Density-dependent selection Relative fitnesses of genotypes depend on population size.
Environmental stochasticity Random environmental variation that affects vital rates of all individuals, or groups of individuals, similarly.
***r*- and *K*-selection** Different phenotypes are selected for small and large population sizes.
Trade-offs Population parameters, for example, $\overline{r}$ and $\overline{\gamma}$ depend on the same phenotype and therefore cannot vary independently.

An Introduction to *r*- and *K*-Selection

Classical population genetics is often based on simplifying assumptions including constant population sizes and stable environments. The theory of *r*- and *K*-selection is conceptually important because it demonstrates that conclusions arising from basic population genetic models can be dramatically altered when more biologically unrealistic assumptions are relaxed from models. First, in populations subject to density dependence in environments without environmental stochasticity, evolution will maximize the carrying capacity *K* if the relative fitness of genotypes depends on population size. Second, including environmental stochasticity in density-dependent models result in an evolutionary process maximizing a more complex function determined by the ecological parameters driving the dynamics of the population. Third, empirical analyses of the theory of *r*- and *K*-selection requires estimation of trade-offs between phenotypic characteristics affecting the growth rate *r* at small population sizes and the response of the growth rate γ to changes in population size.

Deterministic Models

As is the case for many important concepts in modern evolutionary ecology, the concept of *r*- and *K*-selection was first introduced by the American Robert H. MacArthur. In an attempt to include more ecological realism in population genetic models, he showed in a classical paper in 1962 that under density-dependent selection in a stable environment evolution maximizes the equilibrium population size or the carrying capacity *K*. This result is based on the simple assumption that the relative fitness of two genotypes is dependent on population size (Figure 1). By simple stability analyses he was able to derive conditions for two alleles differently affected by changes in population size to remain in the population. An important implication of this result was that evolution no longer tends to maximize the relative growth rate *r* of a genotype in the population, as in the classic theory of Fisher (1930) and Wright

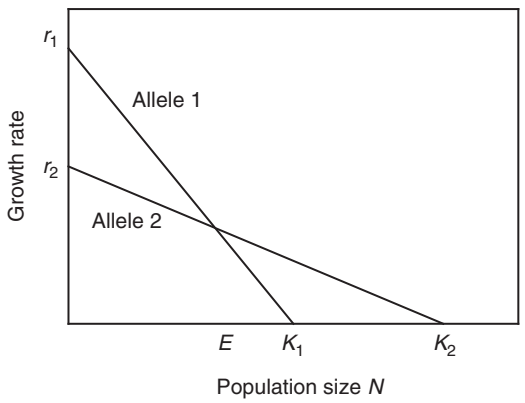

Figure 1 The rate of increase of two alleles as a function of population size assuming a logistic model of density regulation. At population sizes below the intersection point of the lines *E* allele 1 will increase and we get *r*-selection. In contrast, at larger population sizes (above *E*) allele 2 has the higher growth rate, resulting in *K*-selection. r_1 and r_2 are the intrinsic growth rate, and K_1 and K_2 are the carrying capacity of allele 1 and allele 2, respectively (modified from MacArthur, R.H., Wilson, E.O., 1967. The Theory of Island Biogeography. Princeton, NJ: Princeton University Press). *E* is the population size where there is a switch from *r*- to *K*-selection.

 doi:10.1016/B978-0-12-800049-6.00098-6

(1931) for populations that are not density regulated. This is illustrated in Figure 1, where allele 2, which has a lower intrinsic growth rate at small population sizes than allele 1, is favored when population size exceeds a certain level E.

Another important advance was provided by MacArthur and Wilson (1967), who suggested a trade-off between traits affecting selection at small population sizes, when the population is not density regulated, and those favored at larger population sizes, when density dependence is operating. Based on the theory of MacArthur (1962), they argued that high population growth rates should be favored when the number of individuals was small (r-selection). In contrast, at large population sizes, selection should result in increased carrying capacity (K-selection) (Figure 1). As an example of how the trade-off between r- and K-selection could arise, they suggested (MacArthur and Wilson, 1967, p. 151) that in an environment with no crowding, genotypes which harvested the most food to achieve higher productivity in terms of production of offspring should be favored. In contrast, at high population sizes where there is much crowding and intense competition, individuals that can replace themselves with a minimal amount of food should outcompete more wasteful individuals.

This early theory of r- and K-selection was later extended to include more explicit genetic models and deterministic seasonal fluctuations in the environment (summarized in Roughgarden, 1979). An especially important contribution was provided in a series of papers by Brian Charlesworth, that he summarized in his 1994 book *Evolution in Age-Structured Populations*. A central concept in this theory is the critical age-class, which is the age-class with the largest negative effect on the growth of the population. Using the concept of evolutionary stable strategy (ESS) as proposed by Maynard Smith and Price (1973), Charlesworth was able to show, using a haploid model, that if the density regulation is only affected by the number of individuals in the critical age-class, evolution tends to maximize the size of this age-class. More generally, if density regulation is determined by the total number of individuals or biomass in the population, total population size or biomass is maximized.

r- and *K*-Selection in Fluctuating Environments

Much of the prevailing theory summarized above is based on the assumption of a constant, or periodic, environment. When environmental stochasticity caused by random variation in the environment is included, one may assume that selection can be expressed simply by replacing the parameters by their average values. Unfortunately, this is not correct. Tuljapurkar and Orzack (1980) showed that the appropriate measure of fitness in stochastic environments in the absence of density regulation is the long-run growth rate $s = \bar{r} - \frac{1}{2}\sigma_e^2$, where $\bar{r}$ is the growth rate in the average environment and σ_e^2 is the environmental variance defined as the temporal variance in $\bar{r}$. Thus, evolution maximizes s as long as there is no density dependence.

Lande (2007) developed a model in which the dynamics were density-dependent, but with no density-dependent selection. This means that the relative fitnesses of the genotypes were independent of population size. However, the mean relative fitness of a phenotype determining average selection is still not s, but the Malthusian parameter in the average environment minus the environmental covariance between its growth rate and that of the population.

To include density-dependent selection, i.e., that fitnesses of the genotypes respond differently to changes in population size, Lande *et al.* (2009) analyzed a haploid or asexual model of inheritance with theta-logistic density regulation, meaning that population size N is regulated through N^θ. This model represents a general class of density regulation expressed only by a single parameter θ (Gilpin *et al.*, 1976; Lande *et al.*, 2003). For small values of θ density regulation starts to act at small population sizes. In contrast, if θ is large there is almost no density regulation at smaller population sizes, whereas strong density regulation occurs above the carrying capacity K. Thus, the theta-logistic model allows us to vary the form of density regulation and the corresponding stationary distribution of population sizes, assuming large enough population sizes to ignore the effects of demographic stochasticity. For this kind of model with a constant nongenetic θ, Lande *et al.* (2009) showed that evolution maximizes the expectation

$$E(N^\theta) = \frac{s}{r}K^\theta = \left[1 - \frac{\sigma_e^2}{2r}\right]K^\theta$$

where r is the growth rate at small population sizes in the average environment and σ_e^2 is the environmental variance in the population growth rate. Thus, evolution maximizes the average of N^θ over the stationary distribution of population sizes, which is a function of the basic ecological parameters r, K, and σ_e^2 specific for each genotype.

This evolutionary maximization principle for density-dependent population can be used to explore how density-dependent selection acts in fluctuating environments. When σ_e^2 is small, $\left(1 - \frac{\sigma_e^2}{2r}\right)$ is close to 1 and hence evolution maximizes K^θ (and thus K as K and K^θ are obviously ranked identically), as in MacArthur's (1962) model for a constant environment. We also see that for large environmental variances σ_e^2, large s and r are favored, producing r-selection. Lande *et al.* (2009) also showed that there exists, for given values of the other parameters, one optimal value of θ, often around $\theta = 2$.

The results from analyses of density-dependent selection in a haploid model was extended by Engen *et al.* (2013) to include a quantitative character z in a sexual model which enables analysis of the joint process for the mean of the character $\bar{z}$ and log population size in a fluctuating environment. Again, it was possible to derive an evolutionary maximization function. It was shown that the expected evolution of the mean phenotype $\bar{z}$ subject to density-dependent selection was governed by the function

$$Q(\bar{z}) = \frac{\bar{s}(\bar{z})}{\bar{\gamma}(\bar{z})} = \left[1 - \frac{\sigma_e^2(\bar{z})}{2\bar{r}(\bar{z})}\right]g(K(\bar{z}))$$

where $\bar{s}(\bar{z})$is the long-run growth rate of the population in the absence of density regulation so that $\bar{s}(\bar{z}) = \bar{r}(\bar{z}) - \frac{1}{2}\sigma_e^2(\bar{z})$, $\bar{\gamma}(\bar{z})$ is the average strength of density dependence in the population growth rate, and $g(N)$ is an increasing function of N describing the density regulation (for theta-logistic density regulation $g(N) = N^\theta$ and for the logistic model $g(N) = N$). The function is similar to the function maximized by evolution in the simple haploid model of Lande *et al.* (2009),

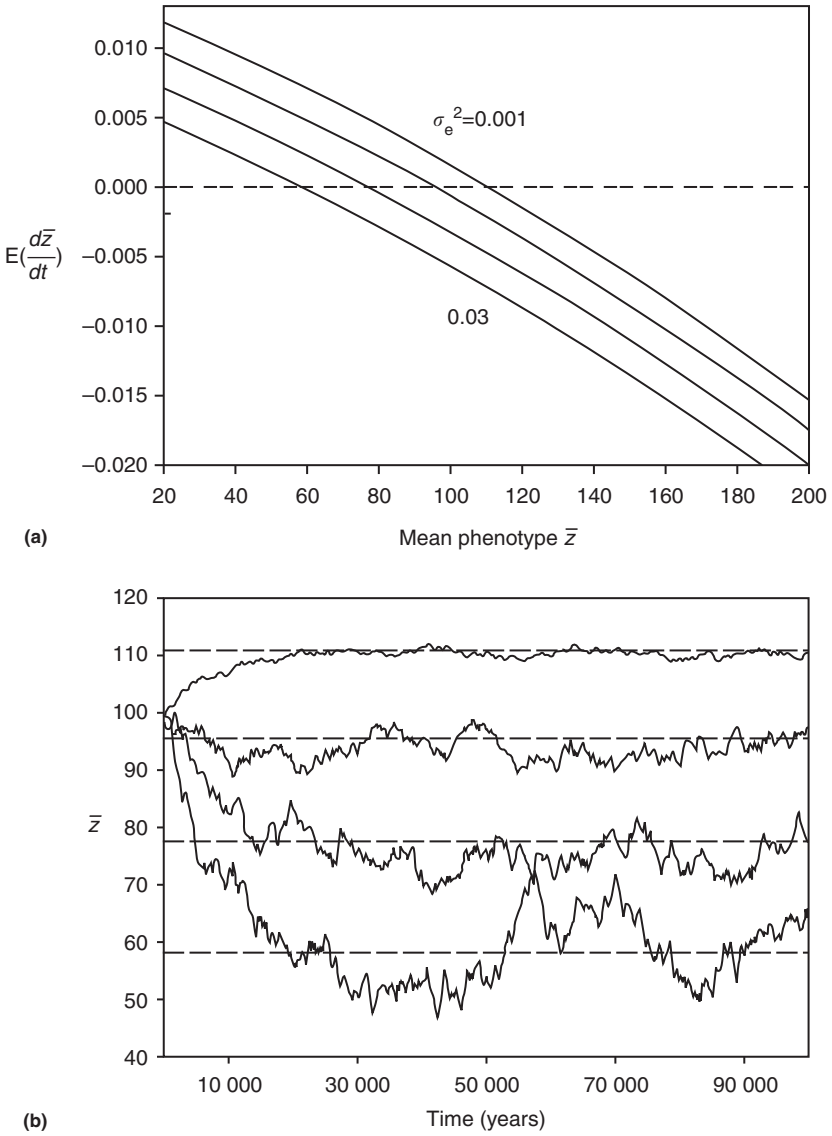

Figure 2 Expected change in the mean phenotype $E\left(\frac{d\bar{z}}{dt}\right)$ as a function of the mean phenotype $\bar{z}$ (a) and simulations of temporal variation in mean body size $\bar{z}$ (b) for different values of the environmental variance σ_e^2. Larger environmental noise yields smaller average body size. The model assumes a trade-off between fitness and susceptibility to increased population density so that both Malthusian fitness and strength of density dependence decrease with increasing z. Thus, a decrease in $\bar{z}$ means increased *r*-selection. The dashed lines in (b) represent the mean values.

but with parameters averaged over all individuals in the population. The expected evolution of the mean phenotype $\bar{z}$ under density-dependent selection will be toward the value z_{opt} maximizing $Q(\bar{z})$. The expected evolution of $\bar{z}$ thus corresponds to an increase of $Q(\bar{z})$, but environmental stochasticity always perturbs it back to values slightly below the maximum (Engen *et al.*, 2013) so that $\bar{z}$ has temporarily stationary fluctuations around the optimal phenotypic value z_{opt}.

We can use the function $Q(\bar{z})$ to analyze the balance between *r*- and *K*-selection. In a constant environment ($\sigma_e^2 = 0$), the mean phenotype evolves to z_{opt} and hence evolution maximizes $N = K$, as first shown by MacArthur (1962). When environmental stochasticity is present, both population size and the mean phenotype will fluctuate. A stationary distribution of $\bar{z}$ is achieved, which produces more *r*-selection for more environmental noise, resulting in evolution toward larger values of $\bar{s}(\bar{z})$ and $\bar{r}(\bar{z})$.

It is necessary that there exists a trade-off between r and γ (or between r and K) because otherwise the evolution of the mean phenotype would always increase $\bar{r}$ and decrease $\bar{\gamma}$, resulting in correlated selection for large $\bar{r}$ and K. To illustrate the effect of such a trade-off, Engen *et al.* (2013) used a simple example, in which Malthusian fitness and the strength of density dependence are both decreasing with increasing body size z. For instance, this may occur in practice if large individuals have lower fecundity but are less sensitive to population density than small individuals. Increased environmental stochasticity then results in *r*-selection toward smaller individuals with higher reproductive rates (**Figure 2**).

Discussion

We have seen that density dependence will produce selection toward large values of r at small densities and larger K when competition for a limiting resource is operating. This assumes a trade-off between the density-independent component of the Malthusian fitness r of a genotype in the absence of density regulation and the sensitivity of its fitness to changes in population size, measured as the strength of density dependence γ. In addition, low stochasticity in the environment will favor a small γ or large K, whereas large environmental stochasticity will cause r-selection (**Figure 2**) and smaller K. Thus, selection due to fluctuations in population size may be an important process to include when estimating expected phenotypic evolution in a fluctuating environment (Boyce, 1984). Some empirical evidence does suggest that such density-dependent selection may have a significant effect on the evolutionary response to fluctuating selection in natural populations (Reed *et al.*, 2013).

Empirical analyses of r- and K-selection are difficult. A major reason for this is that it requires estimates of genetic trade-offs between major life history characters. In general, obtaining such estimates are difficult in natural populations (Kruuk *et al.*, 2008). In analyses of r- and K-selection this represents a particular challenge because estimates of the genetic component of the phenotypic response to variation in population size are required for estimating the additive genetic variance in γ. Many early studies of r- and K-selection were based on comparison of populations or even species in different environments (Pianka, 1970, 1972). This approach is only valid if the environments only differ with respect to the number of individuals present so that all genetically based differences are due to variation in population density. In most cases it is almost impossible to remove environmental effects (Boyce, 1984; Mueller, 1997). Furthermore, Charlesworth (1994, pp. 265–266) pointed out that some of these patterns interpreted as support for r- and K-selection are indistinguishable from those expected from the impact of age-specific variation in selection on vital rates.

Evidence accumulated from laboratory systems provide some support for r- and K-selection strongly affecting evolution of phenotypes in density-dependent populations (Mueller *et al.*, 1991). In fruit flies *Drosophila* spp., for example, r- and K-selection operated through an effect of crowding, resulting in a trade-off in population growth rates at low and high densities. Larval competitive ability increased in populations kept at high densities, whereas early-developing genotypes favored at low densities had low tolerance to ammonia that increases under crowded conditions (Borash *et al.*, 1998).

An illustration of the importance of considering density-dependent selection was provided by Bassar *et al.* (2013), who manipulated population sizes of Trinidadian guppies *Poecilia reticulate*. Strong density dependence was recorded in populations with small risk of predation. Artificial alteration of population size showed that the clear advantage of the high-predation phenotypes exhibited at low densities disappeared at high densities. However, the low-predation phenotypes did not have a consistent advantage at high densities. This shows that the effects of population regulation and density-dependent selection were important to include for explaining adaptive life history variation in this fish species.

An issue that recently has been raised is whether evolutionary phenotypic changes can be produced so rapidly that they can reduce the long-term impact on the biodiversity of rapid human-induced alterations of the environment. In such analyses of, for example, the effects of climate change, it is important to include density dependence in models. For instance, Reed *et al.* (2013) showed that strong selection for earlier breeding in great tits *Parus major* due to an increase in spring temperatures was counteracted by a density-dependent increase in juvenile survival in years with poor breeding success. Similarly, evidence now strongly indicates that harvest alters the dynamics of harvested fish stocks (Anderson *et al.*, 2008). These altered dynamics may produce phenotypic evolution caused by r- and K-selection that can affect the long-term yield of the harvest.

Recombination and Molecular Evolution

AJ Betancourt, Vetmeduni Vienna, Vienna, Austria
M Hartfield, University of Toronto, ON, Canada

Glossary

Adaptation The process of increasing in frequency a trait that is beneficial under natural selection.
Allele A gene type that is present at a locus.
Anisogamy The situation where male and female gametes are highly dimorphic; usually the male produces smaller gametes. Isogamous species are where males and females have similar-sized gametes.
Background selection The loss of variation in the genome through purging deleterious mutation.
Effective population size, N_e A quantity used to describe the genetic diversity present in a population; the principle being that an idealized population of size N_e would harbor the same level of diversity, if all mutations acted independently.
Epistasis The effect where a collection of loci exhibit different fitness, compared to cases where each mutation acts independently.
Fitness Broadly, the ability of an individual to reproduce and leave descendants.
Hitchhiking Where linked alleles (neutral or deleterious) fix with an adaptive allele.
Interference When selection acts on mutations in a non-independent manner (e.g., a deleterious allele hitchhikes to fixation with an adaptive mutant).
Linkage disequilibrium Nonrandom association of mutations in the genome.
Mutation A change made to the molecular sequence of a genome.
Recombination Reciprocal exchange of genetic material.
Segregation When two gene copies are separated and are passed at random during sexual reproduction.

Introduction

Many organisms reproduce sexually – 99.9% of animal species, for instance (Vrijenhoek, 1998) – but the evolutionary reason for the widespread prevalence of sex is not immediately obvious. Sexual reproduction comes at a heavy price: mates must be found, fought for, and won; sexually transmitted diseases braved; and, after all these trials, sexually-produced offspring only carry half the genes of the parent. In fact, as John Maynard Smith pointed out (Maynard Smith, 1978), asexual reproduction should have a twofold advantage, all else being equal. That is, asexual females will reproduce at twice the rate of sexual ones, quickly outcompeting them, so that a mutation causing clonal reproduction in an anisogamous species is expected to quickly take over (**Figure 1**).

Nevertheless, sex is pervasive in many taxa. In fact, phylogenetic analyses (Bell, 1982) show that sexual species tend to occur deeper in phylogenetic trees than asexual ones,

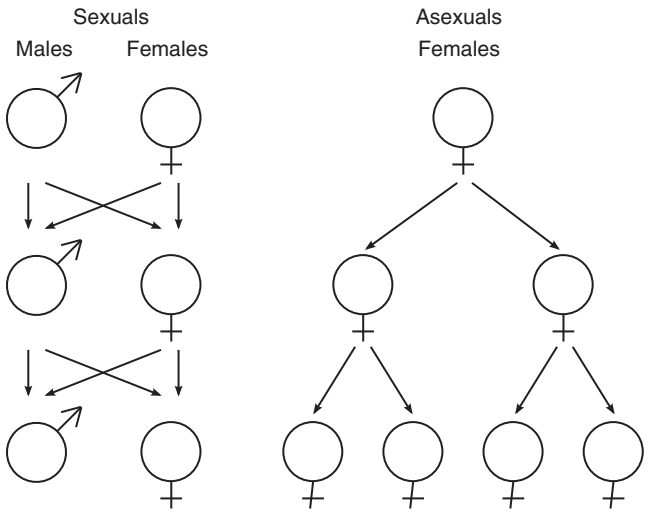

Figure 1 A cartoon describing Maynard Smith's 'twofold cos of sex' argument. The sexual population, on the left, requires a male and a female pairing to reproduce; if one son and daughter are born every generation, the population is maintained at the same size. Asexual females, on the right, can produce two clonal offspring without needing a male partner. Adapted from Hartfield, M., Keightley, P.D., 2012. Current hypotheses for the evolution of sex and recombination. Integrative Zoology 7, 192–209.

suggesting that only sexual species persist through time. For example, within the species *Daphnia pulex*, which has both sexual and asexual forms, the asexual lineages appear to be short-lived (Tucker *et al.*, 2013). What, then, might account for the apparent advantage of sexual lineages? One possibility is that there are immediate advantages to sexual reproduction; for example, receiving care from two parents might improve the survival of offspring. That is, while the twofold cost of sex is useful as a thought experiment, it might rarely be realized in nature, as reproductive rates alone are not always the principal determinant of evolutionary fitness. However, this rationale depends on details of the life history of each species, and is therefore unsatisfying as a general explanation for the prevalence of sex.

Instead, it is generally thought that sexual lineages have a long-term fitness advantage over asexual lineages. Sexual species are expected to adapt faster to changing environments, and to better maintain fitness in constant environments, compared to asexual organisms. The reason is that sex shuffles genomes, making new combinations of genotypes available for selection to act on. Mechanistically, this shuffling comes in two flavors: segregation and recombination between loci (**Figure 2**). Both are expected to promote the spread of beneficial mutations and the purging of deleterious ones. Without segregation, for example, the descendants of a heterozygous individual will remain heterozygous *ad infinitum*, or at least until a second mutation occurs at the same locus. A single beneficial mutation in such a population can increase from low frequency to 50%, but then faces a barrier to fixation. With segregation, there is no such barrier; homozygous individuals are easily generated from heterozygous ones, and the beneficial mutation can fully spread (Kirkpatrick and Jenkins, 1989).

The overwhelming body of research, though, is directed toward the evolutionary benefits of genetic recombination. As we will discuss below, the implications of recombination have been spelled out in a large body of theory, some of which has been tested with molecular data.

Recombination and Adaptation

Theoretical Background

Any selected allele, whether deleterious or beneficial, must begin as a mutation, either as a single or multiple copies. Each copy of the allele will arise on some genetic background, usually one randomly drawn from the population. Without recombination, the fate of the selected allele is strongly affected by whichever genetic background it arises on. For example, a beneficial allele unlucky enough to arise on an unfit genetic background may be lost, driven out of the population along with the deleterious alleles it is linked to. When the fates of selected alleles are non-independent, they are said to 'interfere' with one another. Felsenstein (1974), in an engaging review of the topic, termed this phenomenon 'Hill–Robertson interference,' after the seminal investigation into selection, linkage, and drift interactions by Hill and Robertson (1966). There are several flavors of Hill–Robertson interference, but all ultimately attribute the evolutionary advantage of recombination to its ability to uncouple selected alleles from their genetic backgrounds, so selection can act on them independently.

1. Fisher–Muller interference. Fisher (1930) and Muller (1932) pointed out how asexual populations suffer from interference between beneficial mutations. That is, in a non-recombining population, in order for two (or more) beneficial mutations to fix at the same time, they must occur in the same genetic background. This composition is unlikely, unless the first beneficial mutation to occur has already reached a high frequency. With recombination, two beneficial mutations can occur on different backgrounds, recombine onto the same genome, and sweep to fixation together (**Figure 3**). Thus, fixing two mutations takes roughly half the time that it does in an asexual population (Christiansen *et al.*, 1998), unless mutation rates are high enough to create double mutants without

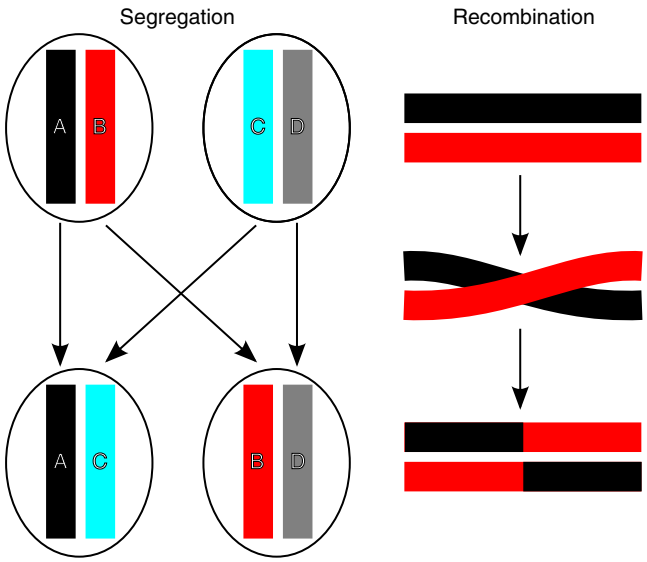

Figure 2 Segregation and recombination during sex. Segregation shuffles the manner in which gene copies (denoted here A–D and labeled with different colors) are organized within genomes. Recombination exchanges material between genomes.

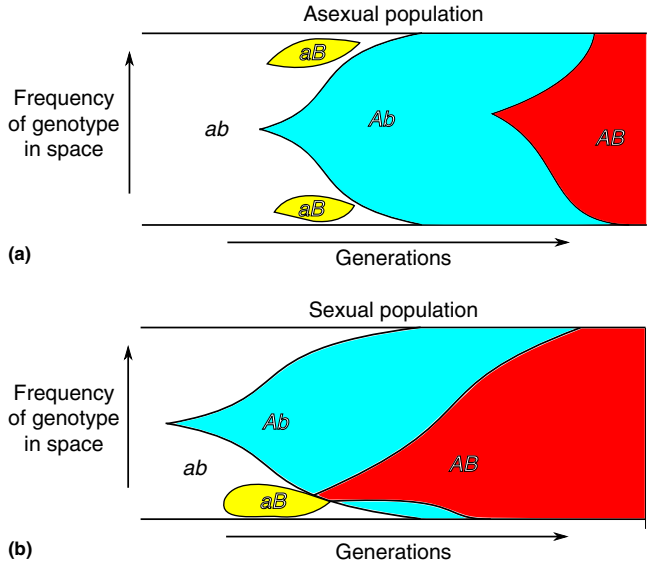

Figure 3 Fisher–Muller argument for the evolution of sex. In asexuals (top), beneficial mutations have to arise and fix in sequence due to competition between them. In sexuals (bottom), however, recombination can form the optimal AB genotype much more rapidly. Adapted from Muller, H.J., 1932. Some genetic aspects of sex. American Naturalist 66, 118–138.

recombination (Kim and Orr, 2005). When applied to microbes, Fisher–Muller interference is sometimes called 'clonal interference' (Gerrish and Lenski, 1998), which can be tested experimentally (e.g., Lang *et al.* (2013)).

2. Muller's ratchet. Muller's (Muller, 1964) ratchet does not describe a failure to adapt to a changing environment, but instead a failure to maintain fitness even in a constant environment. In any population, particularly a small one, it is always possible to lose the fittest current genotype by chance. One way to model this phenomena is to consider deleterious mutations to be Poisson distributed over chromosomes – essentially, distributed in the same way beans dropped onto a chessboard would be randomly spread over the squares. As Haigh (1978) showed, the mean number of mutations would be the ratio of the genomic mutation rate (U) to the average selection coefficient acting against these mutations (s_d). The fraction of deleterious-mutation-free genomes is then just the size of the zero class for the Poisson distribution, $\exp(-U/s_d)$. Thus, if the fraction of individuals carrying no deleterious mutations is expected to be one in a thousand, a population with a census size in the hundreds may not contain even one individual without deleterious mutations. In an asexual population, with no back mutation, there is also no way to regenerate a mutation-free genome – the name 'Muller's ratchet' comes from this irreversibility, as ratchets are wrenches that turn only one direction. Recombination, however, can reverse the process: as long as no particular deleterious mutation fixes, two genomes can recombine to form a reconstituted mutation-free genome.

