotrophic 'protozoa' for which there are reasonable molecular and high-resolution microscopy data, but whose phylogenetic positions are also unclear. Some appear to have affinities with Archaeplastida and/or Sar and/or cryptophytes and/or haptophytes (e.g., Burki *et al.*, 2009, 2012; Shalchian-Tabrizi *et al.*, 2006). These include the small flagellate group telonemids (**Figure 6(j)**), the best known of which are marine predators of other small protists (Klaveness *et al.*, 2005), and Picozoa, a recently discovered group of small flagellates that were originally inferred to be algae but are now known to be heterotrophs (Not *et al.*, 2007; Yoon *et al.*, 2011; Seenivasan *et al.*, 2013). Centrohelids (**Figure 6(k)**) are one of several kinds of 'heliozoan' amoebae that have a subspherical cell body supporting a radiating array of fine microtubule-supported pseudopodia (Zlatogursky, 2012; most other 'heliozoa' belong to Stramenopiles or Rhizaria). The best hypothesis at present is that centrohelids are related to haptophytes (Cavalier-Smith *et al.*, 2015), but this awaits further confirmation.

There are several other heterotrophic groups for whom multigene phylogenies typically suggest relationships with or within Amorphea (i.e., Amoebozoa and Obazoa). These include the collodictyonids, which are free-swimming flagellates (**Figure 6(l)**), ancyromonads and *Mantamonas*, which are very small gliding flagellates, and the amoeboid Rigifilida (Yabuki *et al.*, 2013; Brugerolle *et al.*, 2002; Cavalier-Smith *et al.*, 2014; Glücksman *et al.*, 2011, 2013; Mikrjukov and Mylnikov, 2001; Paps *et al.*, 2013; Zhao *et al.*, 2012). Perhaps the most puzzling protists of uncertain placement are the malawimonads, an otherwise very obscure group of small heterotrophic flagellates that is assigned to excavates by morphological data (Simpson, 2003), but shows closer affinities with Amoebozoa and Obazoa (and/or collodictyonids) in many multigene phylogenies, including most recent phylogenomic-scale analyses of mitochondrial and/or nuclear sequence data (Derelle and Lang, 2012; Derelle *et al.*, 2015; Hackett *et al.*, 2007; Zhao *et al.*, 2012).

Finally, there are still a few well-defined and morphologically distinct groups of living eukaryotes whose affinities remain uncertain, and for which there are no reported molecular sequence data. The best known of these are the spironemids, which are multiflagellated, probably predatory, cells that are occasionally reported in high abundance in soils and sediments (Foissner and Foissner, 1993).

Concluding Remarks

The broader-scale picture of the biodiversity and phylogenetic tree of living eukaryotes may well be largely resolved in the near future. The full extent of undescribed/undersampled protist diversity is not clear at present, however, most newly studied major lineages are likely to be rapidly integrated into a

reasonably accurate eukaryote phylogeny. This is due to the ongoing, even accelerating, efforts to broadly capture protist diversity using culturing approaches, as well as rapidly improving techniques for efficiently obtaining useful genomic/transcriptomic data from difficult-to-culture single cells and from environmental samples (Kolisko *et al.*, 2014; Yoon *et al.*, 2011). Hopefully, the ongoing taxonomic broadening of genomic datasets will also lead to resolution of the still-unclear history of higher-order plastid endosymbioses, especially complex plastids of red algal origin. It will be fascinating to see whether the position of the 'root' of eukaryotes can be pinpointed in the near future – recent evidence and approaches show promise, even though there is little evidence to date for convergence on a well-supported answer (Derelle *et al.*, 2015; Williams, 2014).

One area where there is still a particularly acute shortage of direct information is the early evolution of eukaryotic cells, prior to LECA, and shortly thereafter. While tremendous improvements in the understanding of the Proterozoic fossil record have been wrought in the last 2–3 decades (see Butterfield, 2015), it is surely the case that paleontologists are still scratching the surface. There are a few fossil finds that individually exert a huge influence on our current view of early eukaryote evolution (e.g., Butterfield *et al.*, 1990; Porter and Knoll, 2000), indicating that the next few important finds, whenever they emerge, will be similarly transformative. It is possible, however, that the next important revelations concerning the early history of eukaryotes will stem from microbiology rather than paleontology. New discoveries amongst the probable archaeal relatives of eukaryotes (Spang *et al.*, 2015) might reveal organisms that are genuinely intermediate in cell organization between typical prokaryotes and eukaryotes, ultimately telling us a lot more about the cells from which living protists, and all true eukaryotes, diversified.

Acknowledgments

Thanks to John Archibald, Laura Eme, Michelle Leger, Sergio Muñoz-Gómez, Andrew Roger (Dalhousie University), Matthew Brown (Mississippi State University), Ivan Čepička (Charles University), and Simonetta Gribaldo (Institut Pasteur, Paris) for constructive comments on early or late drafts of the manuscript. The financial support of the Canadian Institute for Advanced Research, Program in Integrated Microbial Biodiversity, is gratefully acknowledged.

Q

Quantitative Genetics in Natural Populations

AJ Wilson, University of Exeter, Falmouth, UK
J Poissant, University of Calgary, Calgary, AB, Canada

Glossary

Adaptation Evolution of phenotypes conferring high fitness.
Additive genetic variance A measure of the variation in a phenotypic trait that is attributable to additive genetic effects.
Animal model A form of linear mixed effect model in which an individual's breeding value is fitted as a random effect. The most widely used statistical method for estimating quantitative genetic parameters in natural populations.
$\boldsymbol{\beta}$ Vector of directional selection, containing individual selection gradients (β) for a set of phenotypic traits.
Breeding value The expected (additive) effect of an individual's genotype on phenotype, usually expressed relative to the population mean phenotype. As a latent rather than directly observable variable it may be estimated by measuring offspring phenotype, or may be predicted using, for example, an animal model. Variance in breeding values is the additive genetic variance.
Directional selection Selection that favours an increase or decrease in the population mean phenotype.
Evolutionary constraint Broadly, any process that reduces the rate of adaptive evolution relative to naïve expectations. Constraint in **G** can be conceptualized as a relative lack of genetic variance in the direction of multivariate selection β.
G matrix Additive genetic variance–covariance matrix for a set of phenotypic traits.
Genetic correlation A standardized measure of the (additive) genetic covariance between two traits.
Genetic merit See breeding value.
Genome-wide association study (GWAS) Test of association between alleles and phenotypes using a genome-wide set of markers.
Genotype-by-environment interaction A phenomenon that occurs when environmental effects on phenotype depend on genotype (and vice versa).
Heritability A standardized measure of additive genetic variance for a trait. Formally estimated (in the narrow sense) as the proportion of total phenotypic variance explained by additive genetic variance.
Identical by descent (IBD) A DNA segment inherited by two or more individuals from a common ancestor.
Indirect genetic effect Causal dependence of one individual's phenotype on the genotype of another.
Latent variable In modeling, latent variables are those that are not directly observed but about which inferences can be made statistically. In quantitative genetic models, individual breeding values are often included as a latent variable.
Linkage disequilibrium (LD) The nonrandom association of alleles at different loci.
Maternal effect Causal influence of some characteristic(s) of mothers on the phenotype of their offspring (over and above the effect of genes inherited).
Molecular pedigree analysis The use of molecular data (e.g., microsatellite genotypes) to determine relationships and/or relatedness among individuals in a population.
Natural selection A causal dependence of fitness on phenotype.
Parent–offspring regression A statistical method for estimating heritabilities and other quantitative genetic parameters. For example, heritability can be estimated as the slope of a regression of offspring trait on midparent trait. Largely superseded by the animal model for studies of wild populations.
Quantitative trait locus (QTL) A locus influencing a quantitative trait.
Selection differential (S) A measure of (directional) selection on a trait. Formally the covariance between trait and fitness.
Selection gradient ($\boldsymbol{\beta}$) A measure of (directional) selection on a trait. Formally the partial regression of fitness on a trait.

Introduction

Quantitative genetics is a field of biological research that attempts to understand how genes affect the expression and evolution of complex phenotypic traits – that is, traits that are influenced by many different genes (as opposed to 'Mendelian traits' determined by a single gene). It is both a theoretical and empirical area of research. Theoretical models predict how

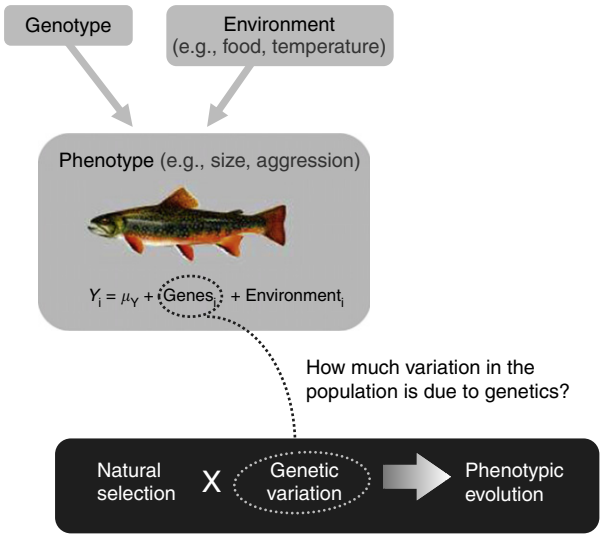

Figure 1 Quantitative genetic theory predicts phenotypic evolution as a function of natural selection and genetic variation (dark gray box). To use this predictive theory, empiricists must therefore estimate the genetic variation underpinning a trait (or traits) of interest. In wild populations this is most commonly done by modeling the individual phenotypes Y_i of animals of known relatedness to each other (see main text for detail). In the simplest case, Y_i is specified as the population mean, plus deviations attributable to genotype (the 'breeding value'), and (unknown) environmental effects experienced.

traits will respond to selection as a function of parameters, such as heritabilities and genetic correlations, that describe their patterns of inheritance and (co)variation in a population (Figure 1). Empirical quantitative geneticists use statistical methods to estimate these parameters, allowing hypotheses about phenotypic evolution to be tested. Because quantitative genetic theory is entirely general, it can be applied to studies of any trait (e.g., disease resistance, growth rate, and social behaviors) in any population. However, because of the type, and amount, of data required to estimate quantitative genetic parameters it is only relatively recently that these methods have been widely applied *in situ* in natural populations. In this article we provide a brief overview of this rapidly growing field of research, highlighting some ways in which quantitative genetic studies of natural populations are helping us to understand phenotypic evolution, and pointing some challenges and opportunities facing the field. Before progressing we first discuss the rationale for studying natural populations, and provide a (very) brief primer of some core concepts for readers with little (or no) prior exposure to quantitative genetics.

Why Study Wild Populations?

The rationale for taking evolutionary quantitative genetics from the lab to the field is simple. Theory tells us that the natural selection leads to adaptation, but only if phenotypic variation arises, at least in part from genetic effects. Field biologists have a long and successful tradition of studying natural selection, both through the optimality framework that characterizes much of behavioral ecology (Davies *et al.*, 2012), and through formal attempts to quantify (putatively causal) relationships between phenotype and fitness (Lande and Arnold, 1983; Endler, 1986; Kingsolver *et al.*, 2001). However, even the strongest directional selection can produce no evolutionary response in the absence of genetic variance. Ultimately the adaptive potential of any population thus depends on the presence of genetic variance for fitness itself (Fisher, 1930). So if we want to understand how traits evolve, and why sometimes they do not (Merilä and Sheldon, 2000), we need to know about genetics as well as selection. How much genetic variation is there in wild populations? How is it distributed within- and among-traits that effect fitness? Do genetic correlations among traits act as evolutionary constraints? Are there interactions between genetic and environmental effects on traits, and – more broadly – how do evolutionary and ecological processes influence each other under natural conditions? These are the sorts of questions that can be, and are being, addressed by researchers using quantitative genetic methods in natural populations.

Given the goal of understanding genetic variation in natural populations, researchers may use data collected from wild populations organisms animals *in situ* (i.e., in the field) or under artificial (or seminatural) conditions in the laboratory. The latter approach is not always feasible, but can be readily applied to studies of insects (Niemela *et al.*, 2013), rodents (Schroderus *et al.*, 2012), some fish (Dingemanse *et al.*, 2012), and many plant species (Pujol *et al.*, 2014). Lab-based studies using wild caught individuals (and their offspring) are sometimes criticized on the grounds that resulting quantitative genetic parameters estimates are less ecologically relevant. In particular, the risk is that, as a consequence of genotype-by-environment interactions, estimated patterns of genetic covariance among traits in the lab will not represent those in the natural environment. Nonetheless, we would argue this drawback will often be more than offset by the increase in experimental tractability. So while we focus primarily on *in situ* studies of wild populations in this article, we take the view that lab and field-based studies are much better seen as complementary, rather than competing, approaches.

Genetic Variation and Covariation: A Brief Primer

Classical quantitative genetics uses known relationships, or pedigree structures, to investigate genetic variation in, and covariation between, phenotypic traits of interest (Figure 1). If the statistical methods used can sometimes seem complex, at least the underlying principle is straightforward. If variation in genes is an important determinant of phenotypic variation then related pairs of individuals will tend to be phenotypically similar because they share alleles identically by descent (IBD). The more closely related individuals are, and so the more alleles they share, the more similar their phenotypes should be. Thus, by statistically quantifying the association between phenotypic and genetic similarity (i.e., relatedness) among individuals in a population we can estimate the genetic variance for a trait. In fact genetic variance itself can be further partitioned into additive and nonadditive components (the latter arising from dominance, epistasis, etc.; Falconer and McKay, 1996). In most wild quantitative genetic studies, the

additive genetic variance is of primary interest since it determines the predictable response to selection (and, more pragmatically, estimating other genetic components is difficult). The more additive the genetic variance, the more rapid a selection response can be. This idea is encapsulated in the univariate breeder's equation, $R = h^2S$. Here R is the per generation change in the mean phenotype (the 'response') which can be predicted as the product of S, a coefficient that measures the direction and strength of selection, and h^2, the narrow sense heritability. Heritability here is defined as the proportion of the phenotypic variance (V_P) attributable to the additive genetic variance (V_A). In reality, the breeder's equation is too simple to generally (if ever) be appropriate for predicting phenotypic change in the wild. This is because almost all the assumptions underpinning the model are likely to be violated in natural populations (Morrissey *et al.*, 2010). However, the point it illustrates nicely is that evolution (R) depends on both selection (S) and genetics (h^2).

In the same way that genetic effects can account for some of the observed trait variation, they may also explain covariation (or correlation) among traits. For instance, in many animals we find that larger individuals are (on average) more fecund. The positive covariance between body size and litter (or clutch) size may be due to environmental and/or genetic effects. If an individual finds itself in a good habitat patch it may acquire more resource than average, allowing it to invest heavily in both growth and reproduction. Here trait covariance is driven by environmental effects. However, if size is heritable, it is also possible that the same genotypes that cause large size also predispose to producing more offspring. One can estimate the contribution of (additive) genetic effects to the covariance COV_A, which is often standardized to a genetic correlation r_G.

For a pair of traits x, y we can define $r_{Gxy} = \frac{COV_{Axy}}{\sqrt{V_{Ax}V_{Ay}}}$.

Nonzero genetic correlations arise from underlying pleiotropy and/or linkage and mean that traits are not genetically independent of one another. As a consequence their selection responses will not be independent either (discussed below).

Development of Quantitative Genetics in the Wild

Applying quantitative genetic approaches to studies of natural populations is not completely straightforward, firstly because relationships among individuals are typically unknown, and secondly because datasets that from wild populations tend to be very different to those collected in carefully planned laboratory experiments. As such analyzing the data requires a somewhat different approach. The development of the field has been tightly linked to two methodological advances that have allowed empiricists to overcome these challenges. The first involved inferring relatedness using molecular markers (Garant and Kruuk, 2005). The second involved the adoption of advanced statistical techniques originally developed by animal breeders (Wilson *et al.*, 2010).

Inferring Relatedness

Estimating genetic variance requires knowing the relatedness among individuals (i.e., the proportion of the genome shared identically by descent). In wild populations where relatedness is typically unknown, two strategies are possible. The first consists in predicting relatedness from an inferred pedigree, with values of, for example, 0.5 between parents and their offspring, 0.25 between half siblings, and 0.125 between cousins. The second is to use estimates of pairwise relatedness made without an explicit pedigree structure.

To determine a pedigree structure it is sometimes possible to infer relationships from observations of social interactions (e.g., nestlings or mother–offspring pairs identified from suckling in mammals). However, this approach can only be used in a few taxa and can be inaccurate. For instance, assuming nestlings are full-siblings is problematic in many passerine birds because extra-pair paternity is common. This, in turn, can lead to biased quantitative genetic parameters and evolutionary inferences (Charmantier and Reale, 2005). The development of molecular markers, mainly microsatellite loci but increasingly single nucleotide polymorphism (SNP) has, broadly speaking, provided a solution to this issue. Given a relatively small set of genetic markers (typically 10–40 microsatellites), one can typically resolve close relationships within a population (e.g., parent–offspring and full-sibs) with satisfactory accuracy, allowing to reconstruct a 'molecular' pedigree even in the complete absence of behavioral information (Pemberton, 2008). Although applicable to a large number of species, molecular pedigree reconstruction is nonetheless dependant on the presence of close relatives, meaning that the approach is most useful in (usually small) populations where a fair number of close relative are likely to be sampled. It should also be noted that molecular pedigrees are generally still imperfect due to genotyping errors and incomplete sampling (Morrissey *et al.*, 2007; Morrissey and Wilson, 2010).

An alternative to using pedigrees to predict relatedness lies in estimating relatedness directly between all pairs of individuals using molecular markers (Wang, 2014). In theory this approach could be superior to pedigree-based methods because it estimates realized rather than expected relatedness (Visscher *et al.*, 2006; Speed and Balding, 2015). For example, under the pedigree approach all full-sibs pairs are assumed to share exactly 0.5 of their genome IBD, while in reality they vary around an expected population mean of 0.5 (Visscher *et al.*, 2006; Speed and Balding, 2015). However, to date the pedigree approach has been preferred in wild populations because estimating genome-wide relatedness accurately requires a very large number of markers. In particular, methods developed to take advantage of the small microsatellite datasets typical of molecular ecology studies over the last two decades tend to be statistically very 'noisy' (Ritland, 1996; Wilson *et al.*, 2003; Frentiu *et al.*, 2008). Note however that this issue can now be overcome by using very high densities of SNP markers (Bérénos *et al.*, 2014) and we anticipate a large growth in such 'pedigree-free' quantitative genetic studies in the very near future as a consequence of the adoption of next generation sequencing technologies.

Linear Mixed Effect Modeling and the 'Animal Model'

Heritabilities, genetic correlations, and other quantitative genetic parameters can be estimated from simple statistical

techniques including linear regression and ANOVA. In particular, parent–offspring regression was used in a large number of early field studies (Grant and Grant, 1995). However, these methods are not very well suited to analyzing the patchy and unbalanced datasets (i.e., lots of missing data and variable family sizes) or complex pedigree structures (i.e., pedigrees containing many classes of relationship, often spanning multiple generations) typical of studies in the wild. Nor do these methods easily allow a researcher to account for uncontrolled environmental effects, for instance spatial or temporal variation in habitat quality. For evolutionary ecologists testing environmental effects on phenotype is often an important aim in itself. In the context of quantitative genetic analyses, when relatives share environments (e.g., nest, maternal, or cohort effects) that are likely to influence phenotypes of interest, accounting for these 'common environment effects' is important to prevent environmentally driven resemblance among relatives from biasing estimates of genetic (co)variances (Kruuk and Hadfield, 2007).

The growth of quantitative genetics in the wild has been driven to a large degree by adoption of linear mixed effect models, and in particular the polygenic 'animal model,' in place of earlier statistical techniques. It is worth pointing out here that animal models are equally applicable to plants; the terminology simply reflects the method's development to allow analysis of complex pedigree structures as found in livestock systems. Early applications of animal models to natural systems immediately demonstrated its enormous potential (Réale *et al.*, 1999; Réale and Festa-Bianchet, 2000; Kruuk, 2004), and this is now by far the most widely used analytical approach. A detailed explanation of the animal model is beyond the scope of this article but see, for example, Kruuk (2004), Postma and Charmantier (2007), and Wilson *et al.* (2010) for treatments intended to be accessible for readers with limited statistical or genetic expertise. For present purposes, it suffices to say that this approach allows estimation of additive genetic (co)variance structures underpinning patterns of trait variation and covariation. To do this, animal models include, for each trait, an individual's genetic merit or 'breeding value' as a random effect. Breeding values are latent variables that represent the effect of an individual's genotype relative to the population mean phenotype. They are usually defined as coming from a normal distribution with mean zero and variance equal to V_A – the additive genetic variance. The expectation that breeding values will covary among individuals as a function of relatedness, means that we can estimate V_A provided we have pedigree (or relatedness) and phenotypic data for individuals in the population.

The animal model approach is equally applicable to single traits or multivariate phenotypes, and so can be used to estimate genetic covariances (COV_A). It is also highly flexible and can, for example, include additional fixed and random effects to account for nongenetic intrinsic sources of variation within and among individuals (e.g., age, date of capture, and sex) and environmental sources of resemblance among individuals (e.g., nest, spatial, or cohort effects). Models can be generalized to cope with non-Gaussian errors (e.g., if the trait of interest is binary or a count), and may be fitted using frequentist (e.g., restricted maximum likelihood) or Bayesian (e.g., Markov Chain Monte Carlo) inference methods in a range of statistical software applications (Gilmour *et al.*, 2006; Ovaskainen *et al.*, 2008; Hadfield, 2010). A brief overview of popular software and associated tutorials are provided in Wilson *et al.* (2010).

Lessons and Limitations

Quantitative genetic analyses have now been used to test specific evolutionary hypotheses about a wide range of phenomena in wild populations. Examples include, but are not limited to studies of maternal effects (McAdam *et al.*, 2002; Wilson *et al.*, 2005), parental care (MacColl and Hatchwell, 2003), mating systems (Reid *et al.*, 2014), phenotypic plasticity (Nussey *et al.*, 2005), senescence (Brommer *et al.*, 2007; Wilson *et al.*, 2008), sexual conflicts (Brommer and Rattiste, 2008; Poissant *et al.*, 2008), social evolution (Charmantier *et al.*, 2007), adaptation to climate change (Gienapp *et al.*, 2008), and predicting selection responses (Morrissey *et al.*, 2012a). This diversity of topics recapitulates the earlier point that quantitative genetic theory and methodology is very general. Space precludes detailed review of empirical findings here and the reader is referred elsewhere for more comprehensive treatments (see, e.g., Gienapp *et al.*, 2008; Kruuk *et al.*, 2008; Wilson *et al.*, 2008; Charmantier *et al.*, 2014). However, some general points emerging from studies to date are worth highlighting.