   As the arguments above suggest, Muller's ratchet is most important in small populations, with high genomic mutation rates (due to either high overall mutation rates, and/or long genomes), or with weak selection (Felsenstein, 1974). Without these factors, the ratchet acts so slowly as to be unimportant; otherwise it can be a powerful force, causing genomic degradation (Charlesworth and Charlesworth, 2000).

3. Ruby-in-the-rubbish interference. Ruby-in-the-rubbish interference (Peck, 1994) describes the loss of beneficial mutations that happen to arise on unfit backgrounds. The original ruby-in-the-rubbish model considers adaptation in an asexual population, where the beneficial mutations are not strong enough to overcome the effect of linked deleterious mutations. In this case, the only beneficial mutations with any chance of not going extinct must arise on deleterious-mutation-free genomes. In sexual populations, recombination can free the beneficial mutation from its loaded genetic background, improving its prospects for success. Cases in which the beneficial mutations are strongly selected for, and therefore override linked deleterious mutations, are more complex. If there are many deleterious mutations, adaptive alleles can still be lost in asexual populations if mutation rates are high (Johnson and Barton, 2002). With pairs of advantageous–deleterious mutations, sex can prevent the fixation of deleterious alleles. The benefit to recombination is greatest if deleterious mutations have slightly lower selection coefficients than their beneficial drivers (Hartfield and Otto, 2011). However, the case with many deleterious mutations affecting adaptive alleles in sexual populations has not yet been fully solved.

In each of these cases, recombination counteracts interference by offering new allele combinations for selection to act on. This effect is only useful, though, when the fittest alleles are not already found together; otherwise, recombination breaks apart optimal genotypes. In technical terms, recombination only provides a benefit if there is negative linkage between beneficial mutations – when genomes more often have a mixture of beneficial and deleterious alleles at different loci, rather than possess only beneficial or only deleterious

alleles. What, then, should give rise to these kinds of nonrandom associations? One answer is epistasis, where individuals carrying multiple mutations have better or worse fitness than expected based on the selective coefficients of the single mutations. However, only specific kinds of epistasis promote increased recombination (see Kondrashov (1988) and Kouyos *et al.* (2007)). A general explanation may simply be that population sizes are limited. As Fisher (1930) pointed out, in any finite population, all possible combinations of alleles never occur, so there will always be nonrandom associations between alleles. In cases where beneficial mutations are coupled, selection will quickly fix these genotypes (and, conversely, rapidly purge genotypes where deleterious mutations are coupled). The upshot is that the genotypes containing a mixture of beneficial and deleterious mutations would, on average, remain segregating for the longest amount of time. Over time, then, most linkage disequilibrium between beneficial mutations is negative, of just the sort to promote an advantage of recombination. Barton and Otto (2005) solidified this logic and showed how associations created in this manner select for increased recombination rates.

Empirical Evidence for an Advantage of Recombination

If there is an advantage of recombination in aiding adaptation, can we see it in molecular population genetic data? Some of the earliest answers to this question come from sex chromosomes, which have evolved independently many times from autosomes. X and Y chromosomes proceed to diverge when recombination between them stops; as the Y only occurs while paired with the X, it can no longer recombine at all. What happens to this non-recombining chromosome? The long-term outcome can be seen on the *Drosophila* Y, for example. In terms of DNA content, this chromosome is huge – roughly twice the size of the X – but it harbors only a handful of genes, compared to thousands on the X. Initially, these chromosomes were identical, but the Y has lost most of its genes, and gained a large amount of 'junk DNA.' By studying young Y chromosomes, we can watch this process in action. For example, there is a very young Y chromosome in *Drosophila miranda*, which still retains many of its genes. Compared to their homologous on the X, however, these copies show less evidence of adaptation (Bachtrog and Charlesworth, 2000) as predicted by the theories outlined above. Similar surveys have been performed in humans (Wilson Sayres *et al.*, 2014), mice (Soh *et al.*, 2014), and plants (Hough *et al.*, 2014); see Bachtrog (2013) for a recent review.

Other studies looking for an evolutionary advantage of recombination have been done within chromosomes, comparing low to high recombination regions. In *Drosophila melanogaster*, for example, there are long regions exhibiting very low recombination rates. Molecular evidence suggests that these regions show fewer substitutions of adaptive alleles and more substitutions of deleterious alleles, compared to regions of average recombination (Betancourt and Presgraves, 2002; Haddrill *et al.*, 2007; Mackay *et al.*, 2012). Gossmann *et al.* (2014) also found such a result in birds, by comparing chromosomes with different average recombination rates. Humans, in contrast, do not show a strong pattern of this type (Bullaughey *et al.*, 2008), possibly due a low rate of adaptive protein evolution in our own species (Eyre-Walker and Keightley, 2009).

Recombination and Neutral Variation

Even in sexual organisms, the amount of recombination can vary, for example, across sexes and individuals, and even across the genome. Studies of how evolutionary rates differ due to this variation have yielded fascinating insights into the effects of selection interference. *D. melanogaster* is an organism that shows a large amount of variation in recombination rates across its genome. In the early 1990s, Begun and Aquadro (1992) used this fact to show that, compared to highly recombination regions, low recombination regions had very little genetic diversity – in these regions, individual sequences of the same gene, which in *D. melanogaster* differ from each other at 1–2% of silent sites, showed only a small fraction of the normal level of variation. They invoked an explanation for which the theory had been worked out 20 years before: hitchhiking of neutral mutations (Maynard Smith and Haigh, 1974), based on Hill–Robertson interference caused by beneficial mutations. Briefly, hitchhiking argues that if selection fixes a single copy of a beneficial allele, it necessarily also fixes any neutral variants that arise on the same background (**Figure 4**). As a result, the nearby regions will be stripped of neutral variation. Recombination, however, allows the selected allele to move to other genetic backgrounds, and be linked to

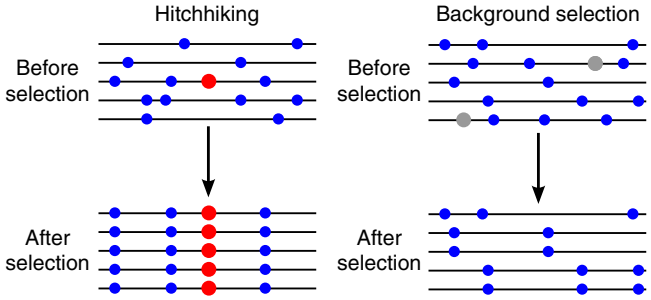

Figure 4 How selective effects reduce genetic variance. Hitchhiking (left) occurs when an adaptive allele, shown in red, spreads to all individuals in the population. Linked neutral mutations (blue dots) are driven with it to fixation as well, unifying the genetic signal around the adaptation. Background selection (right) occurs when deleterious mutations, the gray dots, are lost by selection, and are replaced by other neutral genotyped (after selection, the second genotype is replaced by the third, and the fifth by the fourth).

other neutral alleles; thus, the extent of the region affected by hitchhiking depends on the recombination rate.

More formally, we can see why recombination should affect neutral sequence diversity if we first understand what affects it, namely, mutation rate (u), and the number of ancestors contributing genetic material to a population, quantified as effective population size (N_e). Diversity increases as mutation rate increases, because, as more mutations are introduced into a population, more sites can contain differences. Diversity also increases as N_e increases – if the number of genetic ancestors is small, individuals will be closely related, and therefore genetically similar to one another. Begun and Aquadro were able to eliminate an effect of recombination on mutation rate, and therefore concluded that recombination affects N_e. As diversity is measured across the genome of a single species of fly, it is unlikely that there are different numbers of actual ancestors contributing to different regions of the genome. Instead, it may be that the fixation of beneficial mutations reduces the number of genetic ancestors for long regions in low recombination regions *via* the hitchhiking effect (**Figure 4**).

Hitchhiking, then, appears to explain the relationship between diversity and recombination, which also implies that adaptive evolution is frequent enough to change levels of neutral diversity. However, Charlesworth *et al.* (1993) almost immediately challenged this explanation, pointing out that hitchhiking is not the only possible cause for a relationship between neutral diversity and recombination, recurrent deleterious mutations is another. The reason is that deleterious mutations also reduce the effective population size of linked regions: as they are removed from the population, so is any neutral linked variation (**Figure 4**). Without recombination, the only genomes that ultimately contribute ancestry to the population are those deleterious-mutation-free genomes; that is, the zero class of the Muller's ratchet model. With recombination, some of the genetic material that would have otherwise been lost can recombine onto mutation-free backgrounds. As a result, the effect of background selection, like that of hitchhiking, varies with the recombination rate. Trying to disentangle the two effects still motivates current research, since the two phenomena can be difficult to tease apart (Cutter and Payseur, 2013).

Begun and Aquadro's observations were based on a limited amount of data (appropriate for the time), so it is worth asking how their findings have held up. For *Drosophila*, the answer is quite well, as shown using whole-genome polymorphism datasets (Mackay *et al.*, 2012). Besides *Drosophila*, these effects have been examined in a broad range of taxa (Cutter and Payseur, 2013); though the results are mixed, most other taxa show similar patterns to those in *Drosophila*, with recombination rate positively correlated with neutral genetic diversity. The effect of recombination on N_e is also reflected in patterns seen for weakly selected alleles: alleles whose selection coefficients hover near the value of $1/N_e$, rendering them borderline neutral. A local reduction in N_e can push them under this threshold, so that they act effectively neutrally. In *Drosophila*, sites evolving under weak selection do, in fact, show reduced adaptation in regions of very low recombination. However, this effect appears to be restricted to these regions, rather than scaling with increased recombination rate (Marais *et al.*, 2001; Haddrill *et al.*, 2007; Campos *et al.*, 2014). The reason is likely historical: weakly selected sites will take a long time to reach their equilibrium level of adaptation, while most reduced recombination regions in *D. melanogaster* seem to have only recently suffered from a reduction in recombination rate (Campos *et al.*, 2014). Further, with whole-genome polymorphism data, we have been able to refine our picture of the local effect of selection on linked neutral sites. In the immediate vicinity of putatively adaptive substitutions, there is a dip in average neutral diversity, just as expected under hitchhiking (Sattath *et al.*, 2011), though not in humans (Hernandez *et al.*, 2011). In our own species, the role of background selection is well-established; in fact, the effect of linkage to selected sites has been quantified in a 'background selection map' (McVicker *et al.*, 2009). The contrast between *Drosophila*, which shows evidence consistent with adaptive evolution, and humans, where deleterious mutations appear to play a bigger role, may be due to their contrasting effective population sizes. All else being equal, larger populations may experience higher overall rates of adaptive substitutions: in support of this, mice, which are mammals like humans but have larger population sizes (Phifer-Rixey *et al.*, 2012), show a *Drosophila*-like pattern near substitutions (Halligan *et al.*, 2013).

Conclusion

Here, we have seen how recombination frees organisms to adapt at multiple sites, allows them to preserve the integrity of their genomes, and conserves genetic variation. With reduced sequencing costs, these questions can now be addressed in new species and in new ways. Future results will refine our picture on how recombination shapes genomes, and hopefully throw up unexpected outcomes, generating new avenues of research.

Recombination and Selection

ME Orive, University of Kansas, Lawrence, KS, USA

Glossary

Clonal interference Competition between beneficial mutations in the absence of recombination such that the fate of the lineages carrying the beneficial mutations is not independent of one another.

Genetic load The difference in fitness between the optimum population fitness and the actual mean fitness observed in a population.

The Interaction between Recombination and Selection

The early theory of population genetics focused on individual loci and considered the dynamics of allele and genotype frequency change at these loci one at a time. But the nature of evolving genomes is modular – multiple sites within loci, and multiple loci within genomes. To describe and understand the evolutionary dynamics of these systems requires an understanding of the interplay between evolutionary forces such as selection, and the genetic forces of Mendelian segregation and chromosomal recombination that cause sites and loci to share evolutionary histories, or that free them to follow separate trajectories over time.

The interaction between selection and recombination plays a key role in our understanding of the evolution of sex. At the heart of this discussion has been an attempt to understand when and how the breaking up by recombination of genotypes that have already survived to reproductive age can be beneficial. The evolutionary theory that has focused on nonmechanistic discussions of the origins of recombination shares a common theme – that what recombination breaks apart, it also must necessarily bring together. It is the bringing together of either multiple beneficial or multiple deleterious mutations (in the language of population genetics, the dissolution of *negative linkage disequilibrium*, here defined as the statistical excess of haplotypes combining negative and positive alleles) that lies at the core of modern models of recombination and selection.

Two contrasting approaches have been applied to the evolutionary theory of recombination and selection – *optimality theory* and *modifier theory*. These two approaches differ both in their theoretical details and in their focus on how natural selection acts – optimality theory focuses on equilibrium models that often implicitly employ group selection types of arguments, while modifier theory explicitly focuses on individual selection and the dynamics of evolutionary change.

Optimality Arguments

In optimality theory, the optimization of a specific criterion under various values of key parameters is considered. Optimality criteria for the theory of recombination have included individual or population mean fitness, the time to fixation of a beneficial mutation, the rate of evolution, or the amount of genetic load, among others. The assumption for these types of models is that evolution proceeds in a direction that optimizes the criterion with respect to the evolutionary parameter or parameters of interest. It should be stressed that there is no assumption as to whether real organisms can or will be optimal, nor do the theories explicitly consider whether or not natural selection can act to optimize the parameter. These will depend on details of the natural system, such as the genetic and phenotypic nature of the characteristic under selection, the amount of additive genetic variance that is available for natural selection to act upon, the strength and direction of natural selection, and random effects such as genetic drift (a review of optimality theory in evolutionary biology is given by Parker and Maynard Smith, 1990). Optimality arguments (also called equilibrium models, see Otto and Lenormand, 2002) consider how increased or decreased rates of recombination affect the value of the optimization criterion, which is often a characteristic of a group, such as the population mean fitness. The assumption that follows is that groups with a more optimal value of the criterion would outcompete and replace groups with suboptimal values, and thus the direction that evolution would take recombination is ascertained. The models most often focus on how recombination redistributes mutations that are under selection (beneficial mutations under *Fisher–Muller models*, and deleterious mutations under *Muller's ratchet*, see below), and then in turn how this redistribution by recombination sets the value of the optimality criterion.

Modifier Theory

The second large family of models that consider selection and recombination focus on nonequilibrium situations for the evolution and spread of recombination. They are based on the concept of a modifier locus that alters the level of genetic segregation or recombination and that acts epistatically with the loci that determine organismal fitness (Feldman *et al.*, 1997). In these models, individual selection is explicitly considered, since the focus is on the conditions under which alleles acting to change the rate of recombination will increase in frequency within a population. Work that considered a single large population under a constant selective environment found a very limited set of conditions where modifiers of recombination can spread (Otto and Lenormand, 2002). Less

restrictive conditions are possible with the addition of some type of structure (spatial structure, temporal structure, or the structure imposed by the genetic architecture of the organism).

Important Optimality Models of Recombination and Selection

The Fisher–Muller Model and the Role of Negative Linkage Disequilibrium

It might seem that a clear benefit of recombination is the creation of novel, beneficial genotypes upon which selection can act. However, when alleles are randomly associated across loci (*linkage equilibrium*), the creation of new beneficial combinations of alleles by recombination is exactly balanced by the loss of these beneficial combinations (Felsenstein, 1988). It is only when there is a statistical excess of haplotypes combining negative and positive alleles (*negative linkage disequilibrium*) that recombination gives a benefit (**Figure 1**). A key model for the interaction of selection and recombination is the Fisher–Muller model (Fisher, 1930; Muller, 1932) – here, recombination is beneficial to a population because it brings together new favorable alleles that first arose on different haplotypes. The new beneficial alleles thus are initially in negative linkage disequilibrium, to use modern terminology.

The Fisher–Muller model assumes a population that is finite in size, but large enough that multiple beneficial mutations may segregate at the same time (in a small population, the assumption is that beneficial mutations will either be lost due to drift or fix quickly, so that only one is likely to exist at any given time). In an asexual lineage lacking recombination, new beneficial mutations at different loci that first arise on different genetic backgrounds cannot go to fixation at the same time – they will necessarily compete against one another. These beneficial mutations are in negative linkage disequilibrium. To see this, we might imagine a population fixed for the *a* allele at locus A and the *b* allele at locus B (only the *ab* haplotype exists). If a new, favorable allele (*A* allele) arises in one asexual lineage (so that the combination *Ab* exists), and another new, favorable allele (*B* allele) arises on another asexual lineage (so that the combination *aB* also exists), we have negative linkage disequilibrium. In this case, the combination *AB* is missing, and cannot occur without recombination ($D = p_{AB}p_{ab} - p_{Ab}p_{aB} = 0 - p_{Ab}p_{aB}$ and is necessarily negative).

The advantage of recombination under the Fisher–Muller model is given by a *rate of evolution* optimality argument; recombination allows the population to have a higher rate of fixation of beneficial mutations than a population lacking recombination. Felsenstein (1974, 1988) pointed out that the assumption of finite size is an important aspect, since in an infinite population a proportion μ^2 of either new individuals (for haploids) or new gametes (for diploids) would be double mutants (haplotype *AB*) and the population would then be in linkage equilibrium, and there would be no advantage to recombination.

Hill–Robertson Effect

The Hill–Robertson effect (or *Hill–Robertson interference*, Hill and Robertson, 1966; Felsenstein, 1974) is closely related to the basic idea presented in the Fisher–Muller model, and extends it to describe how genetic linkage, even in the presence of recombination, causes an interaction between selection and genetic drift. The Fisher–Muller model above focused on the interference between beneficial mutations arising in the case of complete linkage (for asexual lineages). But in a finite population, even partial linkage (any deviation from free recombination, or a recombination frequency of $r = 0.5$) causes linked beneficial genes to interfere with each other's ability to reach fixation.

With free recombination, a new beneficial mutation is exposed to selection against all available genetic backgrounds; good and bad backgrounds (with regard to fitness) tend to cancel each other out on average, and thus the average fitness of organisms carrying the new beneficial mutation will only reflect the particular selective advantage of the mutation itself. However, in the case of linkage, the initial association between the beneficial mutation and the background where it arose will persist for some time (until recombination 'frees' the mutation). Thus, under linkage, the average fitness of organisms carrying new beneficial mutations will now also depend on the background within which the mutations arose. This acts to increase the variance in the frequency of the beneficial mutation above what it would be if its spread depended only on its own fitness. In effect, linkage increases the amount of genetic drift (here genetic drift is being measured by the variance in frequency from generation to generation) that accompanies selection, and thus the Hill–Robertson effect can be viewed as a decrease in the effective population size (N_e) for the locus where the beneficial mutation arose. This decreased N_e means that the probability that the beneficial mutation will fix will be less, on average, under linkage than under free recombination. For two linked loci of similar beneficial effects, the probability of fixation reaches a limit of $2N_e r/(2N_e r + 1)$, where r gives the recombination frequency between the two loci.

Muller's Ratchet

In contrast to the models discussed above, the focus of the model proposed by Muller (1964) is on linked deleterious mutations. We consider an asexual lineage with some number of loci at which deleterious mutations may arise; if the population is of finite size, genetic drift may occasionally fix a deleterious mutation. Once this mutation is fixed, the most fit haplotype (the haplotype with the lowest number of deleterious mutations) now carries an additional deleterious mutation – the number of deleterious mutations on the most fix haplotype goes from n to $n+1$. The mean fitness of the population decreases, and the 'ratchet' clicks forward. In the absence of back-mutations and recombination, there is no way to regain the more fit, n deleterious mutation haplotype, and so, as is true of an actual physical ratchet, there is no moving backwards to higher fitness. As pointed out by Felsenstein (1988), Muller's ratchet is a variant of the Fisher–Muller model, which we can see if we focus on the unmutated, favorable variant at each locus. We imagine deleterious alleles arising at different locations (in different loci). Once all of the asexual lineages or haplotypes have at least one deleterious

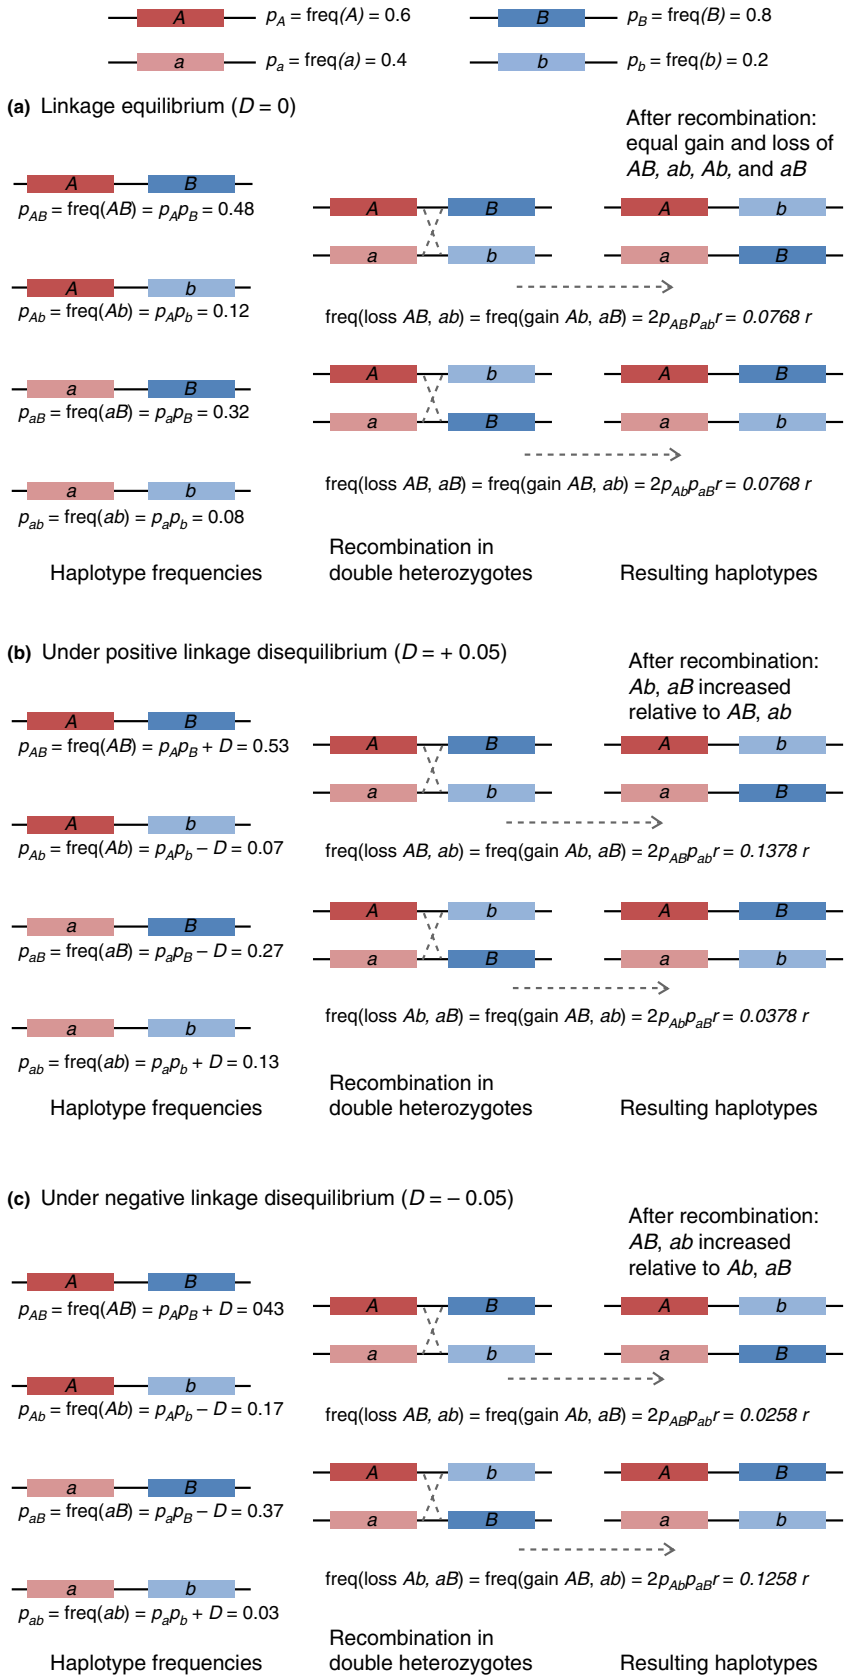

Figure 1 Effects of recombination under (a) linkage equilibrium, (b) positive linkage disequilibrium, and (c) negative linkage disequilibrium. In this example, we assume that the *A* and *B* alleles are favorable and the *a* and *b* alleles are deleterious. Only recombination under negative linkage disequilibrium (where there is a statistical excess of haplotypes combining negative and positive alleles) leads to a relative increase in the proportion of positive + positive haplotypes (*AB*) favored by selection, and of negative + negative haplotypes (*ab*) cleared by selection (panel c).

mutation, the favorable alleles at all of the loci where a deleterious mutation has occurred will be in negative disequilibrium with one another, since there is no haplotype that exists with all of the favorable alleles (and none of the deleterious mutations).

Haigh (1978) gave a quantitative description of Muller's ratchet, where the optimality criterion is the expected number of individuals in the optimal, zero mutation class. We assume that the relative fitness of an individual with k deleterious mutations is $(1-s)^k$, where s is the selective disadvantage per mutation. In a finite population of size N that is undergoing deleterious mutations at a rate of U per genome per generation, the expected number of individuals in the zero class is given by

$$E(n_0) = Ne^{-U/s} \qquad [1]$$

Muller's ratchet moves slowly if at all if $E(n_0)$ is large, and in this case deleterious mutations accumulate independently of one another (this will happen in a population of large size, for example). On the other hand, if $E(n_0)$ is small, the ratchet quickly moves the population distribution along k, so that the average individual in the population has a larger and larger number of deleterious mutations, and the mean fitness of the population becomes smaller and smaller. The expectation given in [1] is smallest for small populations (where drift is strong) and for weakly deleterious mutations (small s) that are easily increased in frequency by drift. This formulation also emphasizes the role that genome size may play in how vulnerable a population may be to Muller's ratchet. If U increases as genome size increases, then $E(n_0)$ necessarily decreases as genome size increases, implying that the ratchet may be more important for larger genomes (Maynard Smith, 1988), and that, all other things being equal, there may be an upper limit on the functional genome size of strictly asexual lineages. This has been an argument for why asexual eukaryotes (with larger genome sizes than asexual prokaryotes) may not persist over long evolutionary timescales.

Selection Fluctuating Over Time and Space – the Red Queen and Other Models

In addition to the above models, where the negative linkage disequilibrium favoring recombination is generated stochastically, there are a very large number of models that consider linkage disequilibrium that is generated deterministically. In these models, *epistatic interactions* (where the fitness effects of alleles at different loci interact such that their total effect is not determined by adding or multiplying their individual effects) are generated by selection that fluctuates over time or space. These include the *Red Queen model* (Van Valen, 1973) where environmental fluctuations (either abiotic, or biotic, such as due to parasites or pathogens) cause the optimal genotype to change from generation to generation, and thus lead to selection favoring changes in the sign of linkage disequilibrium (Maynard Smith, 1988). As an example, imagine that the haplotype combination A_1B_1 is favored in one generation – linkage disequilibrium will build up, due to an overrepresentation of this particular allelic combination. In another generation, when A_1B_1 is no longer favored, recombination breaking up this linkage disequilibrium will be favored – thus this type of selection leads to cyclical changes to both genotype frequencies and linkage disequilibrium. Other families of models depend on environmental variation that is spatial rather than temporal – so-called *Tangled Bank models* and *Lottery models* that focus on the ability of a lineage to occupy ecologically diverse environments (Ghiselin, 1974; Williams, 1975; Maynard Smith, 1976; Bell, 1982; Koella, 1988). For all of these models, linkage disequilibrium is formed via deterministic, nonrandom processes involving epistasis and population structure, and they are thus infinite-population size models.