Genetic Variance Is Widespread and Abundant

A general conclusion emerging from the wealth of empirical studies is that natural populations harbor a good deal of additive genetic variance. This is often true for traits thought to be under strong selection (Kruuk *et al.*, 2008) and in some cases heritable variation has been found even for components of fitness itself (e.g., survival and reproduction; Wilson *et al.*, 2007a). Since selection is expected to reduce genetic variance by fixing beneficial alleles and purging deleterious ones, this has led to interest in the question of what maintains genetic variation (Hunt *et al.*, 2007; Walsh and Blows, 2009). In fact, while it has long been argued that there should be an inverse relationship between genetic variation (measured as, e.g., trait heritability) and the strength of selection, empirical evidence for this is mixed. Where heritability does decline with increasing selection, this pattern may be driven more by environmental contributions to V_P than by changes in V_A (e.g., Merilä and Sheldon, 2000; McCleery *et al.*, 2004, but see Teplitsky *et al.*, 2009 for a counter-example).

Evolutionary Change Is Hard to Predict and to Detect

The widespread finding of (within-population) additive genetic variance leads to an expectation of phenotypic change under the simplest evolutionary models (e.g., the univariate breeder's equation). This is because if traits are usually heritable, meta-analyses of natural selection studies indicate that directional selection (i.e., favouring phenotypic change) is also common (Kingsolver *et al.*, 2001). Conversely, the evidence for stabilising selection or selection that fluctuates in direction over temporal

or spatial heterogeneity appears less compelling (Kingsolver *et al.*, 2012; Morrissey and Hadfield, 2012; Siepielski *et al.*, 2013). While examples of rapid phenotypic change in wild populations are well documented (Hairston *et al.*, 2005), the extent to which these are explained by genetic responses to directional selection (i.e., evolutionary change) as opposed to, for instance, phenotypic plasticity and/or changing population demography (Ozgul *et al.*, 2010) is often less clear and represents a very active line of inquiry (Gienapp *et al.*, 2008).

In fact, for those systems where estimates of both selection and heritability are available, there often seems less change than the breeder's equation predicts (Merilä *et al.*, 2001). There are many possible reasons for mismatches between predicted evolution and observed phenotypic change (see, e.g., Merilä *et al.*, 2001; Walsh and Blows 2009; Morrissey *et al.*, 2010 for in-depth discussion). For instance, there could be evolutionary constraints arising from genetic correlations between a focal trait and other, correlated, traits under selection (Walsh and Blows, 2009); a point we return to below. Alternatively, we may have fundamentally misidentified the 'targets' of selection, interpreting trait-fitness correlations as causal (i.e., selection) when they are not (Morrissey *et al.*, 2010). It is also important to realize that quantitative genetic models predict responses to selection only. This can only reasonably be equated to total phenotypic change if environments are constant and genetic drift is negligible, conditions that will rarely (if ever) hold true. Separating genetic from nongenetic components of phenotypic change is possible using animal model-based approaches (Postma, 2006; Hadfield *et al.*, 2010). In simple terms, temporal trends in (predicted) breeding values over time (e.g., year of birth) should be indicative of genetic change in the population. However, while such trends have been widely claimed in the literature (Coltman *et al.*, 2003; Garant *et al.*, 2004; Wilson *et al.*, 2007b), they are no longer considered statistically robust (see Hadfield *et al.*, 2010 for an explanation of the problem but also a solution to it). This does not mean genetic responses to selection are not occurring in quantitative traits, but it does mean that unambiguously identifying and quantifying them is harder than was previously thought.

Trade-Offs May Not Be as Important as We Thought

Accepting that there is less evolutionary change than might, at least naively, be predicted from our estimates of selection and heritability, we must consider the question of what constrains adaptive evolution. Perhaps the most widely hypothesized form of evolutionary constraint is that of the trade-off between two traits (or fitness components) that 'compete' for resource allocation. An individual with limited resource can only allocate more to one trait (e.g., egg size) at a cost to the other (e.g., egg number). It is widely held that genetic correlations between traits involved in such resource allocation trade-offs should constrain evolution (Roff, 1997). With traits defined so as to be under positive selection (e.g., fecundity and survival), then a constraint arises from a negative genetic correlation. In this scenario, genotypes associated with high fecundity are not necessarily selectively advantageous because they come with the cost of reduced survival. In other words, selection is unable to optimize each trait independently, and the predicted outcome will be a compromise.

Interestingly, while trade-offs are central to many models of evolutionary outcomes in behavioral ecology and life history studies, quantitative genetic analyses of wild populations have often failed to document the negative genetic correlations predicted. In fact positive genetic correlations seem rather more prevalent (e.g., Coltman *et al.*, 2005; Kruuk *et al.*, 2008 for broader scale patterns). This suggests that wild populations can sometimes harbor genetic variance in individual 'quality' *sensu* Wilson and Nussey (2010), perhaps because high-quality genotypes predispose toward greater resource acquisition (de Jong and van Noordwijk, 1992; Wilson, 2014). This is not to say that trade-offs are not important, and there is clearly much work yet to be done. For instance, wider testing of the hypothesis that genetic correlations across environments constrain evolution (Sgrò, 2004; Robinson *et al.*, 2009) would be useful. However, taken at face value, the estimates of genetic correlations emerging from empirical quantitative genetic studies pose an interesting challenge to the pervasive view in evolutionary ecology that trade-offs routinely act as important sources of evolutionary constraint. They also support the view that bivariate (i.e., two trait) models will rarely be sufficient to identify evolutionary constraint (Walsh and Blows, 2009) such that fully multivariate studies are required (discussed further below).

Increasing the Range of Study Organisms and Focal Traits

The need for deep and well-connected pedigrees, combined with a strong interest toward systems were fitness metrics such as lifetime reproductive success are available has led to quantitative genetic studies in wild populations being disproportionately focused on a relatively small number of long-term ecological data sets in which individuals are marked and tracked across their lifetimes (Clutton-Brock and Sheldon, 2010; for specific examples see Kruuk *et al.*, 2002; McAdam *et al.*, 2002; Coltman *et al.*, 2005; Brommer *et al.*, 2007). These datasets are, of course, immensely valuable for all sorts of studies in ecology and evolutionary biology. However, they are also taxonomically biased toward animals, and in particular toward avian (especially passerine) and mammalian (notably ungulate) species frequently living under particular conditions (e.g., super-abundance of nesting sites in the form of nest boxes, predator free islands). Furthermore, the set of traits studied has, to a degree, been constrained by past data collection practices. As a consequence, in studies to date readily measured morphological and life history traits are better represented than, for example, behavioral or physiological ones.

If we hope to learn general lessons from quantitative genetic analyses of natural populations then obtaining suitable data on a greater diversity of taxa and traits should be prioritized. In fact trait diversity is already increasing, with growing interest in, for example, the genetic basis of variation in animal personality (Dingemanse *et al.*, 2009; Poissant *et al.*, 2013), dispersal (Charmantier *et al.*, 2011), disease resistance, and immune function (Graham *et al.*, 2010). Technological development is also rapidly increasing the number of traits that can be studied, for example, gene expression (Wolf, 2013), protein expression (Diz *et al.*, 2012) and (host) microbiomes (Spor *et al.*, 2011). Taxonomic diversity may also be increased through a variety of strategies including wider user of

molecular pedigree analysis in, for instance, fish (Wilson and Ferguson, 2002; Koch *et al.*, 2008) or invertebrates (Bretman *et al.*, 2011), and application of so called pedigree-free methods (Bérénos *et al.*, 2014). Additionally, efforts to better integrate the largely animal-focussed field of wild quantitative genetics, with the field of plant evolutionary ecology should be productive (Stinchcombe, 2014), particularly since plant systems often provide greater scope for experimentation.

Analytical and Statistical Challenges

The biological insights that can be obtained from any statistical modeling approach are properly limited by the quality and quantity of data, and by the validity of the model assumptions. It is perhaps justifiable to say that successfully applying quantitative genetic methods requires a degree of statistical competence (or at least perseverance) not always essential to other approaches. The rapid growth of wild quantitative genetics has been such that – perhaps inevitably – mistakes have been made along the way (e.g., inappropriate use of predicted breeding values to test selection responses as highlighted by Hadfield *et al.* (2010)). Nonetheless, development of models, analytical methods, and tools to help the empiricist has been rapid over the last decade and looks set to continue.

It is worth bearing in mind that while all quantitative genetic studies require a relatively large amount of data, studies in natural populations often suffer from small sample sizes, and so reduced statistical power, relative to those conducted in the lab. Often this simply reflects the intrinsic difficulty of sampling wild, free-living organisms. In addition, the lack of controlled conditions and (commonly) an absence of experimental manipulation can make statistical separation of environmental and genetic influences on phenotype unreliable. This is particularly true if close relatives share environments (Kruuk and Hadfield, 2007). Explicit modeling of environmental effects helps (see Stopher *et al.*, 2012 for an excellent example), especially if combined with experimental approaches such as cross-fostering of eggs or offspring (**Figure 2**) which is possible in some taxa (Hadfield *et al.*, 2013). Of course, models with more effects means estimating more model parameters from the same (limited) amount of data. What this ultimately means is that, while insightful findings emerge from individual case studies, there is a strong need for replication and meta-analyses. This combined with recent interest in making datasets public (Roche *et al.*, 2014) means that studies interrogating multiple datasets at once (Teplitsky *et al.*, 2014) are likely to increase in popularity.

Emerging Directions

Toward a Multivariate View of Adaptation and Constraint

Natural selection does not act on phenotypic traits in isolation from each other. Rather it is the process whereby differences in fitness arise (causally) from among individual variation in the multivariate phenotype (i.e., the set of all traits describing an individual's morphology, behavior, life history, and physiology). Many traits will be under selection, and genetic correlations among them mean that they are not free to evolve independently. Explicit recognition of this leads somewhat inescapably to the view that multivariate studies will be necessary to fully understand adaptation and evolutionary constraint (Blows, 2006; Blows and Walsh, 2009; Walsh and Blows, 2009). If empiricists have been a bit slow to embrace this, opting more commonly to focus on single traits or at best pairs of traits (e.g., homologous male and female traits; Poissant *et al.* (2010) or those putatively linked by trade-offs as outlined above), then there are at least sensible and pragmatic reasons for this. Firstly, it is difficult to obtain phenotypic data on all traits that might be important determinants of fitness, particularly in the field where sampling individuals at all can be challenging! Secondly, as the number of traits to be considered rises, the number of quantitative genetic parameters to be estimated from the data increases rapidly exacerbating the statistical challenges outlined earlier.

Nonetheless, failure to accurately predict change or explain stasis from univariate and bivariate studies of wild populations is leading researchers to model larger sets of traits. The starting point is usually to estimate the additive genetic variance–covariance matrix G among traits and a vector describing directional selection on each trait β, to predict the multivariate response (R) using the multivariate breeders equation, $R = G\beta$ (Lande, 1982). **Figure 3** illustrates this for the simplest (two traits) case, in which negative genetic covariance between positively selected traits constrains adaptation (i.e., the trade-off scenario discussed earlier). Importantly however, this multivariate approach to quantifying adaptive potential and constraint extends to any number of traits in a multivariate phenotype (Coltman *et al.*, 2005; Agrawal and Stinchcombe, 2009; Morrissey *et al.*, 2012b; Teplitsky *et al.*, 2014; Walling *et al.*, 2014).

Social Interactions and Shared Phenotypes

Quantitative genetics allows us to disentangle genetic from environmental influences on phenotype. However, environmental effects on a focal animal's phenotype (and fitness) often arise through social interactions with other individuals. For example, postnatal growth rates in mammals depend on the quantity and quality of milk provided by mothers. In this case, offspring phenotype (growth) depends on the 'environment' provided by a maternal phenotype (milk production). However, if maternal milk production is heritable, then there is a causal link between the genotype of one individual (the mother) and the phenotype of another (the offspring). This type of maternal effect represents one example of what is termed as indirect genetic effect (IGE; Moore *et al.*, 1997) or associative effect (Griffing, 1967, 1976). In the presence of IGE, genetic control of observed phenotypes is shared between interacting individuals, which could be parents and offspring (McAdam *et al.*, 2002; Wilson *et al.*, 2005), mating partners (Brommer and Rattiste, 2008; Teplitsky *et al.*, 2010), competitors (Wilson *et al.*, 2011), or cooperators (Charmantier *et al.*, 2007). Because individuals – and so their genotypes – determine the social environment, social environments can themselves evolve. This could have major implications for our understanding of trait evolutionary dynamics in wild populations. For example, if individuals differ (genetically) in

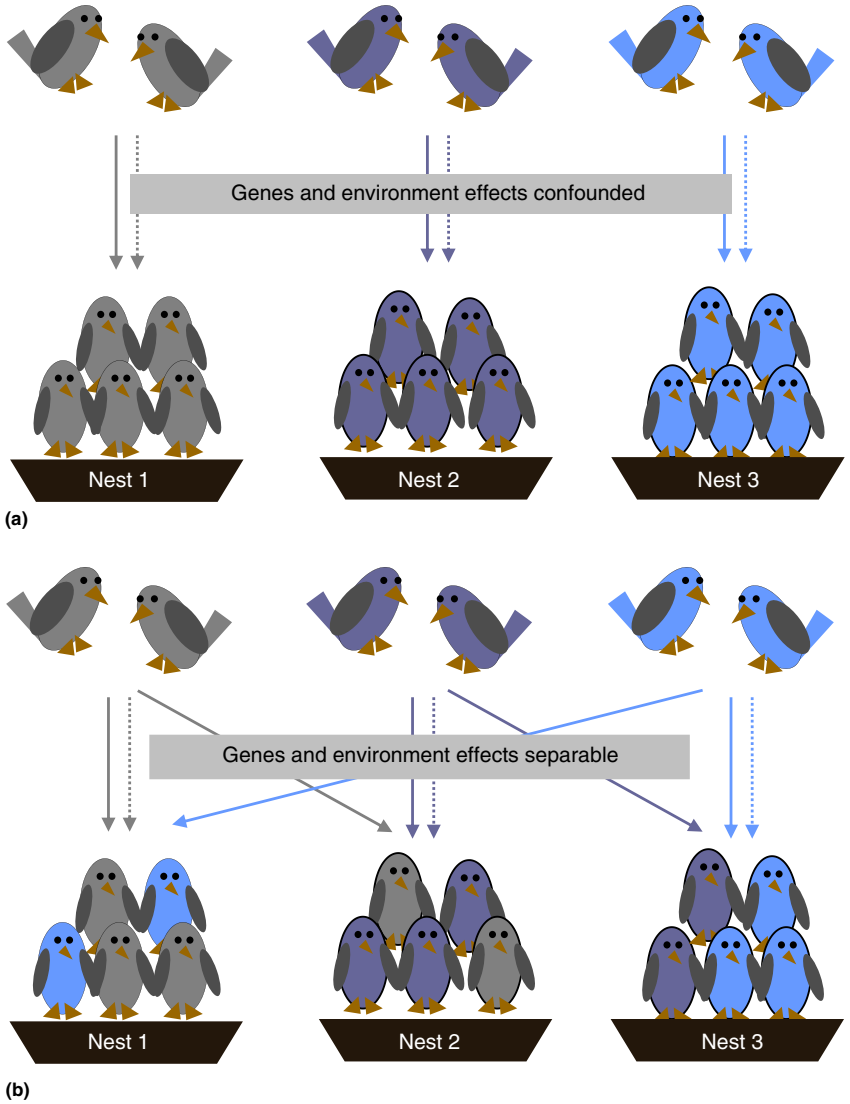

Figure 2 Cross-fostering is an experimental technique useful for disentangling genetic from environmental sources of variation in offspring phenotype. Parental birds influence offspring phenotype both via genetic inheritance (solid arrows) and through provision of the early life environment (dotted arrows, e.g., amount of food being provisioned to the nest). In the absence of experimental manipulation (a) these effects are completely confounded within each family (color) and so difficult to tease apart statistically. This problem is alleviated by cross-fostering designs in which hatchlings (or eggs) are exchanged between nests. Individuals now have genetic siblings elsewhere (i.e., sharing genes but not environment) and foster-siblings in their own nests (i.e., sharing environment but not genes). Cross-fostering is most widely used in wild bird studies but has also been successfully applied to mammals and insects in the lab.

competitive ability then we predict that IGE will act to constrain adaptation of resource dependent life history traits (Wolf, 2003; Hadfield *et al.*, 2011; Wilson, 2014). To date maternal effects have been the most widely studied form of IGE (McAdam *et al.*, 2014), but rapid development of theory and statistically tractable models (Bijma *et al.*, 2007; Bijma and Wade, 2008) means that the IGE framework will increasingly be used to model the quantitative genetics of social interactions.

Genetic Architecture of Quantitative Traits

Classical quantitative genetics approaches do a fairly good job at describing trait inheritance (Lynch and Walsh, 1998) and provide us with predictive models for adaptive phenotypic evolution (Morrissey *et al.*, 2010). However, they do not allow characterizing the loci underpinning trait variation, which considerably limits our understanding of the mechanisms and evolutionary processes involved (Mackay, 2001; Barrett and Schluter, 2008; Slate *et al.*, 2010). While substantial progress has been made toward describing the genetic architecture of quantitative traits in humans (Stranger *et al.*, 2011), agricultural species (Hayes and Goddard, 2001; Hayes *et al.*, 2010), and laboratory models such as *Drosophila melanogaster* and *Mus musculus* (Flint and Mackay, 2009), similar research in natural populations is still in its infancy (Slate *et al.*, 2010; Schielzeth and Husby, 2014). Mostly, this is due to past challenges in developing and genotyping large sets of markers

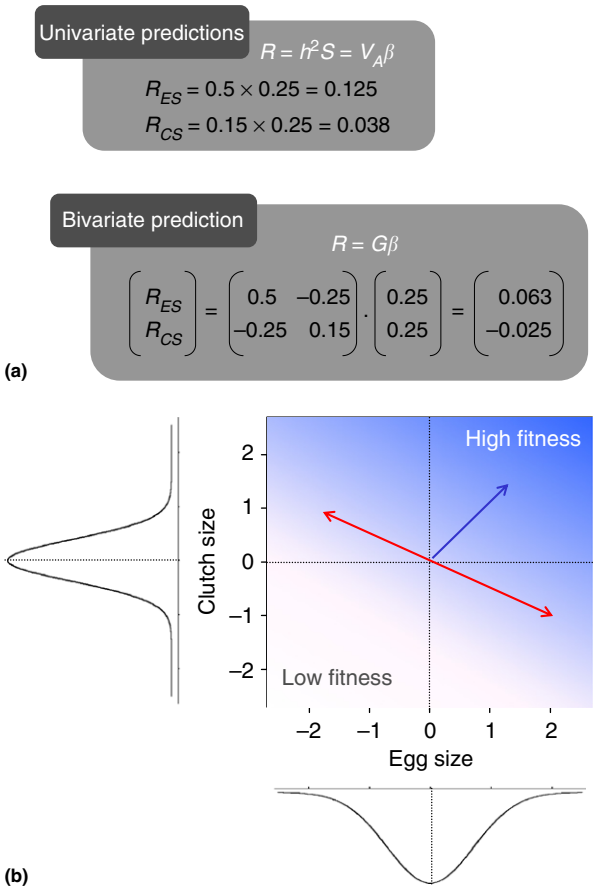

Figure 3 Trade-offs as a source of evolutionary constraint. Imagine a population in which clutch size (CS) and egg size (ES) are both under positive direction selection (with standardized selection gradients β equal to 0.25 on both traits) and genetically variable (with $V_{A(ES)} = 0.5$ and $V_{A(CS)} = 0.15$). While the univariate breeder's equation predicts a moderate increase in mean phenotype for each trait, the predictions responses under a bivariate model are much if there is a negative genetic correlation between them (here $COV_A = -0.25$ so $r_G = -0.91$). In fact, the bivariate model actually predicts a decrease in mean clutch size despite the positive selection on it. This scenario is depicted graphically in (b) where breeding values (black circles) for each trait are normally distributed but also covary negatively. This means that the major axis of genetic variation for the bivariate phenotype (red line) does not align with the direction of selection (blue arrow). Some adaption (i.e., evolution toward darker blue phenotypic space) is still possible so the constraint is not absolute. However, the rate of adaption is limited by the relative lack of genetic variation in the direction of selection.

in non-model organisms. However, as new technologies and approaches are now allowing rapid genotyping at tens to hundreds of thousands of SNP markers at reasonable cost in any species (Slate *et al.*, 2009; Davey *et al.*, 2011), research on the genetic architecture of quantitative traits in natural populations is set to blossom.

Traditionally, research on genetic architectures has focussed on mapping and characterizing loci responsible for phenotypic variation (Lynch and Walsh, 1998). The general principle behind quantitative trait locus (QTL) mapping is fairly simple. In brief, linkage disequilibrium (LD) between genetic markers and causative polymorphisms generates statistical associations between markers and phenotypes, and knowledge about the position of markers in the genome allows 'mapping' those associations (Lynch and Walsh, 1998). In unmanipulated natural populations, QTL are usually mapped using genome-wide pedigree linkage analysis (George *et al.*, 2000; Slate, 2005) or association studies (GWAS; McCarthy *et al.*, 2008). The first approach relies on LD generated by recombination events within pedigrees while the second relies on LD generated by historical recombination (Devlin and Risch, 1995). GWAS offer several advantages over pedigree linkage analysis, including much finer resolution (Devlin and Risch, 1995), increased power (Risch and Merikangas, 1996), and the ability to estimate allele-specific effects. GWAS also offer the practical advantages of not being dependent on the availability of genetic linkage maps, provided that marker positions can be inferred from a genome sequence, and of not requiring pedigree information (Slate *et al.*, 2010; Schielzeth and Husby, 2014). Nonetheless, so far pedigree linkage analysis has been favoured because it only requires a few hundred markers whereas efficient GWAS generally require tens if not hundreds of thousands of markers (Schielzeth and Husby, 2014). However, as large SNP datasets can now be generated with relative ease, GWAS are set to become more common in wild populations (Schielzeth and Husby, 2014).

In situ research in natural populations provides a unique opportunity to study naturally segregating adaptive standing genetic variation in an ecologically realistic setting (Ellegren and Sheldon, 2008). However, it must be stressed that researchers are facing important challenges (Slate *et al.*, 2010; Jensen *et al.*, 2014; Schielzeth and Husby, 2014). In particular, research in humans and other well-studied organisms indicates that QTL mapping often fails to identify many of the loci influencing quantitative traits (Manolio *et al.*, 2009). In studies of natural populations where sample sizes are usually comparatively modest this is likely to be an important issue (Santure *et al.*, 2013; Slate, 2013). This difficulty will also often be exacerbated by an inability to replicate or validate results due to the long-term and unique nature of some study systems and Genotype-by-environment interactions. In that context, new approaches aimed at describing general attributes of genetic architectures, rather than identifying individual loci *per se*, such as partitioning genetic variance among chromosomes or chromosome segments (Hayes *et al.*, 2010; Yang *et al.*, 2011; Robinson *et al.*, 2013), may prove to be particularly valuable. For example, information on the mean and variance of effect sizes across chromosomal segments could be combined with selection estimates to empirically test for a hypothesized relationship between genetic architectures and selection (Rajon and Plotkin, 2013).