Modifier Theories of Recombination

Modifier Theory in Large Populations

Theories considering the fate of modifiers of recombination must consider the balance between two different types of selection – short-term selection on individuals to have the highest mean offspring fitness, and long-term selection to increase the genetic variation in population fitness (Barton, 1995; Otto and Lenormand, 2002). To consider the long-term selection effects, we follow the fate of a modifier allele (M) that alters the recombination rate (r) between a set of loci and consider both the association between those loci (linkage disequilibrium, D) and the amount and type of fitness interactions between the loci (epistasis, ε, **Figure 2**) (for a review, see Feldman *et al.*, 1997). Generally, epistasis generates linkage disequilibrium of the same sign – positive epistasis (where allelic effects on fitness are greater in combination than expected from their individual effects) leads to an overrepresentation of these allelic combinations relative to what we would expect from their marginal frequencies ($D > 0$), whereas negative epistasis (where allelic effects are smaller in combination than individually) generates $D < 0$. As discussed above for optimality models, negative D always favors recombination via its long-term effect on population fitness. When there is recombination within allelic combinations of intermediate fitness that combine both beneficial and deleterious alleles (and have $D < 0$), the haplotypes arising after recombination have either high fitness (beneficial alleles brought together) or low fitness (deleterious alleles brought together). This increases the genetic variation in population fitness, and allows long-term selection to act (**Figure 3**).

The short-term effects of recombination on individual fitness are more complex – these depend on the signs of both D and ε, and also on the form of selection acting on the loci. To try to understand this complexity, we can consider the change in frequency of the modifier allele, Δp_M. We follow the general model of Barton (1995), and consider weak selection, where alleles at two different loci (A, B) change fitness by some small amount individually (s_A,s_B), and interact to give a deviation ε from multiplicative fitness. If the modifier allele changes recombination by a small amount ∂r, the change in modifier allele frequency is then

$$\Delta p_M = -\frac{\partial r p_M q_M D}{r_{MAB}}\left[\varepsilon + s_A s_B\left(\frac{1}{r_{MA}} + \frac{1}{r_{MB}} - 1\right)\right] \qquad [2]$$

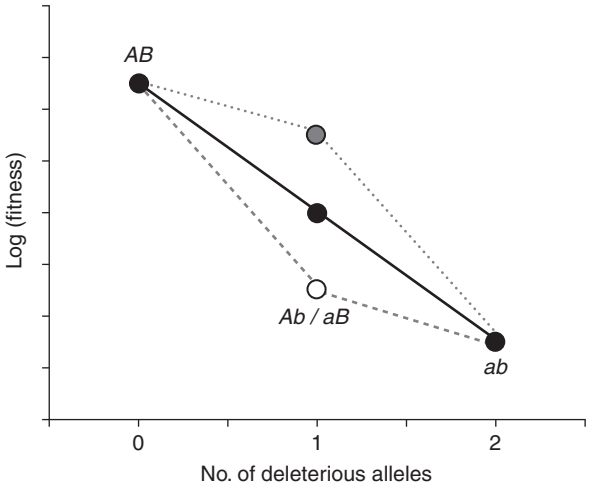

Figure 2 Fitness effects of positive and negative epistasis. In this example, we let *AB* and *ab* have the most extreme differences in fitness, with *AB* having the greatest fitness, and *ab* the lowest fitness. The relative intermediate fitnesses of the *Ab* and *aB* combinations depend on the form of epistasis (we assume for simplicity that *Ab* and *aB* have equal fitness). With no epistasis ($\varepsilon = 0$, black dot, solid black line), the *Ab* and *aB* haplotypes have exactly intermediate fitness. With positive epistasis ($\varepsilon > 0$, white dot, dashed gray line), the *Ab* and *aB* haplotypes are less fit than expected, while with negative epistasis ($\varepsilon < 0$, gray dot, dotted gray line), the *Ab* and *aB* haplotypes are more fit than expected. Adapted from Figure 1, Kouyos, R.D., Silander, O.K., Bonhoeffer, S., 2007. Epistasis between deleterious mutations and the evolution of recombination. TREE 22 (6), 308–315.

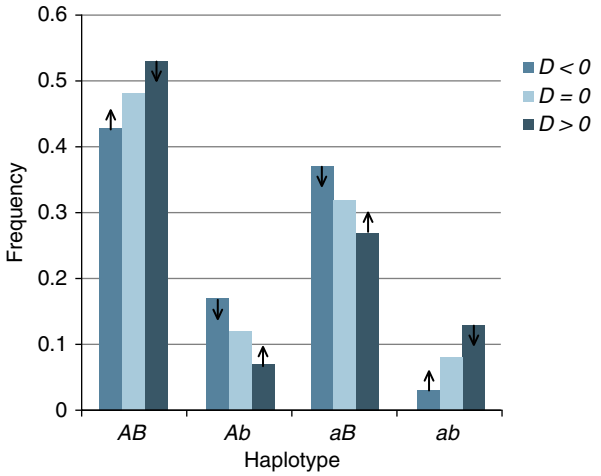

Figure 3 Change in haplotype frequencies under recombination. We imagine a simple case with two loci and two alleles at each locus, leading to four possible haplotypes (*AB*, *Ab*, *aB*, and *ab*). The graphs give the frequencies of the four haplotypes under negative linkage disequilibrium ($D < 0$, medium blue bars), under linkage equilibrium ($D = 0$, pale blue bars), and under positive linkage disequilibrium ($D > 0$, dark blue bars). The values for the haplotype frequencies and for D are as given in **Figure 1**. The black arrows indicate the direction of change for the haplotype frequencies under recombination: for $D > 0$, *AB* and *ab* decrease in frequency, while *Ab* and *aB* increase in frequency, and the opposite is true for $D < 0$. Note that recombination always takes the haplotype frequencies toward the linkage equilibrium values (pale blue bars in center). If we assume that *AB* and *ab* have the most extreme phenotypes (highest fitness and lowest fitness, respectively, as in **Figure 2**), we see that recombination under negative linkage disequilibrium increases the frequency of extreme phenotypes and decreases the frequency of less extreme phenotypes, increasing the ability of natural selection to act. Adapted from Figure 1, Kouyos, R.D., Silander, O.K., Bonhoeffer, S., 2007. Epistasis between deleterious mutations and the evolution of recombination. TREE 22 (6), 308–315.

where r_{MAB} gives the rate of recombination for M, A, and B, r_{MA} the rate for M and A, and r_{MB} the rate for M and B (adapted from Eq. A1.5*e*, Barton, 1995). This equation summarizes both the short- and long-term effects of selection. We can see from [2] that negative D always lead to an increase in the modifier (positive Δp_M), as discussed above. Since the modifier allele needs to stay associated with the beneficial allelic combination it creates long enough for their increase in frequency to also lead to an increase in frequency for the modifier, there is also a dependence on the recombination rate between the modifier and fitness loci (r_{MAB}). These are the results of the long-term effects of selection.

To understand the effects of short-term selection, we note that the effects of changing the average fitness of offspring is greatest when D and ε have opposite signs (more exactly, when $(\varepsilon + s_A s_B)D < 0$; Otto and Lenormand, 2002). As stated above, epistasis generates disequilibrium of the same sign; factors other than epistasis can generate either positive or negative disequilibrium (such as spatial correlations in selection coefficients, generating positive D, or random genetic drift, generating negative D), and thus influence the relative effect of epistasis on the short-term results of recombination (Otto and Lenormand, 2002).

What can cause the conditions that favor a recombination modifier under this type of selection? One situation is that of fluctuating epistasis, where the epistatic effects of allelic combination change over time. This could be caused by biotic coevolution, as described above in Red Queen-type models, if the epistasis imposed by one species is in direct response to linkage disequilibrium arising in the other species (Nee, 1989). A second situation is as a response to directional selection, where there is a need for epistasis to be both weak and negative (Barton, 1995). Many biologically reasonable scenarios would give rise to weak epistasis, but it is not clear if epistasis is generally negative (so that allelic effects are smaller in combination than expected from their individual effects) (see discussion of epistasis, below). Some support for the idea of widespread negative epistasis comes from consideration of stabilizing selection on additive quantitative traits (Maynard Smith, 1988; Charlesworth, 1993), from consideration of mutational load arguments under deleterious mutations (Kondrashov, 1988, but see MacCarthy and Bergman, 2007 for a counter-argument), and from work considering artificial gene networks (Azevedo *et al.*, 2006). Studies seeking to empirically measure epistasis have found mixed results – some have found negative epistasis some positive, and some have found either no epistasis or variable epistasis (some of these are summarized in de Visser and Elena, 2007 and in Kouyos *et al.*, 2007; see references therein).

Modifier Theory in Small Populations – The Role of Genetic Drift

In small populations, genetic drift acts as a stochastic force in generating nonrandom associations. Directional selection acting on beneficial mutations in such populations generates, on average, negative linkage disequilibrium. Allelic associations in positive linkage disequilibrium (either beneficial with beneficial, or deleterious with deleterious) are rapidly either fixed or lost when they arise due to chance – it is combinations that include both beneficial and deleterious mutations that, on average, persist the longest (Barton and Otto, 2005). This leads to increases in frequency for recombination modifier alleles, with the strongest effects occurring in small populations (Otto and Barton, 2001), in large populations where spatial structure increases the effect of genetic drift (Martin *et al.*, 2006), and in population where directional selection is acting simultaneously on multiple loci (Iles *et al.*, 2003). However, this combined effect of genetic drift and directional selection on recombination requires a relatively high rate of beneficial selective sweeps to fix or remove allelic combinations in positive disequilibrium.

Modifiers of Recombination and Genetic Drift in Large Populations

Genetic drift acts in all populations, and so the stochastic effects of finite population size can play a role in large populations as well. Under Hill–Robertson interference (discussed above), genetic linkage is seen to increase the amount of genetic drift near a selected locus, thus reducing the effective population size for the locus when either a beneficial mutation arises or in the presence of purifying selection against a deleterious allele. Keightley and Otto (2006) contrasted the probability of fixation for an allele modifying recombination with a neutral allele, and showed that purifying selection against repeated deleterious mutations provided an advantage to modifier alleles, causing them to fix with a higher probability. Surprisingly, this effect increased with increasing population size.

To understand this somewhat counter-intuitive result, we note that recombination frees the focal locus from Hill–Robertson interference, allowing deleterious mutations to be purged by selection. A larger number of polymorphic loci increases the opportunity for Hill–Robertson interference, which increases the advantage seen for recombination. Larger populations (where genetic drift is overall weaker) will maintain greater polymorphism, and thus see on average a greater amount of Hill–Robertson interference, and a larger advantage to recombination. The Keightley–Otto model gives a truly synthetic treatment of the role of negative disequilibrium where both selection and drift determine how selection on a new mutation affects the fate of other loci, and recombination frees loci from these shared fates.

Epistasis, Genomic Architecture, and Fitness Landscapes

As mentioned above, empirical studies seeking to measure the amount and type of epistasis have found mixed results. Kouyos *et al.* (2006) considered a multilocus model for a recombination modifier under a broad range of epistatic effects, and found that epistatic interactions of a given strength could generate very different types of linkage disequilibrium and that epistatic interactions had the greatest effect under weak selection. Thus it may be that the evolution of recombination under mutation–selection balance is driven by a small number of interactions under weak selection, instead of the average epistasis of all interactions, which is the quantity that is usually measured in empirical studies.

There are several biological scenarios under which the negative epistasis predicted by modifier theory to favor the evolution of recombination might be generated. Among these are density-dependent regulation of population size under limiting resources via truncation selection (Crow and Kimura, 1979; Kondrashov, 1988; de Visser and Elena, 2007) and selection for optimum (rather than maximum flux) along an enzymatic pathway under high competition (low resources) (Szathmary, 1993; de Visser and Elena, 2007). In his *mutational deterministic theory*, Kondrashov (1984, 1988) pointed out that strongly synergistic mutational effects are necessary to avoid excessive mutational load under deleterious mutations, and argued that a genomic mutation rate much greater than unity under this type of selection would allow sexual populations to overcome the two-fold cost of producing males.

It has also been pointed out that negative epistasis can be caused by genetic robustness (phenotypic stability in the face of repeated mutation or other perturbations), so that genetic robustness may favor recombination (Gardner and Kalinka, 2006; de Visser and Elena, 2007). In addition, since recombination increases the variability in genetic backgrounds experienced by a locus across generations, recombination may itself select for greater genetic robustness in sexually reproducing organisms, generating negative epistasis and under this type of selection would allow sexual populations to overcome the two-fold cost of producing males.

Finally, the shape of the fitness landscape experienced by individual alleles is important to how epistasis may shape the evolution of recombination. The presence of *sign epistasis* (where the positive or negative effects of an allele varies across genetic backgrounds) creates a 'rugged' fitness landscape, with local minima and maxima, constraining the possible pathways that evolution can take (Crona *et al.*, 2013). Studies of the effect of this type of fitness landscape on the evolution of recombination have led to contradictory results. In simulation studies, de Visser *et al.* (2009) showed that recombination may prevent populations from escaping local maxima by leading to the break up of 'escape' genotypes. In contrast, Watson *et al.* (2011) considered a model with explicitly modular genomes (viewing genes as necessarily modular units within the larger genome). Using individual-based simulations borrowing ideas from evolutionary computation theory and the genetic algorithm literature, they showed the same advantage of a faster evolutionary rate under recombination seen in the classic Fisher–Muller model, but also saw an additional benefit to recombination. Here, under intragenic epistasis that allowed for local fitness optima, sexual populations were able to access the globally optimal genotype and escape local optima that trapped asexual populations. They pointed out that, in the absence of recombination between loci, competition between

alleles at one locus is interfered with by competition between alleles at another locus, such that *clonal interference* (as defined by Gerrish and Lenski, 1998) acted not only to slow the rate of evolution, but also to limit the overall increase in fitness (Watson *et al.*, 2011). Nowak *et al.* (2014) found only a transitory advantage to recombination under a rugged fitness landscape when selection is strong relative to recombination (at the limit of strong linkage) – here, at longer timescales, it is the recombining populations that become trapped at local fitness peaks. The dependence on the strength of selection is due to the fact that, under relatively weak selection, recombination plays a greater role in breaking up linkage, and allows sexual populations to follow adaptive trajectories defined by 'allele frequency space' rather than 'genotype frequency space' (Watson *et al.*, 2011).

The timescale effect found by Nowak *et al.* (2014) makes clear that an important consideration is how the fitness landscape itself changes with time. At the limit of a constantly changing fitness landscape, the transitory advantage of recombination could continue indefinitely, as long as the timescale of fitness change is shorter than the timescale of advantage for asexual populations. In a model considering the evolutionary dynamics of recombination modifiers under environmental fluctuations, Carja *et al.* (2014) showed that the recombination rate evolved toward a nonzero value that decreased with increasing environmental period. These types of models have an obvious connection to the Red Queen family of models where selection varies across time and/or space.

As genomic data become more readily accessible for a wide range of organisms, further consideration of the form and extent of epistasis, as well as the global and local properties of fitness landscapes, may permit a clearer picture of the interplay between recombination and selection in real populations. However, it is also likely that a single, simple explanation will not suffice – the use of computer simulations and genetic algorithms by researchers seeking more realistic models of genomic evolution has shown the importance of considering both the details of genome structure and the timescale under which evolution is being considered.

Recombination in Bacterial Populations

EJ Feil, University of Bath, Bath, UK

Glossary

Bacteriophage A virus that infects and replicates inside bacteria. Infection may be lytic, which results in the cell bursting and releasing progeny phage, or lysogenic whereby the phage genome integrates into the host DNA.

Exponential bacterial growth (log phase) The phase in the bacterial growth cycle where the number of cells doubles per unit time. The actual rate of growth depends on the conditions and the species in question.

Genome-wide association studies (GWAS) Attempts to identify individual genetic changes, typically single nucleotide polymorphism that is statistically associated with a given trait (e.g., the ability to cause disease).

Housekeeping genes Core genes encoding essential functions relating to central metabolism. These genes are typically assumed to be under strong stabilizing selection.

Lysis Refers to the bacterial cells bursting and releasing their contents (including DNA) into the extracellular milieu. May be brought about by osmotic pressure or the action of enzymes (e.g., lysozyme).

Microevolution Evolution occurring over short-time scales (months, years, and decades), typically within a single species. Contrasts with macroevolution which refers to the emergence of major taxonomic groups over thousands or millions of years.

mecA This gene confers resistance to beta-lactam antibiotics such as Penicillin and Methicillin. It is commonly carried by Gram-positive bacteria such as *Staphylococcus aureus* and *Streptococcus pneumonia*. It encodes a variant penicillin-binding protein (pbp2A) which enables normal cell wall synthesis even in the presence of these antibiotics.

Mobilome This refers to the total complement of mobile genetic elements, including phage, plasmids, and transposons, with the potential to incorporate into the genome of a given bacterial species.

Multilocus sequence typing (MLST) A molecular typing technique based on the nucleotide sequence of a set of seven core housekeeping loci. This approach was the first typing technique to successfully combine automated sequencing technology with the Internet.

Quorum sensing A regulatory system commonly used by bacteria to control gene expression according to population density.

Restriction-modification A system by which bacteria protect themselves against attack by phage. A restriction enzyme is produced which degrades DNA in a site-dependant manner, the modification enzyme protects the host chromosome.

Sporulation The process leading to a metabolically dormant cell (endospore) commonly as a result of stressful conditions such as low nutrient availability. Typically a property of Gram-positive Firmicutes.

Whole genome sequencing The generation of complete sequence data for a given genome. Recently developed next-generation sequencing platforms (such as Illumina MiSeq) provide the means for rapid resequencing of closely related genomes against a given reference.

Introduction

In 1881, Robert Koch first demonstrated the use of solid culture medium for the isolation and growth of pure bacterial cultures, and by the 1890s this new technology gave rise to the use of petri dishes and agar that has remained essentially unchanged ever since. Also unchanged, and understandably so, is a bias in research emphasis on pathogenic bacteria responsible for causing human diseases such as cholera or tuberculosis, over 'environmental' taxa that have less obvious relevance to man. This bias is also evident in this article. However, one fundamental shift has occurred since the days of Koch and Pasteur. The emergence of antibiotic resistance from the 1940s onwards provided an urgent incentive for thinking beyond the petri dish, and recalibrating our view of bacteria in nature as highly diverse, dynamic, and interacting populations. It was quickly appreciated that the rapid acquisition of antibiotic resistance reflects key aspects of the population biology of bacteria, most notably huge population sizes, short generation times, and the ability to share genes through recombination. The advent of large-scale molecular data in the 1980s led to the first serious attempts to incorporate bacteria into formal population biology and microevolutionary frameworks (Caugant *et al.*, 1981; Ochman and Selander, 1984; Guttman and Dykhuizen, 1994; Feil *et al.*, 1995). The rich and complex hues of bacterial molecular diversity uncovered by these initial works have, in recent years, exploded into a kaleidoscopic melange due to the deployment of whole genome sequencing (Whittam and Bumbaugh, 2002; Fraser-Liggett, 2005; Joyce *et al.*, 2002; Koonin and Wolf, 2012; Abby and Daubin, 2007).

Where does all this sequence diversity come from? How is it maintained? Can it be partitioned and cataloged along meaningful epidemiological, ecological, or phylogenetic grounds into 'strains,' 'clones,' 'populations,' or 'species'? Moreover, what are the practical implications of this diversity for combating pathogens, and for gauging the risks of emergence of new resistant or virulent variants? A deep appreciation of the mode and tempo of recombination – the process through which DNA can be re-assorted and redistributed between bacteria as a common resource – is central to addressing all these questions. Here the central characteristics and outstanding questions concerning bacterial recombination, with

an emphasis on comparisons with eukaryotic sex will be outlined.

What Is Bacterial Recombination?

Recombination is a broad term used, somewhat casually, in bacterial population genetics to refer to the transfer of DNA originating from one bacterial cell into another, thus resulting in a hybrid that has genetic contributions from both parental cells. Bacterial gene transfer through recombination is often prefixed as 'horizontal' or 'lateral,' to distinguish it from 'vertical' inheritance which occurs down through the generations from mother to daughter cell. Recombination can arise through multiple mechanisms, which are discussed in detail in a number of excellent reviews elsewhere (Bellanger *et al.*, 2014; Juhas *et al.*, 2009; Thomas and Nielsen, 2005; Narra and Ochman, 2006), and has a commensurate broad range of outcomes. A key distinction is to be made between those events resulting in the acquisition of new genes, typically *en masse*, and cases where existing genes are replaced by different allelic variants of the same genes (orthologs) (Vos, 2009). This latter process occurs much more readily between closely related cells belonging to the same named species, whereas novel genes can occasionally be transferred between unrelated species or genera. These processes occur at different rates within and between named species, and there is no clear evidence that the frequencies of these two types of recombination event are linked (Narra and Ochman, 2006).

There are three main mechanisms for the transfer of DNA between bacteria: transformation, transduction, and conjugation. Details of these can be found in any modern textbook of bacterial genetics. Briefly, transformation describes a process involving the direct uptake of DNA from the environment, followed by integration into the chromosome, a process that requires the cell to enter a state known as 'competence' (Chen and Dubnau, 2004). This is historically significant as the process that led Griffith in 1928 to demonstrate the presence of a mysterious 'transforming principle' (now recognized as DNA) which when released from dead, virulent *Streptococcus pneumonia* cells is able to imbue non-virulent cells with the ability to cause disease (Griffith, 1928). DNA can also be transferred from one cell to another via bacteriophage vectors, a process known as transduction. Given the high abundance of these viruses, particularly in the marine environment (Sime-Ngando, 2014; Weinbauer, 2004), this may well be the most common mode of horizontal gene transfer in nature. Plasmids and integrative conjugative elements transfer genes via conjugation, and transposons can 'jump' within and between chromosomes or plasmids resulting in deleterious consequences for the host through gene disruption, or alternatively conferring a selective benefit through the provision of new advantageous cargo genes (Siguier *et al.*, 2006; Touchon and Rocha, 2007). These and other semiautonomous genetic entities are collectively known as mobile genetic elements (MGEs).

Core and Noncore Genomes

The ability of bacteria to acquire novel genes through horizontal gene transfer is now recognized as playing a major role in rapid adaptation to environmental challenges (Feil, 2004; Young *et al.*, 2006). This is strikingly illustrated by the emergence of antibiotic resistance, which is typically observed a few years after a specific antibiotic is first administered (Laxminarayan *et al.*, 2013; Brandt *et al.*, 2014). Multiple resistances may be conferred through groups of resistance genes linked together on plasmids or transposons, which can be transferred within and between species by recombination. Specialized mobile cassettes can be implicated, such as the Staphylococcal cassette chromosome (*Scc*) in *Staphylococcus aureus* which carries a mecA gene conferring resistance to β-lactam antibiotics, and is the distinguishing genomic feature of methicillin resistant *S. aureus* (MRSA) (Shore and Coleman, 2013). These MGEs form part of the 'noncore' or 'accessory' genome, defined as those genes that are variably present or absent within different strains of the species, usually acquired through horizontal gene transfer and encode specialized, but nonessential, functions. Although resistance genes are typically associated with plasmids, resistance genes can also be carried by phage, along with genes encoding toxins and other virulence factors (Colomer-Lluch *et al.*, 2011). More generally, genes carried by MGEs tend to involve interactions with the environment, the host, or with other bacteria (Rankin *et al.*, 2011). MGEs, and their cargo genes, are themselves prone to high rates of genetic re-assortment, and are usually hybrid (or chimeric) in structure (Bellanger *et al.*, 2014). In contrast, 'core' genes are, by definition, common to all strains of a species, and include those encoding essential housekeeping functions (Feil, 2004). Although the precise repertoire of genes assigned as core and noncore depends on the number of genomes considered (Tettelin *et al.*, 2005), this broad dichotomy is a useful framework for exploring bacterial genomic diversity and adaptation; the core being analogous to the 'operating system' of the cell, whilst the noncore genes are more like plug-and-play software modules for specialized functions.

As discussed in more detail below, homologous recombination does not have equal impact throughout the core genome, and genes in certain functional categories appear to recombine at atypically high frequencies. For example, genes in pathogenic bacteria that encode proteins exposed to the host immune response are often under strong diversifying selection pressure (Evans *et al.*, 2010), and in these cases recombination can contribute significantly to the generation of selectively beneficial diversity. Specific motifs in the genome can also elevate local rates of recombination, leading to the identification of 'hotspots' (Yahara *et al.*, 2014). It has been argued that 'informational' core genes, which include those responsible for essential DNA processing, replication and repair, are likely to be completely recalcitrant to recombination due to multiple protein–protein interactions leading to strong selective constraint, the so-called 'complexity hypothesis' (Jain *et al.*, 1999). However, there are no clear signals in the genomic datasets that any genes, core or noncore, are completely immune to the effects of recombination, including 16s rRNA (Kitahara and Miyazaki, 2013).

Is Bacterial Recombination Akin to Eukaryotic Sex?

Bacterial recombination involves the fusion of DNA from multiple parents to result in a hybrid genome with a novel

genetic repertoire. As such, it is often considered as analogous to eukaryotic sex. Whilst this comparison can be informative, it is important to bear in mind how bacterial recombination fundamentally differs from, and in many ways is even more enigmatic than, genetic re-assortment during meiosis.

The Multiple Ways in Which Recombination Rates Vary

Most pertinently, bacterial recombination differs from eukaryotic sex as it is not tied to reproduction. Rather than being an obligate process that occurs at every generation, the rates and consequences of recombination are broad-ranging and dynamic (Didelot and Maiden, 2010; Vos and Didelot, 2009). The impact of recombination varies widely between different species and lineages. For example, transformable species such as *Neisseria meningitidis* and *S. pneumoniae* recombine at far higher frequencies than *S. aureus* (Feil *et al.*, 2001), though the genetic bases underlying these differences remain unclear. Despite the fact that many genes and pathways responsible for recombination have been identified, a comprehensive comparison of published recombination rates in different species failed to find clear correlates with differences in the repertoires of these genes (Rocha *et al.*, 2005).

In addition to genetic differences, it has also been suggested that ecology may also play a role in shaping the opportunity for gene transfer (Ragan and Beiko, 2009). For example, obligate endosymbionts such as *Buchnera aphidicola*, which can only survive within the body of an aphid and are transmitted between hosts vertically through the maternal line, are assumed to remain ecologically isolated, and therefore to abstain from recombination altogether (Bordenstein and Reznikoff, 2005; Moran and Baumann, 2000). However, other arthropod-associated bacteria such as *Wolbachia* (Baldo *et al.*, 2006) and *Orientia tsutsugamushi* (Sonthayanon *et al.*, 2010) recombine at very high frequencies. This presumably reflects occasional horizontal transmission between hosts resulting in mixed infection and providing the opportunity to acquire exotic DNA. These examples also illustrate how the line of inquiry can be reversed, and evidence concerning recombination rates can inform on the underlying ecology. Similarly, the intracellular, sexually transmitted human pathogen *Chlamydia trachomatis*, which was once thought to be asexual due to its highly specialized niche, is now known to recombine at high frequencies (Joseph *et al.*, 2011; Joseph and Read, 2012). This implies a high rate of mixed infection, thus simultaneously shedding light on the sex life of both the bacteria and of its host.

The apparent rate of recombination may also vary according the evolutionary timescale being considered. A recent study looking at rates of recombination within a clone of MRSA noted that short-term diversification is primarily driven by mutation, but recombination assumes relatively greater prevalence when considering more highly diverged genomes (Castillo-Ramirez *et al.*, 2012). This implies that in order to make meaningful comparisons in recombination rate between species, one should ideally attempt to control for divergence times. Rates of recombination can also vary within a species. Certain combinations of lineages are more biologically suited to DNA exchange than others, owing to the variable presence of capsule (Connor *et al.*, 2012), restriction-modification systems (Waldron and Lindsay, 2006) or other compatibility groups such as pherotypes in *Streptococcus* (Pozzi *et al.*, 1996; Zaccaria *et al.*, 2014). Finally, competence for transformation is rarely constitutive (turned 'on' all the time), but instead arises under certain conditions or phases in the growth cycle. For example, in *S. pneumonia* cells develop competence simultaneously during exponential growth via a quorum sensing mechanism (Lee and Morrison, 1999), and in *Bacillus subtilis* competence is linked to stress and sporulation (Schultz *et al.*, 2009).

Bacterial Sex Is Localized

Bacterial recombination is unidirectional, and asymmetrical in terms of the contribution from each parent. Rather than a new hybrid individual representing 50% from the mother and 50% from the father, bacterial recombination involves a 'recipient' (major parent) and a 'donor' (minor parent). The donor may contribute only very localized fragments of DNA, perhaps a few hundred base pairs, thus resulting in the addition or replacement of a single gene, or even a fragment of a gene (Smith *et al.*, 1991; Lin *et al.*, 2009). The size of imported DNA depends upon the underlying mechanism. Very broadly, transformation tends to result in highly localized replacements of a few hundred base pairs or a few kilobases of DNA. Transduction typically results in the transfer of 20–50 kb (the amount of DNA being restricted by the physical capacity of the phage head), whereas conjugation can result in the transfer of hundreds of kilobases, at least in the laboratory. The largest homologous recombination event so far described in natural bacterial populations was noted in a strain of MRSA, where the imported donor DNA replaced $>20\%$ of the genome (~ 625 Kb) in a single 'cut and paste' (Robinson and Enright, 2004; Holden *et al.*, 2010). Other large replacements have been noted in this species (Robinson and Enright, 2004), in other Gram-positive taxa (He *et al.*, 2010; Brochet *et al.*, 2008) and, most recently, in the Gram-negative species *Klebsiella pneumonia* (Chen *et al.*, 2014). The underlying mechanism for these large replacements remains obscure, as does their evolutionary significance regarding adaptation and virulence.

Recombination does not impact on the chromosome randomly with respect to genomic position. Studies in *Escherichia coli* and *S. aureus* have noted lower rates of recombination (and, curiously, lower GC content) around the terminus of replication (Touchon *et al.*, 2009; Everitt *et al.*, 2014), and elevated rates of core gene recombination around regions experiencing high rates of gene flux (gain and loss); in the case of *S. aureus*, these regions are associated with MGEs (Everitt *et al.*, 2014). The genomes of some species, most notably *Haemophilus influenza* (Mell *et al.*, 2012) and the pathogenic *Neisseria* (Frye *et al.*, 2013), contain short conserved uptake sequences that provide regions of localized homology and promote the integration of 'self' DNA at specific sites (Mell and Redfield, 2014). 'Hotspots' of recombination in the *S. pneumonia* genome are associated with selection for antibiotic resistance and serotype-switching (Chewapreecha *et al.*, 2014). Modeling and experimental evolution approaches has also been used to characterize the heterogeneity of recombination events in this species (Mostowy *et al.*, 2014; Croucher *et al.*, 2012).

Recombination and Evolutionary Analyses

Analytical approaches to reconstructing phylogeny or past demographic changes, calibrating rates of evolution, establishing genotype–phenotype associations (genome-wide association studies; GWAS) need to be carefully tailored to account for the possible confounding effects of too much, or too little, recombination. Phylogenetic analysis is a key case in point, as recombination acting on single gene loci will result in discordant trees when different genes are used (**Figure 1**). This formed part of the motivation for developing multilocus sequence typing (Maiden *et al.*, 1998), where multiple (typically seven) physically unlinked core loci are sequenced in order to define strains. The use of multiple loci provided additional informative sites, thus increased resolution, but also provided a buffer against the possible confounding effects of recombination acting on one of the seven genes. Whilst this reasoning acknowledged that recombination can result in conflicting and misleading trees, there is also an implicit assumption that the frequency of recombination has not been so great that all phylogenetic signal is eroded. In other words, by identifying and then excluding all regions of the genome that have been affected by recombination (typically all noncore regions and a certain fraction of the core), it should be possible to reconstruct a true evolutionary history of a set of strains based on the parts of the genome that remain, the so-called 'clonal frame' (Croucher *et al.*, 2013; Milkman and Bridges, 1990). This logic appears to be mostly sound, and forms the central tenet for a number of recent analytical developments aimed at detecting recombination from whole genome data (Croucher *et al.*, 2014; Falush *et al.*, 2003; Marttinen *et al.*, 2012).

However, as tends to be the way with bacteria, what is true for the majority of species is not necessarily true for all, and in some cases recombination may have been so rampant that there is no remnant of a clonal frame (Shapiro *et al.*, 2012). In such a scenario, any attempt to reconstruct the 'true' tree will be futile, and alternative approaches based on networks, such as splits decomposition (Huson, 1998), should be deployed (Kloepper and Huson, 2008). Conversely, it is possible that recombination detection procedures may be overly sensitive, thus raising the possibility of excluding potentially informative data. A recent short report (Hedge and Wilson, 2014) noted by simulation that tree topology based on whole genome sequences is in any case largely robust to the effects of recombination. However, it is clear that recombination can

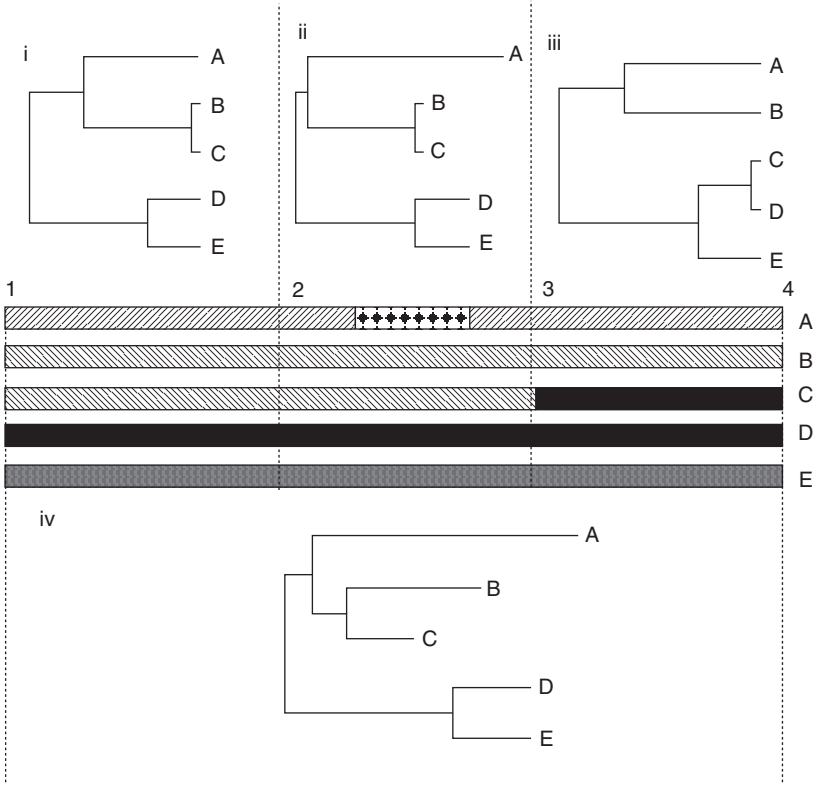

Figure 1 The effects of recombination on phylogenetic analysis. The patterned bars (A–E) represent aligned sequences which are divided into three regions (1–2, 2–3, and 3–4). Two recombination events are illustrated. Sequence 'A' has imported a diverged short block within the middle region (2–3). The donor of this sequence is not included in the sample. Sequence C is a hybrid of sequences B and D. Within regions 1–2 and 2–3, sequence C is identical to sequence B (sequence B is the 'major' parent). Within region 2–3, sequence C is identical to sequence D (sequence D is the 'minor' parent). Trees i–iii represent phylogenetic analyses based on regions 1–2, 2–3, and 3–4 respectively. Tree iv represents the tree obtained from the complete sequence (all regions). Note that tree i is based on sequences unaffected by recombination, and thus can be said to represent the 'clonal frame.' The topology of this tree is preserved in trees ii and iv, although the branch lengths are distorted. The topology of tree iii is discrepant from the clonal frame, as sequence C has imported DNA identical to sequence D in region 3–4.

seriously distort branch lengths, which is likely to compromise inferences concerning demographic changes and evolutionary rates. Intriguingly, rather than providing a solution to this problem, the authors of this study noted that the exclusion of recombined sites appears to make things worse.

GWAS refer to attempts to identify causal links between specific phenotypes with underlying genetic variation. These procedures were originally developed for use on data from sexual eukaryotes and in particular humans (Stranger *et al.*, 2011). Recently, GWAS has been successfully deployed on bacterial genome data, and helped to identify genetic changes associated with host adaptation (Sheppard *et al.*, 2013) and virulence (Laabei *et al.*, 2014). However, a key difficulty lies in the fact that the rate of recombination in bacterial genomes is typically far lower than for sexual species. This means that informative sites tend to be in a state of linkage disequilibrium, where the presence of one single nucleotide polymorphism (SNP), or allele, at locus X is strongly predictive of the presence of a second SNP or allele at locus Y. This makes it difficult to identify which site is primarily responsible for the observed phenotype, as any single phenotype might be associated with a large number of linked genetic changes. Recombination acts to break linkage, thus moderating this problem, and ongoing work is focussing on how best to tease apart individual genetic changes potentially responsible for a given phenotype in bacterial data where rates of recombination are relatively low (Yue and Schifferli, 2014).

Sex with the Dead

The contribution of the minor parent (donor) to bacterial recombination does not require this parent to be living or even extant, which is clearly a profound departure from eukaryotic sex. Transformation involves the uptake of DNA originating from lysed cells that can be preserved in the environment long after the bacterial cell itself has died (Nielsen *et al.*, 2007). Indeed, a recent report has even suggested that very short tracts of ancient DNA, bizarrely from extinct mammoths, could in principle be captured and utilized by bacteria in the wild, a process the authors called 'anachronistic evolution' (Overballe-Petersen *et al.*, 2013; Overballe-Petersen and Willerslev, 2014). Whilst the significance of this process remains unclear, it is surprisingly rare for the original donor of cargo genes carried by phage or plasmids to be unambiguously identified. Although this certainly in part reflects our patchy sampling of the bacterial biosphere, there is no reason to suppose that a single, original donor of these genes must actually exist. It is possible to imagine that genes and linked groups of genes could persist in perpetuity in a kind of nomadic limbo; circulating and recombining through the currents of the mobilome with occasional integration into amenable host chromosomes, but without a permanent residence. Such a view is awkward even for microbial taxonomists (who are easily disoriented). It is curiously both reductionist in the sense that complex genomes arise through combining simple genes, and at the same time holistic as it supposes that single genomes reflect a sample of a much larger gene pool (Frost *et al.*, 2005; Kunin *et al.*, 2005). This model also challenges the classical picture of the relationship between phage and their hosts; the long-term role of these MGEs as essential vehicles of gene transfer and adaptation being more akin to that of a benign pollinator than of a parasite.

Promiscuity and Specious Species

Eukaryotic sex has been proposed to represent both an underlying cause and a definition of species boundaries. The biological species concept (BSC) is a model whereby conspecifics are defined based on their ability to produce fertile offspring. Whilst the BSC is far from perfect even for eukaryotes (consider plant or bird hybrids, for example) it is more or less hopeless as a general rule for bacteria. Not only is there a broad range of recombination rates between different bacterial taxa, but DNA transfer may occasionally occur across phylogenetic distances so large that even the most ardent taxonomic 'lumper' could not accommodate donor and recipient into a single species. Similarly, taxonomic 'splitters' will take discomfort from observations that, even within freely recombining species defined though clinical, phenotypic, and genetic criteria (such as *S. pneumoniae* or *N. meningitidis*), gene flow does not always appear to be equally likely between all members of the population but, as discussed, can instead be structured according to subgroups. Again, this represents a significant departure from the assumptions of a truly sexual species where, by definition, there are no such biological restrictions to gene flow within species (**Figure 2**).

Despite these difficulties, the incorporation of relative rates of recombination remains a common feature of models attempting to explain the emergence and maintenance of ecologically relevant clusters (Nowell *et al.*, 2014; Cadillo-Quiroz *et al.*, 2012; Shapiro *et al.*, 2012; Cohan and Koeppel, 2008), although whether these clusters can be formally equated to 'species' remains an open question (Gevers *et al.*, 2005). Speciation models also draw on the role of the pan-genome, and the ecological opportunities afforded by the acquisition of new adaptive genes, as discussed earlier. The species *Bacillus anthracis* provides an illustrative example. In terms of genome-wide phylogeny, there is little reason to promote *B. anthracis* to species status, as it is highly related to the more benign soil dwelling bacteria *Bacillus thuringiensis* and *Bacillus cereus* (which are also not distinct from each other on the basis of phylogeny (Baillie and Read, 2001)). However, *B. anthracis* has a distinguishing ecological feature that is only too obvious, and one that can be clearly ascribed to recombination; that is, the ability to cause anthrax. *Bacillus anthracis* has acquired this ability courtesy of two plasmids (pXO1 and pXO2) that carry toxin and capsule genes respectively, and it is these plasmids that essentially define the species. Whilst in principle, the distribution of acquired genes (or MGEs), rather than phylogeny, could be used more broadly to define ecologically meaningful groups, it is typically very difficult to pin down the relevant ecological parameters, let alone identify the associated genetic changes. Perhaps it is a legacy of the petri dish that basic data pertaining to bacterial ecology, specifically the contribution to the selective landscape of abiotic factors (environmental conditions) and biotic factors (host adaptation, phage and competition, and cooperation with other bacteria), currently lags far behind the advances in genomics.

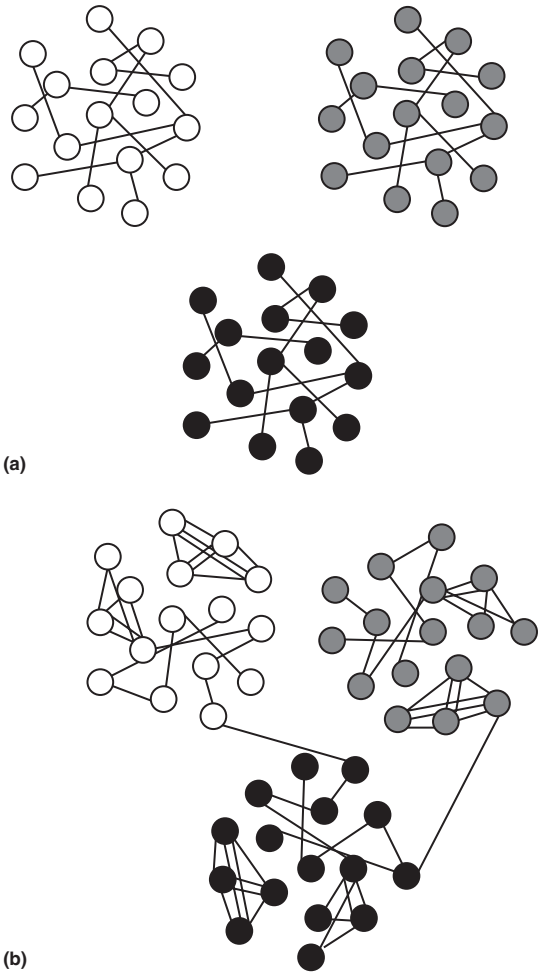

Figure 2 Gene flow and species borders. In sexual species (a), the biological species concept states that gene flow is equal and random with respect to members of the same species, and there is no gene flow between species. In asexual, but recombining, bacteria (b), gene flow may be nonrandom within named species, and can also occur between members of different species.

Why Do Bacteria Recombine?

In addition to mechanistic differences, comparisons between bacterial recombination and eukaryotic sex are also informative from an evolutionary perspective. The debate as to why bacteria recombine at all is often coined within the theoretical framework developed to explore the evolution of eukaryotic sex. The arguments have been outlined in a recent excellent review (Vos, 2009), and center on the fitness gains conferred through combining adaptive alleles from different lineages (clonal interference (Cooper, 2007)), the prevention of the inevitable loss of fitness in the absence of sex through mutation of the most adaptive class (Mueller's Ratchet (Andersson and Hughes, 1996)) and introducing adaptive mutations in optimal clonal backgrounds (sign epistasis (Weinreich *et al.*, 2005)). The ability to respond to rapidly changing biotic and abiotic pressures also forms a key component of models addressing the advantages of sex. The Red Queen hypothesis describes the requirement for the continual generation of diversity (diversifying selection) in order to maintain an adaptive genotype in response to dynamic selection pressures, such as from the host immune response or from coevolving phage. Thus, recombination represents an important mechanism to generate diversity in genes encoding surface exposed proteins that act as phage-binding sites (Betts *et al.*, 2014) or are immunologically relevant (Lipsitch and O'Hagan, 2007). Similarly, as discussed earlier, recombination provides an important response to strong directional selection pressure resulting from exposure to antibiotics.

Finally, the lottery model highlights the advantages of generating diversity through sex when selection pressures are unpredictable or conditions are particularly stressful. This is the most common method used to explain the broad observation in eukaryotes that sex is linked to dispersal; for example, winged aphids are sexual, wingless aphids are not. The notion that novel environmental challenges can at least in part be met through genetic variation driven by recombination also has some currency in bacterial world. Competence for transformation is often associated with stress and low nutrient availability (Antonova *et al.*, 2012), and the link between sporulation and competence for transformation in *B. subtilis* potentially provides a link between sex and dispersal.

On the flip side, bacterial recombination may also come at an evolutionary cost by disrupting adaptive genes and gene combinations. The dichotomy of bacterial genomes into a relatively stable core and a highly dynamic noncore may represent a strategy by which bacterial are able to rapidly diversify and adapt to new challenges through recombination, whilst simultaneously moderating this potential cost. This can help to explain why 'hotspots' of recombination and areas of high gene flux tend to be restricted to specific sites in the genome. The separation between the 'sexual' and 'nonsexual' components of the genome might be even more obvious in cases where the latter is represented by extrachromosomal elements. For example, the genome of *Borrelia* species is composed of a highly stable linear chromosome, and a multitude of small, highly dynamic, and largely uncharacterized plasmids (Qiu and Martin, 2014).

Other arguments have been put forward to explain why bacteria have evolved to take up and incorporate DNA that do not focus on the resultant generation of diversity (Michod *et al.*, 2008). The mechanism of homologous recombination is fundamentally linked to DNA repair, and the genes involved are thought to have evolved primarily for this function (Michod *et al.*, 1988). A further line of thought suggests that DNA uptake from the environment is a nutritional requirement, and DNA integration into the chromosome is simply an occasional by-product of eating DNA (Sinha *et al.*, 2013). Finally, the arguments above relating to the advantages of sex assume that selection is operating on the level of the host bacteria. It is, however, possible that gene transfer may reflect selection pressure operating on MGEs vectoring the genes, or even on individual ('selfish') genes themselves (Wagner, 2009).

Concluding Comments

In this article the author has attempted to sketch out the key properties of bacterial recombination, and compared the

process to eukaryotic sex both mechanistically and in terms of evolutionary relevance. Whilst the author has highlighted fundamental ways in which these processes differ, the comparison remains a useful one, and in the end one must simply draw on the analogy where appropriate, rather than seek an entrenched view in one camp or the other. One key point is that bacterial recombination encompasses a fantastically diverse range of mechanisms and consequences, and that generalizations, even with regard to the most fundamental questions, must only be put forward with extreme caution.

Regulatory and Coding Changes in Developmental Evolution, Roles of

AA Sadier, University of Illinois, Urbana, IL, USA

Glossary

***cis*-Regulatory elements or CREs** CREs are regions of non-coding DNA that regulate the transcription of their related genes. They comprise promoters directly upstream the start site of transcription, and enhancer that can reside within introns, 5′ and 3′ UTR of or up to tens of kilobases of the gene they regulate. They typically regulate gene transcription by functioning as binding sites for transcription factors.

Coding sequence A part of a gene that will be translated into a mature mRNA or a protein.

Duplicated genes A portion of DNA that comprise genes and/or its control region that are duplicated during evolution.

Epistasis It is a phenomenon that consists of the effect of one gene being dependent on the presence of one or more other genes.

Frameshifts The addition or deletion of a number of nucleotide(s) that causes a shift in the reading frame of the codons.

Immunofluorescence A technique that allow the *in situ* detection of protein by using an antibody against the protein of interest.

Indel The insertion or deletion of a DNA sequence.

***In situ* hybridization** A type of hybridization that use a probe (generally labeled RNA) to localize an express RNA of interest in a fixed tissue. In developmental biology, this technique is widely used to visualize expression patterns of genes in tissues

Non-synonymous substitution A point mutation that result in a change in protein sequence.

Pleiotropy The fact that a mutation or a gene is at the origin of multiple presumably not related phenotype. Consequently, a mutation in a pleiotropic gene may have an effect on some or all traits simultaneously.

Positive selection In population genetics positive selection is a mode of natural selection in which an extreme phenotype is favored over other phenotypes, shifting over the allele frequency of the genotype in the direction of that phenotype.

Synonymous substitution A point mutation that, thanks to the genetic code redundancy, do not affect the protein sequence.

Transcription factor It is a protein that blinds a specific CRE in the genome, modulating the expression of its related genes.

One central question in evolutionary biology is how species evolve, and more precisely, which mechanisms lead to such diverse phenotypes. Since the discovery of genes, biologists have long sought to understand the source of this variation, i.e., which genes and sequence changes are responsible for the evolution of morphological diversity (Carroll, 2008). Because organisms are mostly shaped during embryonic development, developmental genes became the most important candidates for variation. It has long been understood that changes in morphological evolution happened through the alteration of embryonic development (Gould, 1977; Raff and Kaufman, 1983). During most of the twentieth century, changes in protein coding genes (**Figure 1**) were thought to be the primary source of morphological evolution (Wittkopp and Kalay, 2012), essentially because they were easier to study. However, the discovery of *cis*-regulatory regions (CREs) that control the expression of genes through space and time revealed new sources of phenotypic variation (Jacob and Monod, 1961; Britten and Davidson, 1971; King and Wilson, 1975; Raff and Kaufman, 1983; Carroll, 1995; reviewed in Wray, 2007; or Stern and Orgogozo, 2008). At the beginning of the 1980s, the discovery of *Hox* genes and their regulation (McGinnis *et al.*, 1984; Scott and Weiner, 1984; Graham *et al.*, 1989; Duboule and Dollé, 1989 reviewed in Carroll, 2008) radically changed our vision of the evolution of genomes and fully introduced CREs as important players in morphological evolution as well as changes in protein sequences. The relative importance of coding versus CRE changes for the generation of novelties was a subject of some debate. In this article, author will review the main arguments on both sides using case studies will be reviewed.

Coding versus *cis*-Regulatory Sequences

Changes in Coding Sequences

Nature of changes in coding sequence

The coding region is the part of a gene that encodes the final gene product, which can be a protein or a mature RNA. Changes in the coding regions are all changes that alter the amino acid sequence or the mature RNA (**Figures 1(a)** and **1(b)**) but their importance depends on the mutation type. The impact of synonymous and nonsynonymous mutations is very different. In the first case, synonymous mutations do not give rise to a change in protein sequence but can affect transcription efficiency or mRNA stability (Stern and Orgogozo, 2008). The impact of these changes in morphological evolution is usually discreet and only a few cases have been reported (Stam and Laurie, 1996; Nackley *et al.*, 2006). In contrast, nonsynonymous mutations can give rise to drastic changes in the function of the protein (see Edar and Oca2 examples in the next section). A change in a functional domain could change protein structure, stability, activity, binding properties,

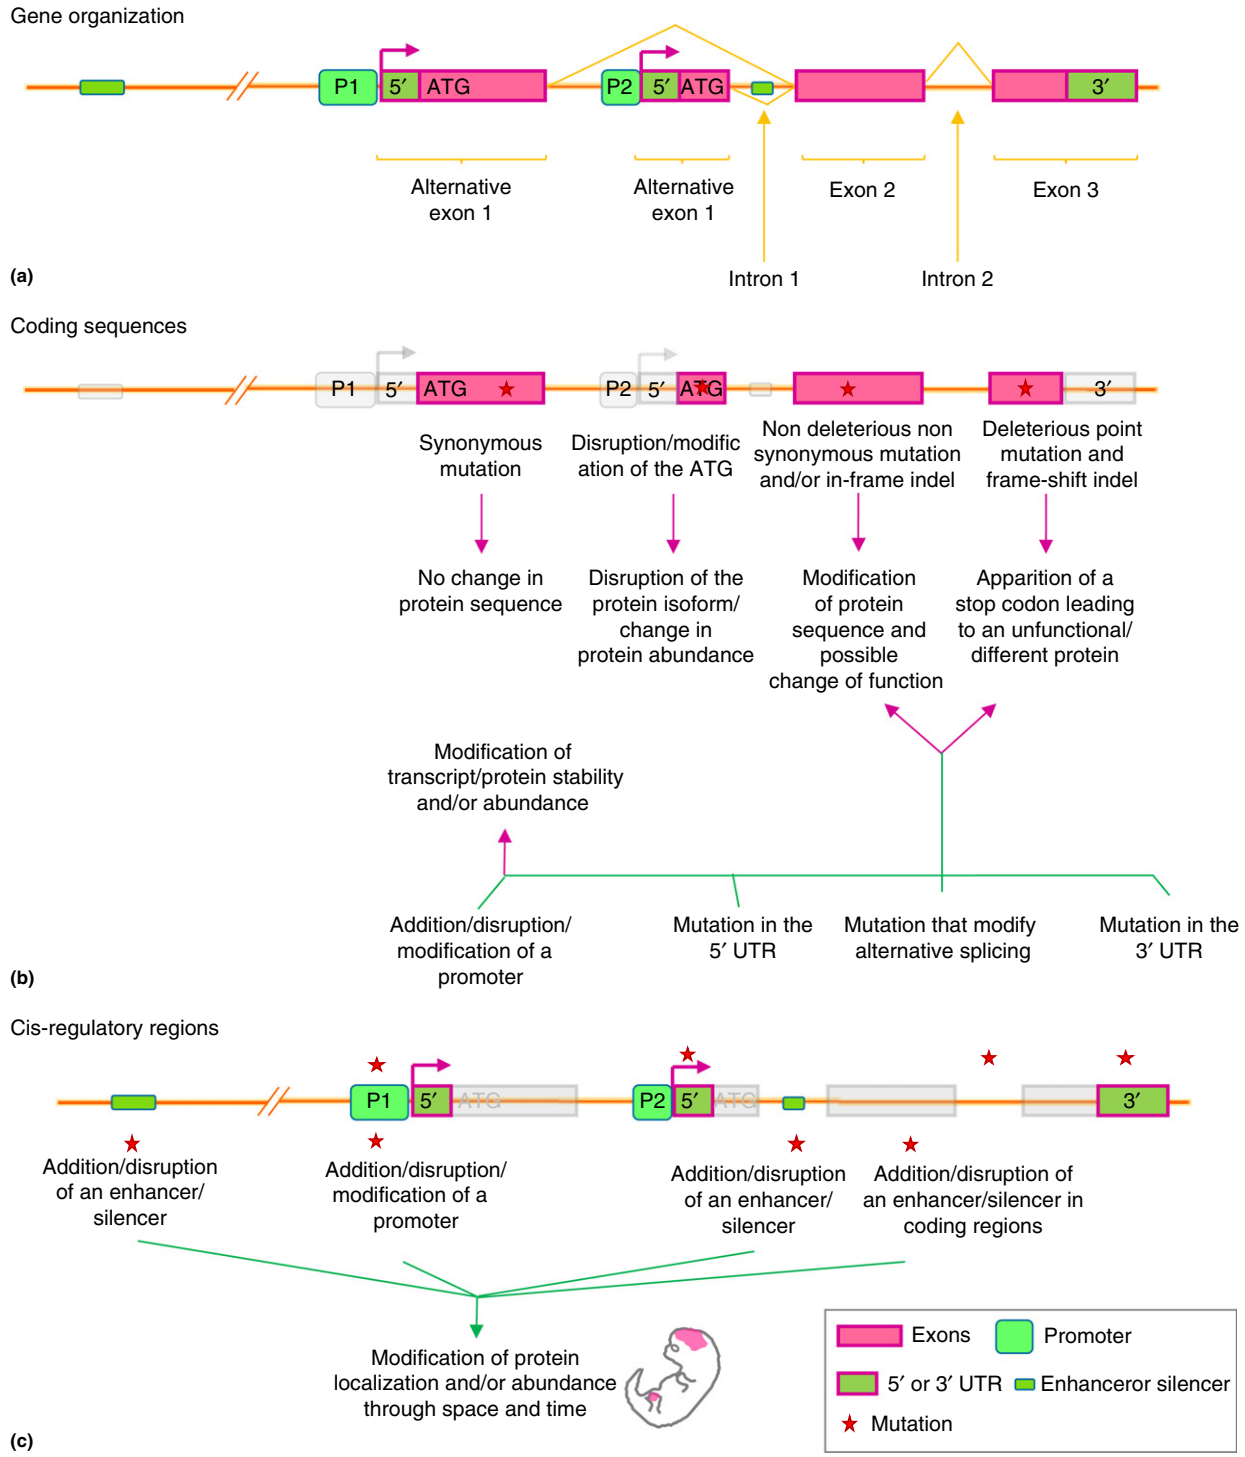

Figure 1 Organization of CRE and coding parts of a theoretical gene and the impact of different classes of mutations. (a) Organization of a theoretical gene with enhancers upstream and inside an intron, two alternative isoforms driven by two alternative promoters, and three exons. (b) Coding sequences and associated mutations. Synonymous mutations do not change protein product but nonsynonymous or in frame indel can change protein sequence as well as a stop codon or a frameshift. These changes can lead to a truncated or new or nonfunctional protein. Modification of the kozak sequence of an ATG can lead to changes in protein abundance or isoform disappearance. (c) *Cis*-regulatory sequences and associated mutations CRE mutation can be classified in two groups: mutations that change protein structure, stability, and abundance in a pleiotropic way and mutations that change protein expression and abundance through space and time. A mutation can add, remove, or modify a CRE leading to changes in protein localization and/or abundance. Mutations in promoters can modify protein localization and/or abundance as well as the apparition of a isoform. Modification in the 5′ and 3′ regions can modify the transcript stability and protein abundance. Mutations can also modify alternative splicing and lead to the generation of new isoform.

or whole function. Thus, nonsynonymous mutations are generally predicted to contribute more to phenotypic evolution than synonymous mutations (Stern and Orgogozo, 2008). A modification of coding sequence can also occur by frameshift mutations, which cause a shift in the reading frame of the codons and thus, a change in the whole sequence of the rest of the amino acids. Finally non-frameshift insertions or deletions could modify small domains or parts of the protein and can be at the origin of big changes in the protein function or properties as well as minor changes.