Conclusions

Since the late 1990s we have witnessed a rapid increase in the number of quantitative genetic studies of wild populations *in situ* (Charmantier *et al.*, 2014). As developments in genotyping technologies and analytical techniques are now set to democratize this type of analysis to virtually any species, the

field will likely see an even more dramatic increase in popularity in the years to come. Although there are important limitations and challenges, if the goal is to understand phenotypic evolution in the wild as a dynamic and ongoing process, then quantitative genetic analyses provide clear benefits. This is because, in contrast to other approaches in evolutionary ecology (e.g., behavioral ecology and life history theory), it rejects the implicit assumption that adaptation can be studied while ignoring all genetic considerations. By recognizing that adaptive evolution depends on both natural selection and genetic (co)variation, quantitative genetic studies of wild populations provide understanding of both how natural selection has shaped phenotypes in the past, and how it will do so in the future.

Quantitative Genetic Variation

TFC Mackay, North Carolina State University, Raleigh, NC, USA

Natural populations exhibit variation for most measurable aspects of their phenotypes: morphology, physiology, behavior, and disease susceptibility. This phenotypic variation is typically continuously distributed and correspondingly these phenotypes are called 'quantitative traits' (Falconer and Mackay, 1996; Lynch and Walsh, 1998). The continuous variation arises from genetic complexity and environmental sensitivity: segregating alleles at multiple loci mean that many genotypes can give rise to the same phenotype, and the same genotype can have different phenotypic effects in different environments. Quantitative genetic variation is the substrate for phenotypic evolution in natural populations and for selective breeding of domestic crop and animal species. Quantitative genetic variation also underlies susceptibility to common complex diseases and behavioral disorders, as well as responses to pharmacological therapies. Knowledge of the detailed genetic underpinnings of variation for quantitative traits is thus critical for addressing unresolved evolutionary questions about the maintenance of genetic variation for quantitative traits within populations and the mechanisms of divergence of quantitative traits between populations and species; for increasing the rate of selective improvement of agriculturally important species; and for the development of novel and more personalized therapeutic interventions for improving human health.

The birth of genetics began with Mendel's discovery of the laws of segregation and independent assortment of alleles with large qualitative effects that can be tracked in pedigrees. However, these laws seemed to contradict the observation that many traits vary continuously and that offspring phenotypes were often near the average of both parents. Early in the twentieth century, Fisher resolved the apparent contradiction between the discrete nature of Mendelian inheritance with the continuous variation for quantitative traits, and provided the theoretical basis for understanding quantitative trait genetics (Fisher, 1918). Each locus affecting a quantitative trait has the same properties as a Mendelian locus. The differences are that the phenotypic effects are smaller and need to be measured (as opposed to categorized); there are many such loci acting together; the quantitative effects are sensitive to the environment; and the population allele frequencies need to be taken into account.

Properties of Quantitative Traits

To understand how individual loci with discrete allelic differences can give rise to patterns of trait variation, we can consider the simple case of a single diploid locus with two alleles, and thus three genotypes (A_1A_1, A_1A_2, A_2A_2; by convention, the A_2A_2 genotype is associated with decreased values of the trait). Building from this simple bi-allelic model is not meant to imply that traits in nature have such a simple genetic basis, but rather, provides the foundation upon which our understanding of multi-locus inheritance can be constructed. The mean value of each genotype is the population mean, averaged across all other segregating genotypes and the range of environments experienced by the population. These mean values, which are expressed in the units in which the phenotype is measured, can be assigned general genotypic values of $+a$ (A_1A_1), d (A_1A_2), and $-a$ (A_2A_2). These values are scaled relative to the midpoint between the two homozygotes, which is set to zero. Thus the additive effect, a, is one half of the difference in mean phenotype between the two homozygous genotypes; and the dominance effect, d, is the difference between the mean phenotypic value of the heterozygous genotype and the average of the two homozygous genotypes (Falconer and Mackay, 1996). d can vary to express any degree of dominance from $d = +a$ (the A_1 allele is dominant), $d = -a$ (the A_2 allele is dominant) to anything in between. If $d = 0$, we call the effect additive (or co-dominant) because the mean phenotype of heterozygotes is the same as the mean of the two homozygotes; $d > +a$ and $d < -a$ represent cases of over- and under-dominance, respectively.

Mendelian loci often exhibit a phenomenon called 'epistasis,' whereby the effects of one locus mask the effects of another and give rise to distorted segregation ratios in a cross of doubly heterozygous genotypes. Epistasis can be modeled for quantitative traits by considering the joint effects of two loci affecting the trait, A and B, each with two alleles. Thus, there are 9 possible two locus genotypes. If the effects of these genotypes can be predicted given the homozygous or dominance effects at each of the two loci (e.g., the effect of genotype $A_1A_2B_1B_1$ is $d_A + a_B$), then we say the two loci act additively. Note that we use the same word, additive, to refer to absence of dominance at a single locus and absence of epistasis for multiple loci. If, however, the effects of the two locus genotypes are not equal to those expected from the two individual loci, then there is epistasis, which is parameterized by additive by additive (aa_{AB}), additive by dominance (ad_{AB}, da_{AB}), and dominance by dominance interactions (dd_{AB}) (Falconer and Mackay, 1996; Mackay, 2014). These interaction effects are not restricted to the traditional epistatic effects detected for Mendelian loci, but can take on any quantitative value. The hallmark of epistasis for a quantitative trait is that the additive and/or dominance effect of one locus varies, depending on the genotype of the interacting locus (Mackay, 2014). Of course epistatic interactions are not constrained to occur between only two loci but can be of higher order and very difficult to parameterize.

Alleles affecting quantitative traits can take on a range of effects depending on the physical and social environment experienced by the individuals with the same genotype, a phenomenon called 'phenotypic plasticity.' These effects can be large, if the individuals are reared in very different environments (sometimes called macro-environments) or more subtle, when environmental conditions are tightly controlled. Thus, even genetically identical individuals reared in the same environments will have different phenotypes, called environmental

 doi:10.1016/B978-0-12-800049-6.00041-X

noise or micro-environmental plasticity (Falconer and Mackay, 1996; Lynch and Walsh, 1998). To further complicate matters, different genotypes can have differential plastic responses to the same large environmental change (called genotype by environment interaction (GEI)) or the same range of micro-environments (Falconer and Mackay, 1996; Lynch and Walsh, 1998). In addition, different genotypes may experience different environments because of their phenotype (called genotype–environment correlation). Examples of the latter include feeding dairy cows according to their milk yield, training race horses according to their pedigree, and 'niche construction' in nature (Falconer and Mackay, 1996).

Finally, quantitative trait phenotypes can differ between different populations if the allele frequencies at the loci affecting the trait differ, even if the underlying genetic architecture is identical. This is easy to visualize by considering just one locus. If a population is fixed for the A_2A_2 genotype, then the population mean will be $-a$, whereas if the population is fixed for the A_1A_1 genotype, the population mean will be $+a$.

When we say that we wish to understand the genetic architecture of any quantitative trait, this is what we need to know (Mackay, 2001). (1) The numbers and identities of genes at which mutations affecting the trait arise, and the subset of these genes at which alleles affecting the trait segregate in natural populations. (2) The distribution of allelic effects of new mutations and segregating variants in nature. This could range from alleles of large effect segregating at a few loci to alleles of small effect segregating at many loci; or an exponential distribution of allelic effects with alleles with moderately large effects segregating at a few loci and alleles with small effects segregating at a large number of loci. (3) The effects of new mutations and segregating alleles on other quantitative traits (pleiotropy), including intermediate molecular phenotypes and reproductive fitness. (4) The manner in which alleles at multiple loci interact (additive or epistatic). (5) The answers to the above questions in a range of ecologically relevant environments, and the magnitude of GEI. (6) The identity, site class (i.e., regulatory or coding regions), and allele frequencies of causal molecular variants.

This seems like an impossible task, given the nonlinearity of the genotype–phenotype map for quantitative traits. In the pre-genome era, the general principles of genetic architecture have been worked out by realizing that although the loci cannot be individually distinguished, they collectively affect the trait variance. Further, relatives resemble each other for quantitative trait phenotypes; the extent of the resemblance depends on how close the relationship is. These two principles can be combined to infer the relative contribution of genetic and environmental variance to the phenotypic variance of a quantitative trait by measuring trait phenotypes on collections of related individuals (Falconer and Mackay, 1996; Lynch and Walsh, 1998). This allows the relative contributions to be estimated, and for the different sources of genetic variation to be distinguished by comparing different types of relatives, as described in more detail below.

Partitioning Variance Components

We begin with a description of the components of phenotypic variation (σ^2_P) for the trait; a quantity that can be readily estimated by measuring the trait on a sample of individuals from the population of interest. We know that we can broadly partition this into a component attributable to all sources of genetic (σ^2_G) and environmental (σ^2_E) variation. The genetic variance can be further partitioned into components consisting of additive genetic variance (σ^2_A), dominance variance (σ^2_D), and epistatic interaction variance (σ^2_I) (Falconer and Mackay, 1996; Lynch and Walsh, 1998). These genetic variance components are themselves complicated, and are functions of additive, dominance, and epistatic effects of all loci contributing to genetic variation of the trait and their allele frequencies. Genotype–environment correlation adds $2cov_{GE}$ (the correlation is parameterized by the covariance to retain the units of variation) to the phenotypic variance; and genotype–environment interaction adds σ^2_{GE} (Falconer and Mackay, 1996; Lynch and Walsh, 1998). In experimental quantitative genetic analyses, genotypes are randomized across standardized environmental conditions, so there should be no contribution of genotype–environment correlation or interaction to the phenotypic variance. However, this is not possible in natural settings. If cov_{GE} exists and we do not know about it, the practical consequence is that it is considered part of the genotype, and σ^2_G is increased by $2cov_{GE}$ (Falconer and Mackay, 1996). If we do not know the environments experienced by the individuals, σ^2_{GE} increases σ^2_E. σ^2_E can itself be partitioned into components due to any shared common spatial ($\sigma^2_{Ec(S)}$), temporal ($\sigma^2_{Ec(T)}$), or maternal ($\sigma^2_{Ec(M)}$) environments, which increase the phenotypic resemblance of related individuals over and above that due to genetic relatedness, and the residual, environmental variance (σ^2_{EW}) (Falconer and Mackay, 1996; Lynch and Walsh, 1998). In experimental quantitative genetic studies, $\sigma^2_{Ec(S)}$ and $\sigma^2_{Ec(T)}$ can usually be avoided or estimated; $\sigma^2_{Ec(M)}$ can be more problematic, especially for mammals.

Now let us consider the causes of phenotypic resemblance among relatives: this is because they share the same alleles and sometimes genotypes (called genetic covariance) and also because they share environments (common environmental variance). (Note that here we refer to the genetic covariance among individuals, not between traits as discussed in later chapters.) The probability that relatives share alleles due to having a common ancestor is the coefficient of relatedness, r; and the probability that relative share genotypes due to common ancestry is u. In a random breeding population, $r = ½$ for parents and offspring and full-siblings (both parents in common); $r = ¼$ for half-siblings (one parent in common), and $r = 1$ for monozygotic twins. Relatives in a random mating population can only share genotypes due to common ancestry if their pedigree can be traced back to the same individual(s). For example, $u = 0$ for parents and offspring and half-siblings and $u = ¼$ for full-siblings. The following expression gives the genetic covariance for any degree of relationship in a random mating population: $cov_G = r\sigma^2_D + u\sigma^2_D + r^2\sigma^2_{AA} + ru\sigma^2_{AD} + u^2\sigma^2_{DD} + r^3\sigma^2_{AAA} + r^2u\sigma^2_{AAD} + ru^2\sigma^2_{ADD} + u^3\sigma^2_{DDD}$ etc. (Falconer and Mackay, 1996; Lynch and Walsh, 1998). For most relatives, the largest coefficient is for the additive genetic variance, and coefficients on the epistatic variance terms are small (at most ¼). The exception is monozygotic twins, for which $r = u = 1$. However, it should be noted that all estimates of additive variance from data on relatives include

fractions of the higher order additive by additive interaction variances, and that for n loci there are n additive effects but of the order of n^2 pairwise interactions, n^3 three-way interactions, etc.

Inbreeding (mating of related individuals) causes a re-distribution of genetic variance between and within inbred lines. If all genetic variance is additive, the variance within inbred lines is $(1-F)\sigma_A^2$ and between inbred lines is $(1+F)\sigma_A^2$, where F, the inbreeding coefficient is the probability that alleles are identical by descent (i.e., from the same common ancestor) (Falconer and Mackay, 1996; Lynch and Walsh, 1998). Thus, if lines are inbred to homozygosity, $F = 1$ and there is no genetic variance within each line, while the genetic variance between lines is double that in the outbred population from which they were derived. With dominance and epistasis, the re-distribution of genetic variance depends on allele frequencies of the underlying loci, so there is no general solution in terms of variance components in the base population until $F = 1$. At that point, the genetic variance between inbred lines is $2\sigma_A^2 + 4\sigma_{AA}^2 + 8\sigma_{AAA}^2 + \ldots$; i.e., pairwise and higher order epistatic interactions contribute to genetic divergence between fully inbred lines (Falconer and Mackay, 1996; Lynch and Walsh, 1998).

We can readily estimate the regression of offspring phenotypic values on those of their parents, as well as estimate the intraclass correlation coefficient among full- or half-sib families. These simple classic designs serve to illustrate the complexities of estimating genetic variance components for quantitative traits. Regressions (b) or intraclass correlations (t) are, respectively, estimates of the phenotypic covariance between offspring and parents divided by the total phenotypic variance, or of the phenotypic covariance between full- (or half-) sib families divided by the total phenotypic variance. If we ignore three-way and higher epistatic interactions, the expected genetic and environmental contributions to each in an outbred population are as follows (Falconer and Mackay, 1996; Lynch and Walsh, 1998):

Regression of offspring on one parent:

$$b_{OP} = \frac{\frac{1}{2}\sigma_A^2 + \frac{1}{4}\sigma_{AA}^2 + \sigma_{Ec(OP)}^2}{\sigma_P^2}$$

Intraclass correlation of full sibs:

$$t_{FS} = \frac{\frac{1}{2}\sigma_A^2 + \frac{1}{4}\sigma_D^2 + \frac{1}{4}\sigma_{AA}^2 + \frac{1}{8}\sigma_{AD}^2 + \frac{1}{16}\sigma_{DD}^2 + \sigma_{Ec(FS)}^2}{\sigma_P^2}$$

Intraclass correlation of half sibs:

$$t_{HS} = \frac{\frac{1}{4}\sigma_A^2 + \frac{1}{16}\sigma_{AA}^2 + \sigma_{Ec(HS)}^2}{\sigma_P^2}$$

Thus, in each case, we have two estimates (the regression or intraclass correlation and the total phenotypic variance) and several unknowns (additive genetic variance plus other sources of genetic variance and any spatial, temporal or maternal common environment). Thus, we can estimate the joint contribution of all terms in the numerators of these expressions, but cannot partition them further. In principle, we could estimate some individual components by comparing genetic covariance for different degree relatives. However, this is difficult in practice because the estimates of variance components have high standard errors and require extremely large sample sizes. Organisms can be inbred to homozygosity as well as outcrossed, providing the opportunity to infer the relative contribution of additive genetic and interaction variance components and enable more sophisticated experimental designs, but these are not generally applicable to all organisms. Finally, common environment effects in organisms where they cannot be eliminated or accounted for will always bias the estimate of genetic covariance upwards.

Heritability

Of all the genetic variance components, σ_A^2, the additive genetic variance, is the most important for two reasons. First, it makes the largest contribution to the resemblance of most types of relatives. Second, the additive genetic variance is defined so that it represents the fraction of the genetic variance that is transmitted from parents to offspring. An important concept in quantitative genetics is the narrow sense heritability (h^2), which is defined as the ratio of additive genetic variance to the total phenotypic variance ($h^2 = \frac{\sigma_A^2}{\sigma_P^2}$) (Falconer and Mackay, 1996; Lynch and Walsh, 1998). Put simply, the narrow sense heritability of a quantitative trait is the reliability of an individual's own phenotype as an indicator of its 'breeding value'; the proportion of the deviation of a parent's phenotype from the population mean that is expected to be transmitted to the progeny. If an individual's phenotype is x units above average, then the average phenotypic value of the offspring will be xh^2 units above average. This concept underpins the ability of a population to respond phenotypically to natural or artificial truncation selection: if parents are chosen based on the deviation of their average phenotypic value ($\overline{X}$) of a quantitative trait from the population mean (μ), then the average phenotype of their offspring will be $h^2(\overline{X} - \mu)$ units above the population mean. The narrow sense heritability can be readily estimated (with differing degrees of bias and precision) as $2b_{OP}$, $2t_{FS,}$ and $4t_{HS}$; from response to truncation selection; and using more elaborate experimental designs (Falconer and Mackay, 1996; Lynch and Walsh, 1998).

Heritability can be a slippery concept. The word suggests that it refers to whether or not a phenotype is inherited; this is not true. All phenotypes are inherited in the sense that developmental genetic programs are responsible for their manifestation. Heritability is a population concept and refers to the fraction of the variation in phenotypes among individuals that is due to additive genetic variance. Additive genetic variance in turn depends on allele frequencies at contributing loci and can be different in different populations if allele frequencies are different. Neither does additive genetic variance convey information about the gene action of contributing loci; additive variance is generated for loci with dominance/recessive gene action as well as epistasis over a wide range of allele frequencies. Heritability can also differ between populations if they experience different environments. Heritability therefore conveys no information about any difference in mean phenotype between populations (Falconer and Mackay, 1996; Lynch and Walsh, 1998).

Quantitative Trait Loci Mapping

Estimation of variance components, particularly the additive genetic variance, is critical for predicting short-term responses to natural or artificial selection. However, addressing the questions raised above regarding the genetic architecture of quantitative traits requires that we know the causal molecular polymorphisms, their gene action (additive, dominance, epistatic effects), and their allele frequencies. This information is required in order to predict individual phenotypes from genotypes (as opposed to mean offspring phenotypes). In this case, both additive as well as non-additive genotypic effects are important, even if they contribute little to the total additive variance of the trait. Mapping the quantitative trait loci (QTLs) affecting natural variation for quantitative traits is achieved using polymorphic marker loci with clear Mendelian segregation in linkage or association mapping populations (Falconer and Mackay, 1996; Lynch and Walsh, 1998). The principles of QTL mapping have been known since the early twentieth century; however, only recently has the discovery of abundant molecular markers, advances in rapid and cost-effective genotyping methods, including whole genome sequencing, and the development of sophisticated statistical and computational methods facilitated the molecular dissection of quantitative traits in a wide range of organisms.

QTL mapping requires a population for which there is genetic variation for the trait of interest, and in which individuals have been phenotyped for the trait and genotyped for a panel of molecular markers. In a classical linkage mapping population, correlations between the unknown variants affecting the quantitative trait and the molecular marker genotypes (this correlation is called linkage disequilibrium, LD) are generated by producing segregating progeny from two parental lines that are genetically divergent for the trait. In an association mapping population, LD between the causal variants affecting the trait and the molecular markers are generated by many generations of recombination during the population's history. In both cases, QTLs are detected if there is a difference in trait phenotype between the genotypes at a marker locus (Falconer and Mackay, 1996; Lynch and Walsh, 1998). This simple test is repeated for all markers (or pairs of markers) in a genome scan. Evidence for association is then evaluated after accounting for the multiple tests performed.

The choice of experimental design for QTL mapping is largely predicated by the biology of the organism being studied. Linkage mapping has the advantage that all alleles are at intermediate frequencies, which increases the power of mapping; and that LD is generated by the experimental design and not attributable to other causes that could give rise to spurious associations. However, linkage mapping interrogates a small sample of genetic diversity in the population (this can be partially ameliorated by constructing populations from four or eight parental lines); and the precision of mapping is limited by the numbers of recombination events that occur when creating the population. In contrast, association mapping can have greater mapping precision given the many generations of recombination experienced by most outbred populations and samples a wider range of genetic diversity. The drawbacks of association mapping are that very large numbers of marker loci are needed to account for the larger number of recombination events; the power to detect QTLs declines as the allele frequencies decrease (and individual rare alleles cannot be interrogated at all); and LD can be caused by population processes not related to genetic linkage (e.g., population structure that is not accounted for) that can cause spurious associations. Very large sample sizes are required in both linkage and association mapping studies to detect alleles with small to moderate effects with *P*-values that are low enough to pass multiple testing criteria (Falconer and Mackay, 1996; Lynch and Walsh, 1998).

Lessons Learned

Some general conclusions regarding the genetic architecture of quantitative traits have emerged from high-resolution QTL mapping studies in humans and especially in model organisms such as yeast, *Drosophila*, *Arabidopsis*, and mice (Mackay, 2001; Flint and Mackay, 2009; Mackay *et al.*, 2009; Mackay, 2014).

1. Most quantitative traits are indeed highly polygenic, with hundreds, if not more, contributing loci with additive effects. The corollary is that the individual additive effects are typically small, and together contribute only a small fraction of the total genetic variation in association mapping populations, especially in humans. This could be because the total additive genetic variance is overestimated due to the contribution of dominance and epistatic variance and/or because the effects of causal variants are underestimated when they are in LD with the marker locus.
2. The genetic basis of variation for quantitative traits inferred from mapping natural variants is typically novel and distinct from that inferred by studies of mutations with large effects. Possibly segregating variation may not be maintained in natural populations at loci that are required for wild type expression of the trait, and, conversely, mutagenesis screens miss (or ignore) loci at which mutations with subtle effects could affect quantitative traits.
3. Variants affecting quantitative traits have highly context-dependent effects; i.e., their effects differ in magnitude and/or direction in different genetic backgrounds (epistasis), different environments (GEI), and between males and females (genetic variation in sexual dimorphism). Thus, additive effects of alleles with highly context-dependent effects may not be detectable when averaged over multiple environments and/or genetic backgrounds. On the other hand, context-dependent effects are important. Epistatic interactions reveal genetic networks affecting quantitative traits, and genotype by environment variation and genetic variation in sexual dimorphism are potential mechanisms maintaining genetic variation for quantitative traits in natural populations.
4. Molecular variants, not genes, are the relevant unit of observation. Different variants in the same gene can have different effects on the same trait, and different variants in the same gene can independently affect different traits. Therefore, genes but not variants may be highly pleiotropic.

5. Most variation affecting quantitative traits does not cause amino acid changes in protein coding genes, but rather synonymous polymorphisms in coding regions (possibly associated with mRNA stability) and putative regulatory polymorphisms in promoters and introns that could affect transcription factor binding and mRNA splicing, and affect the amount, timing, or tissue-specific pattern of expression. Joint mapping of variants that affect both organismal phenotypes and intermediate molecular phenotypes such as networks of correlated gene expression traits, metabolites, and proteins will yield novel biological insights by which multiple polygenic perturbations affect quantitative traits.