There are many examples of how changes in coding sequence lead to morphological evolution (Martin and Orgogozo, 2013). Many of them result in loss of function, modification of protein activity or abolition of the protein's function. In the next paragraph, the different impacts of coding changes in morphological evolution by reviewing two interesting cases studies will be highlighted.

The Edar mutation in Asian populations

First, as previously mentioned, some mutations can alter protein function. This case is highlighted by the receptor Edar from the EDA pathway (Figure 2(a)), a signaling pathway involved in the development of ectodermal appendages in vertebrates (including tooth, hair, nail, feather, and external glands such as mammary glands). This pathway has long been known to be involved in morphological evolution (Thesleff, 2002; Colosimo *et al.*, 2005; Sadier *et al.*, 2014), originally from studies that pinpointed its role in the establishment of tooth morphology. Interestingly, a mutation in Edar was identified by genome-wide scans as being under positive selection in humans (Sabeti *et al.*, 2007; Bryk *et al.*, 2008; Fujimoto *et al.*, 2008). The replacement of a conserved valine in the death domain of the protein, which is crucial for the establishment of the downstream signaling of the pathway (NF-κB, Figures 2(a) and 2(b)), by an alanine was selected for in Asian and Native American populations. A T to C substitution in the respective codon is at the origin of a gain of function that enhances NF-κB signaling and leads to thicker hair (Figure 2(c)). Other tests with this allele in mice showed that this mutation not only increases hair thickness but also alters the mammary gland branching pattern, and increases the number of sweat glands (Figure 2(d)), showing the impact of

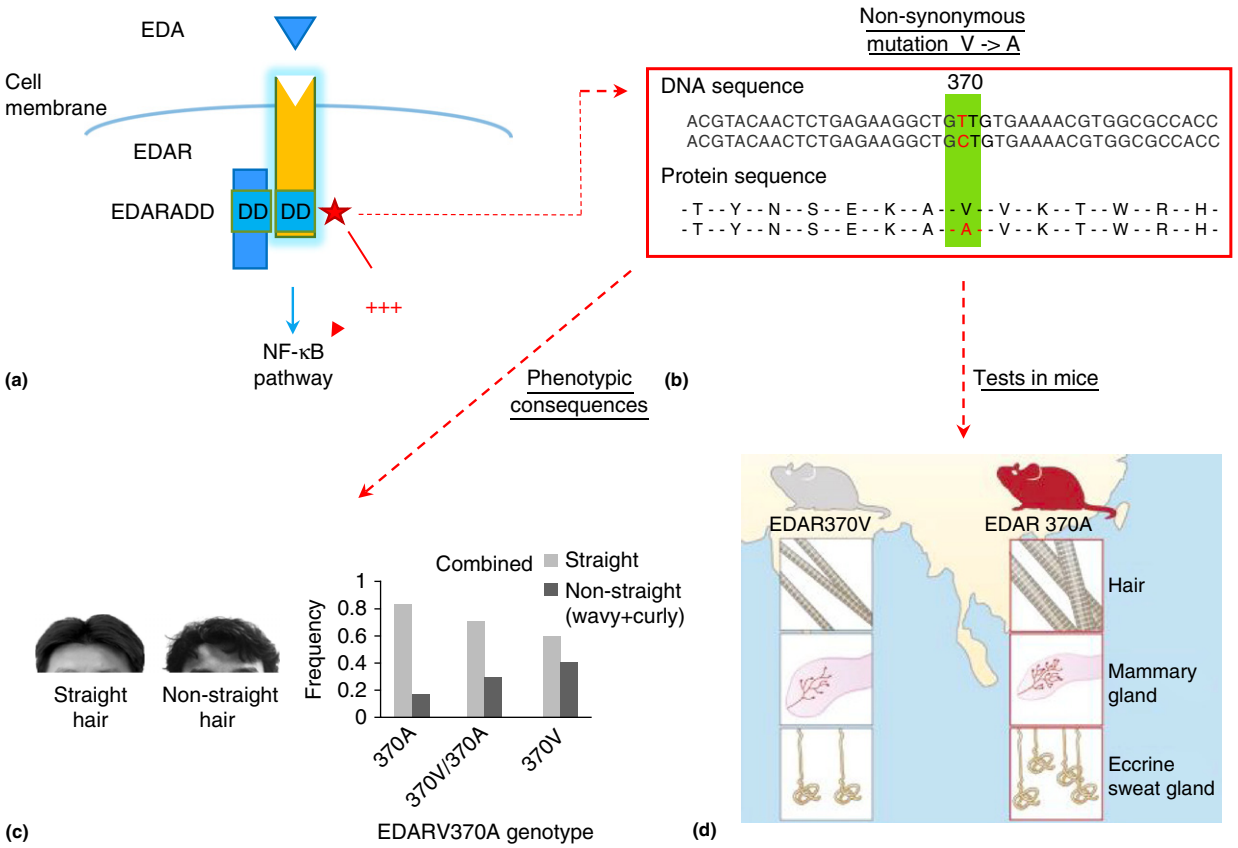

Figure 2 The Edar mutation in V370 is responsible for phenotypic changes. (a) The EDA pathway and the Edar mutation. The EDA pathway is composed by a ligand EDA, a receptor EDAR and an adaptor EDARADD. When EDA binds EDAR, the adaptor EDARADD is recruited and EDAR and EDARADD interacts by their death domains (DD) leading to the activation of the NF-κB pathway. The mutation V370 to A370 in human is located in the death domain and lead to an higher activation of the NF-κB pathway, knowing to be involved in phenotypic changes (Sadier *et al.*, 2014). (b) Genomic and protein sequence of the Edar mutation. (c) Phenotypic consequences of the 370V to 370A mutation, the A370 mutation is associated with thicker hair. The phenotype is shown on the left panel and the association between phenotypes and genotypes is indicated in the right panel. (d) Phenotypic consequences of the 370A mutation in mice, the human 70A mutation lead to thicker hair, highly branched mammary glands and more exocrine sweat glands showing the pleiotropy of changes in coding sequences.

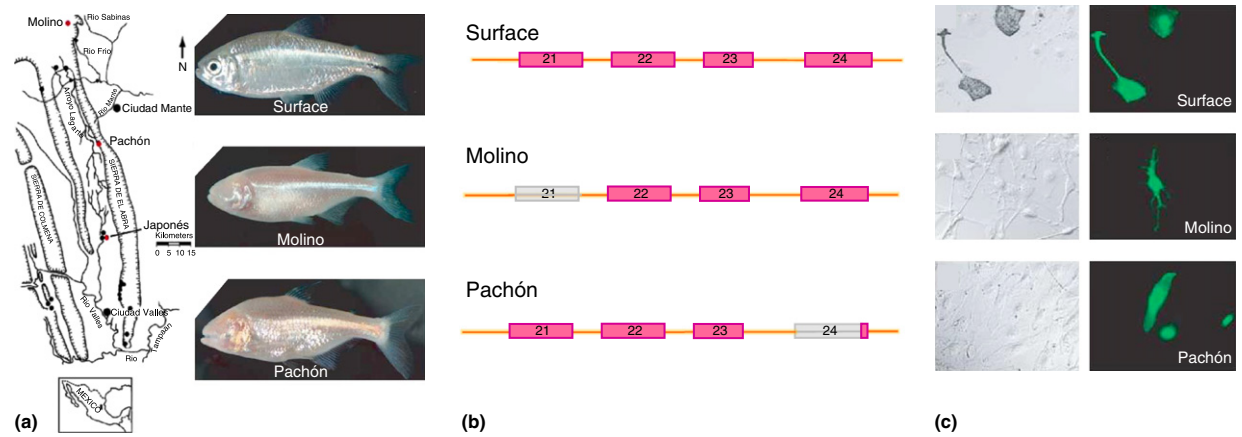

Figure 3 The *Oca2* locus is responsible for the cave fish albinism. (a): Map of the area in Mexico where the different cave populations are found. Caves with red dots are Molino and Pachón, all of which contain a majority of albino individuals. Inset map at bottom shows the location of the region within Mexico. Representative surface, Molino cavefish and Pachón cavefish are shown in right. (b) Coding changes at the origin of albinism. Organization of the last four exons of the *Oca2* gene in surface, Pachón and Molino fishes. Pachón nonsynonymous mutations are not shown as they are not implicated in albinism phenotype. (c) Complementation experiments in *Oca2*-/- melanocyte cells Surface, Molino and Pachón proteins were expressed into *Oca2*-/- melanocyte cells. Surface *Oca2* are able to rescue the pigmentation in melanocytes *Oca2*-/- cells, whereas Molino or Pachón *Oca2* protein failed. Transfection efficiency is vizualized by control with GFP in the right panel.

this mutation on various organs. This example perfectly illustrates the pleiotropic impact of mutations in developing genes as they are often involved in different processes.

The Oca2 gene in Astyanax populations and albinism

The *Oca2* gene in *Astyanax* (a freshwater characiform fish) populations provides a good example of modification of protein function by deletion of a part of a gene. *Astyanax* populations are a classic example of regression of certain traits in a particular environment. Compared to surface fishes, cave populations exhibit convergent losses of their eyes and pigmentation (**Figure 3(a)**). To identify possible loci at the origin of these losses, a genetic screen was performing by a genome-wide linkage map study between surface and cave populations (Protas *et al.*, 2006). In the two blind unpigmented cave fish populations that were studied in detail (Pachón and Molino), changes were identified in the coding sequence in *Oca2*, a gene implicated in pigmentation. In Pachón, two amino acid changes are observed (**Figure 3(b)**) as well as a deletion of a part of exon 23 and exon 24 that changes the protein sequence. In Molino, the entire exon 21 was missing. To test if these changes are at the origin of albinism, these mutations were functionally tested in a melanocyte cell line deficient in *Oca2* (**Figure 3(c)**). The results revealed that both deletions were unable to rescue the loss of pigmentation in cell lines whereas surface *Oca2* can, showing that both mutations are at the origin of albinism in *Astyanax*. This example thus shows how deletion of a coding sequence can be used repeatedly to produce a phenotype leading to parallel evolution and convergence.

Changes in *cis*-Regulatory Sequences

Regulatory sequences were discovered in 1961 by Jacob and Monod, who described the lac operon in bacteria. Soon, they pinpointed the importance of two distinct components for the proper function of all genes: the function of its product and the circumstances under which the product is produced (Wray, 2007). Thus, the discussion about potential evolutionary impact of mutations in what they called the 'operator' was introduced quickly after the discovery of CREs, even before the characterization of all types of CREs. The discovery of *Hox* genes in 1984 (reviewed in Carroll, 2008) highlighted the importance of regulatory changes in evolution as the remarkable conservation of the *Hox* coding sequence was not compatible with the diversity of body plan of vertebrate animals. Later, the spread of sequencing technology allowed a better understanding of genomes and the identification and characterization of many types of regulatory sequences.

Regulatory changes comprise all changes in regulatory regions of a gene (**Figures 1(a)** and **1(c)**), that controls where and when a gene is expressed. These changes are most often located in the promoter, enhancer, silencer, 5′UTR or 3′UTR regions of a gene, although in some cases, regions of coding sequence have been reported to act as transcription factor binding sites and thus act as CREs. Their organization around their related gene is generally modular, that is, each CRE can act more or less independently of the others. Indeed the modification of one given CRE will potentially affect gene expression only in a single developmental context through space and time. As for coding sequences, these changes could be due to a substitution of a nucleotide or an indel (i.e., insertion or deletion) of a DNA fragment. These changes could modify, add, or remove a CRE (see example below). Thus, unlike with coding sequence changes, the modification of CREs do not affect the function of the protein but its expression through space and time. In the next part, we will review some case studies of such variation to browse the role of such changes during evolution. Some other examples are given in Martin and Orgogozo (2013).

The yellow gene and the Drosophila pigmentation

This *yellow* gene is a historical example of CREs evolution using the fruit fly as a classical developmental model. Among the

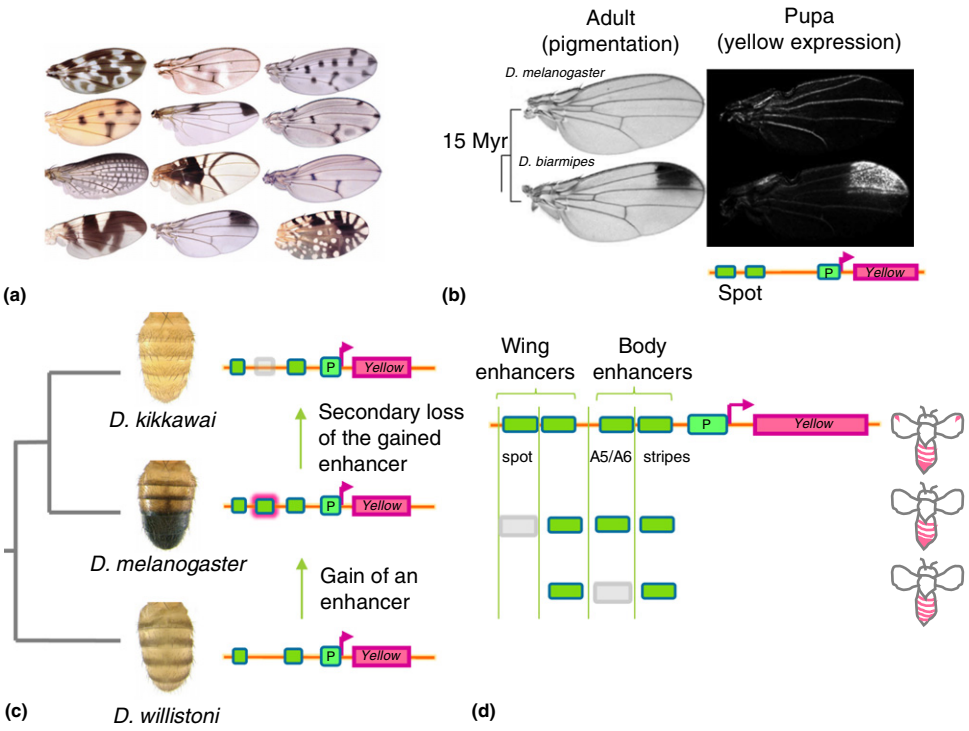

Figure 4 The evolution of the *Drosophila* pigmentation by *cis*-regulatory elements of yellow. (a) Wing pigmentation pattern diversity across higher Diptera. This plate illustrates the diversity of wing pigmentation patterns. (b) The expression of yellow prefigure wing pigmentation. The spot of dark pigmentation at the tip of the male wing of *D. biarmipes* is a new trait evolved among species of the *D. melanogaster* group superimposed on the ancestral pattern. Yellow is revealed by a specific antibody (right) in pupa. (c) Evolution of pigmentation pattern in A5/A6 segments in the *D. melanogaster* group in the *D. melanogaster* species group, the male abdominal pigmentation pattern is variable. In the ancestral situation, illustrated with *D. willistoni*, both sexes carry an identical segmental stripe pattern (green arrows). *D. melanogaster* males have evolved fully pigmented posterior segments (A5 and A6). This pattern has been secondarily lost in *D. kikkawai*. (d) The yellow locus and the resulting phenotypes. The two regions that control wing and body pigmentation are shown. In some species, the spot enhancer is not present or was secondary lost leading to the absence or loss of the wing spot. In other species, the spot enhancer is not present and the A5/A6 enhancer was secondary loss leading to unspotted and unpigmented species. The other wing enhancer as well as the one that control stripes in the body region are conserved. This example illustrates perfectly the modular organization of CREs of a gene.

well-known genes involved in pigmentation in *Drosophila melanogaster*, *yellow* is one of the most characterized. In the *D.* melanogaster species group, males of some species harbor dark spots at the anterior tip of their wings whereas those of other species have colorless wings (**Figures 4(a)** and **4(b)**; Prud'homme *et al.*, 2006). To decipher the genetic basis of these changes, immunofluorescence experiments in the spotted *D. biarmipes* and the unspotted *D. pseudoobscura* and *D. melanogaster* species were performed (Gompel *et al.*, 2005). These experiments showed that both spotted and unspotted species share a uniform low expression of *yellow* in the entire wing, except for a high expression zone in the spot of the spotted species. Because of these modifications of expression patterns, the authors concluded that a change in the sequences that control the expression of yellow occurred in spotted species, explaining this local high expression of *yellow*. The characterization of regulatory regions of *yellow* confirmed this idea: the expression of *yellow* is driven by a 800 bp long CRE in both species (**Figure 4(b)**). However, in spotted species, mutations gave rise to new binding sites for transcriptions factors that are controlling wing development, leading to the overexpression of *yellow* in spots. In conclusion, the gain of new CREs corresponding to transcription factors implicated in wing development lead to the generation of a new phenotypic pattern.

Interestingly, other studies at the *yellow* locus have revealed the importance of the modular organization of CREs for the evolution of phenotypes. Indeed, gain and loss of enhancers at this locus are also responsible for the differential pigmentation of the abdomen segment A5/A6 in different species (Jeong *et al.*, 2006). Immunofluorescence and transformation experiments demonstrate that the loss of *yellow* expression in the A5 and A6 segment of some Drosophila species is due to a disruption of another specific CRE that allows the expression of *yellow* in these particular regions. It is finally important to notice that both wing spots and abdomen pigmentation have been lost repeatedly in distinct lineages, both implicating the *yellow* locus. Thus, as for coding sequences, parallel evolution is likely to arise repeatedly for certain CREs.

In conclusion, the *yellow* locus illustrates perfectly the modularity of CRE for the expression of a gene at different places and times during development. Moreover, it shows that the modification of the expression of genes can be easily fine-tuned by the addition or removal of various enhancers or repressors elements around the gene (Prud'homme *et al.*, 2007).

Pitx1 enhancers in sticklebacks and the evolution of the pelvic region

The modification of the locus *Pitx1* in sticklebacks *Gasterosteus aculeatus* is also a case study of extreme morphological evolution. Three-spine sticklebacks have the ability to live both in freshwater and the ocean even if most of the population lives in the latter. Freshwater populations are supposed to have been isolated during the last glacial retreat in newly formed isolated lakes, thus becoming adapted to their novel environment (Bell and Foster, 1994). While ocean stickleback harbor full skeletal pelvic structures, some populations of freshwater stickleback exhibit a reduction or loss of skeletal armor (dorsal spine and pelvic girdle), a trait associated with reduced calcium and fewer large gap predators (Shapiro *et al.*, 2004; **Figure 5(a)**). To decipher the changes at the origin of these variations, the authors crossed marine and freshwater populations and mapped the responsible genetic locus. The *Pitx1* locus was shown to have the major effect of such variation. When looking at the sequence of *Pitx1* in each population, no protein coding changes were found in the freshwater one compared to the marine one showing that the casual mutation must be regulatory. Moreover, mRNA localization experiments by *in situ* hybridization (**Figure 5(b)**) showed that freshwater populations lack *Pitx1* expression in the pelvic region. Yet, the region was not fully characterized in this study, and the exact nature of the regulatory changes remained unclear. A few years later, another study carried on these experiments (Chan *et al.*, 2010). First, to avoid changes linking to a different transcription factor context, the authors crossed two freshwater populations that partially or totally lack the pelvic part of the sticklebacks and confirmed that the loss of expression is due to a modification of a CRE at the *Pitx1* region. Then, a high resolution mapping between marine and pelvic-reduced sticklebacks identified a 124 kb region of interest containing *Pitx1* and another gene. The study of the correlation of microsatellites with the absence or presence of pelvic phenotypes in natural population reduced this interval to 23 kb in the intergenic region of *Pitx1*, a region which is conserved in teleosts and may thus contain ancestral enhancers. Finally, a smaller putative 2.5 kb enhancer, *Pel* (**Figures 5(c)** and **5(d)**), cloned upstream *Pitx1* driven by a drhsp70 promoter was used in transgenic experiments to successfully restore pelvic expression in reduced pelvic fishes. The sequencing and analysis of this region in various fishes identified a 1868 bp deletion in this region, as well as other independent deletions of this locus in various independent freshwater populations of sticklebacks.

As a conclusion, this example clearly shows how a deletion of a CRE can lead to morphological changes and can also be selected repeatedly. It also perfectly shows the challenges involved in fully characterizing a CRE and the need to perform multiple experiments to decipher such changes in a natural population. Finally, this case highlights how the fine-tuning of CRE can produce different levels of expression leading to a

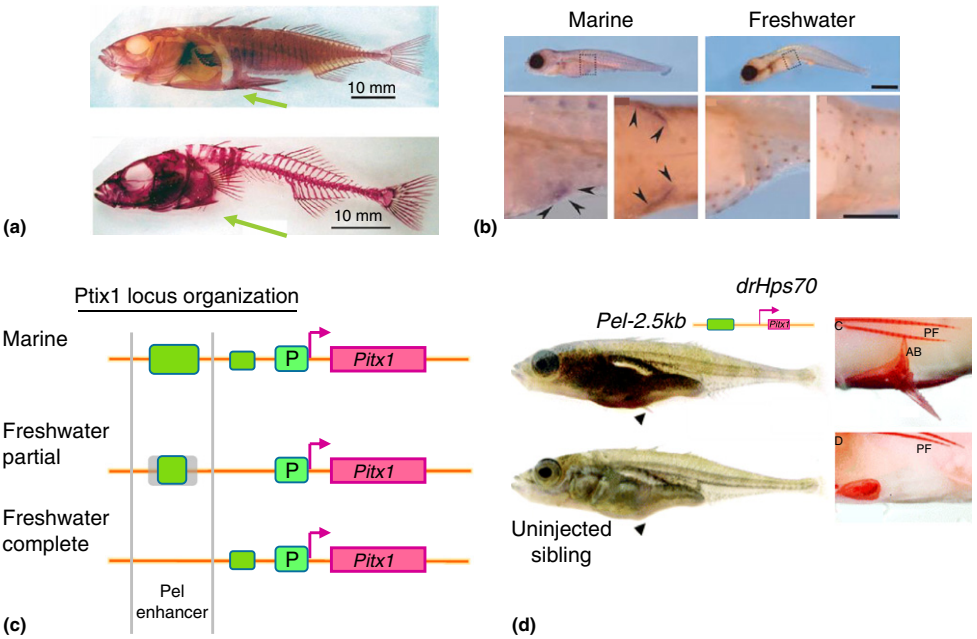

Figure 5 The loss of a Pitx1 enhancer in sticklebacks is responsible for loss of pelvic structures. (a) Three morph of three-spine sticklebacks. Marine population exhibit a complete morph whereas freshwater populations have a partial or complete reduction of this structure indicated with a green arrow. (b) *In situ* hybridization of the *Pitx1* gene in marine and Paxton freshwater sticklebacks, in marine sticklebacks, *Pitx1* gene is expressed in the pelvic region whereas no expression is detected for the Paxton freshwater stickleback. (c) Schematic region of the *Pitx1* locus Marine populations possess the enhancer that drive *pitx1* expression in the pelvic region whereas freshwater populations have partial or complete deletions of this enhancer leading to partial or complete reduction of the pelvic region. Others enhancers that drive *pitx1* expression in at different space and time during development are conserved in the two populations. (d) The Pel-2.5 kb that contains the enhancer is sufficient to rescue pelvic structure in freshwater population Juvenile pelvic-reduced stickleback expressing a *Pitx1* transgene driven by the Pel-2.5-kbSALR enhancer is compared with uninjected sibling. External spines form only in transgenic fish (arrowhead). Right panel: alizarin red-stained pelvic structures of adult transgenic fish compared with parental phenotype.

variation in phenotypes. Another interesting case of extreme morphological change was also observed in sticklebacks with the EDA pathway (see coding sequence, Colosimo *et al.*, 2005) that also exhibit a reduction of armor plate in a specific environment. The mutation is not yet identified but is thought to be linked to *cis*-regulatory mutation.

The Primacy of Coding versus CRE in the Generation of Novelties

The First Debate

Around 2006–07, as the evo-devo field started to be well established, many researchers tried to build a synthesis of what evo-devo was and what the important questions of the field were. Among them, the question about the nature of the genetic changes at the origin of evolutionary changes was central and debated (this subject was intensively reviewed in the following papers: Wray, 2007; Hoekstra and Coyne, 2007; Prud'homme *et al.*, 2007; Carroll, 2008; Stern and Orgogozo, 2008). Following the discovery of *cis*-regulatory sequences, many researchers argued that they represented most of the variation at the origin of evolutionary novelties. First, as transcription is viewed as a dynamic process that gives rise to different expression levels of a gene, it can be fine-tuned depending on the external context with less deleterious effects on the organism, whereas changes in coding sequences are often pleiotropic and could have dramatic effects. Second, the organization of CRE around a gene is modular and thus, the expression level of a gene can be modified at one point in space and time while the essential functions are maintained. Of course, it allows the evolution of a specific part without modifying the other parts. Third, the mutations in CRE are often codominant, as suggested by allele-specific studies of transcript abundancy. On the contrary, mutations in coding sequences that are often recessive and thus are supposed to play a lesser role as natural selection generally operate far more efficiently on codominant mutations. Four, developmental genes are often pleiotropic and share different roles at different spaces and times during development. Thus, a mutation that could give an advantage for one organ can be deleterious for another.

Some argued against this idea, stating that there is no valid reason to assume a preponderance of evolutionary relevant mutations in any particular part of the genome (Coyne and Hoekstra, 2007; Hoekstra and Coyne, 2007) and that some forms of protein evolution can avoid the negative consequences of pleiotropy, for example, by gene duplication. To reply to that comment, some authors have tried to estimate the impact of both types of changes on morphological evolution with their actual data and make predictions about their relative importance (Stern and Orgogozo, 2008), raising the idea of the importance of considering population and developmental studies simultaneously. They found that both types of mutations are important and are at the origin of morphological evolution but that the CREs and coding changes explain variations at different frequencies. More precisely, above the species level, the authors found that changes implicated in morphological variation are more common in CREs than in coding sequences. Thanks to the recent development of genomics, the debate has grown broader in scope.

The Coding and CRE Changes in the Actual View of Genotype/Phenotype Relationship

The question of the primacy of coding versus CRE changes in developmental evolution is part of the bigger question of the relationship between genotype and phenotype. In the last 10 years, the development of new generation sequencing, including transcriptomics, and modelization lead us to rethink our view about genotype/phenotype relationship toward an integrative view including all levels of variation such as the transcriptomic variation, the effect of population size or the influence of environment on the penetrance of a phenotype (Martin and Orgogozo, 2013; Orgogozo *et al.*, 2015). Moreover, some changes are at the frontier between coding and CRE changes and thus, are difficult to place in this debate. For example, during gene or genome duplication, both coding and regulatory region are duplicated and can then evolve differentially from the original copy and be sources of variation. The most famous case in evo-devo is of course the *Hox* genes that are present in four clusters in vertebrates, coming from a single locus before rounds of duplication. Another example is the mutations that arise in the coding sequence of transcription factors that are coding changes but that, due to the regulatory function for the expression of genes, lead to changes in the expression of genes such as CRE mutations. The impact of such changes is discussed in (Cheatle Jarvela *et al.*, 2014) who highlight that coding sequence changes in transcription factors can themselves be modular and affect only certain tissues. One reason for this is the generation of alternative isoforms that can lead to multiple versions of a gene depending on the cellular context. More broadly, many developmental genes present different isoforms (reviewed in Kalsotra and Cooper, 2011; Kelemen *et al.*, 2012) enhancing the evolutionary potential. These changes are both coding and CRE changes as they modify the protein while representing changes in gene expression. Some examples were already shown to have phenotypical implications, such as the *Edaradd* gene in mammals (Sadier *et al.*, 2015) or the BRANCHED1a gene in potatoes of which a new isoform controls the potato plant's architecture (Nicolas *et al.*, 2015).

Although the debate about the primacy of coding versus CREs change in morphological evolution remains, more and more studies are emerging view this question as a reductionist approach while recognizing its interest to identify such changes (Orgogozo *et al.*, 2015). As both coding and CREs are important players in morphological evolution, future syntheses would benefit from integrating all levels of interaction between developmental genes and the multiple environmental variables that interact to create phenotype.

Reinforcement

R Hopkins, The Arnold Arboretum of Harvard University, Harvard University, Boston, MA, USA

Glossary

Allopatry Describes two organisms or species living or growing in two separate geographic areas.
Post-zygotic reproductive isolation A barrier to reproduction that occurs after the formation of a zygote; encompasses hybrid inviability and hybrid sterility.
Pre-zygotic reproductive isolation A barrier to reproduction that occurs prior to the formation of a zygote; encompasses habitat, behavioral, temporal, and mechanical isolation.
Reinforcement The process by which natural selection favors the increase in reproductive isolation (RI) in order to decrease costly hybridization and mating.
Reproductive isolating barrier A mechanism that impedes or prevents the interbreeding of two populations or species.
Sympatry Describes two organisms or species living or growing in the same geographic area.

Introduction

Reinforcement is the process by which natural selection favors the increase in reproductive isolation (RI) in order to decrease costly hybridization and mating. This is one of the important ways in which natural selection can contribute to the process of species formation. Reinforcement involves selection favoring a trait because it causes reproductive isolation. This process is in contrast with the more commonly invoked role of natural selection favoring locally adapted traits that, as a by-product of their primary selected function, happen to cause RI. Reinforcement is often thought of as a multi-step process, which starts with a period of allopatric divergence between taxa allowing for the accumulation of post-zygotic RI. When the two diverging taxa come into secondary contact in sympatry, hybrid mating is either costly, or it produces maladapted or sterile hybrids. This cost to hybridization creates selection for traits that decrease mating between the two taxa.

The History of Reinforcement

The conceptual roots of the theory of reinforcement can be traced back to Alfred R. Wallace and his efforts to explain the role of natural selection in the process of species formation (Wallace, 1889). In fact, historically the process was referred to as the 'Wallace Effect.' Wallace argued that selection should favor the increase of RI in its own right in order to prevent the swamping effects of intercrossing between species.

> It will occur to many persons that, as the infertility or sterility of incipient species would be useful to them when occupying the same or adjacent areas, by neutralizing the effects of intercrossing, this infertility might have been increased by the action of natural selection (Wallace, 1889, p. 173).

Although Wallace's general hypothesis that selection can favor reproductive isolation has been proven correct, the details in the argument have been improved and clarified in the ensuing decades. Specifically, it is now known that reinforcement favors RI mechanisms that act prior to the selective cost of hybridization, i.e., via pre-zygotic RI mechanisms.

During the Modern Synthesis, the notion that selection can favor an increase in RI simply to stop costly hybridization regained popularity. Theodosius Dobzhansky championed this hypothesis and argued for its importance during the process of speciation.

> Where hybridization jeopardizes the integrity of two or more adaptive complexes, genetic factors which would decrease the frequency or prevent the interbreeding would thereby acquire a positive selective value, even though these factors by themselves might be neutral (Dobzhansky, 1940).

In the 1950s, Frank Blair, who studied a hybrid zone of two narrow-mouthed toad species in central Texas, coined the term 'reinforcement.' He observed that these two species had more divergent mating songs in sympatric populations than in allopatric populations and hypothesized that this reinforced species boundaries (Blair, 1955). Blair suggested,

> The argument for reinforcement of isolation mechanisms through selection against hybridization is premised on the hybrids being at a disadvantage in competition with the parental types (Blair, 1955, p. 479).

Since the Modern Synthesis there have been countless studies, across the tree of life, identifying reproductive isolating barriers that likely evolved due to reinforcement. For example, reinforcement caused divergence of plumage color in sympatric populations of the European black and white *Ficedula* flycatchers (Saetre *et al.*, 1997). In allopatric populations, males of the two species have the same plumage color but in sympatric populations their plumage differs. Females in sympatry prefer their conspecific male plumage color and consequently there is less hybridization between species. A wealth of studies on insects has found evidence of reinforcement as well. In particular, *Drosophila* species from across the globe show evidence of greater RI in sympatry than in allopatry. In Australia, *Drosophila* species produce different

sexual pheromones in allopatric and sympatric populations (Higgie *et al.*, 2000). On the African island of São Tomé, sympatric *Drosophila* species have higher post-mating pre-zygotic reproductive isolation than allopatric individuals (Matute, 2010). And, in California, individuals from sympatric populations of *Drosophila* species show stronger conspecific mate preference than individuals from allopatric populations (Noor, 1999). Mammals have also diverged due to reinforcement. Two subspecies of the house mouse hybridize along a thin contact zone from Denmark through the Czech Republic. Mate-choice tests demonstrate that sympatric males prefer conspecifics and mate assortatively at higher rates than do allopatric males (Smadja and Ganem, 2005). This enhanced RI is likely caused by divergence of pheromone production in sympatry. Although less exhaustively studied than animals, plants also show evidence of reinforcement. For example, one of two co-occurring species of *Areneria* in the South Eastern United States has evolved high rates of autonomous self-fertilization, which has consequently decreased heterospecific pollen transfer (Fishman and Wyatt, 1999). The preponderance of studies suggests that reinforcement is widespread and that it is an important mechanism driving the evolution of RI during the process of speciation.

From Pattern to Process – Criteria for Reinforcement

The pattern of greater pre-zygotic RI in sympatry than in allopatry is often associated with reinforcement and therefore has been used to help identify possible examples of the process in nature. Of course, other evolutionary forces, such as local adaptation, can cause similar patterns of divergence so it is important to empirically demonstrate that the pattern is a result of the process. **Table 1** describes four criteria for showing that divergence is caused by reinforcement.

Each of these criteria addresses an important aspect of the reinforcement hypothesis, but rarely are all four investigated. Thoroughly investigating reinforcement is difficult in many systems because hybridization rates are hard to quantify, lifetime fitness is not always possible to assess, and isolating the effect of a single trait on reproductive isolation is challenging. Reinforcement in Texas *Phlox* represents one case study in which all criteria have been met (see **Figure 1**). *Phlox drummondii* has light-blue flower color throughout most of its range; but where it overlaps with the sister species *Phlox cuspidata*, which also has light-blue flower color, *P. drummondii* has dark-red flower color. The pattern of similar flower color in allopatry and different flower color in sympatry is consistent with reinforcement driving flower color divergence (Levin, 1985). A series of studies have investigated the criteria listed in **Table 1** and support the reinforcement hypothesis. Criterion 1 was investigated by performing crosses between the two *Phlox* species and determining that hybrid offspring are largely sterile (Ruane and Donohue, 2008). Multiple experiments have demonstrated that the evolution of *P. drummondii* flower color from ancestral light-blue to dark-red in sympatry decreases hybridization, thus satisfying criterion 2. Specifically, a common garden field experiment including both species of *Phlox* directly measured hybridization under natural conditions and found that dark-red flowered individuals hybridized 50% less than light-blue flowered individuals (Hopkins and Rausher, 2012). Furthermore, pollinator observation experiments showed that butterfly pollinators move pollen less frequently between the two species of *Phlox* when they have different colors than when they have the same color (Hopkins and Rausher, 2012). Results from common garden field experiments, pollinator observations, and population genetic modeling demonstrate that the benefit of reduced hybridization caused by having a dark-red flower color in sympatry outweighs the cost associated with this trait (Hopkins and Rausher, 2014; Hopkins *et al.*, 2014; Hopkins and Rausher, 2012). These studies address criterion 3 by showing that net selection favors the dark-red flower color in sympatry because of its role in decreasing hybridization. Criterion 4 was also tested using the common garden field experiment: other selective pressures that might effect fruit production or survival were quantified and shown to be insignificant (Hopkins and Rausher, 2012).

It remains difficult to prove that reinforcement is the cause of divergence in many species. Nonetheless, additional interesting questions involving the causes and consequences of reinforcement are beginning to be addressed. For example: Does divergence in sympatry cause reproductive isolation with conspecifics in allopatric populations? Is there a cost to reinforcement or does natural selection, or sexual selection, also favor traits under reinforcing selection? What is the genetic basis of reinforcement? Why is divergence due to reinforcement often asymmetric with only one sympatric species showing trait value changes?

Table 1 Criteria for demonstrating that reinforcement is responsible for trait divergence in sympatry

1. Hybridization has a selective cost
   When reinforcement drives the evolution of reproductive isolation, the selective mechanism is the cost of hybridization. Therefore it must be demonstrated that hybridization or hybrid mating is costly.
2. Trait divergence in sympatry decreases hybridization
   Not all divergence in sympatry causes an increase in reproductive isolation; It must be demonstrated that a novel phenotype actually decreases hybridization or mating between sympatric taxa.
3. The decrease in hybridization increases net fitness of individuals with the derived trait
   If reinforcement drives the evolution of trait divergence then individuals in sympatry with the derived trait should have a fitness advantage because of the reduction in hybridization. It should be shown that this reduction in hybridization outweighs any pleiotropic costs.
4. Other evolutionary processes do not explain divergence
   Evolutionary processes such as local adaptation to environmental variation and ecological character displacement can also cause patterns of divergence between allopatric and sympatric populations. It is therefore important to test alternative hypotheses about the mechanism of selection.

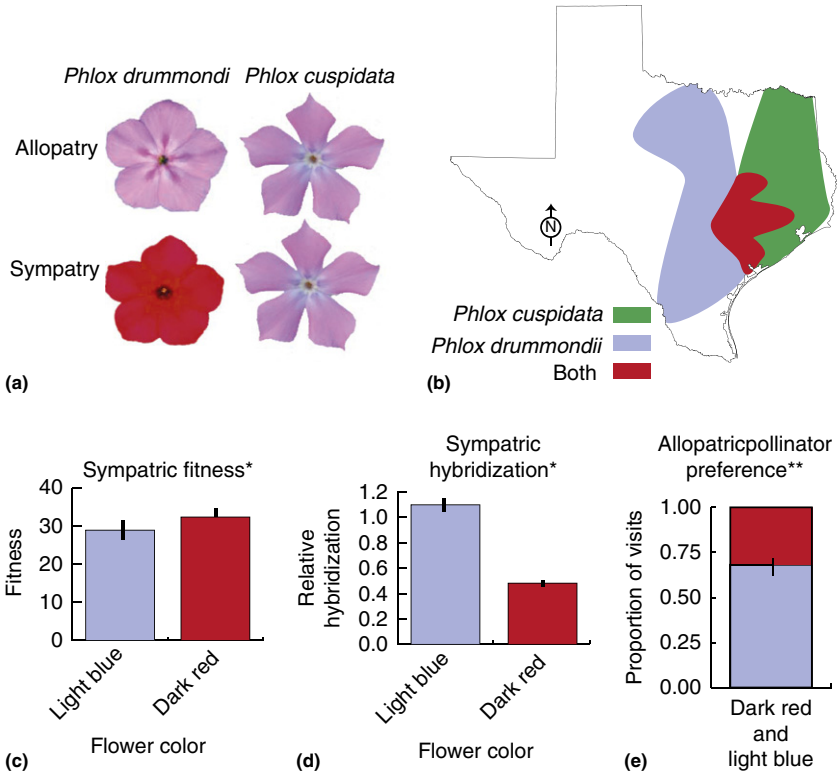

Figure 1 Case study of reinforcement in *Phlox drummondii*. (a) Pictures of *P. drummondii* and *P. cuspidata* flowers from allopatric and sympatric populations. Note the color divergence of sympatric *P. drummondii* flowers. (b) Schematic diagram of *Phlox* range in Texas showing sympatric area (in red) where *P. drummondii* has dark-red flower color. (c) *P. drummondii* fitness estimates from common garden field experiment in the sympatry showing no significant difference between dark-red and light-blue flowered individuals. (d) Relative hybridization rates of dark-red and light-blue flowered *P. drummondii* individuals with *P. cuspidata* showing the advantage of being dark-red in sympatric populations. (e) Pollinator preference for light-blue over dark-red *P. drummondii* flowers in allopatry showing a selective advantage for the ancestral light-blue flower color. * Indicates data derived from Hopkins and Rausher (2012). ** Indicates data derived from Hopkins and Rausher (2014).

Macro-Evolutionary Patterns

Scientists have been investigating reinforcement on a case-by-case basis in order to learn how, when, and why selection favors reproductive isolation. Despite the abundance of research, this strategy gives only a vague notion of the prevalence or importance of reinforcement during the process of speciation. Therefore, researchers have used comparative methods to look for macro-evolutionary patterns of divergence that might suggest the prevalence of reinforcement.

The rich history of empirical investigations of RI in *Drosophila* provided the first comprehensive dataset to evaluate the general importance of reinforcement in speciation. Coyne and Orr used a comparative approach based on the hypothesis that RI between taxa increases as genetic divergence between taxa increases (Coyne and Orr, 1989, 1997). Allopatric taxa are expected to evolve pre-zygotic and post-zygotic RI at equivalent rates with increasing genetic distance, but if reinforcement is acting, sympatric taxa are predicted to have a faster rate of pre-zygotic RI evolution than post-zygotic RI evolution with increasing genetic distance. These studies found strong evidence that pre-zygotic RI evolved faster than post-zygotic RI with increasing genetic distance in sympatric taxa but not in allopatric taxa, and therefore concluded that reinforcement contributed to speciation in *Drosophila*. Most subsequent comparative studies have also found evidence supporting the importance of reinforcement during speciation (Yukilevich, 2012; Grossenbacher and Whittall, 2011; Howard, 1993; Noor, 1997). In general, these studies find evidence of enhanced pre-zygotic RI in sympatric species that likely suffer from costly hybridization.

In the future, these large datasets used to understand the prevalence of reinforcement can also be used to investigate why and how reinforcement occurs. Are there particular groups of organisms more likely to diverge due to reinforcement than other organisms? Does reinforcement affect diversification or extinction rates? Are there particular types of traits that tend to respond to reinforcing selection? There is a wealth of knowledge to be gained from future macro-evolutionary studies of reinforcement.

Reproductive Isolation with Gene Flow

Despite the abundance of studies that suggest the prevalence of reinforcement, the feasibility of the process has been hotly debated. Reinforcement requires RI to evolve between two species that are still hybridizing. Hybridization between species can result in gene flow between the diverging species. Gene flow homogenizes differentiation and thus hybridization

can impede divergence and prevent reinforcement from evolving. Gene flow could cause new alleles conferring increased RI that arise in one species to recombine into the other species. Under this scenario, gene flow breaks down linkage disequilibrium between the alleles causing post-zygotic RI and the new alleles causing pre-zygotic RI. For example, in the *Phlox* system, gene flow could have recombined the derived alleles causing dark-red flower color in *P. drummondii* into *P. cuspidata*. If this had occurred, the two species would, once again, share the same flower color and hybridize.

The idea that gene flow would homogenize differentiation in sympatry led to the hypothesis that reinforcement could not evolve, was very rare, or only occurred if gene flow did not exist between the diverging species (Butlin, 1987). This belief sparked extensive theoretical work investigating the evolutionary conditions under which reinforcement can evolve (reviewed in Howard, 1993; Servedio and Noor, 2003; Kirkpatrick and Ravigne, 2002). The general finding from this body of work is that reproductive isolation can actually evolve in sympatry. Selection does have to be strong compared to gene flow and direct selection due to an ecological advantage can significantly aid the evolution of reinforcement. This theoretical work should stimulate empirical work that actually measures the strength of reinforcing selection and tests the model's predictions.

The Genetics of Reinforcement

The dilemma of reproductive isolation evolving in sympatry has also sparked theoretical work investigating the genetic basis of reinforcement. Specifically, it has been shown that the genetic architecture of the reproductive isolating mechanism can influence the success of reinforcing selection. If a mutant allele increases RI when it occurs in either or both of the two sympatric species, then reinforcement is more likely to be successful. This is referred to as a one-allele mechanism (Felsenstein, 1981). For example, an allele that increases 'choosiness' or reduces dispersal could cause both sympatric species to mate more frequently with conspecifics than heterospecifics. Despite much hypothesizing about the types of traits that could be one-allele mechanisms of reinforcement, it has only actually been identified once. *Drosophila pseudoobscura* individuals that co-occur with *Drosophila persimilis* show a greater reluctance to hybridize than individuals from allopatric populations. The sympatric allele at one locus, *Coy-2*, that increases assortative mating in *D. pseudoobscura*, has also been shown to increase assortative mating when it is occurring in *D. persimilis* as well (Ortiz-Barrientos and Noor, 2005). In other words, the same allele in either species will cause a decrease in hybridization. The one-allele mechanism overcomes the problems associated with gene flow because recombination of the derived assortative mating allele into the sympatric species will increase reproductive isolation instead of decrease it.

Besides some work on genetic architecture of trait variation caused by reinforcement, little is known about the genetics of reinforcement. In fact, *Phlox* is the only system for which the genes involved in reinforcement have been identified. Flower color variation in *P. drummondii* is caused by expression variation in two genes known to be involved in pigment production in flowering plants. Yet even in this case, we know little about the evolutionary history of these genes. Did a single mutation arise once and spread or are there multiple mutations causing the same changes in flower color? Did the alleles causing flower color variation arise under selection or were they segregating in the population prior to the two *Phlox* species hybridizing? Clearly, much more research is needed before we can determine if there are particular genetic or genomic patterns associated with reinforcement.

Future Directions

Unlike some other areas of speciation research, there is a rich history of both theoretical and empirical studies on reinforcement using many species as models. Many of these studies focus on determining whether reinforcement exists. Although it is still important to determine if divergence is driven by reinforcing selection, a growing amount of work is beginning to investigate more nuanced questions about how and why reinforcement occurs.

In order to understand how reinforcement occurs we must learn more about the genetic basis of trait variation caused by the process: What are the genes? What type of mutations? Are the mutations from standing genetic variation or novel mutations?

In order to understand why reinforcement occurs we must learn more about strength of the evolutionary forces acting during the process: How strong is reinforcing selection? How much gene flow is there between sympatric species? How is the cost of hybridization distributed across sympatric species?

Additionally, for many systems it is difficult to identify reinforcement, so determining if there is a genomic signature of reinforcement may aid in our understanding of the prevalence of this process. Answers to these questions will bring us much closer to understanding the role of natural selection in the origin of species.

Reproductive Isolation, Postzygotic

RM Calhoun, RL Kanippayoor, and AJ Moehring, Western University, London, ON, Canada

Glossary

Allopatric speciation Form of speciation, wherein new biological species arise while inhabiting different geographical regions.
Epistasis An interaction between two or more genes.
Gene flow The free movement of genes (or alleles) between populations.
Gene transposition The movement of a gene from one position in the genome to another position in the genome, either on the same or different chromosome.
Polyploidization Whole genome duplication.
Reproductive isolation When individuals from two separate populations are unable to mate and/or produce fit offspring.
Speciation The evolutionary process wherein two separated populations are reproductively isolated from each other and are thus new biological species.
Sympatric speciation Form of speciation, wherein new biological species arise while inhabiting the same geographical region.
X-linked gene Genes located on the X chromosome.

The accumulation of genomic differences between diverging species can cause those genomes to become incompatible with one another. This can eventually lead to the termination of gene flow between those species when their hybridization yields only sterile or inviable offspring (Haldane, 1922; Coyne and Orr, 1989). This evolutionary phenomenon, referred to as postzygotic isolation, is a widespread and severe barrier to interbreeding, which, in the context of speciation, enables diverging species to form and subsequently become maintained as distinct reproductive communities. The prevalence of postzygotic isolation among sexual organisms is owed to the observation that any two species' genomes that evolve independently of one another will, given enough time, acquire genetic changes that interact unfavorably with each other within a hybrid background, causing the hybrids to be dysfunctional in some way (Coyne and Orr, 1997). If these dysfunctions are severe enough, the hybrids are among the first and last progeny for any prospective fusion of evolutionary lineages, allowing the persistence of each species as a unique and distinct type.

Hybrid dysfunction is mediated through either extrinsically and/or intrinsically manifested barriers. For extrinsic barriers, an incompatible genome × environment interaction occurs as a result of hybrids being phenotypically intermediate between divergent ecological optima (Grant and Grant, 1992; Hatfield and Schluter, 1999). Hybrids are competitively unsuited to either parental niche, and comparatively inferior to either parental species' pure offspring. These individuals are then selected against naturally and/or sexually and are eventually removed from the population. For example, among benthic and limnetic forms of stickleback fish, hybrids grow slower in a natural environment than in a lab environment, indicating that extrinsic factors (i.e., resource distribution), not intrinsic factors, are hindering their development in a way that does not seem to affect either parental species (Hatfield and Schluter, 1999, but see Rundle and Whitlock, 2001).

For intrinsic barriers, an incompatible genome × genome interaction results in a failure to form a fully viable and fertile individual (Forejt and Ivanyi, 1974). Male sterility has been observed to occur due to failures during spermatogenesis (e.g., no sperm, aberrant sperm head morphology, immotile sperm), abnormal testes development, failure to transfer sperm, or failure of sperm to survive within a female's reproductive tract (Koref-Santabañez, 1963; Forejt and Ivanyi, 1974; Kulathinal and Singh, 1998; Good *et al.*, 2008; Civetta and Gaudreau, 2015). Female sterility arises as failure of sperm to survive within the reproductive tract of hybrids, and failures in germ-line development (Engels and Preston, 1978; Santibañez *et al.*, 2009). Hybrid dysfunction resulting in inviability has been demonstrated to occur due to cellular errors in mitosis (Sawamura, 1997) and nuclear transport (Tang and Presgraves, 2009). There are certainly additional mechanisms of hybrid sterility and inviability beyond those listed above. The abundance of essential stepwise interactions during reproduction and development ensures that some form of hybrid dysfunction is bound to emerge over time as a consequence of structural (genomic) and/or functional (genic) evolutionary divergence (**Figure 1**).

Structural Genomic Variation and Postzygotic Isolation

From a structural (genomic) perspective, the rearrangement, transposition, and polyploidization of chromosomes are known to be integral players in postzygotic isolation. Indeed, genomic rearrangements are often predictive of reproductive isolation – the more heterokaryotic, the higher the degree of reproductive isolation (Basset *et al.*, 2008; Charron *et al.*, 2014). Chromosomal rearrangements, specifically inversions (inverted segments of the genome), may potentially play a pivotal role in speciation, especially when inversions segregate between a species pair (**Figure 2**). Inversions, such as those that differ between *Drosophila pseudoobscura pseudoobscura* and *Drosophila persimilis*, have been demonstrated to harbor loci for hybrid sterility (Noor *et al.*, 2001a,b). Inverted regions containing genes whose alleles give rise to hybrid sterility may persist due to linkage between the hybrid sterility allele(s) in

 doi:10.1016/B978-0-12-800049-6.00063-9

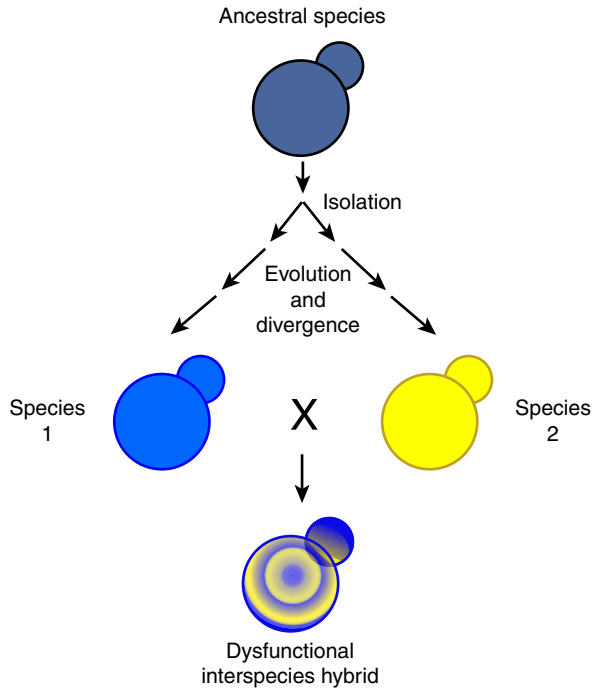

Figure 1 Isolated populations evolve and diverge from one another, eventually forming new species. When these species interbreed, the resulting hybrid offspring is dysfunctional due to divergent loci coming together within a single individual.

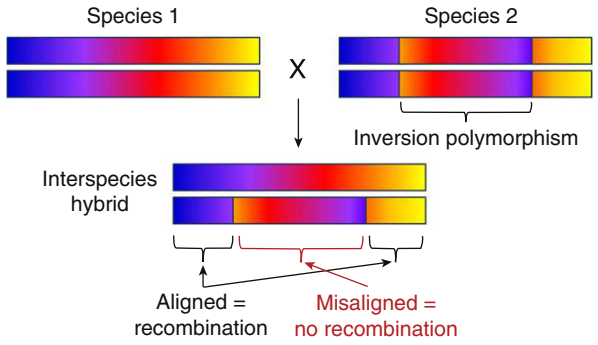

Figure 2 Inversion polymorphisms between species can prevent gene flow for genes that are within the inversion. Regions of the genome that are in the same order (e.g., blue and yellow on ends) can undergo recombination, shuffling the genomes of the two species in subsequent generations, allowing the alleles of one species to potentially be crossed back into the genome of the other species. The inverted region in the middle does not recombine, causing those alleles to be inherited only as a single unit.

either parental genetic background (Noor *et al.*, 2001b). As such, gene flow may occur between the species for those loci that fall within non-inverted regions, allowing selection to purge out any genes that confer hybrid sterility. Conversely, hybrid sterility genes within the inverted regions cannot be purged and persist. Inversions are also capable of triggering adaptive divergence and preventing lineage-defining polymorphisms from being separated by recombination – evolutionary processes that are both potentially capable of snowballing into eventual postzygotic isolation (Kirkpatrick and Barton, 2006; Noor *et al.*, 2001b). Lastly, the inversions themselves can induce meiotic errors, either disrupting or inducing inappropriate recombination leading to hybrid sterility and inviability (Noor *et al.*, 2001a; Zanders *et al.*, 2014). While these models have been shown to influence the speciation process in some species pairs, they do not apply to species that are homosequential and contain the same gene order.

In addition to within-chromosome rearrangements like inversions, other genome modifications have also been demonstrated to affect postzygotic isolation. One such mechanism is gene transposition. For example, the *JYalpha* gene is ancestrally located on the fourth chromosome in the *Drosophila melanogaster* subgroup, but has transposed (moved) to the third chromosome in *Drosophila simulans* (Masly *et al.*, 2006). Later-generation hybrids between *D. melanogaster* and *D. simulans* that possess a homozygous *D. melanogaster* third chromosome and a homozygous *D. simulans* fourth chromosome completely lack a copy of the *JYalpha* gene. These hybrid males produce mostly immotile sperm, suggesting that *JYalpha* influences a hybrid's fitness (Masly *et al.*, 2006).