Future Prospects

The genomics revolution and advances in computational power now enable us to perform genotype–phenotype mapping studies on the scale and with the density of molecular markers required to simultaneously identify many genes affecting variation for quantitative traits. In the foreseeable future, this will extend to complete genome sequences of all individuals in large mapping populations as well as measurements of gene expression and other molecular endophenotypes, giving unprecedented insights into the biological underpinnings of complex traits, and pleiotropic connections among traits. As the new technologies mature and become cost-effective, all organisms will become model organisms, enabling us to understand the genetic basis of wide-ranging ecological specializations and adaptations. Finally, we now have the tools to address long-standing unanswered questions in evolutionary quantitative genetics, including (but not limited to) the mechanisms maintaining quantitative genetic variation, the polygenic mutation rate, the molecular basis of GEI, the cause of limits to long-term selection, and phenotypic stability in the face of genetic and environmental variation. The future of evolutionary quantitative genetics is bright.

Glossary

Eigenvector A linear combination of the original variables (here, traits). The set of eigenvectors of a matrix (such as **G** or **P**) are themselves uncorrelated (mutually orthogonal), and completely describe the (phenotypic or genetic) 'space.'
Eigenvalue The scale factor describing the length of the associated, normalized, eigenvector. The eigenvalues of **P** describe the phenotypic variation for the associated linear combination of measured traits (eigenvector). Likewise, the eigenvalues of **G** describe the additive genetic variation along the axis defined by the corresponding eigenvector.
G The additive genetic variance–covariance matrix.
Genetic space The multidimensional (n dimensional where n is the number of traits considered) space in which the additive genetic breeding values of all individuals in the population occur. Eigenvectors of **G** describe axes (directions) of genetic space, and the associated eigenvalues describe the 'additive genetic' variation in those directions (for the specific population under consideration). When traits are highly genetically correlated with one another, the 'rank' of the genetic space will be less than n, with the trait combinations associated with genetic variance fewer than the total number of traits measured.
Linkage disequilibrium The nonrandom co-inheritance of alleles at different loci.
Matrix diagonalization Decomposition of a square matrix into its eigenvalues (a diagonal matrix) and eigenvectors (the new set of axes corresponding to the eigenvalues).
P The phenotypic variance–covariance matrix.
Phenotypic space The multidimensional (n dimensional where n is the number of traits considered) space in which the phenotypes of all individuals in the population occur. Eigenvectors of **P** describe axes (directions) of phenotypic space, and the associated eigenvalues describe the variation in those directions for the population under consideration. When traits are highly correlated with one another, the rank of the phenotypic space will be less than n. Different populations might occupy different regions of phenotypic space due to different trait values.
Pleiotropy The effect of an individual allele on more than one trait.
Rank The number of nonzero eigenvalues of a matrix, corresponding to the dimensionality of space.
Subspace The $(n-x)$-dimensional space described by a subset (x) of eigenvectors from an original $n \times n$ trait matrix. When traits covary, the population might be predominantly distributed in few dimensions of the phenotypic or genetic space.

Evolution, change through time, depends on a shift in the frequency distribution of genotypes between generations. For traits under a known selection pressure (S), we can predict the change in mean phenotype ($\Delta\bar{z}$) from one generation to the next using the breeder's equation: $\Delta\bar{z} = h^2 S$ (Lush, 1937). The extent to which trait values are transmitted from parent to offspring (i.e., trait heritability in the population, h^2) will determine how much of the difference in trait mean between selected individuals (μ^*) and the total population (μ: $S = \mu^* - \mu$) is transmitted to the next generation. However, natural selection is thought to typically act on functionally interrelated sets of traits, not on individual traits in isolation (Dobzhansky, 1956; Lewontin, 1970; Lande and Arnold, 1983; Phillips and Arnold, 1989), and co-inheritance of traits, due to pleiotropy or linkage disequilibrium, is also prevalent (Lande, 1980; Falconer, 1981; Paaby and Rockman, 2013). Therefore, the multivariate extension of the breeder's equation, is more typically used to predict phenotypic evolution. In the multivariate extension, the vector of change in trait mean ($\Delta\bar{z}$) depends on the scaling of the selection vector (β) by the additive genetic variance–covariance matrix, **G** (**Figure 1**). This symmetrical $n \times n$ matrix (where n is the number of traits being considered) (**Figure 1**), which summarizes the pattern of additive genetic (heritable) variation within the set of traits, is the primary parameter capturing the potential of populations for evolutionary change over ecological timescales.

The accuracy of evolutionary prediction depends on the constancy of **G** over the timescales that we might want to predict evolution. Unfortunately, the evolution of **G** cannot be theoretically predicted because change in **G** depends on the influence of many, typically unknown, factors such as the characteristics (frequency, effect size, and genomic location) of the alleles that underpin **G**, and on the shape of the adaptive landscape (Turelli, 1988; Jones *et al.*, 2003; Jones *et al.*, 2004; Guillaume and Whitlock, 2007; Revell, 2007; Arnold *et al.*, 2008). This theoretical uncertainty about the evolution of **G**, and the desire to know whether we could use the information on genetic variation currently present in a population to predict future or reconstruct historical responses to selection resulted in the birth of a new empirical field of research, comparative quantitative genetics, at the beginning of the twenty-first century (Steppan *et al.*, 2002).

The general pattern emerging from these empirical studies is that G-matrices estimated from different populations are likely to be broadly similar (Steppan *et al.*, 2002; McGuigan, 2006; Arnold *et al.*, 2008; Walsh and Lynch, 2014). However, examples of rapid, radical changes in **G** exist (Steppan *et al.*, 2002; Walsh and Lynch, 2014), and we cannot assume a

The multivariate breeder's equation

$$\begin{pmatrix} \Delta z_1 \\ \vdots \\ \Delta z_n \end{pmatrix} = \begin{pmatrix} G_{11} & \cdots & G_{1n} \\ \vdots & \ddots & \vdots \\ G_{n1} & \cdots & G_{nn} \end{pmatrix} \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_n \end{pmatrix}$$

(a)

Example of application to real data

$$\begin{pmatrix} -0.05 \\ -0.17 \\ -0.28 \end{pmatrix} = \begin{pmatrix} 0.26 & 0.07 & 0.16 \\ 0.07 & 0.35 & 0.08 \\ 0.16 & 0.08 & 0.39 \end{pmatrix} \begin{pmatrix} 0.42 \\ -0.38 \\ -0.82 \end{pmatrix}$$

Eigenanalysis of G

	Eigenvector 1	Eigenvector 2	Eigenvector 3
Eigenvalue	0.553	0.296	0.151
Trait 1	0.51	–0.19	0.84
Trait 2	0.46	0.88	–0.08
Trait 3	0.73	–0.43	–0.54

(c)

Figure 1 Dissecting the parameters for predicting multivariate phenotypic evolution using the breeder's equation. (a) The multivariate breeder's equation predicts the evolution of a set of traits (vector of change in trait means, Δz) from the selection gradients (vector of selection coefficients for each trait, $\boldsymbol{\beta}$) and the additive genetic variance–covariance matrix (**G**). In **G**, the genetic variance associated with each trait appears on the diagonal, and the covariances between each pair of traits on the off-diagonal. The subscripts can be used to specify the traits associated with each entry, for example, G_{12} is the genetic covariance of trait 1 with trait 2; G-matrices are symmetrical – that is, the covariance between trait 1 and trait 2 is the same as the covariance between trait 2 and trait 1. (b) A three-trait example of the breeder's equation parameters. Here, all traits positively covary with one another (all off-diagonals of **G** are positive), but trait 1 is under positive selection while the other two traits are under negative selection (the selection coefficients in $\boldsymbol{\beta}$). The positive genetic covariance among all traits causes the response to multivariate selection (Δz) to be biased away from the direction of selection ($\boldsymbol{\beta}$), including a small response in Trait 1 against the direction of selection (i.e., a reduction in the phenotypic mean rather than an increase as predicted from the selection coefficient in $\boldsymbol{\beta}$). (c) The eigenanalysis of the example **G** presented in (b). Each eigenvector (reported in columns) is of unit length (**Box 2(A)**), with the corresponding eigenvalue giving the length (genetic variance in that direction). The values for each trait for a given eigenvector are called the trait loadings, and they reflect the relative contribution of that trait to the magnitude of the eigenvalue.

constant **G** under any conditions. Moreover, through well-designed experiments, including appropriate null hypotheses, comparative quantitative genetics has moved beyond proving or disproving the stability of **G**. These data are building our understanding of how the evolutionary processes of selection, drift, migration, and mutation drive changes in **G**, a field of research that is likely to increase in impact as advances in molecular genetics move us closer to characterizing the architecture underlying quantitative trait variation (Yang *et al.*, 2010; Scoville *et al.*, 2011). Here, we will first describe methods used to characterize variation among G-matrices, developing the language used to discuss **G**, and then briefly consider what comparative quantitative genetics has determined about the evolution of **G**.

How do We Describe G?

Organisms are made up of very many traits, and we expect that these traits are interdependent both in terms of their effects on fitness and in their genetic basis. As such, to understand the evolution of the genetic variance underlying these complex phenotypes, we need to think about higher dimensional spaces. Simple graphical approaches are effective for comparing two-trait (**Figures 1–4**) and possibly three-trait (**Box 1**) matrices, but beyond that, we rely on matrix algebra and trigonometry to distill and describe the geometry of **G** (Lynch and Walsh, 1998; Strang, 1998; Blows, 2007).

One basic idea that is helpful for talking about **G** is that of 'space.' Each individual in a population can be thought of as occupying a position in phenotypic space (**Figure 2(a)**) and the dimensionality of phenotypic space depends on the number of coordinates required to define an individual's position in that space. Phenotypic space can have as many dimensions as the number of traits that are measured, but might have fewer if traits covary. For instance, if the value of an individual for one trait can be exactly predicted from their value for a second trait (i.e., the traits are perfectly correlated), then the dimensionality of this two-trait phenotypic space is reduced to one (**Figure 2(b)**). Individuals also occupy a position in genetic space, described by their breeding values (**Figure 2(c)**). An individual's position in genetic space is translated to their position in phenotypic space through the processes of development, although this developmental mapping between genetic and phenotypic space remains an unresolved challenge for most traits. Just as for phenotypic space, genetic covariance among traits can also reduce the number of dimensions in genetic space.

Symmetrical covariance matrices, such as **G**, can be diagonalized to find a set of orthonormal eigenvectors and eigenvalues (**Figures 1(c)** and **2(d)**). The orientation of eigenvectors and the magnitude of eigenvalues describe the geometry of the (genetic) space, and form the basis of many methods for comparing **G**. Basically, the eigenvectors of **G** are unit-length (**Box 2**) linear combinations of the measured traits that describe directions in genetic space. The corresponding eigenvalues describe the length of the vector, indicating the amount of genetic variation for that specific direction in genetic space. If all our traits of interest were genetically independent of one another, then each eigenvector would correspond exactly to one trait, and the eigenvalues would be equal to the additive genetic variance of that trait. At the opposite extreme, if all traits covary perfectly with one another, there would be a single eigenvector, with the eigenvalue equal to the sum of the individual trait genetic variances. Real **G** are likely to fall between these extremes.

We can describe differences in the geometry of **G** using three terms based on the eigenanalysis: rank, size, and shape. Rank (or dimensionality) is the number of independent

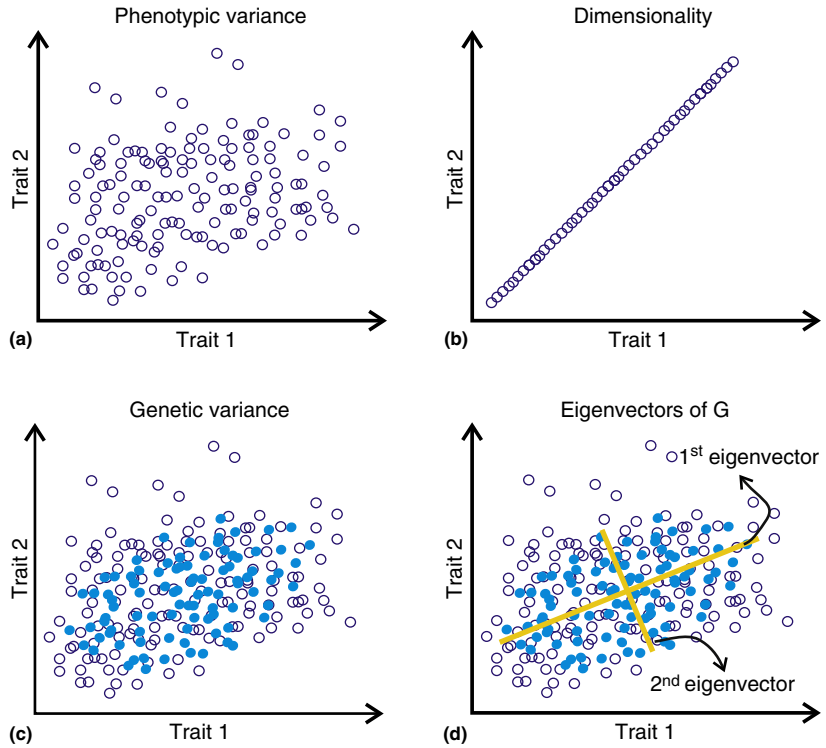

Figure 2 Illustration of some matrix geometry concepts. In any population, we can characterize differences among individuals through their phenotypic values. (a) Shows the values of two traits for individuals in our hypothetical population. This phenotypic space has a maximum number of dimensions equal to the number of traits measured, but if traits covary then the dimensionality of the phenotypic space can be reduced. For example, if two traits perfectly covary, such that the value of one can be predicted from the value of the other, as in (b), the dimensionality of the space is reduced to a single axis. When we measure individuals from a breeding design, whether by planned crosses or the maintenance of a pedigree, we can partition phenotypic variation to determine each individual's breeding values (the average value of the trait in their offspring). This distribution of breeding values (shown in (c)) is the variation that underpins **G**. We can diagonalize this **G** (as in Figure 1(c)) to examine the organization of genetic variance in multidimensional space. (d) For a two-trait matrix, diagonalization returns two unique (orthogonal – at right angles to one another) linear combinations of the measured traits (shown in yellow), each associated with different amounts of variation (indicated here by the lengths of the vector, corresponding to the eigenvalue).

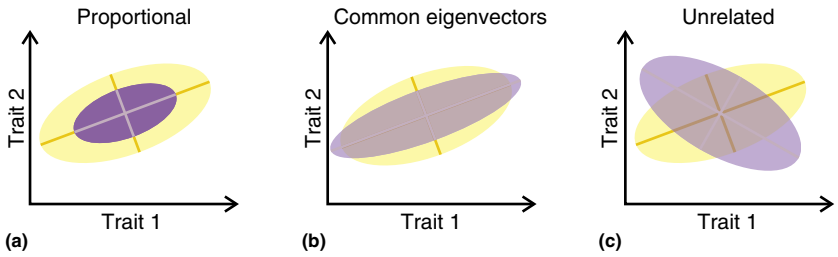

Figure 3 Size and shape variation in **G**, illustrated for two taxa (shown in yellow and purple). Matrices might differ from one another in: (a) size (the total genetic variance); (b) the amount of genetic variation associated with specific, shared, eigenvectors, as apparent in differences in eigenvector length; and (c) in orientation (the directions of eigenvectors in genetic space). In (a), the purple population has a smaller G-matrix than the yellow population, but the matrices are proportional with the same relationship between trait 1 and 2 identified by the eigenvectors. In (b), the purple taxon has more variation associated with eigenvector 1 than does the yellow taxon. However, because the total genetic variation is the same in both populations, this leaves less genetic variation for eigenvector 2 in the purple taxon compared with the yellow taxon. In (c), the purple population has a negative genetic covariation between the two traits, while the yellow population has a positive covariation, but the total variance in the two traits is the same in both populations.

directions (eigenvectors) in genetic space, determined by the number of eigenvalues that are greater than zero (Mezey and Houle, 2005; Hine and Blows, 2006). Typically, most of the genetic variance is found in relatively few dimensions (eigenvectors) of genetic space (Kirkpatrick, 2009), suggesting rank of genetic space might be less than the number of traits. However, whether we can distinguish a given eigenvalue from zero will depend greatly on the power of the experiment, specifically the sample size; with small sample sizes, the power to demonstrate that small variances (such as associated with

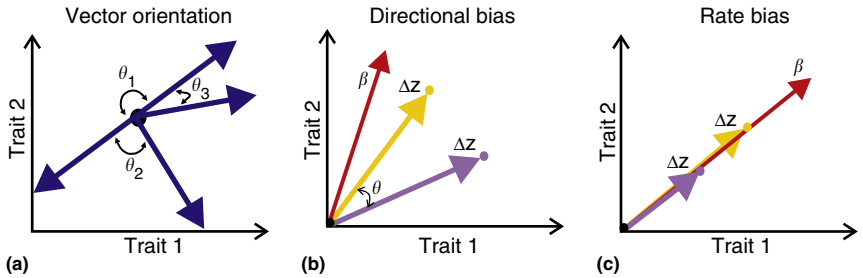

Figure 4 The effect of **G** on the response to selection. (a) Unit-length vectors (**Box 2(A)**) can differ in orientation, from indicating opposite directions in phenotypic (genetic) space ($\theta_1 = 180°$), to being orthogonal to one another ($\theta_2 = 90°$) to being coincident (0°) through any value in between (e.g., $\theta_3 = 25°$). (b) When two taxa have **G** that differ in shape (orientation of variation and the distribution of variation among different directions), the biasing effects of **G** on the response to the same selection gradient (**β**) results in the taxa following different evolutionary trajectories and evolving different mean phenotypes, Δz. (c) When **G** differ only in size, and the geometry of **G** coincides with the selection gradient, populations might diverge in mean phenotype because of greater evolution in a population with a larger **G** (yellow taxon).

lower eigenvalues) are greater than zero will also be commensurately small, and a conclusion of low rank is more likely than in a study with the same distribution of genetic variance, but large sample sizes. Because of the uncertainty (error) associated with estimating eigenvalues, differences in rank are not considered a reliable indicator of differences in **G** (Kirkpatrick, 2009; Blows and McGuigan, 2015). The size of **G** is simply how much genetic variance there is in the trait set, and is determined by the sum of the eigenvalues of **G** (the trace), which must equal the sum of the genetic variances of the original traits (**Figures 1(b)** and **1(c)**). Shape is determined both by the eigenvectors and eigenvalues of **G**; we will consider shape in further detail below as it relates directly to matrix comparison methods (see also **Figure 3**).

How do We Compare G?

Before delving into methods for comparing G-matrices, let us consider the common problem of estimation error. Accurate estimation of **G** requires a large sample size; consequently, empirical estimates of **G** are associated with relatively large error because of logistical constraints limiting the sample size. This sampling variance needs to be taken into account when comparing G-matrices so that we can ask whether any observed differences are greater than we might expect to occur through random sampling error. A widely used approach is randomization or bootstrapping, in which individuals (or the genetic group, e.g., families or sires) are randomly re-assigned among taxa, **G** is reestimated using the same model as for the observed data, and this process is repeated many (~1000) times to generate a distribution, reflecting random sampling, of variation among G-matrices (e.g., Calsbeek and Goodnight, 2009; Roff *et al.*, 2012).

For G-matrices that contain many traits, traits with non-Gaussian (non-normal) distributions, or are estimated from a complex multigenerational pedigree where the genetic unit that should be randomized is not simply family or sire, a Bayesian approach provides a useful way of generating a null distribution for hypothesis testing (Hadfield *et al.*, 2010; Robinson and Beckerman, 2013; Aguirre *et al.*, 2014). Bayesian analyses, in combination with Markov chain Monte Carlo (MCMC) methods (Gelman *et al.*, 2004), can be applied to diverse pedigrees and trait types, to generate the posterior distribution for not only **G**, but also other experimental factors that might contribute to phenotypic variation, greatly facilitating hypothesis testing (Ovaskainen *et al.*, 2008). Under this framework, it is possible to generate a null model **G** by applying the randomization step to the posterior predictive distribution of breeding values (Hadfield *et al.*, 2010; Aguirre *et al.*, 2014), and therefore to generate a null distribution for among-taxa **G** without having to reestimate **G** many times, a great benefit because the computational demands of these analyses can be limiting.

Once we have both our estimates of observed **G**, and their associated errors, as well as an appropriately constructed null **G**, we can compare **G** among groups. Below we outline several methods for comparing **G**. Further detail and background on methods for comparing **G**, including other methods we do not mention, can be found elsewhere (Hansen and Houle, 2008; Calsbeek and Goodnight, 2009; Roff *et al.*, 2012; Aguirre *et al.*, 2014), and we particularly recommend reading Chapter 36 of Walsh and Lynch (2014). As we indicated above, many of the methods for comparing **G** are based on eigenanalyses. However, the focus of the methods as we outline them below is in understanding how G-matrices differ in their distribution of genetic variance. As has been discussed previously (e.g., Cheverud, 2007), eigenvectors themselves do not necessarily reflect underlying genetic causal factors. However, it is not the directions of eigenvectors that are interpreted in the methods described below, but instead it is the genetic variance associated with these different regions of the genetic space.

Flury and Krzanowski Methods

One of the most influential early developments in comparative quantitative genetics was the adaptation by Phillips and Arnold (1999) of Flury's (1988) common principal components (CPC) model. CPC analyses allow a hierarchy of comparisons to determine whether matrices differ in size (proportional matrices: **Figure 3(a)**) or shape, either in the amount of genetic variance associated with specific eigenvectors observed in all matrices under consideration (common eigenvectors: **Figure 3(b)**) or through divergence in orientation of eigenvectors (unrelated structure: eigenvectors are not shared among different **G**: **Figure 3(c)**).

Box 1

Three-dimensional illustrations of the phenotypic and genetic space. The following code takes the G-matrix in **Figure 1(b)** and generates a distribution of phenotypic and genotypic (breeding) values for a population consistent with that G. Code then follows to draw three dimensional versions of **Figures 2(a)** and a modified version of **Figure 2(d)** where only genetic space and the eigenvectors of G are plotted. Last we project the selection and response vectors onto the genetic space as in **Figure 1(d)**. Using your mouse, you can rotate these figures and view them along any of the three axes to consider the shape of phenotypic and genetic space for these three hypothetical traits.

Box 2

A. General Formulae

There are several operations that are widely used in comparative quantitative genetics, irrespective of the specific method being used to compare matrices. First, we need to be able to describe the effects of size and orientation separately and to do this we work with vectors that are of unit length (so-called normalized vector) such that:

$$\boldsymbol{b}^{\mathrm{T}}\boldsymbol{b} = 1 \qquad [A1]$$

where $\boldsymbol{b}$ is any vector, and $^{\mathrm{T}}$ indicates the transpose of the vector. Vectors are normalized by dividing each element by the square root of the sums of squares of all elements.