Another path to postzygotic isolation is whole genome duplication (a.k.a. polyploidization), which is a frequently-occurring phenomenon in plants. These duplication events are capable of forming new species within a single generation (Johnston, 1980; Haig, 1991). This is due to the immediate presence of postzygotic isolation: diploid ($2n$) plants that undergo a genome duplication event (to tetraploid, $4n$) produce only inviable triploid seeds with their diploid ancestor, a phenomenon known as the 'triploid block' (Marks, 1966). The triploid block acts through abnormal development of the endosperm, a specialized ephemeral tissue that supports the developing embryo (Ramsey and Schemske, 1998; Li and Berger, 2012). The endosperm, a product of plant sperm cells (haploid) fusing with the central cell (diploid), ends up with a 2:1 maternal to paternal genome ratio, and any deviations from this ratio (e.g., through interploidy hybridization; Johnston *et al.*, 1980) affects endosperm development. A skew toward an increase in the maternal genome size inhibits the proliferation of the endosperm (Haig and Westoby, 1991; Scott *et al.*, 1998), whereas an increase in the paternal genome results in endosperm excess. This effect suggests that not only is the endosperm sensitive to ploidy imbalance, but the effect of the imbalance is dosage dependent and based on the inherited parental genome. Similarly, imprinted genes can play a role in the dosage-sensitivity of the endosperm, as seen with the paternally expressed *ADM* gene that causes seed abortion when over-expressed in triploid *Arabidopsis* seeds (Kradolfer *et al.*, 2013).

Genome duplication can also lead to postzygotic isolation through the presence of the duplicate copies (paralogs) of every gene in the genome. Either the original or duplicate copy of a gene often becomes nonfunctional, sub-functional, or acquires a new function. In the context of speciation, this can lead to postzygotic isolation if this process differs between two populations (reviewed in Sweigart and Willis, 2012). In the case of two strains of *Arabidopsis thaliana*, early embryo death is seen when there is a loss of function at duplicated copies of the histidinol-phosphate amino transferase genes, *HPA1* and *HPA2* (Bikard *et al.*, 2009). Similarly, within two subspecies of

rice, *Oryza sativa indica* and *Oryza sativa japonica*, pollen from their hybrids cannot germinate as a function of lost alleles for the duplicated genes, *DOPPELGANGER1* (*DPL1*) and *DOPPELGANGER2* (*DPL2*; Mizuta *et al.*, 2010).

Allelic Divergence, Genomic Conflict, and Postzygotic Isolation

From a genic perspective, hybrid dysfunction likely arises due to a genomic conflict that asymmetrically arose (and resolved) in one of the host species genomes but not the other (Hutter and Ashburner, 1987; Coyne and Orr, 2004). When these two genomes come into contact, the underlying conflict is uncovered, resulting in hybrid dysfunction. Thus, hybrid dysfunction arises due to negative interactions between two (or more) divergent genetic loci. If interspecies hybrids do survive and reproduce, it is often the case that hidden recessive incompatibilities will be increasingly unmasked, resulting in the eventual breakdown of the hybrid population. For example, the viability of hybridized cichlid fish degenerates after each generation with the fitness of first filial (F_1) hybrids, decreasing by 43%, and the fitness of F_2 hybrids decreasing by an additional 21% (Stelkens *et al.*, 2015).

Using traditional mapping techniques, several genes have been uncovered that contribute – to some degree – to hybrid dysfunction. Most of the sterility genes have been identified within *Drosophila* (reviewed in Presgraves, 2010). The first hybrid sterility gene to be identified was *Odysseus* (*Ods*), an X-chromosome gene that acts recessively to contribute to the sterility of later-generation male offspring between *D. simulans* and *Drosophila mauritiana* (Perez *et al.*, 1993; Sun *et al.*, 2004). The genetic interactors for *Ods* have yet to be identified, but it is known that its autosomal interactor(s) must also act recessively, and epistatic interactions with other nearby X-chromosome genes are required in order to fully induce hybrid sterility (Perez and Wu, 1995), indicating that the underlying mechanism by which this gene gives rise to sterility is complex.

The X-linked gene *Overdrive* (*Ovd*) was shown to cause both sterility and segregation distortion in F_1 hybrid males from *Drosophila pseudoobscura bogota* females mated to *D. p. pseudoobscura* males, suggesting a possible linked genetic basis between the two processes (Phadnis and Orr, 2009). Since this species pair is young in its divergence time, it can provide insight into the early stages of speciation since it is unlikely to have accumulated a high density of genetic incompatibilities – a dilemma that researchers face in many older species (Matute *et al.*, 2010). It is known that *Ovd* has undergone rapid evolution (Phadnis and Orr, 2009); however, the genes that interact with *Ovd* to give rise to both hybrid sterility, as well as segregation distortion, have yet to be determined. Additional mapping has been employed to identify regions along the X chromosome and autosomes that may interact with *Ovd* to induce hybrid sterility and segregation distortion in this species pair (Phadnis, 2011).

Sterile hybrid males produced from subspecies, *Mus musculus musculus* and *Mus musculus domesticus* have smaller testes and no sperm produced. *Hybrid sterility 1* (*Hst1*), located on chromosome 17, was identified as the region responsible for this spermatogenic failure (Forejt and Ivanyi, 1974; Good *et al.*, 2008). More than three decades later, the *Hst1* region was fine-mapped to the single locus *Prdm9*, which was found to be expressed in both the ovaries and testes of mice (Mihola *et al.*, 2009). *Prdm9* encodes a histone 3 lysine 4 (H3K4) trimethyltransferase, which activates genes that are necessary during meiosis. Null mutations of the *Prdm9* gene in nonhybrid male and female mice result in the arrest of spermatogenesis and oogenesis. Furthermore, sterility was rescued in hybrid males using an artificial chromosome carrying a functional *Prdm9* gene (Mihola *et al.*, 2009). To date, there have been no interacting genes identified.

Like hybrid sterility, a number of loci have also been identified that contribute to hybrid inviability. The first hybrid inviability loci to be identified are a pair of interacting genes that rescue male hybrid lethality between two species of *Drosophila*. Mutation of either the autosomal *Lethal hybrid rescue* (*Lhr*) gene in *D. simulans* (Watanabe, 1979) or the X-linked *Hybrid male rescue* in *D. melanogaster* (*Hmr*; Hutter and Ashburner, 1987; Hutter *et al.*, 1990) rescues inviable hybrid males. It was later discovered that lethal hybrid females of this same species pair can be rescued by either a mutation of the *D. simulans* autosomal *maternal hybrid rescue* (*mhr*) gene (Sawamura *et al.*, 1993), or by the *D. melanogaster Zygotic hybrid rescue* (*Zhr*) gene (Sawamura *et al.*, 1993; Sawamura and Yamamoto, 1997).

Using deficiency mapping, two nuclear pore proteins have also been identified as lethality factors in later-generation hybrid males between *D. melanogaster* and *D. simulans*. *Nucleoporin 160* (*Nup160*) and *Nup96* are both autosomal genes that are members of the nuclear pore complex, which serve to traffic molecules between the cytoplasm and the nucleus (Presgraves *et al.*, 2003; Tang and Presgraves, 2009). The *D. simulans Nup* gene, when homozygous, interacts with an as-yet unidentified *D. melanogaster* locus.

Recently, a new mechanism for the evolution of postzygotic isolation emerged in the study of hybrid yeast. Here, recessive genetic incompatibilities between the hybridized genomes of *Saccharomyces cerevisiae* and *Saccharomyces bayanus*, affect spore viability (Greig *et al.*, 2002). A recessively acting nuclear gene located on chromosome 13 of *S. bayanus*, AEP2, affects the translation of an *S. cerevisiae* ATP synthase subunit mitochondrial gene, OLI1 (Lee *et al.*, 2008). Specifically, AEP2 does not properly function alongside the mitochondria of *S. cerevisiae*, leading to defects during mitochondrial respiration and ultimately spore inviability. This provides evidence that, in addition to nuclear–nuclear interactions, hybrid dysfunction may also arise from nuclear–mitochondrial gene incompatibilities.

Meiotic Drive and Postzygotic Isolation

At its inception, meiotic drive was largely criticized but has regained some popularity due to compelling evidence put forward in the last few years (review in McDermott and Noor, 2010). Generally, meiotic drive is the phenomenon wherein unequal segregation of chromosomes or alleles during meiosis allow for the overrepresentation of that element within a population or species. Drivers (or selfish elements) arise as a

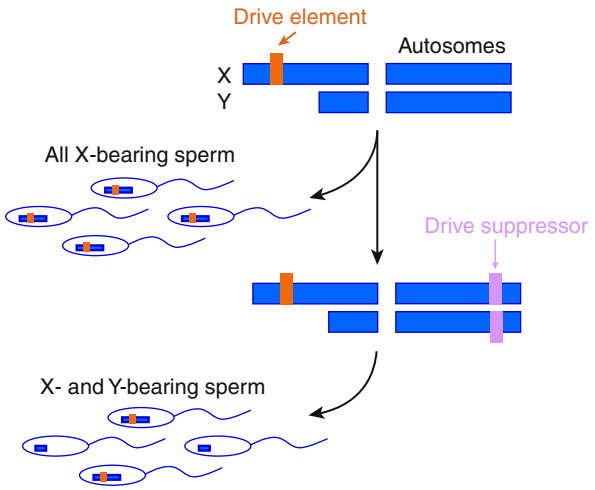

Figure 3 Meiotic drive leading to sex ratio skew. A meiotic drive element (orange) on the X chromosome causes all sperm to be X-bearing, and thus all resulting offspring to be female. A suppressor element that inhibits the drive element eventually arises on the autosomes, returning the offspring sex ratio back to normal.

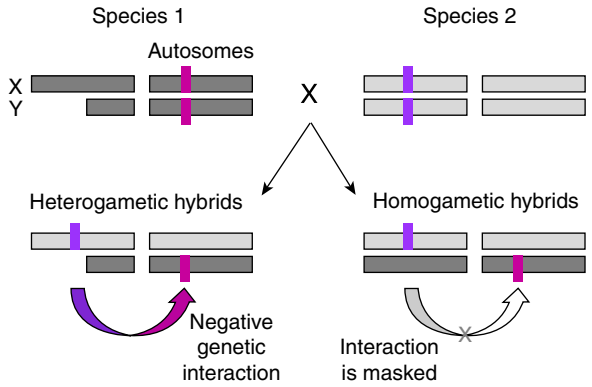

Figure 4 Dominant interactions and Haldane's Rule. A recessive allele from Species 2 on the X chromosome (purple) has a negative interaction with a dominant allele from Species 1 on the autosomes (pink) when placed together within a heterogametic (XY or ZW) individual, leading to hybrid dysfunction. The recessive allele on the X chromosome is masked by its corresponding homolog when it is instead within a homogametic individual, preventing hybrid dysfunction from forming.

means to increase the presence of that selfish element within the next generation. Drivers on the X chromosome may compete during the course of sperm development, leading to deviations from the normal representation of X- and Y-bearing sperm (Figure 3). A lack of Y-bearing sperm produced during spermatogenesis will affect the sex ratio within subsequent generations, which is detrimental for the population. As such, suppressor elements evolve (usually on autosomes; Hurst and Pomiankowski, 1991) to counteract the effects of these selfish elements. Separated populations will likely evolve unique sets of drivers and suppressors. If individuals from these two populations mate and produce offspring, a mismatch between drivers and suppressors will cause hybrid dysfunction to occur. To date, many lines of evidence have provided links between chromosomal drive and hybrid sterility, but there has yet to be any link for hybrid lethality (reviewed in McDermott and Noor, 2010).

Haldane's Rule

Despite the myriad means postzygotic isolation may come about, there is nonetheless a widespread consistency as to which sex these incompatibilities arise in first. This principle, known as Haldane's rule, states: "When in the F_1 offspring of two different animal races one sex is absent, rare, or sterile, that sex is the heterogametic sex" (Haldane, 1922). Thus hybrid dysfunction is expected to occur first among the XY or ZW bearing sex of the species before their homogametic counterpart (Coyne, 1985). Additionally, the 'large X effect,' another sex chromosome centric pattern, notes that the contributions of the X chromosome to postzygotic isolation between species are disproportionately larger than their autosomal partners (reviewed in Presgraves, 2008). Studying the genetic basis of speciation via sex chromosomes has been governed by both the interaction between the X and Y chromosomes (Haldane's rule) and the clearly 'large X effect' exhibited by the X chromosome (Coyne, 1985, 1992; Coyne and Orr, 1989; Charlesworth *et al.*, 1987; Masly and Presgraves, 2007). It is obvious that the sex chromosome plays an integral role during speciation (Masly and Presgraves, 2007; Presgraves, 2008), and explanations of how this effect entangles with Haldane's rule is currently addressed by two primary theories.

Genetic Incompatibilities and the Dominance Theory

The issue of how species can accumulate differences that do not negatively interact with their own genetic background, but are nonetheless deleterious in a hybrid background, has been addressed by the Bateson–Dobzhansky–Muller incompatibility (BDMI) model (Bateson, 1909; Dobzhansky, 1934; Muller, 1940). In this model, each species acquires a new non-deleterious allele at a different genetic locus, and thus these alleles are able to sweep to fixation within their respective local populations. However, while each of these new alleles on its own is not deleterious, they do not interact well with one another, giving rise to dysfunction when in contact within an interspecies hybrid. Over time, additional loci that would have a negative epistatic interaction within a hybrid are likely to arise.

The Dominance theory has been proposed to explain how these incompatible genetic factors within hybrids could explain the trend noted by Haldane's rule. In the simplest form of the Dominance theory, hybrid sterility and inviability are the result of an incompatible interaction between one or more recessive X-linked factor(s) and one or more autosomal-linked factors (Figure 4; Orr and Turelli, 1996). For two species able to produce a hybrid male (XY), the X-chromosome is inherited from one species (e.g., Species A), whereas one set of autosomes is inherited from both species (Species A and B). An improper interaction (BDMI) between the recessive X-linked gene(s) of Species A and the autosomal gene(s) of Species B affects the male's development, rendering it sterile or inviable. Alternatively, hybrid females (XX) do not suffer from the same fate, as they inherit an X-chromosome from both parental

species, thus allowing the recessive X-linked gene(s) of Species A to be masked by the X-linked gene(s) of Species B. This prevents (or at least reduces) the interaction between foreign genomes of Species A and Species B, enabling hybrid female development to occur without the emergent compromises to fertility or viability present within hybrid males.

While the Dominance theory is conceptually robust, over the past few decades, geneticists working toward the identification of speciation genes have encountered controversial and sometimes conflicting data that have muddied the predictive and explanatory powers of the Dominance theory as originally presented, particularly as an explanation for hybrid sterility (Perez *et al.*, 1993, 1995; Presgraves *et al.*, 2003; Masly *et al.*, 2006; Tang and Presgraves, 2009; Presgraves, 2010). Part of the difficulty in resolving the theory is the paucity of loci that have been identified as contributing to hybrid dysfunction in the first generation, as most of the loci that have been identified can only act in later-generation hybrids. Additionally, given that genetic incompatibilities between species continuously accumulate over time, there currently exists no obvious and easy means of determining (1) the sequence and types of barriers as they arose and (2) their relative contributions to isolation (if at all). The second question is particularly important as barriers that arise after total speciation has been achieved are redundant and bear no impact on species formation or maintenance (Orr, 1995; Matute *et al.*, 2010).

Postzygotic Isolation Contributing to Increased Behavioral Isolation

Geographically, postzygotic isolation is expected to occur in any allopatric scenario if given enough time for divergence (Coyne and Orr, 1997). However, if contact is resumed between incipient species, partial postzygotic isolation may accelerate speciation in an evolutionary process referred to as reinforcement (Dobzhansky, 1975). In this scenario, selection against matings that would produce hybrids occurs as a means of preventing the production of these unfit offspring. For example, hybrid males produced between two species of chorus frogs have reduced fertility, and these males also experience reduced acceptance by courted females, resulting in a fourfold greater reduction to gene flow than would result from reduced fertility alone, reinforcing the isolation between the two species (Lemmon and Lemmon, 2010). Reinforcement appears to be prevalent among sympatrically diverging species, often leading to earlier-occurring and stronger reproductive isolation (Coyne and Orr, 1997).

Reproductive Isolation, Prezygotic

MG Ritchie, University of St Andrews, St Andrews, UK

Glossary

Allochronic isolation Reproductive isolation arising due to differences in the timing of reproduction between two nascent species.

Assortative mating The tendency of individuals to mate with similar individuals, particularly of the same species.

Crossbreeding Matings between individuals of two nascent species; synonymous with interbreeding or intercrossing.

Gametic isolation Reproductive isolation arising due to interactions between the gametes of nascent species (for example, less efficient fertilization of ova by sperm of the other type).

Mechanical isolation Reproductive isolation arising due to differences in the shape of male and female genitals between two nascent species.

Pollinator isolation Reproductive isolation arising due to differences in the pollinators used by nascent species.

Prezygotic isolation Reproductive isolation arising due to any factor which reduced the opportunity for sperm and eggs of nascent species to meet and fuse.

Reinforcement The exaggeration of sexual isolation between nascent species in order to prevent the production of deleterious hybrids.

Reproductive character displacement The exaggeration of sexual isolation between good species in order to prevent the production of deleterious hybrids, usually due to increased divergence in mating traits and preferences in sympatry.

Sexual isolation Decreased sexual attractiveness between potential mating partners of nascent species.

Sexual selection Selection arising due to differences in mating success.

Prezygotic Isolation

Reproductive isolation represents a breakdown in the ability to reproduce successfully with sexual partners of another type of organism, and speciation requires a build up of reproductive isolation between diverging types of organism until gene flow is sufficiently rare or ineffective that the entities are considered 'good species.' Traditionally this was thought to require complete or near complete cessation of gene flow, though increasingly absolute reproductive isolation is thought to be too stringent a criterion (Mallet, 1995; Wu, 2001). Factors which influence prezygotic isolation are those that come into play before gametes of the different types meet and form zygotes. After this point postzygotic isolation occurs, and this simple classification of categories of reproductive isolation based on pre- and post-gametic fusion has been widely adopted since Dobzhansky originally categorized major factors influencing the origin of species into various 'reproductive isolating mechanisms' (Dobzhansky, 1937). However, it is important to appreciate that all factors influencing reproductive isolation act in combination. If cross-matings between males and females of different types are half as likely as within types we say their isolation index (I) is 0.5. If the viability of their offspring is also around 50% these are equally effective barriers to gene flow, and acting together will produce a combined I of 0.75, though prezygotic isolation will have made a greater contribution to the overall isolation only because it occurs first (Coyne and Orr, 2004).

Causes of Prezygotic Isolation

Many aspects of an organism's ecology, breeding system, and behavior will influence the potential for crossbreeding, and these will diverge under the influence of a wide range of sources of natural and sexual selection, as well as historical contingencies. Courtship behaviors of animals and pollination strategies of plants are probably the most obvious and widely researched factors influencing prezygotic isolation, but it is important to appreciate that these occur within a much broader context of divergent ecological adaptations.

Allopatry, the occupation of geographically disjunct locations, will inevitably stop the opportunity for crossbreeding. While it is trivial to say that few African and Asian elephants have the opportunity to crossbreed due to their historical biogeography, smaller-scale changes in spatial or temporal distribution provide an important setting for evolutionary divergence due to reduced potential for crossbreeding. Plants will adapt to different habitats, for example, occupying wetter versus drier regions of a landscape, or specialize to different regions of altitudinal gradients. If pollen dispersal is restricted between these habitats, some prezygotic isolation will inevitably follow (see later description of *Anthoxanthum*). Phytophagous insects which feed upon such plants, or lay eggs in their fruit within which larvae develop, may also start to show assortative mating. This is the statistical tendency for like-with-like matings to be more common, and need not be due to mate choice, so if mating takes place on or around the preferred plant, assortative mating can arise without any divergence in courtship behaviors. A famous example of this (because it played an important role during debates about the probability of sympatric speciation) is the fruit fly *Rhagoletis* (Dambroski *et al.*, 2005). Even if there is free migration between habitats but migrants perform less well in one habitat, statistically this will lead to a form of assortative mating due to 'immigrant inviability,' and a particularly well-worked recent example of this is provided by the walking stick *Timema*

 doi:10.1016/B978-0-12-800049-6.00064-0

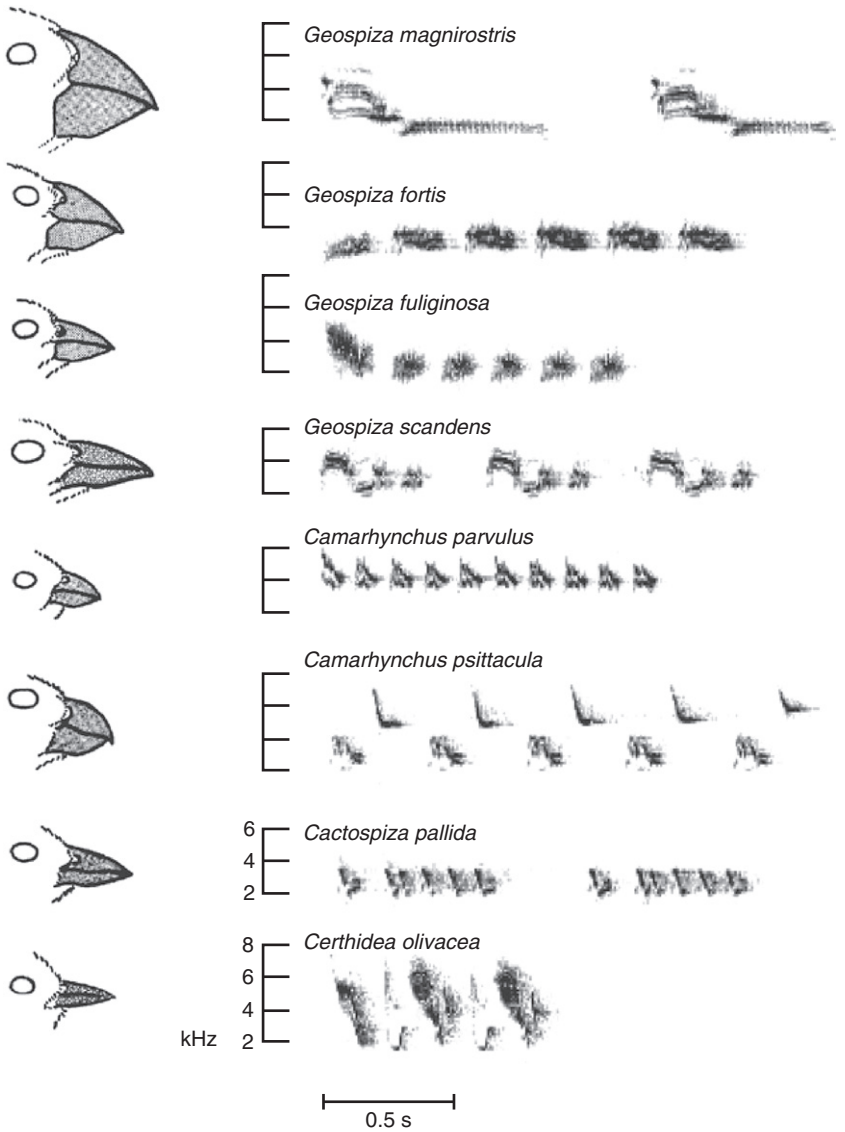

Figure 1 Beak morphology and song spectrograms from eight species of Darwin's finches. Interspecific variation is evident in both morphology and song structure. Birds with larger, more cumbersome beaks tend to produce songs with lower rates of syllable repetition and with more narrow frequency ranges. Reproduced from Podos, J., Nowicki, S., 2004. Beaks, adaptation, and vocal evolution in darwin's finches. Bioscience 54, 501–510, with permission from Oxford University Press.

(Nosil, 2004). Any system of ecological specialism which leads to a reduction in mating opportunities between individuals with different specializations may lead to pre-mating isolation as an indirect consequence of ecological or habitat divergence. Indeed, the traditional division of prezygotic isolating factors into different subcategories (e.g., temporal, ecological, sexual, pollinator) could all be seen as simply different forms of ecological specialization (Sobel *et al.*, 2010; Nosil, 2012).

There are now several examples where the potential relationship between ecological selection, assortative mating, and prezygotic isolation has been investigated. Different ambient light environments in water can select for different colors and color preferences in stickleback, and lead to assortative mating (Boughman, 2001). The extent to which ecological specialization will directly affect prezygotic isolation depends on how strong a functional link there is between biological features selected upon by the ecology and those which influence assortative mating. A classic example of ecological selection, specialization, and speciation is that of Galapagos finches adapting to specialize on different forms of seed, which alters beak morphology. Each species of Galapagos finch has a different song (**Figure 1**) and there is a relationship between beak morphology and song structure even within bimodal populations (Huber and Podos, 2006). Because song in turn influences female mate choice, there is a route where ecological specialization could link to assortative mating (Podos and Nowicki, 2004). A more direct link is provided by the mimetic wing patterns of *Heliconius* butterflies. Mimicry patterns diverge under ecological selection – in this case selection due to Mullerian mimicry – but as these wing patterns also influence

mate choice, assortative mating would directly follow wing pattern divergence (**Figure 2**; Merrill *et al.*, 2012, 2014). Theoretical studies have demonstrated that such exceptional functional linkage can more rapidly produce speciation by prezygotic isolation (Smadja and Butlin, 2011), and such traits have sometimes been called 'single gene' traits because of probable pleiotropy underlying their genetic control, or even 'magic traits' (Servedio *et al.*, 2011). If different traits involved in adaptation and assortative mating are caused by independent genes, the evolution of prezygotic isolation may be more difficult because selection would have to create strong associations between these genes, for example, by genetic linkage (Felsenstein, 1981; Gavrilets, 2003; Smadja and Butlin, 2011).

Although there are a multitude of ways in which ecological adaptation could influence assortative mating, two aspects of ecological specialization deserve special mention, both because of their likely importance, but also because they provide fantastic examples of adaptation and speciation.

Allochronic Isolation

When an organism chooses to breed can be as important to prezygotic isolation as where or how an organism reproduces. Divergence of flowering time in plants is a widespread cause of reduced gene flow between diverging species. The grass *Anthoxanthum* has adapted to heavy metal polluted soil around mines in wales, and differences in flowering time have evolved between adjacent populations. Reduced potential for cross-pollination due to this restricts gene flow by almost 50% (I = 0.46) between populations adapted to polluted soil from unadapted meadow populations. Remarkably, a series of studies show that these patterns have remained stable for around 40 years (**Figure 3**), strongly suggesting that these are maintained by a balance between selection against hybrids and gene flow (Antonovics, 2006). In animals, breeding period can also greatly reduce gene flow. One of the most spectacular examples of temporal isolation in insects is the periodical *Magicicada* cicadas of North America (**Figure 4**). Different broods of these cicadas emerge synchronously from their underground larval stage as adults in dramatic numbers, and it is thought that predator satiation is one of the most important selective factors favoring co-emergence. In different geographic regions broods appear in different years. Periodical cicadas have the longest life cycles of insects and different broods have life cycles based on prime numbers of years, and two well-studied species groups emerge either every 13 or 17 years. Sympatric broods of these types would therefore only have the opportunity to hybridize once every 221 years. Remarkably, following some detailed detective work, it has been demonstrated that a relatively newly described 13 year species *Magicicada neotredecim* seems to be derived from a brood of the 17 year species *Magicicada septendecim*, which 'accelerated' its life cycle to emerge synchronously with a local 13 year brood of *Magicicada tredecim*, so changes in the periodicity of the life cycle can occur, and will allochronic isolation between *M. neotredecim* and its ancestor (Simon *et al.*, 2000; Cooley *et al.*, 2001). Could these changes occur due to developmental plasticity, or could they provide an example of a major change in prezygotic isolation due to only a key change in a single gene or a gene regulatory network? While the mechanisms of life history divergence in cicadas will be extremely challenging to work out, phylogeographic studies suggest that changes in

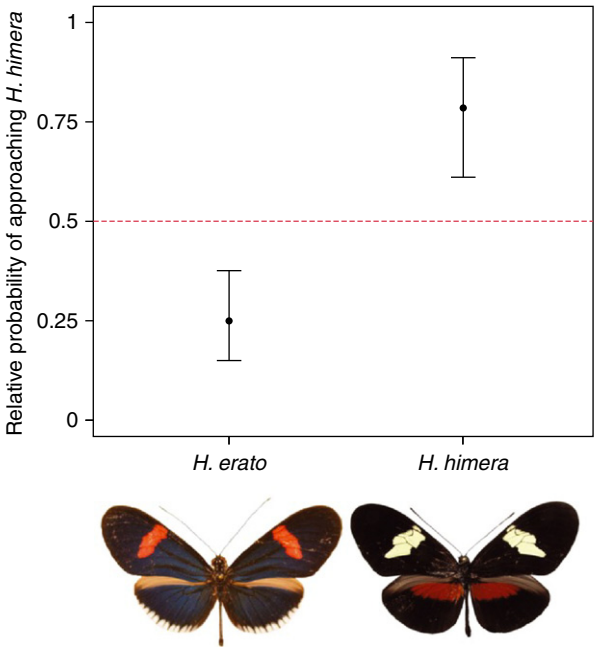

Figure 2 The relative probability of approaching *Heliconius himera* mounted females by *Heliconius erato cyrbia* and *H. himera* males (below left and right, respectively), where one would indicate a complete preference for *H. himera* and zero a preference for *H. erato cyrbia*. Dashed red line represents a relative probability of 0.5 (i.e., no preference). Reproduced from Merrill, R.M., Chia, A., Nadeau, N.J., 2014. Divergent warning patterns contribute to assortative mating between incipient Heliconius species. Ecology and Evolution 4, 911–917, with permission from John Wiley and Sons.