If we have more than one normalized vector, $\boldsymbol{b}$ and $\boldsymbol{a}$, for example, we can determine how different their orientation is by calculating the angle between them. We could report this as the dot product (ranging from -1 to 1), which is the sum of the products of the corresponding entries:

$$r = \boldsymbol{b}^{\mathrm{T}}\boldsymbol{a} \qquad [A2]$$

Alternatively, we can report the vector differences as an angle in radians:

$$\theta = \cos^{-1} r \qquad [A3]$$

which can be converted to degrees (ranging from 0° to 180°) by multiplying θ by $(180/\pi)$.

We can also determine how much genetic variation is available for any given vector (i.e., trait combination) by projecting it through the G-matrix of interest (Lin and Allaire, 1977). So, for any taxon, $1 \ldots t$, we can determine the genetic variance in any vector $\boldsymbol{b}$ by projecting it through the relevant population $\mathbf{G}$:

$$V_{G_t} = \boldsymbol{b}^{\mathrm{T}}\mathbf{G}_t\boldsymbol{b} \qquad [A4]$$

B. Krzanowski Common Subspace

Krzanowski's method is aimed at determining whether matrices share a common subspace. If we include all of the eigenvectors of our $\mathbf{G}$ of interest we are constrained to recover a common subspace (Blows *et al.*, 2004). Instead, we consider a subspace of each $\mathbf{G}_t$, $\mathbf{A}_t$, which is the first j eigenvectors of $\mathbf{G}_t$. The number of eigenvectors to be considered can be defined in two ways (Aguirre *et al.*, 2014). First, we can consider the first $n/2$ eigenvectors of each $\mathbf{G}$, where n is the number of traits. Alternatively, we could define the subspace based on the proportion of additive genetic variance accounted for. In either case, the number of dimensions (eigenvectors) of the subspace matrix ($\mathbf{H}$) that can be interpreted, without constraining the method to recover a common subspace, is equal to the rank of $\mathbf{A}_t\,\mathbf{A}_t^{\mathrm{T}}$ for the $\mathbf{A}_t$ with the fewest number of eigenvectors included. Aguirre *et al.* (2014) compared these two approaches for deciding how many eigenvectors to include in $\mathbf{A}_t$ and found that the second, defining $\mathbf{A}_t$ based on the proportion of the variance captured, uncovered greater similarity among $\mathbf{G}$.

Having defined our $\mathbf{A}_t$, we can determine the common subspace shared among $\mathbf{G}$ using (Krzanowski, 1979):

$$\mathbf{H} = \Sigma_{t=1}^{p}\mathbf{A}_t\mathbf{A}_t^{\mathrm{T}} \qquad [B1]$$

For each eigenvector of $\mathbf{H}$, $\boldsymbol{b}_i$, we can determine the angle (θ) between that eigenvector and the subspace of the G-matrix of the tth population, $\mathbf{A}_t$:

$$\theta_t = \cos^{-1}\left\{\left(\boldsymbol{b}_i^{\mathrm{T}}\mathbf{A}_t\mathbf{A}_t^{\mathrm{T}}\boldsymbol{b}_i\right)^{0.5}\right\} \qquad [B2]$$

These angles (θ_t) then tell us which $\mathbf{G}$ has diverged the most from the common subspace shared by all $\mathbf{G}$ in the analysis. Finally, we can project the eigenvectors of the common subspace ($\boldsymbol{b}_i$) through each $\mathbf{G}$ (using A4) and determine whether $\mathbf{G}$ differ in the magnitude of genetic variance associated with the common subspace.

C. Vector-Based Approaches

For a given selection gradient, $\boldsymbol{\beta}$, represented as a column vector for traits 1 to n, and a given $\mathbf{G}$ we can determine the response to selection (Δz) using the multivariate breeder's equation (Lande, 1979), represented here in matrix form (see also **Figure 1**):

$$\begin{pmatrix}\Delta z_1\\ \vdots\\ \Delta z_n\end{pmatrix} = \begin{pmatrix}G_{11} & \cdots & G_{1n}\\ \vdots & \ddots & \vdots\\ G_{n1} & \cdots & G_{nn}\end{pmatrix}\begin{pmatrix}\beta_1\\ \vdots\\ \beta_n\end{pmatrix} \qquad [C1]$$

By comparing among taxa how this response is biased away from $\boldsymbol{\beta}$ by $\mathbf{G}$ we can determine whether the taxa differ in their evolutionary trajectory because of differences in $\mathbf{G}$. Comparison of the direction of evolution can be made by calculating the angle (A3) between Δz vectors. Alternatively, we could consider the magnitude of the evolutionary response in the different taxa by projecting $\boldsymbol{\beta}$ through $\mathbf{G}$ (A4). Differences in both direction and magnitude are captured by the difference in response (e.g., the distance between the two endpoint dots in **Figure 4(b)**), given by Hansen and Houle's (2008) equation:

$$\begin{aligned} d(\boldsymbol{\beta}) &= |\Delta\overline{z_1} - \Delta\overline{z_2}|\\ &= |(\mathbf{G}_1 - \mathbf{G}_2)\boldsymbol{\beta}| = \sqrt{\boldsymbol{\beta}^{\mathrm{T}}(\mathbf{G}_1 - \mathbf{G}_2)^2\boldsymbol{\beta}} \end{aligned} \qquad [C2]$$

Instead of considering the response to an hypothesized direction of evolution, we can probe $\mathbf{G}$ using any other unit-length vectors, including a large set of random vectors spanning the phenotypic space (Cheverud and Marroig, 2007). We can assess similarity among matrices based on whether they differ (more than among the null model $\mathbf{G}$ representing sampling error) in the direction or magnitude of predicted responses.

D. Tensors

Two approaches exist for determining the difference between just two covariance matrices. First, we can determine the relative difference between the matrices by first finding the ratio (Flury, 1983; Mitteroecker and Bookstein, 2009; Houle and Fierst, 2013; Bookstein and Mitteroecker, 2014):

$$\mathbf{C} = \mathbf{A}^{-1}\mathbf{B} \qquad [D1]$$

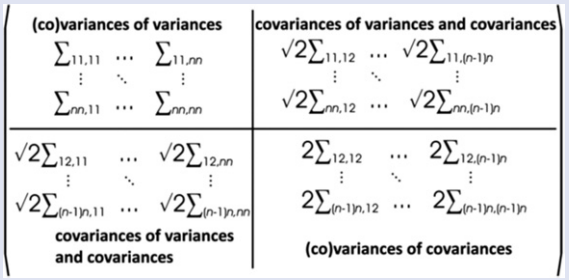
where '$^{-1}$' indicates the inverse of the matrix.

Alternatively, we could find the difference between the two matrices on the absolute scale by first taking the difference (Schott, 2010):

$$\mathbf{C} = \mathbf{A} - \mathbf{B} \qquad [D2]$$

By diagonalising **C** it is then possible to summarize the way in which the two matrices differ the most. This idea of scaling matrices by one another can be generalized to many matrices by the genetic tensor analysis. The method is undeniably complex; here, we simply provide an overview, and refer readers to Hine *et al.* (2009) for details.

To interpret divergence in **G** among taxa we must first calculate a 2nd-order representation, **S**, of the 4th-order tensor, $\sum_{\mathbf{G}}$. The mapping of $\sum_{\mathbf{G}}$ to **S** results in four quadrants, as described in detail in Hine *et al.* (2009) and illustrated below (see also Aguirre *et al.*, 2014).



The eigentensor approach depends on two steps of diagonalization. First, eigenanalysis of **S** uncovers the eigentensors, which are analogous to the eigenvectors of **G** in that they describe the subspaces where independent aspects of variation among **G** exist, and their associated eigenvalues describing the variance in that subspace. When dealing with multiple **G**, this allows that different **G** might have evolved through independent changes, driven by different evolutionary processes.

We can then rearrange these eigentensors into their own 2nd-order representations, allowing us to calculate the eigenvalues and eigenvectors of the eigentensors. This second analysis identifies the trait combinations contributing to the among-matrix subspaces captured by each eigentensor. Note, unlike the diagonalization of a standard variance–covariance matrix, diagonalization of eigentensors can result in negative eigenvalues. This occurs when increases in genetic variance associated with one combination of traits is opposed by a decrease in genetic variance associated with a second, independent, combination of the measured traits.

The Flury method was developed based on product-moment covariance matrices, and while it is readily applicable to comparisons of such matrices, for the more derived variance-component matrices, typical of estimates of **G**, the degrees of freedom are unknown, and the CPC model cannot be applied with certainty. Krzanowski (1979) proposed a related approach, also focused on common subspaces, which has been adapted to the comparison of **G** (Blows *et al.*, 2004; Aguirre *et al.*, 2014). Like CPC, Krzanowski's approach is focused on determining whether G-matrices share a common subspace, that is, whether the different G-matrices have eigenvectors in common. Krzanowski's common subspace differs from CPC both by being more broadly applicable to **G** from different designs, and more limited in that it is focused only on the subspace associated with the most variance, not the entire genetic space (**Box 2(B)**).

The Krzanowski method is really a three-step procedure (**Box 2(B)**). First, through some matrix algebra we calculate a matrix that contains the subspace common to the G-matrices we are interested in comparing. Second, we apply eigenanalysis to this new matrix to determine whether all of our G-matrices share eigenvectors; if they do not, we can then determine which **G** differ from the common subspace the most by calculating the angle (**Box 2(A)**) between the subspaces of each **G** and the common subspace. First and second steps of Krzanowski's approach focus solely on the orientation of the eigenvectors of **G**, however, as made clear by the CPC hierarchy, even if matrices share a common subspace, they might differ in the magnitude of the genetic variance associated with this subspace. Hence, in the third step, we use vector projection (**Box 2(A)**) to calculate the length of each eigenvector of the common subspace matrix in the space of each **G**. Thus, the Krzanowski method can be used to identify linear trait combinations (covariances) that are unique to different taxa, and to characterize differences in the genetic variation associated with the common subspace.

Vector Approaches

There are several broadly similar approaches that assess the similarity (or dissimilarity) of G-matrices through the use of vectors (**Box 2(C)**). For multivariate phenotypes, the evolutionary response ($\Delta\bar{z}$) will be biased away from the direction of selection (β) by the genetic variance to an extent that will depend on the geometry of **G** (Lande, 1979). The multivariate breeder's equation quantifies this biasing effect of **G** (**Figure 1**; **Box 2(C)**) and analytical comparisons of G-matrices from different populations can distinguish differences in orientation of the corresponding response vectors (**Figures 4(a)** and **4(b)**)

and in the magnitude of the evolutionary response (**Figure 4(c)**). This type of informed comparative approach, based on the breeder's equation, can be applied using an estimated selection gradient (Hansen and Houle, 2008; Chenoweth *et al.*, 2010; Aguirre *et al.*, 2014), or a hypothetical selection gradient which reflects a researcher's prior observations of selection in their study system (Calsbeek and Goodnight, 2009; Stinchcombe *et al.*, 2010). Alternatively, if there is no prior information on selection, we can probe the entire phenotypic space using a large set of unit-length random vectors (Cheverud and Marroig, 2007). In the absence of knowledge of the selection regime, the biological interpretation of the differences in G-matrices depends on the aims of the study. For example, Marroig *et al.* (2011) focused at the trait level, comparing **G** in terms of the predicted direct and indirect evolution of each trait contained within **G**, allowing them to draw conclusions about the evolutionary potential of individual traits. In contrast, Aguirre *et al.* (2014) focused on the total phenotypic space described by the measured traits, identifying the specific directions in phenotypic space that differed significantly among taxa in the associated genetic variation, and thereby evolutionary potential.

Tensors

The final method that we will consider is the genetic tensor approach (Hine *et al.*, 2009, 2011; Robinson and Beckerman, 2013; Aguirre *et al.*, 2014), which is possibly the most versatile, but also the most intuitively challenging, approach for determining if matrices differ. The power of the genetic tensor approach lies in its generality – it considers the entire genetic space of each **G** and it can be used to compare any number of G-matrices simultaneously. A useful first step is recognizing that **G** is a 2nd-order tensor – each element in **G** is denoted by two indices, for example, the covariance between traits 1 and 2 can be identified as G_{12} (**Figure 1**). To compare the elements of different G-matrices we need four indices – the covariance of traits x and y in population 1 with traits w and z in population 2, $G_{xy,wz}$. Because of this dependence on four indices, we refer to the matrices describing the variation among G-matrices as 4th-order tensors.

Although the idea of working with 4th-order tensors sounds intimidating, for the simple case where we want to compare only two G-matrices, all this complexity boils down to simple scaling of one matrix by the other (**Box 2(D)**). As recently highlighted by Bookstein and Mitteroecker (2014), a two-matrix comparison is closely related to multivariate analysis of variance (MANOVA) followed by a principal components analysis (PCA): first multiplying one **G** by the inverse of the other (the matrix equivalent of division); and then subjecting the resultant matrix to an eigenanalysis. This eigenanalysis identifies linear combinations of traits that differ between the two G-matrices, in decreasing order of the amount of variance they differ by. Although algebraically complex (**Box 2(D)**), the eigentensor approach is conceptually an extension of this simple approach – first we generate a matrix capturing the differences among G-matrices and then we decompose that matrix to determine the divergence in genetic covariance among our G-matrices, and the characteristics of those independent axes (eigenvectors) of divergence (**Box 2(D)**).

Admittedly this sounds complicated; however, the mathematical complexity is justified by the ease and accuracy of the biological interpretation that is permitted. For example, Hine *et al.* (2009) applied a tensor approach to characterize the divergence in the genetic variance associated with a set of eight contact pheromone traits among nine natural populations of *Drosophila serrata*. Most (68%) of the divergence among G-matrices was due to a change in genetic variance for one linear combination of pheromones – increasing or decreasing all pheromones simultaneously. This trait combination was associated with greater genetic variance, and thus more potential to evolve, in the northern most populations (Hine *et al.*, 2009).

Evolutionary Processes and G

How does **G** evolve? As this matrix depends on allele frequencies, it will evolve through the same processes as allele frequencies do – mutation, migration, selection, and drift. Teasing apart the relative effects of different processes relies on experimental populations in which the contribution of different processes is manipulated, with findings from such studies potentially contributing to the interpretation of divergences in **G** of wild populations (Phillips and McGuigan, 2006). Nonetheless, relatively few manipulative experimental evolution studies have considered the changes in **G** when one evolutionary process is known to dominate. Below, we consider what is known from these manipulative experiments.

Under random genetic drift, theory predicts additive genetic variance will decrease as alleles are lost through sampling error, and **G** of populations diverging through drift should be proportionally smaller (e.g., **Figure 3(a)**) than the ancestral **G**. This prediction of proportionality suggests proportionality itself might be a criterion for determining whether **G** has diverged through drift rather than selection (Roff, 2000). In several taxa, inbreeding has been experimentally imposed to test the effect of drift on genetic variance. Most of these studies have considered few traits, and reported on individual trait variances (the diagonal of **G**) only. Moreover, contrary to the prediction that additive genetic variance will decrease under drift, inbreeding has been observed to often increase additive genetic variance (e.g., Bryant and Meffert, 1993; van Heerwaarden *et al.*, 2008). A possible mechanism driving this counterintuitive result is the conversion of nonadditive genetic variance to additive genetic variance (Barton and Turelli, 2004). This effect might therefore be greatest for life history traits, which are expected to harbor the most nonadditive genetic variance.

What happens to the covariances under drift? Phillips *et al.* (2001) bred 52 pairs of brothers and sisters of *Drosophila melanogaster*, and compared **G** for wing shape among these and the ancestral population. The average **G** of the 52 inbred populations, as predicted, was proportionally smaller than the ancestral **G**. However, when Phillips and colleagues inspected **G** from each of the 52 populations individually, they found that they differed not just in total size, but in shape as well, with changes in orientation and in the distribution of variance

among directions. Because these changes in shape differed among populations, they canceled one another out, resulting in no net change in shape across the large sample of populations. Similarly, idiosyncratic effects on covariances have been observed in other taxa (e.g., Calsbeek and Goodnight, 2009), suggesting that for the unreplicated experiments represented by many natural populations, the expectation that proportionality of **G** reflects drift, and conversely that nonproportional change indicates the action of selection, is not likely to be met.

In contrast to the expectation of proportional decrease in **G** under drift, the unknown genetic targets of selection make theoretical predictions of changes in **G** due to selection more challenging. Further, the small size of most experimental populations make it more difficult to impose selection without allowing drift to also operate, and changes in the **G** of nonselected control populations (e.g., Wilkinson *et al.*, 1990) challenge interpretations of the effects of selection on **G**. One factor that is likely to impact on the evolution of **G** is variation in the selection regime; are populations evolving under stabilizing selection in a constant environment, or are they experiencing novel environments and directional selection? Computer simulations suggest that stabilizing selection will promote the stability of **G** (Jones *et al.*, 2003; Revell, 2007), while directional selection might alter **G**. Perhaps most simplistically, under novel directional selection, the size of **G** is predicted to increase if the phenotypic response to selection depends on increased frequency of rare alleles (Barton and Turelli, 1987; Reeve, 2000). Increased genetic variance under artificial selection in the laboratory has been observed (Blows and Higgie, 2003; Hine *et al.*, 2011), but whether rare alleles typically contribute to continued evolutionary change remains an open question. Changes to **G** might be particularly dramatic if the alleles underlying the selection response have large effects on phenotype (Agrawal *et al.*, 2001). However, because the contribution of an allele to **G** depends on its frequency, variation among G-matrices from different populations, or the same population at different times, might be transitory, only appearing while adapting populations are segregating alleles at intermediate frequencies.

We know very little about how novel alleles, arising through mutation, might change **G**. One theory is that selection drives the evolution of the mutational machinery to cause the mutational variance and covariance matrix, **M**, to align with selection (Jones *et al.*, 2014). Under this scenario, we would not expect mutation to have much impact on **G**. However, Camara and Pigliucci (2000) induced mutations in *Arabidopsis thaliana* and applied Flurry's CPC analysis to show that the geometries of **G** pre- and post-mutagenesis were unrelated, or shared only some common components. Estimates of **M** and **G** from outbred populations evolving under different types of selection are needed for us to understand whether mutation is likely to alter **G** over time frames of interest.

From studies in naturally evolving populations, there are three general themes apparent (Doroszuk *et al.*, 2008; Walsh and Lynch, 2014), which are consistent with several of the theoretical expectations. First, the size of **G** might be more labile than its shape. Second, when the environment changes, presumably causing a population that was under stabilizing selection to come under directional selection toward a new adaptive optimum, **G** is likely to change. Third, while the environment (and selection) remains similar, **G** might not evolve. Nonetheless, there remains considerable variation in observations from natural populations, which makes it difficult to predict the evolution of **G** for any specific case. One aspect of variation in natural populations that is likely to be contributing to this lack of consensus is the effect of the environment on the expression of genetic variance. Phenotypes, which are measured to estimate **G**, can respond plastically to environmental variation; if that environmental variation also influences the way that genetic information contributes to phenotypes, through context-dependent allelic contributions, then **G** is also likely to respond to environmental variation (McGuigan *et al.*, 2011; Berger *et al.*, 2013; Bjorklund *et al.*, 2013; Li *et al.*, 2014). How much this non-evolutionary component of variance contributes to among-population variation in G-matrices is unclear, as is the evolutionary consequences of environment-specific **G** (McGuigan and Sgro, 2009).

As we pointed out above, estimates of **G** will typically be associated with large sampling errors. Furthermore, because we need to know the population pedigree, **G** can be difficult to estimate for many organisms and impossible for some (e.g., extinct taxa). These difficulties led Cheverud (1988) to suggest substituting the phenotypic variance–covariance matrix, **P**, for **G** when making evolutionary predictions. If the environmental effects on the traits are similar to the genetic effects, which might occur if environmental and genetic factors act through the same developmental processes, then **P** is expected to be very similar to **G** (Cheverud, 1984). In contrast to the complex breeding designs and analyses required to estimate **G**, **P** can be estimated as a simple product-moment covariance matrix and is estimated more accurately than **G** from a given dataset. Furthermore, P-matrices have statistical properties that are more amenable to certain types of analyses, such as CPC. Comparisons of phenotypic and genetic correlations have revealed some similarity (Cheverud, 1988; Roff, 1996; Waitt and Levin, 1998), although the extent of the similarity might depend on the trait type. Different types of traits are affected to a different extent by environmental variation, reducing the similarity of **P** and **G** for some trait types (Willis *et al.*, 1991; Roff, 1996; Hadfield *et al.*, 2007). Importantly, we still do not know how different **G** and **P** need to be to affect conclusions about the response of populations to future selection, or the processes that might have contributed to the divergence of covariance matrices. Comparative analyses of **P** provide information on variation in what selection can act on in each population, but whether these analyses provide insight into the transmission of that selection response across generations is still not clear.

Quantitative Trait Variation, Molecular Basis of

F Seidl, R Linder, and IM Ehrenreich, University of Southern California, Los Angeles, CA, USA

Glossary

Additive genetic effect The effect of substituting one allele at a locus with another allele. For a given bi-allelic locus, this value is typically measured as half of the difference between the mean phenotypic values of the two homozygotes.

Cloning The process of refining a quantitative trait locus to specific genes and genetic variants that have phenotypic effects. Cloning typically requires a combination of genetic mapping and genetic engineering techniques.

Co-immunoprecipitation A biochemical approach for studying physical interactions among proteins and other molecules.

Cryptic genetic variation Polymorphisms that only show phenotypic effects when a genetic or environmental perturbation occurs.

Dominance When a heterozygote exhibits a phenotype that is associated with one allele of a quantitative trait locus.

Dominance genetic effect For a given bi-allelic locus, the difference between the phenotype of heterozygotes and the average phenotype of the two homozygotes.

Dominant negative When one allele of a gene also prevents another allele from functioning when they co-occur in a heterozygote.

Fluorescence resonance energy transfer A microscopy approach for studying physical interactions between proteins.

Genetic background effect When the effect of an allele is influenced by the genome in which the allele occurs.

Genetic buffering When inherited mechanisms prevent mutations and genetic variants from having phenotypic effects.

Genetic interactions (or epistatic interactions) When sets of two or more genetic variants show a combined phenotypic effect that is nonadditive.

Genome An organism's complete set of genetic material.

Genotype–environment interaction When the effect of one or more genetic variants change across environmental conditions. Alternatively, when the effect of the environment changes across genotypes.

Haploinsufficiency When a diploid organism possesses a single functional copy of a gene, resulting in insufficient gene product and an abnormal phenotypic state.

Heritability The proportion of variance in a trait that is explained by genetic factors, as opposed to the environment.

Linkage The tendency of genes or alleles that are located on the same chromosome to be inherited together.

Linkage disequilibrium The nonrandom association of genetic polymorphisms at different loci. Linkage disequilibrium is expected among sites that are closely linked, but may also arise for other reasons, such as selection on loci that both influence a beneficial phenotype.

Orthologs Genes that occur in different species, but have the same evolutionary origin and molecular function.

Pleiotropy When a genetic variant influences multiple traits.

Quantitative trait gene A gene that harbors a genetic variant that has a phenotypic effect.

Quantitative trait locus A region of the genome that harbors one or more genetic variants with phenotypic effects.

Quantitative trait nucleotide A genetic variant that contributes to heritable variation in a phenotype.

Statistical genetic architecture A statistical characterization of a phenotype's genetic basis. This may include information on the number of loci that contribute to a phenotype, as well as their effects and interactions.

Yeast two-hybrid A molecular approach for studying physical interactions between proteins.

Introduction

Genetic mapping is commonly used to dissect quantitative traits that are important to agriculture, evolutionary biology, and medicine (Mackay *et al.*, 2009; Georges, 2007). Most mapping efforts detect quantitative trait loci (QTLs) that span tens to hundreds of genes (Remington *et al.*, 2001; Flint and Mott, 2001). These QTLs are useful for studying the statistical genetic architecture of a phenotype. However, they are of limited value in determining how a trait is specified at the molecular level (Flint *et al.*, 2005; Drinkwater and Gould, 2012).

Knowing how genetic variants alter cellular and developmental processes to produce phenotypic changes is important for many reasons. Such knowledge can be used to improve our ability to predict individuals' phenotypes based on their genotypes and to treat heritable diseases with targeted therapies (Albert and Kruglyak, 2015). Moreover, this information can reveal the types of functional genetic variants that segregate in populations and provide a potential substrate for evolution (Seidel *et al.*, 2011).

To determine the functional mechanisms that give rise to heritable phenotypic variation, specific quantitative trait genes (QTGs) and quantitative trait nucleotides (QTNs) for a trait must be identified (Mackay *et al.*, 2009; Georges, 2007; Remington *et al.*, 2001; Flint *et al.*, 2005; Drinkwater and Gould, 2012; Aitman *et al.*, 2010; Liti and Louis, 2012; Weigel and Nordborg, 2005; **Figure 1**). After these QTGs and QTNs have been determined, bioinformatic and experimental approaches can be used to assess how alleles of these factors

 doi:10.1016/B978-0-12-800049-6.00059-7

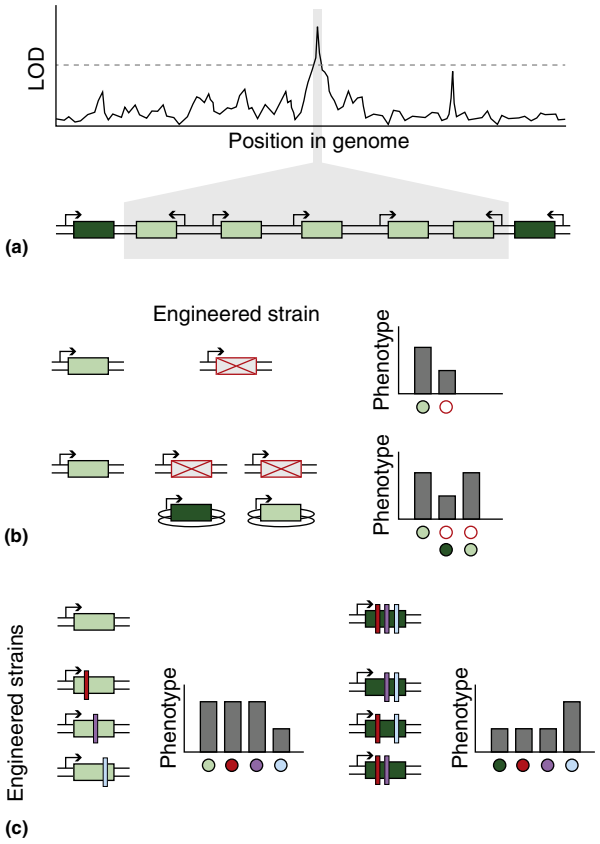

Figure 1 Determining the molecular factors underlying a quantitative trait locus (QTL). An abstract example of how quantitative trait genes (QTGs) and quantitative trait nucleotides (QTNs) are typically identified is shown. In (a), a QTL is detected at the resolution of five genes. To identify the QTG, different strategies may be employed, such as gene deletion and plasmid complementation (b). Gene replacement, in which genetic engineering is used to switch the allele of a gene that an individual carries, and complementation by crossing are other approaches that might be used to go from QTL to QTG. Further resolving a QTG to a specific QTN may be achieved by replacing individual nucleotides (c). We use haploid examples for simplicity. Furthermore, we note that these approaches may be more difficult for genes that are involved in genetic interactions (Mackay, 2014; Taylor and Ehrenreich, 2015) or show different effects across genetic backgrounds (Chandler *et al.*, 2013). In such cases, it might be necessary to conduct the experiments shown in this figure in multiple genetic backgrounds.

functionally differ (e.g., Deutschbauer and Davis, 2005; Grisart *et al.*, 2004; Smith and Kruglyak, 2008; Rosas *et al.*, 2014; Yvert *et al.*, 2003; Filiault *et al.*, 2008; Smemo *et al.*, 2014; Balasubramanian *et al.*, 2006; Fridman *et al.*, 2004; Johanson *et al.*, 2000). Furthermore, combinations of QTNs can be examined at the molecular and systems levels to assess how these variants collectively influence a trait (e.g., Sudarsanam and Cohen, 2014; Zhu *et al.*, 2008).

In this article, we describe how research on the molecular basis of heritable phenotypes enhances our understanding of quantitative genetics. We discuss the distinct insights into phenotypic variation that arise from moving beyond QTLs, and identifying QTGs and QTNs. We then highlight how work on the molecular basis of quantitative trait variation has begun to shed light on functional mechanisms that give rise to commonly observed quantitative genetic effects.

Characterizing the Molecular Basis of a Quantitative Trait

Determining the molecular basis of a quantitative trait requires pinpointing QTGs and QTNs, and assessing how changes in molecular function caused by these variants result in phenotypic effects. Here, we describe specific insights gained at each of these steps.

Identifying QTGs

Relative to mapping QTLs at the resolution of many genes, determining specific QTGs represents a major step forward in our understanding of a trait's molecular basis (Flint *et al.*, 2005; Drinkwater and Gould, 2012; Weigel and Nordborg, 2005). This is because a QTG connects diversity in a phenotype to variation in specific biochemical, metabolic, and regulatory processes. Making these links to molecular mechanisms is the easiest when the genes that contribute to trait variation were previously identified through mutagenesis screens, and characterized using biochemical and molecular approaches (e.g., Rosas *et al.*, 2014; Filiault *et al.*, 2008; Balasubramanian *et al.*, 2006). In such instances, this prior knowledge can be used to formulate hypotheses about the mechanisms that enable alleles of a QTG to differ in their phenotypic effects. This is true even in non-model species, where valuable information about a QTG's function can be obtained from its orthologs in model organisms. However, efforts to identify QTGs can also discover new genes and novel functions for known genes (e.g., Seidel *et al.*, 2011), thereby advancing our core knowledge of the genetics and development of the species and trait of interest.

Characterizing QTNs

While QTGs reveal specific genes and pathways involved in heritable trait variation, QTNs provide valuable insights into how these QTGs contribute to phenotypic diversity. Once a QTN has been identified, primary sequence analysis can be used to predict the polymorphism's effect on its cognate gene and protein. QTNs can affect transcription and translation, alter protein structure and activity, or have other effects at the molecular level (see **Figure 2** for some examples). After QTNs have been found, molecular, cellular, developmental, and physiological assays can be conducted to study how these polymorphisms result in phenotypic changes (e.g., Deutschbauer and Davis, 2005; Grisart *et al.*, 2004; Smith and Kruglyak, 2008; Rosas *et al.*, 2014; Yvert *et al.*, 2003; Filiault *et al.*, 2008; Smemo *et al.*, 2014; Balasubramanian *et al.*, 2006; Fridman *et al.*, 2004; Johanson *et al.*, 2000). For a polymorphism located in a *cis*-regulatory element, one might examine whether the SNP causes a change in transcription factor binding or gene expression. Likewise, for a QTN that changes the amino acid sequence of a protein, one might look at its effects on protein activity, stability, or physical

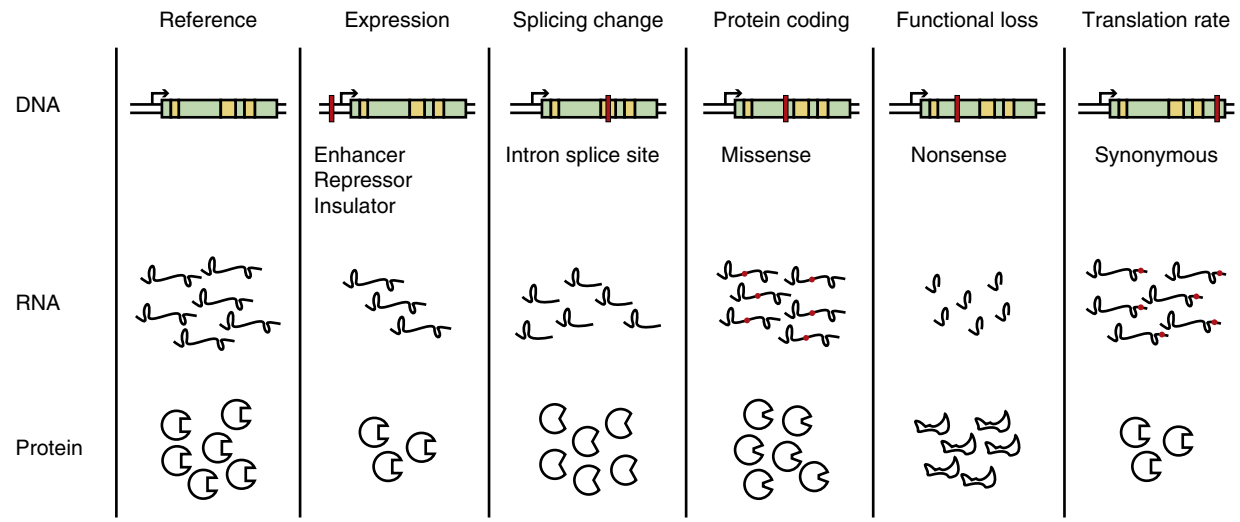

Figure 2 Molecular effects of quantitative trait nucleotides (QTNs). Here, we show a number of ways that polymorphisms can lead to functional changes in quantitative trait genes (QTGs) at the levels of gene regulation and protein function. Effects are separated roughly into the levels of DNA, RNA, and protein.

interactions with other proteins. After examining how a QTN alters the activity of a gene, it is important to assess how this functional perturbation impacts downstream cellular, physiological, and developmental processes. In some organisms, these studies can be performed in individuals that are genetically identical other than at a QTL. Such individuals can be produced using either crossing (e.g., Kooke *et al.*, 2012) or genetic engineering (e.g., Storici *et al.*, 2001) and serve as a powerful resource for determining how a QTN's effect is transduced from the molecular level to the phenotypic level.

Studying the Mechanisms by which Multiple QTNs Influence a Trait

Given that quantitative traits arise due to the effects of multiple QTNs, determining how these factors collectively influence a phenotype is important. This is especially true when sets of QTNs involved in genetic–environment and genotype–environment interactions influence a phenotype (e.g., Gerke *et al.*, 2010, 2009; Taylor and Ehrenreich, 2014). A variety of techniques, such as yeast two-hybrid (Fields and Song, 1989), fluorescence resonance energy transfer (Ma *et al.*, 2014), and co-immunoprecipitation (Sambrook and Russell, 2006), can be used to study how pairs of QTNs affect direct functional interactions between genes. However, a large fraction of nonadditive genetic variation may arise due to statistical interactions that occur between QTNs that are involved in different pathways and cellular processes (Omholt *et al.*, 2000; Gjuvsland *et al.*, 2007; Taylor and Ehrenreich, 2015). This suggests that examining the effects of multiple QTNs at the systems level is important. An increasingly common strategy for such work is to measure global gene expression, as well as the levels of metabolites, proteins, and other molecular intermediates, across genetically distinct individuals (Ayroles *et al.*, 2009; Civelek and Lusis, 2014). By integrating these data with information on the identities and functions of QTNs, researchers can develop network models that explain how gene regulation, metabolism, and physiology are influenced by multiple polymorphisms (Zhu *et al.*, 2008; Rockman, 2008). These models can then be linked to phenotypic outcomes, thereby providing insights into the systems level mechanisms that specify variation in a trait (Zhu *et al.*, 2008; Rockman, 2008).

The Molecular Underpinnings of Quantitative Genetic Effects

Heritable variation in quantitative traits arises due to QTNs that influence the activities and functions of genes, proteins, pathways, and networks. Given that all organisms are comprised of these same building blocks, shared functional mechanisms may underlie commonly observed quantitative genetic effects, such as additivity, dominance, pleiotropy, genetic interaction, and genotype–environment interaction (Omholt *et al.*, 2000). Here, we summarize how these different classes of statistical effects may arise at the molecular level.

Additivity

A large fraction of quantitative trait variation is caused by additive QTNs that act independently of the genetic background in which they occur (Hill *et al.*, 2008). Although many QTNs are likely additive because they have subtle loss- or gain-of-function effects on their cognate genes, even seemingly large molecular perturbations, such as deletions of entire genes, can have additive effects (e.g., DeLuna *et al.*, 2008; Baryshnikova *et al.*, 2010). This suggests that part of the reason that some QTNs appear to be additive is that their phenotypic effects are constrained by genetic buffering. A number of mechanisms are known to buffer biological systems against the effects of genetic variants and the environment, including redundancy among genes and pathways, genetic network architecture, and specific proteins and protein complexes (e.g., heat shock proteins) (as discussed in Hartman *et al.*, 2001; Gu *et al.*, 2003;

Rutherford, 2000; Jeong *et al.*, 2001; Jarosz *et al.*, 2010; Boone *et al.*, 2007; Kitano, 2004 and elsewhere).

Dominance

The molecular basis of dominance has long been a subject of interest among both empiricists and theorists (e.g., Keightley, 1996; Kacser and Burns, 1981; Orr, 1991). Extensive research on mutations and QTNs has identified a number of general molecular mechanisms that result in dominance (Wilkie, 1994). One of the most straightforward causes of dominance is when a QTN has a complete or partial loss-of-function effect on its cognate gene, which is complemented in a heterozygote (**Figure 3(a)**). However, loss-of-function alleles can also be dominant if they result in 'haploinsufficiency,' which occurs when heterozygotes possess a level of an important transcript or protein that falls below a critical threshold (**Figure 3(b)**). 'Dominant negatives' are an additional class of dominant QTN; such variants prevent the other allele of a gene from functioning properly (**Figure 3(c)**). Gain-of-function polymorphisms can exhibit dominance if they increase the abundance of a transcript or protein above a tolerable threshold, or lead to a new spatiotemporal expression pattern (**Figure 3(d)**). Gain-of-function dominant alleles can also arise at the level of protein structure–function relationships: a dominant polymorphism may change a protein's activity or structure, or may even render a protein toxic to cells (Wilkie, 1994). Overdominance may occur if being heterozygous at a locus confers higher fitness than being homozygous. A classic example of such overdominance is the genetic polymorphism that causes sickle cell anemia. This same variant provides protection against malaria and is therefore beneficial in parts of the world where malaria is prominent. Thus, individuals that are heterozygous for the sickle cell allele receive some protection against both malaria and sickle cell disease (Serjeant, 2013).

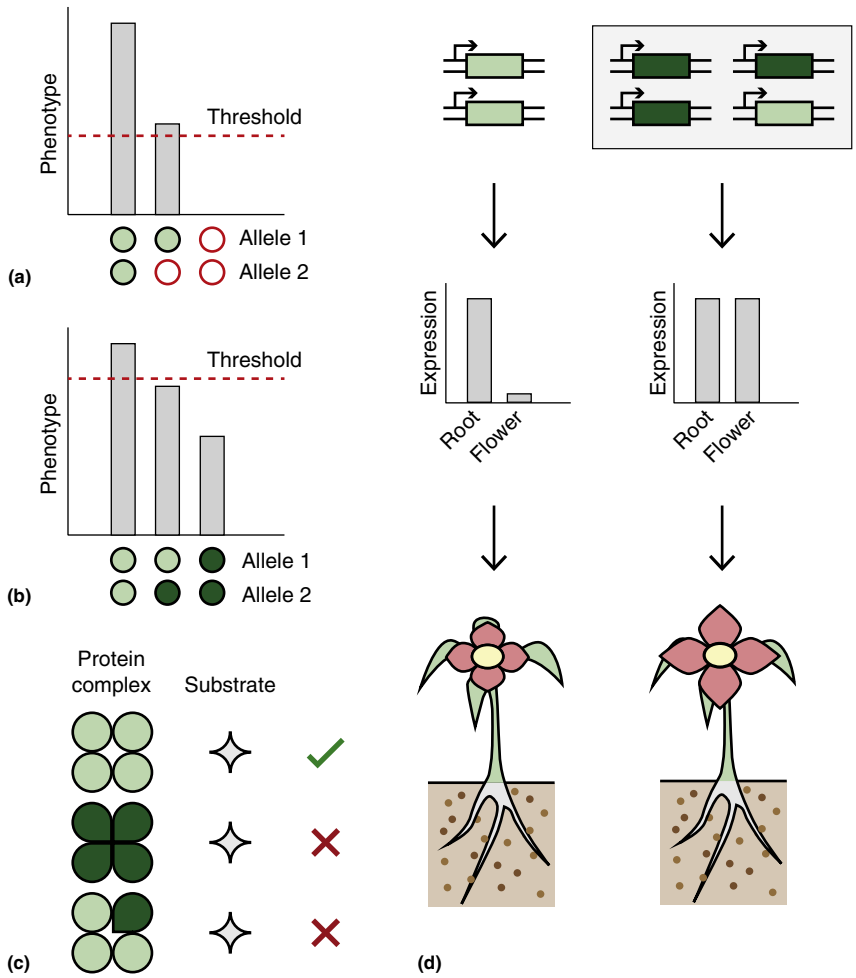

Figure 3 Mechanisms of allelic dominance. As described in the text, dominance can arise due to a number of reasons at the molecular level. (a) Shows an example where a single copy of a gene is sufficient to maintain gene dosage above a required threshold. In contrast, (b) shows an example where a single loss-of-function allele at the level of gene expression is sufficient to reduce gene dosage below a required threshold. (c) Illustrates an example of a dominant negative, where the dominant allele prevents the other allele from functioning. This component of **Figure 3** is based on a figure shown in Alberts *et al.* (2002). In (d), a quantitative trait nucleotide (QTN) causes a gene to be expressed in a new tissue (commonly referred to as 'ectopic expression'), resulting in an increase in flower size that segregates in a dominant manner.

Pleiotropy

When a QTN either directly or indirectly has an effect on multiple traits, it is described as 'pleiotropic' (Paaby and Rockman, 2013; **Figure 4(a)**). As shown in **Figure 4(b)**, a pleiotropic QTN may affect a trait that plays a role in determining an individual's outcome for other phenotypes. Alternatively, a QTN may directly impact multiple downstream pathways that each influences a distinct phenotype (**Figure 4(c)**). Distinguishing between direct and indirect pleiotropy requires knowing the pathways and networks that underlie a trait, as these forms of pleiotropy may be indistinguishable at the phenotypic level. Research attempting to find common features of pleiotropic genes suggests that genes with higher levels of pleiotropy tend to encode proteins that are distributed throughout more cellular compartments or tissues, and are involved in more protein–protein interactions (He and Zhang, 2006; Dudley *et al.*, 2005). Genetic mapping studies focused on quantitative traits have also provided an additional important insight into pleiotropy: pleiotropic QTLs often harbor multiple QTNs that influence different traits, rather than a single QTN that affects multiple traits (Chen and Lubberstedt, 2010). Because closely linked QTNs that underlie distinct phenotypes will segregate together in a population if they are in linkage disequilibrium, the traits they affect may be correlated. Thus, cloning the QTGs and QTNs underlying pleiotropic QTLs is essential for determining the molecular basis of correlations among traits.

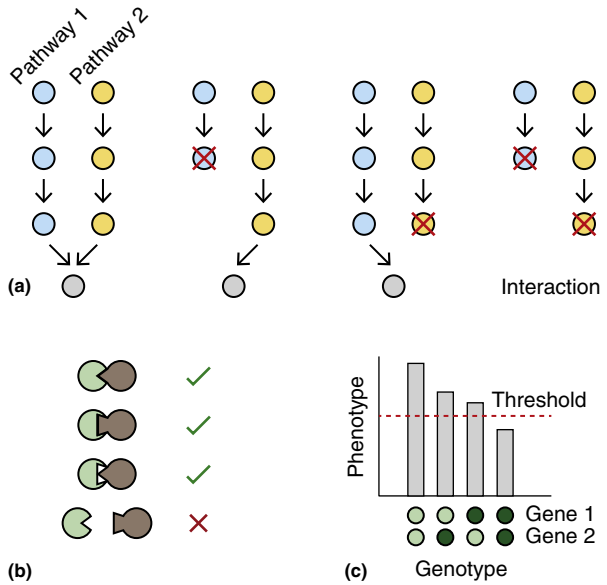

Figure 4 Mechanisms of genetic interactions. We show some mechanisms that can cause genetic interactions, using haploid examples for simplicity. In (a), loss-of-function quantitative trait nucleotides (QTNs) in parallel pathways that converge on the same metabolite or downstream gene result in a genetic interaction when they occur in a particular combination. In (b), two QTNs that disrupt protein structure show an interaction by preventing protein complex formation. Lastly, in (c), we illustrate how combinations of QTNs can impact the level of an important metabolite, protein, or transcript, resulting in a phenotypic effect when the level falls below a threshold.

Genetic Interactions

Genetic interactions occur when the effects of QTNs depend on an individual's genotype at other positions in the genome. These interactions can involve two QTNs (referred to as 'gene–gene interactions') or more than two QTNs (referred to as 'higher-order genetic interactions'). The mechanisms underlying gene–gene interactions have largely been determined through work on large collections of mutants in model organisms (Boone *et al.*, 2007; Lehner, 2011). Typically these interactions arise when genetic variants compromise two pathways or protein complexes that act in parallel, or perturb proteins that function in the same complex (Boone *et al.*, 2007; **Figures 5(a)** and **5(b)**). However, other sources of gene–gene interactions have been proposed; these include the disruption of robustness and the uncovering of otherwise cryptic genetic variants, combinations of QTNs collectively altering the dosage of critical biomolecules either above or below a threshold level (**Figure 5(c)**), and variation in gene regulatory networks (Omholt *et al.*, 2000; Gjuvsland *et al.*, 2007; Lehner, 2011). Less is known about the mechanisms underlying higher-order genetic interactions because these interactions have proven to be more difficult to detect and dissect than gene–gene interactions (Taylor and Ehrenreich, 2014; Pettersson *et al.*, 2011). The most likely source of higher-order genetic interactions is thought to be combinations of three or more genetic variants in gene regulatory networks (Gjuvsland *et al.*, 2007; Taylor and Ehrenreich, 2015). However, there has yet to be empirical proof that this or any other mechanism underlies higher-order genetic interactions.

Gene–Environment and Genotype–Environment Interactions

Many QTNs show effects that depend on the environment. Interactions with the environment can involve single genetic

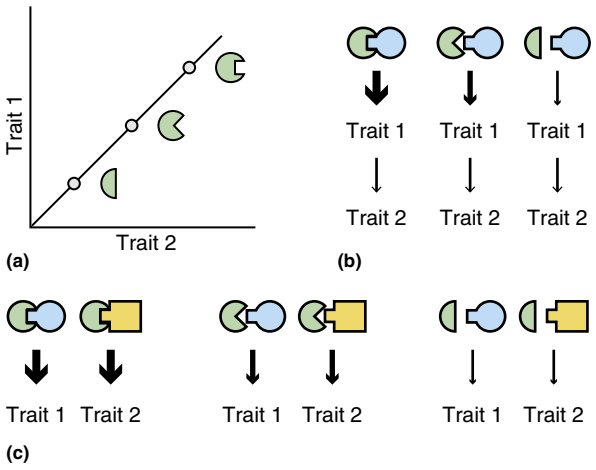

Figure 5 Mechanisms of pleiotropy. Quantitative trait nucleotides (QTNs) that occur in genes that regulate multiple phenotypes can cause correlated trait changes (a). In this figure, we show how this can arise due to polymorphisms that alter the function of a single protein. In (b), QTNs directly affect Trait 1 and only influence Trait 2 through Trait 1. In (c), QTNs directly affect Traits 1 and 2 by influencing how the protein interacts with different partners involved in the respective phenotypes.

variants (referred to as 'gene–environment interaction') or multiple genetic variants (referred to as 'genotype–environment interaction') (Des Marais *et al.*, 2013). The molecular basis of gene–environment and genotype–environment interactions may depend on the conditions being considered and the mechanisms an organism uses to perceive these conditions. Gene–environment and genotype–environment interactions can arise from QTNs in sensors that respond to specific environmental cues (e.g., Filiault *et al.*, 2008; Balasubramanian *et al.*, 2006). Furthermore, transcription factors, signaling cascades, or other components of the cell that act downstream of these sensors and mediate perception of cues may harbor QTNs that interact with the environment (e.g., Smith and Kruglyak, 2008). Biological systems can also show more general responses to the environment (Des Marais *et al.*, 2013). For example, temperature can generally change the kinetic rates and patterns of physical interactions among proteins. Environmental change may also disrupt an organism's ability to buffer itself against genetic variants, thereby uncovering genetic variants that typically do not have phenotypic effects (Gibson and Dworkin, 2004; Paaby and Rockman, 2014).

Conclusion

Quantitative genetics has historically been a field rooted in statistics. However, statistical patterns of heritable phenotypic variation result from the individual and collective effects of functional genetic variants that segregate in populations. Thus, work aimed at identifying these factors and examining how they exert their effects is crucial for bridging the gap between our statistical and molecular understanding of heritable trait variation. Such information will be crucial in improving our ability to predict and treat heritable diseases, and will also likely improve our understanding of how traits evolve in natural populations. Moving forward, technological advances in genetic mapping and genome editing (Ryan *et al.*, 2014; Cong *et al.*, 2013) are likely to accelerate progress in this area. Such research will undoubtedly continue to improve our understanding of the molecular mechanisms that determine the relationship between genotype and phenotype.

Quaternary Biogeography and Climate Change

JL Blois and JE Williams, University of California, Merced, CA, USA

Glossary

Albedo The reflecting power of a surface.
Ancient DNA (aDNA) DNA that has survived in the remains of ancient organisms.
Meridional overturning circulation A global oceanic circulation pattern wherein surface waters in the high latitudes are cooled, thereby becoming denser; this dense water sinks and flows toward the equatorial regions. In tropical and subtropical regions around the world these waters eventually mix with other waters, becoming less dense, and they return to the surface to ultimately flow toward the higher latitudes and complete the circuit.
No-analog assemblages Combinations of species observed at particular places and times in the past that are not seen anywhere on the landscape today.

Introduction

The Quaternary, which started 2.588 million years ago (Ma) and encompasses both the Pleistocene (2.588 Ma to 11.7 thousand years ago (ka)) and the Holocene (11.7 ka to the present), is characterized by substantial climatic and biogeographic change. Climatically, this time period is known as the 'Ice Ages' because the earth has cycled between a series of cold glacial and warmer interglacial periods (Hays *et al.*, 1976). A significant amount of biogeographic change also occurred, including the evolution of *Homo sapiens* in Africa and subsequent dispersal to the rest of the world, and the evolution of modern biotic communities (Blois and Hadly, 2009; Henn *et al.*, 2012). Finally, this time period also encompasses the Anthropocene, a proposed new epoch within the Quaternary characterized by significant human impacts on natural processes (Zalasiewicz *et al.*, 2011).

Here, we discuss Quaternary climate change and biogeography, primarily using examples from North America over the past 21 000 years. This well-studied time period encompasses the most recent transition from a glacial to an interglacial period (Denton *et al.*, 2010). It also saw the spread of humans from Eurasia into North and South America (Achilli *et al.*, 2013; Hamilton and Buchanan, 2010; Henn *et al.*, 2012), the near-global extinction of large megafauna (e.g., Barnosky *et al.*, 2004; Koch and Barnosky, 2006), and significant population-level changes in vegetation and the surviving smaller animals (e.g., Blois *et al.*, 2010; Gill *et al.*, 2009; Williams *et al.*, 2004). Many of these biogeographic changes happened, at least in part, due to climate change (e.g., Barnosky *et al.*, 2004; Lorenzen *et al.*, 2011; Williams and Jackson, 2007). Thus, the Quaternary and the last 21 000 years in particular provide baselines for expected rates and magnitudes of climate change in normal conditions, as well as for how populations, species, communities, and ecosystems have responded to those changes.

Quaternary Climate Change

Orbital Variation and Quaternary Glacial–Interglacial Cycles

The Quaternary occurred at the end of a long-term cooling trend that followed the warm early Eocene climatic optimum roughly 50 Ma. Thus, while the glacial–interglacial cycles that characterize the Quaternary encompass both cold and warm times, even the warm periods are colder than most times in the Cenozoic (the past 65 million years) (**Figure 1**; Zachos *et al.*, 2001). This long-term cooling trend facilitated the development of extensive ice sheets in both the southern and northern hemispheres. While permanent ice sheets have been in place in Antarctica for tens of millions of years (Kennett, 1977; Zachos *et al.*, 2001), the start of the Quaternary, 2.588 Ma, roughly coincided with the development of permanent ice sheets in the northern Hemisphere (Ruddiman and Raymo, 1988).

One of the most striking physical features of the Quaternary is the periodic growth and decline of the northern hemisphere ice sheets, which provide visible evidence of the accompanying climatic changes that occurred throughout the Quaternary. These glacial–interglacial cycles are driven primarily by changes in the position of the earth relative to the sun, which fluctuates due to orbital variations (Raymo *et al.*, 2006). Together, orbital variations influence the amount and distribution of solar radiation across the earth and the seasonal contrasts of solar radiation, pacing the build up and dissipation of large ice sheets at the poles (Lisiecki and Raymo, 2005; Raymo *et al.*, 2006; Ruddiman, 2008; Zachos *et al.*, 2001).

Orbital variations have a number of consequences for both marine and terrestrial environments and physical landscapes, including interrelated changes to ice sheets, sea levels, CO_2 and other atmospheric gases, temperature, and aridity. Ice sheet buildup is spurred initially by orbitally forced decreases in summer insolation which causes summer cooling, amplified (at least in North America) by changes in vegetation from forest to tundra (Kageyama *et al.*, 2004). Subsequent feedbacks between land and ice through changes to albedo, changes in the altitude of ice sheets, and restriction of freshwater flows into the adjacent oceans helps amplify the buildup of the ice sheets (Kageyama *et al.*, 2004). Increases in the extent and volume of ice on land correspond to decreases in sea levels, which were dramatically lower during glacials, for example, reaching around 120 m below present-day sea level (Denton *et al.*, 2010).

Similar to the role of insolation in glacial inception, deglaciation is initiated when summer insolation increases. However, increases in summer insolation do not always cause glacial terminations; other factors are also important (Denton

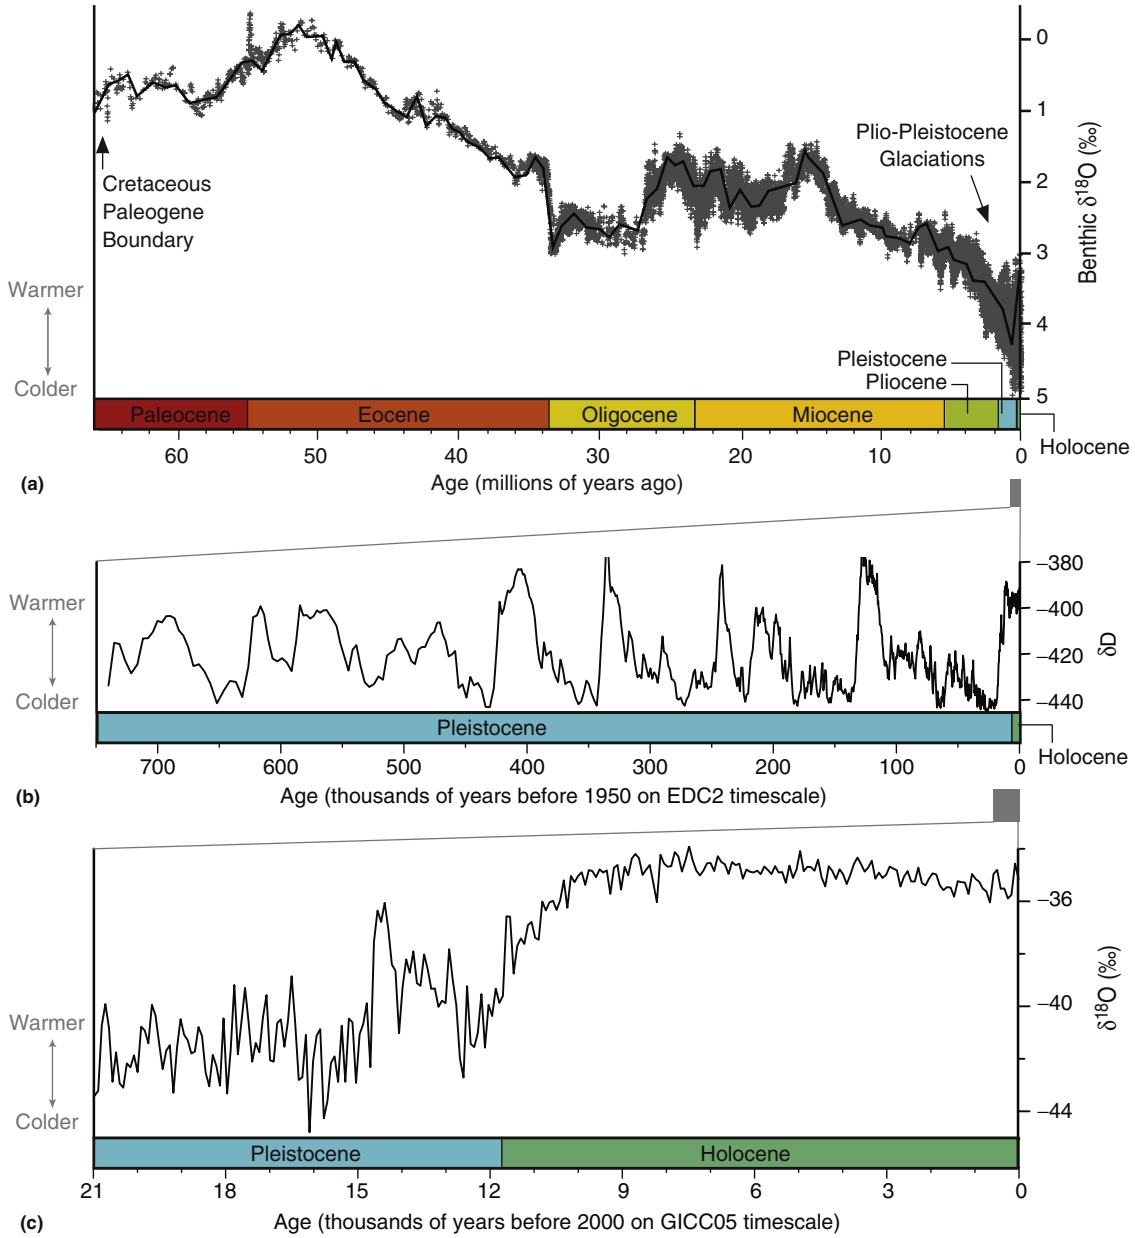

Figure 1 Three views of climate change across the Cenozoic. et al., 2010). One factor appears to be continental ice volume: when continental ice volume nears its maximum, enough fresh meltwater flows from the continental ice sheets into the North Atlantic to decrease North Atlantic meridional overturning circulation. This initiates a cascade of global effects to both oceans and atmospheres that causes atmospheric CO_2 levels to rise high enough to sustain an interglacial (Denton *et al.*, 2010). Sea levels also rise during transitions from glacial to interglacial states as the large amount of water formerly locked up as ice on land drains into the ocean (Lambeck *et al.*, 2002). Changes to the ice sheets and sea levels during deglaciation affect the physical space available to terrestrial and marine species; in some places (e.g., northern North America), new physical space becomes available to terrestrial species as ice sheets melt and retreat northward, whereas in other locations physical environments are lost as sea levels rise (e.g., coastlines). The converse is true of the physical changes that occur during glacial inceptions.

Each glacial and interglacial period was unique – in magnitude of warming and cooling, in duration, and in the variation in short-term climate events overlain on the glacial–interglacial cycles (Augustin *et al.*, 2004; Petit *et al.*, 1999). However, several general patterns emerge. Glacial–interglacial cycles in the early Pleistocene were characterized by high-frequency cycles of relatively low magnitude, and cycles were symmetric; that is, duration of the glacial–interglacial transitions (entry into interglacial) was relatively similar to that of the interglacial–glacial transitions (termination of glacial) (Ruddiman and Raymo, 1988; Tziperman and Gildor, 2003). However, the periodicity and magnitude of glacial–interglacial cycles changed between 1 Ma and 600 ka (**Figure 1**): cycles became longer (less frequent, on the order of 100 000 years duration), and the amplitude of each cycle increased (Lisiecki and Raymo, 2005; Ruddiman and Raymo, 1988). Since then, the duration of the glacial portion of the cycle has been between 80 000 and 120 000 years in length (Denton *et al.*, 2010). In addition, the rates of change at the initiation and termination of glacials became asymmetric: initiation of glacial periods was slow, characterized by an oscillating buildup, but termination of the glacial period was rapid (Denton *et al.*, 2010; Tziperman and Gildor, 2003).

Rapid Climate Change and the Last Glacial–Interglacial Transition

A majority of the biogeographic data available for the Quaternary are from the most recent glacial–interglacial transition, so we focus on this transition to illustrate the decadal to millennial-scale climatic variability that accompanies the more general glacial to interglacial transition (**Figure 1**). We also illuminate specific patterns and mechanisms of shorter-term variation that occurred at earlier glacial–interglacial transitions (e.g., Raymo *et al.*, 1998).

The global climate transition from the Last Glacial Maximum (LGM) *ca.* 21 ka to the start of the Holocene interglacial period 11.7 ka was marked by collapse and retreat of the ice sheets, substantial rises in sea levels, and relatively rapid global warming (Denton and Hughes, 2002). However, these changes did not occur smoothly and monotonically but were instead marked by starts and reversals, and periods of rapid change followed by periods of little change. For example, ice sheet retreat and corresponding changes in sea levels were discontinuous (Carlson and Winsor, 2012). In North America, the Cordilleran and Laurentide ice sheets covered northern North America, and an additional ice sheet still occurs on Greenland. Portions of these ice sheets reached their maximum extent as early as 30 ka and persisted at maximal extent until roughly 19 ka (Carlson and Winsor, 2012; Clark *et al.*, 2009), at which point they extended south of the 49th parallel into the United States. The most rapid rates of ice sheet retreat occurred around 19 ka and during the Bølling–Allerod warm period (14.7–12.9 ka), though final collapse of the Laurentide did not occur until 8.2 ka (Carlson and Winsor, 2012). Sea level rose in spurts corresponding to changes in the ice sheets, and finally leveled off around 6 ka (Carlson and Winsor, 2012). Altogether, sea levels rose roughly 120 m across the last glacial–interglacial transition (Denton and Hughes, 2002).

Global temperatures rose 3–5 °C on average from the LGM to the present (Jansen *et al.*, 2007), but the transition was marked by substantial spatial and temporal variability. Among the most significant climatic changes during deglaciation were two periods of rapid warming with an intervening cold interval, all of which occurred within roughly 3000 years (**Figure 1**; Steffensen *et al.*, 2008). Following initial deglaciation, rapid warming occurred around 14.7 ka during the entry into the Bølling–Allerod period. For example, a Greenland ice core showed that around 9 °C degrees of warming occurred within 70 years (Severinghaus and Brook, 1999). The causes of this event are still being investigated, but warming was likely related to reduced amounts of freshwater runoff into the North Atlantic (Liu *et al.*, 2009; Denton *et al.*, 2010). Following this warm period, the climate system entered into the Younger Dryas (12.9–11.7 ka) when large pulses of freshwater into the North Atlantic reduced meridional overturning circulation and thus global heat transport (McManus *et al.*, 2004). The end of the Younger Dryas was marked by rapid warming into the Holocene interglacial, on the order of 5–10 °C in Greenland in as little as a few decades (Dansgaard *et al.*, 1989; Severinghaus and Brook, 1999; Taylor *et al.*, 1997). Both of these rapid climate changes have been detected in diverse proxy records around the world (Clark *et al.*, 2009) and were truly global events, though the details differ between the northern and southern hemispheres and the magnitude of climate change was variable across space and time. Changes were also seen in many other aspects of the climate system, such as temperature, aridity, and the seasonality of both (e.g., Bartlein *et al.*, 1998).

Holocene Variability

Climates also varied during the Holocene interglacial period, but the magnitude of change was generally less than during deglaciation (**Figure 1**; Mayewski *et al.*, 2004; Shuman, 2012; Viau *et al.*, 2006). Mayewski *et al.* (2004) identified at least six periods of rapid climate change occurring throughout the Holocene of varying durations. Each event experienced significant enough change that it was detected in global arrays of paleoclimate proxy records (though not every site showed every change). The first period (9–8 ka) was a cool period in the northern Hemisphere. It represented a lagged response to orbital forcings at the end of the Pleistocene and corresponded to the final collapse of the Laurentide ice sheet into the North Atlantic Ocean at 8.2 ka (Alley *et al.*, 1997). Low latitude regions generally saw increased aridity during this time. Subsequent Holocene periods of rapid climate change were also characterized generally by polar cooling and tropical aridity (Mayewski *et al.*, 2004). The primary exception is the most recent period of climate change, 600–150 years BP, when the polar regions were cool but low latitudes wet. The most significant Holocene climate changes involved changes in aridity rather than temperature.

Quaternary Biogeography

Overall, the environmental variation that characterized the Quaternary – both in climates and in physical environments – significantly affected the biological diversity of the globe (e.g., Blois and Hadly, 2009). Understanding these impacts and how

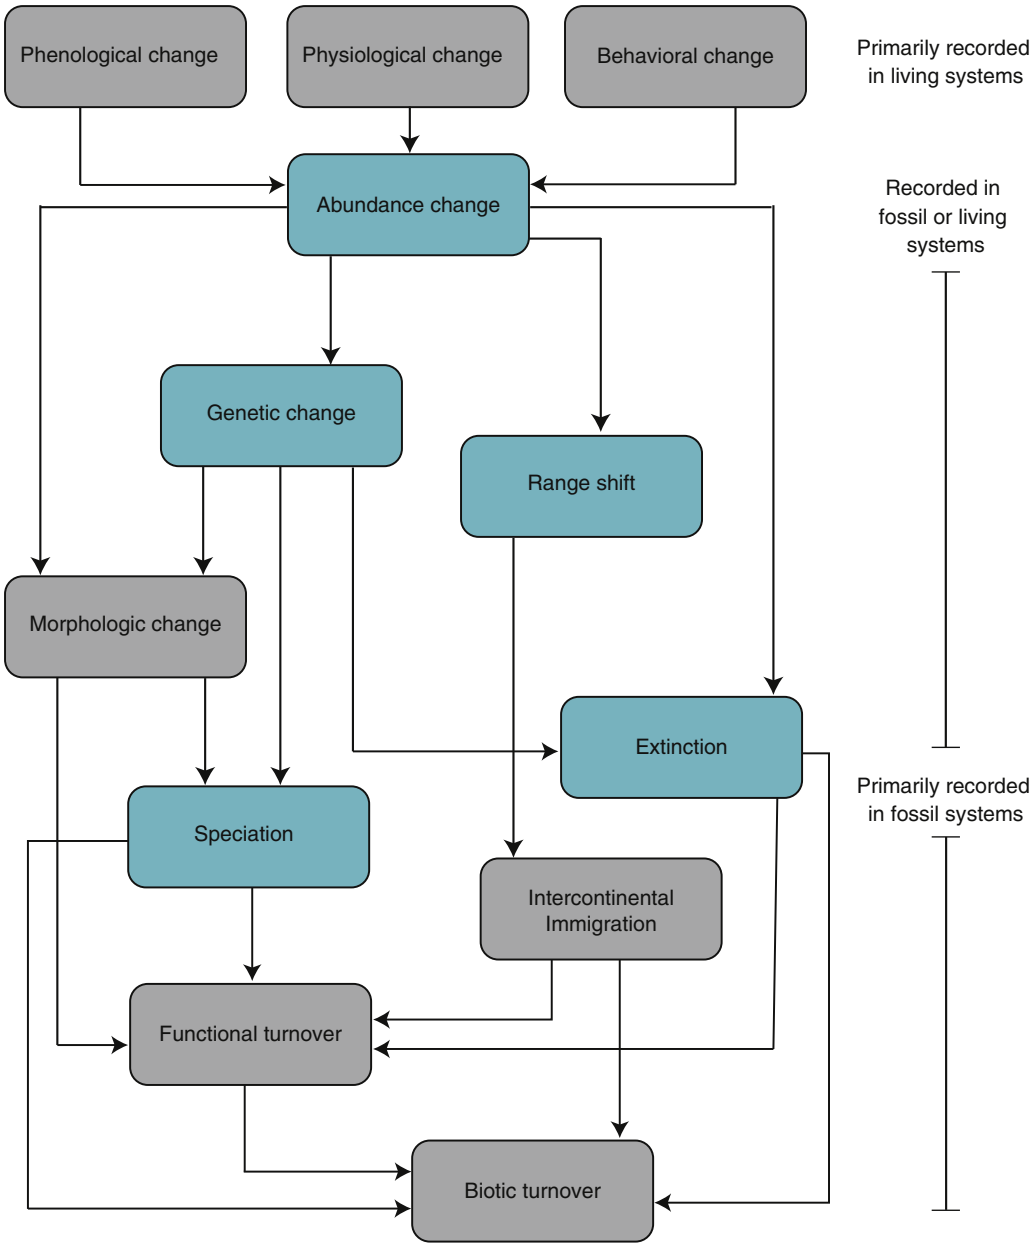

Figure 2 Different responses that species may exhibit to climate change, and the systems (modern and/or fossil) in which they are typically studied. For simplicity, only the main pathways between responses are indicated. Responses discussed in the text are highlighted in teal color. Modified with permission from Blois, J.L., Hadly, E.A., 2009. Mammalian response to Cenozoic climatic change. Annual Review of Earth and Planetary Sciences 37, 181–208.

organisms have responded to past climate changes is important for designing effective conservation strategies that optimize the ability of extant species to persist in the face of significant future climate changes. Below, we review some of the biogeographic changes that occurred in response to Quaternary climate change (Figure 2; Blois and Hadly, 2009), among them abundance changes, genetic structure and diversity changes, range shifts, speciation, and extinction. These changes are not independent of one another, nor are they the only responses that can be exhibited by species (e.g., physiological or morphological responses are also seen in response to climate change; Millien *et al.*, 2006; Pörtner and Farrell, 2008); however, they are the responses most often detected in fossil systems. We then examine how changes within single populations and species scale up to biogeographic responses detected at the assemblage and ecosystem levels.

Population and Species Responses to Climate Change

Abundance change

One of the first responses that a species shows to climate change is changes in abundance (Lundberg *et al.*, 2000). Because abundance changes determine the size and/or location of populations within a species distribution, they can drive other observed responses to climate change such as genetic

change, morphological change, and range shifts (**Figure 2**; Blois and Hadly, 2009; Hewitt, 2000). As climate changes and the abundance of a species decreases or increases, the species' ability to withstand perturbations will similarly decrease or increase (Johnson, 1998; Kiessling and Aberhan, 2007; Nogués-Bravo *et al.*, 2008; Purvis *et al.*, 2000).

Abundance is a function of the amount and availability of suitable habitat present (Andrewartha and Birch, 1954; del Monte-Luna *et al.*, 2004). How abundance changes as climate changes is a complex function of the interaction between climate and/or habitat change, life history strategies, habitat preferences of a species, and interactions with other species (e.g., Forchhammer *et al.*, 2002). Although a single species has a general range of conditions within which it can survive (e.g., its environmental niche *sensu*; Grinnell, 1917; Soberón, 2007), the specific shape of environmental fluctuations (e.g., magnitude, duration, and rate of climate change), combined with intraspecific variation in tolerances within populations (such as between adults and juveniles), can result in many possible outcomes: sustained populations, periodic extirpation-recolonization events, or permanent extirpation (Jackson *et al.*, 2009).

In the fossil record, abundance changes appear to be largely individualistic responses that vary according to the environmental niche of each species (Blois *et al.*, 2010; Terry *et al.*, 2011; Williams *et al.*, 2004). Paleo-records have also shown that rapid climate change can affect population abundances almost immediately, at times leading to rapid ecosystem restructuring. For example, Yu (2007) determined that forested vegetation in New Jersey responded to the Bølling–Allerod warming event with a lag of at most 200 years (**Figure 1**), with the cold-tolerant *Picea* declining and the warm-tolerant *Pinus* increasing. Responses to subsequent rapid cooling during the Younger Dryas (**Figure 1**) again occurred almost immediately (e.g., decreased abundances of warm-tolerant oak). Similarly, rapid vegetation response to climate changes led to the restructuring of communities elsewhere in northeastern North America, where pine, hemlock, and spruce abundances declined only to be replaced by another dominant species (e.g., Shuman *et al.*, 2009). Changes in abundance have also been seen in mammals in response to late Quaternary climate changes (e.g., Blois *et al.*, 2010; Grayson, 2006), though limits of dating precision and the taphonomy of many mammalian fossil deposits do not typically allow accurate assessment of mammalian responses to rapid climate change.

Genetic change

The advent of ancient DNA (aDNA) has identified significant genetic changes that occurred within species across the past several millennia. Under optimal preservation conditions such as in permafrost settings, aDNA as old as 50 000–65 000 years old can be recovered (Willerslev *et al.*, 2003), though in some exceptional cases recovery of much older aDNA is possible (e.g., Orlando *et al.*, 2013). Ancient DNA provides the opportunity to study the impact of climate change on the structure and genetic diversity within past populations and species (e.g., Hadly *et al.*, 2004; Hofreiter *et al.*, 2004b; Hofreiter and Stewart, 2009). Genetic change is a result of population-level processes such as recombination, mutation, selection, random genetic drift, and gene flow (Charlesworth *et al.*, 2003), all of which take place in species over tens to thousands of years. Most of these processes may be influenced by climate, either directly such as when climate selects for or against key traits or indirectly through abundance or habitat change, which influences gene flow and genetic drift. For example, aDNA has been used to determine changes in the relative abundance of ancient populations (Chan *et al.*, 2006; Hadly *et al.*, 2004; Lorenzen *et al.*, 2011), whether populations became connected or remained isolated during periods of climate change (Hadly *et al.*, 2004, 1998; Hofreiter *et al.*, 2004a; Teacher *et al.*, 2011), and whether and which clades survived across periods of climate change (Brace *et al.*, 2012; Foote *et al.*, 2013; Fulton *et al.*, 2013). Species reservoirs of genetic diversity and their potential for genetic change may become increasingly important for species to successfully adapt to anthropogenic climate change (e.g., Jump and Penuelas, 2005).

Range shifts

One of the most prominent and well-supported responses that species have to climate change is range shifts, both today and in the past (Lyons, 2003; Ordonez and Williams, 2013; Sexton *et al.*, 2009; Tingley *et al.*, 2009; Waltari *et al.*, 2007). Species ranges are limited at broad scales by environmental factors such as temperature, precipitation, and relative humidity (Brown *et al.*, 1996; Eronen and Rook, 2004). As climate changes and environmental gradients shift, species may track their preferred environments at varying directions and rates according to each species physiological limitations (Graham *et al.*, 1996; Tingley *et al.*, 2009; Walther *et al.*, 2002). At one end of the scale, changes in climate may result in only minimal adjustments to species ranges, particularly for species that are not tightly controlled by climate or are located in regions with a large amount of topographic and thus microclimatic complexity (Ackerly *et al.*, 2010; Loarie *et al.*, 2009). On the other hand, changes in climate may result in large range shifts, particularly in areas where climate velocity is large and for species that have good dispersal capabilities (Loarie *et al.*, 2009; Ordonez and Williams, 2013; Schloss *et al.*, 2012). Shifts in species ranges are a direct result of changes in abundance (**Figure 2**), and occur when existing populations are extirpated and/or new populations are formed just beyond the edges of ranges (**Figure 3**; Walther *et al.*, 2002). Range expansion is due to episodes of colonization into favorable habit (Walther *et al.*, 2002), and the rate at which a species colonizes new habitat is dependent upon many factors such as climate change, dispersal capability, and microclimate (Lesser and Jackson, 2013). At the very broadest scale, species can move into entirely different continents, such as when humans crossed the Bering land bridge into North America (Achilli *et al.*, 2013; Goebel *et al.*, 2008). These events are more rare than within-continent range shifts and are often accompanied by speciation or biotic turnover.

Studies on extant species have illuminated the processes that may underlie present and past range shifts. Not all species alter their ranges in response to climate change, but the species that do are typically ones that live at higher latitudes or elevations and are often found near the edge of their physiological limits (Hickling *et al.*, 2006; McCain and King, 2014; Walther *et al.*, 2002). The magnitude and direction of range shift depends on the species life history characteristics

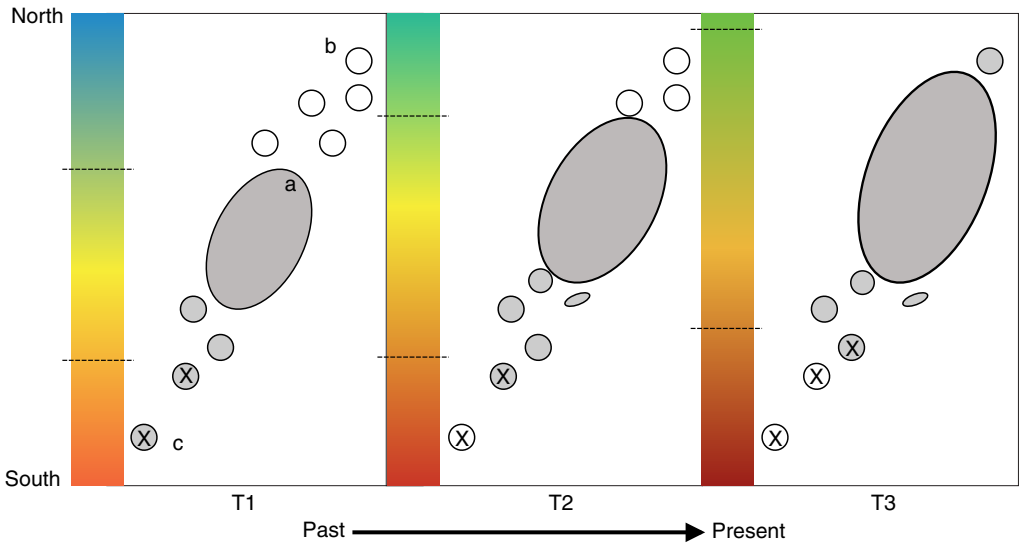

Figure 3 Potential range shifts of a species as a response to climate change across three time periods. In each panel from time 1 (T1) to time 3 (T3), the geographic extent remains the same but the climatic gradient across space shifts from colder (blue) to warmer (red). At T1, the species is able to persist in a range of environments (gray filled circles), though some of them are unsampled (X) so the range limits (both geographic and climatic, indicated by the dashed line) appear to be narrower than they are. They are not able to persist in other environments (unfilled circles). With increasing global temperatures (e.g., from T1 to T3) individuals from the northern leading edge of the distribution will colonize new localities in search of habitats with suitable climates. As temperatures continue to increase from T2 to T3, previously unsuitable habitats become suitable as local climates warm, while previously suitable habitats become unsuitable. Finally, when temperatures reach a maximum (T3), populations at the southern trailing edge of the distribution become extirpated, due to the loss of suitable habitat. Also, the entire species range has shifted in geographic space to the north. Shifts have occurred in climate space as well (i.e., temperatures at the southern localities are warmer at T3 than anything observed in T1). Shifts in climate space arise from, potentially, adaptation to warmer climate regimes in the south, but adaptation was not as strong as empirically observed because some localities from warm places were unsampled in T1, creating the perception of a narrower climatic niche.

such as dispersal ability, their sensitivity to the environment, and the amount of climate change that occurs at a local scale (McCain and King, 2014). Species that have narrow tolerance ranges are affected more by climate change than species that can tolerate varied climates and habitats (Liow *et al.*, 2009; McCain and King, 2014).

The location and distribution of species are also a function of biotic interactions. Direct evidence shows that biotic interactions such as competition can regulate the extent of a species range (Sexton *et al.*, 2009). Additionally, species ranges are smaller at lower latitudes, suggesting that increased biotic interactions and competition in areas with higher species diversity, i.e., the tropics, can dictate the size of a species distribution (Brown *et al.*, 1996; Rapoport, 1982). However, the extent to which biotic interactions are detected in the fossil record is limited (Blois *et al.*, 2014).

Information about past species localities has been fairly well preserved in the fossil record and these data have been aggregated in public databases (i.e., FAUNMAP) and museum repositories (Brewer *et al.*, 2012; Uhen *et al.*, 2013), facilitating reconstruction of species ranges at various times in the past (Graham *et al.*, 1996; Lyons, 2003). For example, between the Pre-Glacial to Glacial and Glacial to Holocene time periods, North American mammals shifted their ranges more northward than they did southward (Graham *et al.*, 1996; Lyons, 2003). Plant populations also generally expanded northward across the late Quaternary. Davis and Shaw (2001) provided evidence of this northward shift by examining spruce pollen percentages in lake sediments from eastern North America and determined that spruce had a more southerly range approximately 21.5 thousand years ago compared to 500 years ago. Similar changes occurred in many other plant genera (Davis, 1983; Huntley and Webb, 1989). The advent of paleo-species distribution modeling (SDM) and paleoclimate simulations has facilitated correlation of past changes in species distributions with climate change (Nógues-Bravo, 2009; Svenning *et al.*, 2011; Varela *et al.*, 2011). Paleo-SDMs have provided insight into, for example, the potential location of glacial refugia (Gavin *et al.*, 2014; Svenning *et al.*, 2008), how past distributions changed as climate changed (e.g., Nogués-Bravo *et al.*, 2008; Ordonez and Williams, 2013; Rodriguez-Sanchez *et al.*, 2010), and the role of climate in past extinction events (Lorenzen *et al.*, 2011; Nogués-Bravo *et al.*, 2008).

Speciation

The many glacial–interglacial cycles of the Quaternary may have driven speciation within many plants and animals by shifting climate zones, forming and/or removing environmental barriers, and fragmenting populations (Barnosky, 2005; Hewitt, 1996). Habitat fragmentation can result in populations that are isolated from one another; if isolation persists for an extended period of time, substantial genetic divergence could occur between populations and result in speciation (Barnosky, 2005; Hewitt, 2000; Kadereit *et al.*,

2004; Stewart *et al.*, 2010). However, whether and for how long a population is isolated depends on the interaction between the nature of the barrier and the species environmental tolerances (Hewitt, 2000, 1996). For example, if a species is adapted to cooler climates it will occupy refugia during warmer climate cycles (which are typically short in duration during the Quaternary), whereas species that are adapted to warmer climates will occupy refugia during the longer glacial periods; these differences in isolation time can also affect the timing of divergence between species (Gavin *et al.*, 2014; Kadereit *et al.*, 2004; Stewart *et al.*, 2010).

Because so many climate fluctuations occurred, the rate of speciation during the Quaternary should be elevated compared to similar time periods without glacial–interglacial cycles (Avise and Walker, 1998). However, evidence has been provided both for (Jakob *et al.*, 2007) and against (Barber and Jensen, 2012) climate-induced speciation. The glacial and interglacial cycles led to the isolation of populations for relatively short periods of time (at most, approximately 100 thousand years), which resulted in intraspecific genetic differences. In some cases, these genetic differences led to speciation events (Brochmann and Brysting, 2008; Galbreath and Cook, 2004; Jakob *et al.*, 2007). However, the rates of speciation during the Quaternary period are not higher than previous time periods, at least for mammals (Barnosky, 2005; Bobe and Behrensmeyer, 2004), perhaps because the duration of isolation was not long enough to facilitate speciation in these groups. The reconnection of fragmented populations during favorable conditions may have allowed for increased gene flow, which resulted in lower than expected speciation rates for the Quaternary period (Barnosky, 2005; Klicka and Zink, 1997; Zink *et al.*, 2004).

Extinction

A major extinction event occurred during the Quaternary between approximately 50 ka and 10 ka (Barnosky *et al.*, 2004; Koch and Barnosky, 2006). During this time, 97 of the 150 largest mammalian genera went extinct across all continents (Barnosky *et al.*, 2004; Lyons *et al.*, 2004; Roberts *et al.*, 2001), though extinction severity was spatially heterogeneous. Africa was not affected as heavily as the other continents and only lost 18% of its genera, whereas continents such as North America and South America lost 76% and 86% of their genera, respectively (Nógues-Bravo *et al.*, 2010). Megafaunal extinction was also heterogeneous through time (Barnosky *et al.*, 2004; Hofreiter and Stewart, 2009; Stuart and Lister, 2012).

Many hypotheses about the cause of the megafaunal extinction have been postulated, but the two main hypotheses are climate change and human interactions (Barnosky *et al.*, 2004; Koch and Barnosky, 2006; Lyons *et al.*, 2004). Humans clearly impacted megafaunal populations and caused some species to go extinct, but the exact mechanisms of human impact are still unclear. Potential human drivers of extinction include habitat degradation and fragmentation by practices such as deforestation and fire (Burney *et al.*, 2004; Robinson *et al.*, 2005), overhunting (Brook and Johnson, 2006; Lyons *et al.*, 2004; Martin, 1967), and pandemic disease introduced by humans (Alroy, 2001; Rothschild and Laub, 2006). Of these drivers, the leading hypothesis is overhunting (Barnosky *et al.*, 2004; Haynes, 2013; Koch and Barnosky, 2006; Lyons *et al.*, 2004; Martin, 1967). Several studies have examined the timing of the megafaunal extinctions on each continent and found a strong correlation between human arrival and megafaunal extinction (e.g., North America and Australia; Barnosky *et al.*, 2004; Johnson *et al.*, 2013). Human arrival has also been correlated with the extinction of other groups such as birds (Steadman, 1995). The ability of humans to severely impact megafauna through overhunting is thought to result from the naivety or lack of coevolution of animals with humans on most continents and the slow reproductive rates of large mammals (Haynes, 2013; Lyons *et al.*, 2004; Zuo *et al.*, 2013). However, many of the extinct megafauna show no signs of being hunted by humans (Grayson, 1984; Koch and Barnosky, 2006) and some species may have coexisted with humans for thousands of years before going extinct (Lima-Ribeiro and Diniz-Filho, 2013; Wroe *et al.*, 2004). Another alternative is that extinction could have occurred due to indirect effects of hunting (Lyons *et al.*, 2004), such as habitat change or ecological cascades resulting from extinction of just a few key megafaunal species (Gill *et al.*, 2009). All of these factors contribute uncertainty about the total impact of overhunting on megafaunal extinction (Sandom *et al.*, 2014).

Climate change at the end of the last glacial period has also been hypothesized as a cause of megafaunal extinction, perhaps by reducing the types and quality of habitat available to the animals and thus reducing the resources necessary to support species (Koch and Barnosky, 2006). For example, the megafaunal extinction rate was positively correlated with the magnitude of climate change on all continents except for South America, which only had a moderate amount of climate change during the late Quaternary period (Nógues-Bravo *et al.*, 2010). Some species went extinct before the local arrival of humans and the timing of extinction was correlated with significant climate changes in some systems, ruling out humans as the cause of extinction for those taxa (Barnosky, 1986; Stuart and Lister, 2012; Wroe *et al.*, 2013). Despite the apparently clear link between extinction and climate, the climate change hypothesis has had a difficult time explaining why only large mammals were affected and not other groups such as marine organisms or plants (Lyons *et al.*, 2004; Martin, 1984), though size-dependent differences in reproductive rates may have been a factor (Johnson, 2002; Zuo *et al.*, 2013). Also, large mammals that were nocturnal, arboreal, and lived in inaccessible forests (e.g., mammals that were not as exposed to human hunting) were not as drastically affected by the megafaunal extinction (Koch and Barnosky, 2006). Finally, climate change hypotheses have a difficult time explaining why there was an increased extinction rate for large mammals during the LGM and not in previous glacial periods (Lyons *et al.*, 2004).

Although many studies have proposed either humans or climate change as the culprit for the late Quaternary megafaunal extinctions, recent studies show that the mechanism of extinction for many species is likely a combination of both human impacts and climate change (Haynes, 2014; Lorenzen *et al.*, 2011; Nogués-Bravo *et al.*, 2008; Prescott *et al.*, 2012). These studies postulate that climate change altered species abundances and distributions at the end of the last glacial period, such that the smaller populations were more susceptible to overhunting from humans (e.g., Nogués-Bravo *et al.*, 2008). Since some continents had high extinction rates with low climate change (Nógues-Bravo *et al.*, 2010) and other species went extinct with no evidence of human hunting or interference, extinction mechanisms are likely location- and/or species-specific.

Community Responses to Climate Change

The combined effect of changes within individual species across the late Quaternary led to significant changes in community attributes such as diversity, evenness, and composition. For example, the small mammal assemblage in northern California showed significant losses in diversity across the last glacial–interglacial transition, even though no small mammal species went globally extinct (Blois *et al.*, 2010). These changes were similar to those seen in other small mammal assemblages across the west (e.g., Grayson, 2006; Lyman, 2014) and were postulated to be due to climate change favoring more generalist species (Blois *et al.*, 2010).

Another significant biogeographic change was the appearance and disappearance of 'no-analog' assemblages. Small mammals occurred in no-analog assemblages, where species that today live in very different and spatially separated localities coexisted in the past (e.g., Graham *et al.*, 1996). No-analog assemblages have also been seen in plant communities and were linked to climate changes. For example, peak dissimilarity in plant assemblages occurred at the same time as peak dissimilarity in climates, in both Alaska and eastern North America (Williams and Jackson, 2007) and dissimilarity in northeast pollen assemblages spiked at times of significant climatic transitions (Shuman *et al.*, 2009). Similarly, spatial dissimilarity among plant assemblages in eastern North America peaked from 14–11 ka. These relationships were primarily due to climatic factors (Blois *et al.*, 2013) and not to biotic interactions (Blois *et al.*, 2014). Despite the clear evidence for the impact of climate change on assemblage structure and diversity, biotic interactions (at least cross-trophic interactions) clearly also were a factor. For example, no-analog conditions were closely correlated with the functional loss of megafauna from the system, indicating that herbivory by megafauna was a key driver maintaining plant assemblages (Gill *et al.*, 2009, 2012).

Conclusion

Overall, the Quaternary encompassed a time of significant climatic and biogeographic change. While species and communities responded to a multitude of drivers, the physical and climatic changes that affected the earth system over the past several million years were primary. However, much of the data for both climatic and biogeographic processes in the Quaternary is drawn from the past few millennia – from the LGM to the present. Although this perspective has provided a detailed understanding of biogeographic responses to deglaciation and global warming, comparatively less is known about biogeographic responses to environmental change during the thousands and millions of years prior to the LGM, and across other periods of rapid climate changes. Additionally, much of the focus has been on biogeographic responses of a few groups, such as pollen or mammals, due to the different nature of the fossil record between groups. Today, however, biogeographic patterns and processes are being altered by extensive human impacts, so much so that a new geological epoch has been proposed, the Anthropocene (Zalasiewicz *et al.*, 2011). The extent to which ecological processes today are altered compared to the past is unknown, and a question that can only be answered by combining paleo- and present-day data. Integrating paleobiogeographic data from multiple components of our biotic systems, understanding responses of all components across periods of rapid warming events, and establishing relevant biogeographic baselines for past processes all represent key frontiers in paleobiogeography and avenues that are particularly relevant for conservation for present-day species.