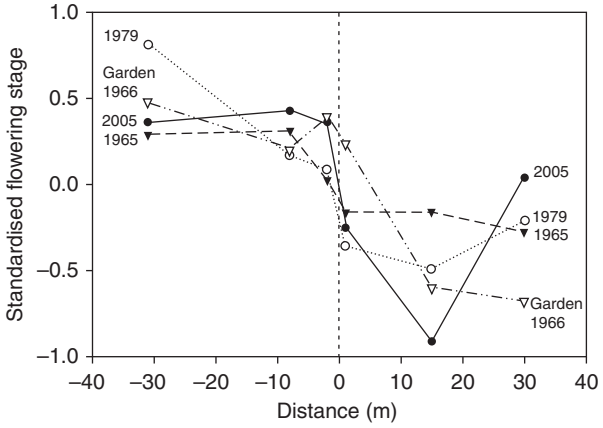

Figure 3 Mean flowering stage at specific transect positions across the mine boundary (at '0') of *Anthoxanthum odoratum* in 1965, in common garden conditions in 1966 and in the field in 1979 and 2005. Results are remarkably consistent across this time period. Reproduced from Antonovics, J., 2006. Evolution in closely adjacent plant populations x: Long-term persistence of prereproductive isolation at a mine boundary. Heredity 97, 33–37, with permission from Nature Publishing Group.

life cycle have occurred several times, favored by selection for co-emergence (Sota *et al.*, 2013). Less spectacular examples of allochronic isolation are more amenable to genetic investigation, and do suggest that allochronic isolation has the potential to be influenced by a changes in a few key genes. Diurnal mating periods differ between closely related species of *Drosophila* and therefore potentially cause assortative mating (Sakai and Ishida, 2001). Diurnal cycles and other aspects of behavioral and physiological rhythmicity of flies are regulated by only a few 'clock' genes, and moving *period*, one such clock gene, between different species of flies can change their diurnal pattern of mating activity. *Drosophila melanogaster* flies carrying the *period* gene of *Drosophila pseudoobscura* show a *D. pseudoobscura*-like activity cycle, being more active at dusk rather than dawn. Interestingly, such *D. melanogaster* flies show assortative mating in the laboratory with respect to the origin of the introduced gene (*melanogaster* or *pseudoobscura*), probably due to associated changes in sensitivity to different behavioral rhythms (Tauber *et al.*, 2003), providing an experimental example of how a change in a key clock gene could influence prezygotic isolation.

Pollinator Isolation

If plants evolve to utilize different pollinators, prezygotic isolation will build up due to reduced cross-pollination (Grant, 1981). A spectacular example of such divergence is provided by the monkeyflowers *Mimulus cardinalis* and *Mimulus lewissii*, which are pollinated by hummingbirds and honeybees, respectively. Changes in floral morphology associated with attraction of and pollination by these distinct pollinators seems to show relatively simple segregation and early studies mapped some large effect quantitative trait loci for these floral differences (Bradshaw *et al.*, 1995). Introgression of a single one, effecting floral color, between species changed patterns of pollinator visitation (Bradshaw and Schemske, 2003). Ramsey *et al.* (2003) examined components of reproductive isolation between these species in the field and found that cross-pollination hardly ever occurred. Both ecological differences and pollinator isolation were the most important forms of isolation, though pollinator effects were almost sufficient to provide complete isolation where plants coexisted. Orchids are a famous example of insect pollination (Darwin, 1877) and many species are sexually deceptive with morphology and chemical cues 'fooling' insects into attempted copulations with the flowers. Whitehead and Peakall (2014) neatly demonstrated that high (>90%) levels of prezygotic isolation between sympatric *Chiloglottis* orchids was due to variation in attractive volatile compounds present on the flowers. Genetic analysis failed to find any introgression between the species in the field, yet forced crosses between them showed hybrid vigor. Hence, once more, the prezygotic isolation due to pollinator specialization seems to be the primary cause of speciation in the field. However, the extent to which prezygotic isolation is a cause or effect of such specialization is an important question, but hard to disentangle from such studies.

Sexual Isolation in Animals

Of all the features of organisms that can influence prezygotic isolation, the most studied and debated is sexual isolation in animals. Put simply, the most obvious reason why animals fail to crossbreed is because males are less likely to court females of another species, and females should be even less likely to accept the courtship of heterospecific males. It is striking that elaborate male courtship displays and morphologies can show dramatic divergence between closely related species (Darwin, 1871). Controlled quantitative comparative studies suggest that speciation rate is higher in lineages in which sexual selection might be heightened, such as those with more polygamous mating systems or showing higher sexual dimorphism. However, such evidence is not especially strong (Kraaijeveld *et al.*, 2011). There is more convincing evidence that sexual selection may act alongside ecological adaptation, as discussed earlier for some mating traits (Ritchie, 2007; Maan and Seehausen, 2011).

There are broadly two ways in which mating behaviors may diverge and cause prezygotic isolation, due to sexual selection operating within a species, or due to direct selection for prezygotic isolation. Sexual selection is a very prevalent force in animal evolution. In a typical mating system, male–male competition and female mating preference can act strongly on male morphology and behavior to produce elaborate courtship traits which help to outcompete other males or to induce females to mate (Andersson, 1994). Genomic comparisons show that sex-biased genes evolve more quickly between species, probably due to sex-specific selection including sexual selection (Ellegren and Parsch, 2007), and considerable progress is being made in identifying the genetic changes

responsible for sexual isolation in model organisms such as *Drosophila* (Chertemps *et al.*, 2007; Fan *et al.*, 2013). One of the superficially simplest ways in which sexual selection might lead to rapid differences of traits and preferences between populations is the dynamic coevolution of female preferences and male traits that is thought to occur due to potential 'Runaway Selection' (Fisher, 1958; Lande, 1981; Andersson, 1994). If traits evolve together in different directions in different populations, it is widely expected that assortative mating will arise as an indirect consequence of this form of sexual selection (Lande, 1982; Uyeda *et al.*, 2009). At one level, this seems obvious if traits and preferences change in a coordinated manner due to coevolution, then mismatches between males and females from different areas of the (phenotypic or geographic) distribution should lead to assortative mating (floral morphology reflecting differences in pollinator shape, such as moth probosces and floral tube length may be a loosely analogous pre-fertilization barrier in plants). However, enhanced sexually selection may not always increase speciation rates. Increased male–male competition may lead to a diminution of the importance of female preferences, increasing gene flow (Parker and Partridge, 1998). In a particularly interesting model, Servedio and Burger (2014) found that when species make secondary contact following allopatric divergence of traits and preferences, strong female preferences can actually inhibit divergence even when male traits are under some ecological selection. This happens because introgression of strong preference genes across hybrid zones can lead to greater effective gene flow because they enhance the mating success of males with the locally maladaptive trait. These males have a relatively high reproductive success simply because of the presence of these females, due to immigration. The authors argue that the role of the runaway or coevolutionary models of sexual selection in speciation is overestimated and that other forms of selection on male traits and female preferences must be more important. Females are under selection to choose with the best males available, which may be those with the most elaborate traits if they are condition dependent, therefore providing reliable indicators of male genetic quality, or more simply to gain proximate rewards or reduce costs of mating. Potentially more complex processes incorporating condition-dependent signaling of local adaptation, again linking sexual isolation with ecological or habitat selection, may be more effective (van Doorn *et al.*, 2009).

Another way in which sexual isolation could evolve quickly in animals (and preygotic isolation in plants) is under direct natural selection to avoid the production of interspecific hybrids. If postzygotic isolation were complete, there would be strong natural selection to favor increased assortative mating to prevent gamete wastage and other potential costs of cross-mating. We have seen earlier that the periodical cicada *M. septendecim* accelerated its life cycle to produce the 13 year *M. neotredecim*, which gained protection by co-emergence with *M. tredecim*. However, this also created the opportunity for hybridization between these two now co-emerging species. The mating system of cicadas is dominated by the characteristic loud calls of males and *M. neotredecim* has evolved a change in fundamental song frequency which distinguishes its song from that of *M. tredecim* in sympatry (Marshall and Cooley, 2000). This is a nice example of reproductive character displacement, an increase of isolation mechanisms where species overlap geographically (though in the case of *Magicicada* the source of selection against crossbreeding is not entirely clear (Cooley *et al.*, 2006)).

More contentious than reproductive character displacement is whether prezygotic isolation can increase if postzygotic isolation is not complete, in the face of ongoing gene flow between forms with partially unfit hybrids. In other words, could prezygotic isolation evolve in order to prevent the production of partially fit hybrids? This idea, usually termed 'Reinforcement' and credited to Alfred Russell Wallace, has proven to be remarkably controversial (Howard, 1993; Butlin, 1995; Noor, 1999; Servedio and Noor, 2003) (unfortunately, the terms reinforcement and reproductive character displacement are not always used consistently, but the key issue is distinguishing the evolution of prezygotic isolation in the face of gene flow versus increasing assortative mating between 'good species' (how to phrase this relies on cross-referencing?)). The controversy arises because (like sympatric speciation) it requires reproductive isolation to build up and become complete against the countervailing effects of gene flow and recombination breaking down associations between genes that underlie assortative mating and postmating isolation. Current consensus seem to be that such reinforcing selection can be successful in both animals and plants, but that this is relatively less important than intraspecific selection due to sexual selection or pollinator competition.

Mechanical Isolation

If males and females of different animal species do meet and attempt to copulate, there can be an additional barrier to insemination. Often the most dramatic sexually dimorphic differences between animal species are male genitalia, and correctly identifying many closely related insect species may require an intimate knowledge of male genital shape. Almost 200 years ago the 'Lock and Key' hypothesis proposed that male and female genitalia correspond in shape in order to prevent hybridization (Dufour, 1844; Shapiro and Porter, 1989; Masly, 2012). Detailed studies show complex morphological interactions occur between male and female genitalia during copulation (Jagadeeshan and Singh, 2006). However, as with sexual isolation, there are several reasons why dramatic changes in genital shape are thought not have evolved primarily in order to cause prezygotic isolation, but rather under intraspecific sources of selection such as sperm competition or antagonistic sexual interactions. Male–male competition may commonly drive genital shape, with males competing for strategic placement of sperm in the female reproductive tract or overcoming female reluctance to mate (Arnqvist, 1998; Eberhard, 2004). The remarkable corkscrew morphology of the male duck penis and female reproductive tract may arise as a counter-strategy to coercive mating (Brennan *et al.*, 2010), and detailed analyses of coevolution of genital morphology of waterstriders have suggested that sexually antagonistic selection may predominate in their evolution (Arnqvist and Rowe, 2002). A bizarre recent discovery of a group of Brazilian cave insects where females have intromittent organs, and these differ between species, seems to have arisen due to genitalic sex-role reversal following

behavioral sex-role reversal (Yoshizawa *et al.*, 2014). However, there are one or two potential examples of reproductive character displacement for genital shape (e.g., Hollander *et al.*, 2013), so interspecies interactions is one potential source of selection on genital morphology. Also, it has been suggested that the importance of genital differences of animals to prezygotic isolation may be underappreciated if the differences are sensory, such as tactile, rather than simply differences in physical structures (Coyne and Orr, 2004). Finally, it could be extremely difficult identifying the precise role of genital divergence in the evolution of prezygotic isolation, because strong mechanical incompatibilities would presumably exert strong selection for rapid pre-mating isolation on both sexes (heterospecific mating can have strong direct fitness costs, including lethality, for females (Sota and Kubota, 1998; Ting *et al.*, 2014)).

Gametic Isolation

Events occurring after insemination or pollination can still cause prezygotic isolation (sometimes termed PMPZ, for postmating prezygotic isolation). Pollen can germinate less effectively on the styles of other plant species, and pollen tube growth can be slower or blocked by the host flower tissue (**Figure 5**). Such barriers can be remarkably effective, in cross-pollination experiments between the sunflowers *Helianthus petiolaris* and *Helianthus anuus*. Rieseberg *et al.* (1995) showed that there was almost complete isolation even if 1:9 mixtures of homo- to heterospecific pollen was introduced to the styles. The mechanism was unknown, but acted post-germination and pollen tube growth. The evolution of mechanisms of self-incompatibility in plants may predispose some plant species to PMPZ isolation and genes involved in, for example, pollen tube interactions with the female genotypes are being identified (Shimizu and Okada, 2000). In animals there is a very dynamic source of selection post-insemination, with sperm competition, potential cryptic female choice of sperm and antagonistic interactions between male semen components and female reproductive physiology all occurring within this arena. The latter is particularly likely to drive complex coevolution between both intersexual and intrasexual gene interactions within the female reproductive tract. Because cross-mating between diverging populations will be rare, such interactions may not have been subject to consistent selection. The outcomes of rare interactions are hard if not impossible to predict, but almost certainly include less efficient insemination of sperm encountering reproductive tracts they have not previously coevolved with. There is now an abundance of evidence that PMPZ barriers to cross mating are common in animals. Interestingly, there are very few if any examples of alien sperm being more successful, which might be predicted under coevolutionary models of sperm-reproductive tract interactions.

The final step before zygote formation is fertilization. Once more coevolution is a predominant feature of sperm–egg interactions (Frank, 2000) as egg membranes are usually under strong selection to resist deleterious polyspermy, whereas sperm are obviously strongly selected to permeate egg surfaces, and additional features can contribute to rapid evolution of molecules involved in gamete recognition (Palumbi, 2009). A failure to pierce the membrane of eggs from another population may be an important barrier to cross mating between divergent races of *D. melanogaster* (Alipaz *et al.*, 2001), and genes involved in gametic isolation show particularly rapid divergent evolution in marine spawning organisms (Moy *et al.*, 2008). Some form of direct sperm–egg barrier seems to exist in a wide range of organisms (Howard *et al.*, 2009). Their importance to overall prezygotic isolation will depend on the relative strength of other barriers which act earlier in reproduction, so, for example, gametic effects are likely to be most important in wind pollinated plants or those with generalist pollinators, or broadcast spawners.

Relative Rates of Evolution

The relative importance of the various forms of pre- and postzygotic isolation to speciation differs between organisms and ecologies. While there is a general belief that pre-mating isolation may evolve more quickly than postmating incompatibilities in many groups, especially under strong sexual selection in animals, controlled quantitative comparisons of the rate of appearance of pre- and postmating isolation are rare. In sexually dimorphic darter fish, sexual isolation does evolve more quickly than postzygotic isolation (Mendelson, 2003). A quantitative analysis of 19 plant species pairs found several

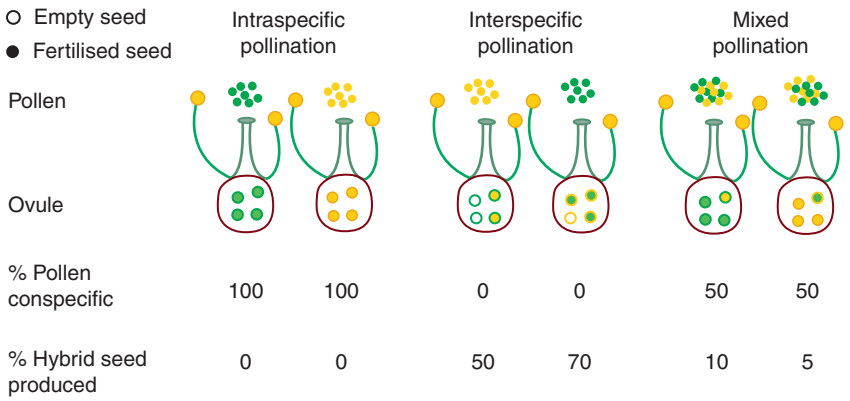

Figure 5 Illustration of PMPZ (postmating but prezygotic isolation) in plants. Reproduced from Baack, E., Melo, M.C., Rieseberg, L.H., Ortiz-Barrientos, D., 2015. The origins of reproductive isolation in plants. New Phytologist 207, 968–984, with permission from John Wiley and Sons.

components of prezygotic isolation were stronger than any hybrid incompatibilities (though the authors only consider homoploid comparisons) (Lowry *et al.*, 2008). The most influential comparative studies were initiated by Coyne and Orr (1989, 1997) who compiled comparative data on pre- and postzygotic isolation scaled by estimates of divergence times from studies of *Drosophila*. These showed two striking patterns. Firstly, there was a broad correspondence between the evolution of pre- and postzygotic isolation, especially in allopatry. However, the second pattern was an accelerated rate of evolution of prezygotic isolation between sympatric species, especially at low levels of genetic divergence. This has been interpreted as evidence in favor of reinforcement of prezygotic isolation (the absence of strong prezygotic isolation between allopatric species of similar divergence implies that sympatry accelerates the evolution of prezygotic isolation). Perhaps most convincingly, asymmetries in pre- and postzygotic isolation follow the pattern predicted by reinforcement (Yukilevich, 2012). For example, if crosses between males of species A and females of species B produce more poor hybrids than the alternate cross, prezygotic isolation is likely to be stronger in this direction. These data provide the most compelling case for the importance of prezygotic isolation in early speciation in animals (Turelli *et al.*, 2014) and the possibility of speciation in sympatry or parapatry (Yukilevich, 2014). Postzygotic isolation will be low in the early stages of divergence, so perhaps additional factors about sympatry such as ecological character displacement also select for assortative mating (note also that all of these estimates of isolation in *Drosophila* are lab-based, so assortative mating could be much higher within natural ecologies). In a related study, Funk *et al.* (2006) showed that ecological divergence is associated with reproductive isolation in a wide range of organisms.

Conclusions

Multiple factors have the potential to influence prezygotic isolation during evolutionary divergence. Most commonly, prezygotic isolation will arise as an indirect response to ecological divergence acting on where, when and how organisms mate, but direct selection on male–female interactions due to sexual selection or antagonistic selection, and pollinator–plant coevolution will also cause prezygotic isolation to evolve. Direct selection for sexual isolation can also occur. We need more comparative studies making controlled comparisons of types of reproductive isolation between species showing a wide range of levels of divergence to assess the relative importance of these different forms of reproductive isolation.

Responses to Climate Change, Evolution and

MW Kelly and B Thapa, Louisiana State University, Baton Rouge, LA, USA

Glossary

Common-garden experiment An experiment in which a number of genotypes are raised in a common environment in order to quantify the genetic component of phenotypic variation.

Phenology Timing of seasonal life-history events, such as reproduction, migration, or emergence from winter dormancy.

Phenotypic plasticity The capacity of one genotype to produce multiple phenotypes when exposed to different environments.

Quantitative genetics The study of continuous traits and the statistical analysis of the relative contributions of genetic and environmental effects on phenotypic variation.

Introduction

Climate change may put as much as 35% of the earth's biota at risk of extinction (Thomas *et al.*, 2004; Maclean and Wilson, 2011). Species in a changing environment can escape extinction through shifts in geographic range, phenotypic plasticity, or evolutionary adaptation (Williams *et al.*, 2008). All three of these processes will probably occur simultaneously in most populations, but initial projections of climate-driven extinction risk focused mainly on changes in the availability of habitat (Thomas *et al.*, 2004), and tended not to incorporate evolutionary thinking. However, recent work has shown that evolution can happen on rapid (ecological) timescales, and could play an important role in rescuing some species and populations from extinction (Bell and Gonzalez, 2009; Hoffmann and Sgrò, 2011; Hendry, 2013; Munday *et al.*, 2013). Studies of evolutionary responses to climate change seek to understand both past responses to climate and the role that evolutionary adaptation might play in increasing species' resilience to the effects of future change.

Evolution by natural selection depends on the presence of heritable variation and selection (variation in fitness). If heritable variation is present, changing climate is expected to drive evolution by altering selection regimes in a variety of ways. Increases in maximum temperatures will favor increased heat tolerance (Somero, 2012), while changes in mean temperatures will favor new temperatures of optimal performance (Higgins *et al.*, 2014). In many terrestrial habitats, climate change will be associated with changes in rainfall patterns (Dai, 2012) favoring increased desiccation tolerance in some taxa (Eads *et al.*, 2012). In many terrestrial species, phenology (the timing of seasonal events) is driven by day length as well as temperature, and so climate change will impose selection on response to day length (e.g., earlier spring emergence) to better match the timing of seasonal events to temperature (Bradshaw and Holzapfel, 2008). Indeed, many studies have documented earlier flowering times (Anderson *et al.*, 2012) and earlier migration and breeding in birds (Charmantier and Gienapp, 2014), but it is also difficult to document whether these represent evolutionary or purely plastic responses. Increased atmospheric CO_2 may also select for increased efficiency of photosynthesis, to take advantage of available CO_2, although there is little evidence that wild populations have actually been able to do this (Collins and Bell, 2006; Leakey and Lau, 2012; but see Grossman and Rice, 2014). Climate change may also select for changes in dispersal patterns, and the ability to take advantage of new patterns of resource availability (Pulido and Berthold, 2010; Buckley *et al.*, 2012; Bridle *et al.*, 2014). Finally, and maybe most importantly, climate change will impose new patterns of selection by altering species interactions (Karell *et al.*, 2011; Gilman *et al.*, 2012; Urban *et al.*, 2012; Herstoff and Urban, 2014). In this article, we will discuss the evidence that species have already evolved in response to climate change and methods for assessing potential for future adaptation.

Retrospective Studies: Responses to Recent Climate Change

Across the globe, species have undergone shifts in phenology and shifts in geographic range. These have now been documented in thousands of species in diverse habitats, and represent a clear global footprint of ongoing climate change (Parmesan, 2006; Chen *et al.*, 2011). But to what extent do observed responses involve evolutionary change? For most traits, an organism's phenotype is the product of both its genotype and its environment, and it can be difficult to disentangle environmental and genetic effects. If a population shows phenotypic change over time in response to a changing environment, that change may be due to adaptation (a change in the genetic makeup of the population in response to selection), plasticity (a change in the phenotypes expressed by the same genotypes in response to different environments) (West-Eberhard, 2003), or both. In order to document that a population has evolved in response to climate change, researchers must be able to show not just that phenotypic change has occurred, but that the change in phenotype was driven, at least in part by a change in the genetic makeup of the population. Relatively few studies have been able to demonstrate conclusively that a change in phenotype observed in response to climate change has a genetic basis (Merilä and Hendry, 2014).

 doi:10.1016/B978-0-12-800049-6.00302-4

Table 1 Methods for assessing past evolutionary change

Approach	*How it works*	*Examples*
Resurrection ecology	For species with seeds or with dormant eggs, researchers rear offspring from past and present populations in a common environment to test for evolutionary change	Rearing seeds from different years in a common environment revealed that an annual plant (*Brassica rapa*) had evolved earlier flowering time in response to a drought (Franks *et al.*, 2007)
Multiyear common garden experiments	Researchers rear organisms under common conditions across multiple years	Between 1972 and 1996, the pitcher plant mosquito (*Wyeomyia smithii*) evolved earlier emergence times (Bradshaw and Holzapfel, 2001)
Animal model analyses	If researchers have pedigree data for the population they are studying, quantitative genetic statistical techniques can be used to estimate the relative contributions of genetic and environmental effects on the trait of interest. If applied through time, animal model analyzes can be used to understand whether the genetic contributions to a trait have changed over successive generations	In a long-term study of laying dates and fitness in great tits (*Parus major*), females varied in the strength of their response to warmer temperatures, and this variation in plasticity was heritable. Furthermore, the degree of plasticity was correlated with lifetime reproductive success, especially in later decades (Nussey *et al.*, 2005)
Molecular genetics	Researchers genotype organisms from the same population over successive generations at molecular markers thought to be tied to climate adaptation	Over 20 years, a cline in the alcohol dehydrogenase polymorphism in Australian *Drosophila* shifted, so that southern populations came to resemble the allele frequencies that had been found in more northern populations 20 years earlier (Umina *et al.*, 2005)

There are several methods for disentangling environmental and genetic influences on traits through time (Table 1). These include resurrection ecology, common-garden experiments replicated through time, quantitative genetic animal model analyses, and the use of molecular genetics to measure changes in allele frequencies through time and space. Below we will discuss three case studies attempting to document evolutionary responses to climate change, each using a different technique: a study of spring emergence times in pitcher plant mosquitoes, a study of breeding date in songbirds, and a study of changing allele frequencies in Australian *Drosophila*.

Emergence Date in Pitcher Plant Mosquitoes

For many organisms in temperate environments, the timing of emergence from winter dormancy is a key component of survival and reproductive success: those that emerge too early may be killed by late spring cold-snaps and those that emerge too late may lose out in the race to acquire resources and mates. The mosquito *Wyeomyia smithii* occurs throughout much of eastern North America, and breeds exclusively in pitcher plant *Sarracenia purpurea* (Figure 1). *Wyeomyia* undergo winter dormancy, and emerge in the spring in response to lengthening days. The day length that triggers emergence varies among northern and southern populations, with longer days required to trigger emergence in northern populations. In the last 40 years, *Wyeomyia* have begun to emerge earlier in the spring, especially in more northern populations. Researchers Christina Holzapfel and William Bradshaw were able to show that this shift was due to a genetic change by rearing mosquitoes under common conditions in the laboratory (Bradshaw and Holzapfel, 2001). Mosquitoes collected and reared in the laboratory in 1996 emerged at a shorter day length than those that had been collected from the same populations and reared under the same conditions in 1972. Common-garden experiments replicated through time in this way can be a powerful method for demonstrating evolutionary change. However, they depend on being able to accurately replicate past experimental conditions in current experiments.

Figure 1 Between 1972 and 1996, the pitcher plant mosquito (*Wyeomyia smithii*) evolved earlier emergence times in response to warming temperatures (Bradshaw and Holzapfel, 2001).

Breeding Date in Birds

A wide variety of bird species are migrating and nesting earlier in the spring in response to warming temperatures, but no

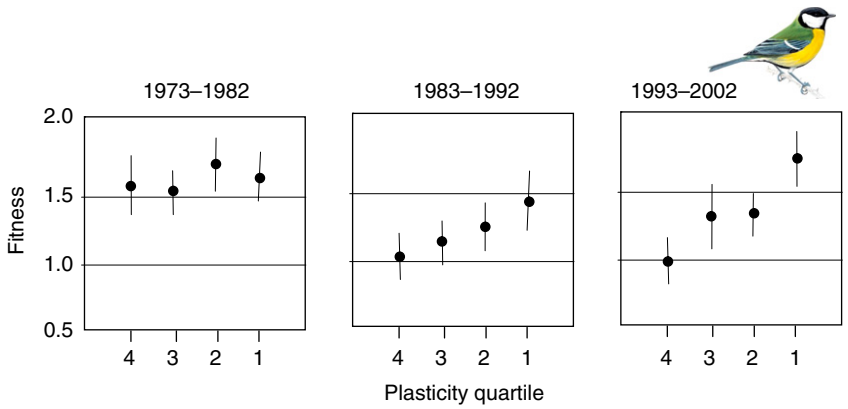

Figure 2 In the great tit (*Parus major*) plasticity of laying date in response to temperature is positively related to fitness, and the strength of this relationship has been increasing through time. Modified from Nussey, D.H., Postma, E., Gienapp, P., Visser, M.E., 2005. Selection on heritable phenotypic plasticity in a wild bird population. Science 310, 304–306.

study has conclusively demonstrated that these shifts represent an evolutionary, rather than purely plastic change in phenology (Charmantier and Gienapp, 2014). One of the most extensive datasets on breeding dates and fitness in birds is a long-term study of great tits (*Parus major*) in the Hogue Veluwe, a national park in the Netherlands. In the last four decades, the emergence of this population's caterpillar prey has shifted earlier in the spring while laying dates of this population have not, resulting in a mismatch between peak food abundance and the timing of reproduction (Visser *et al.*, 1998). Nussey *et al.* examined data collected on laying dates for hundreds of female birds between 1973 and 2004. They found that females laid earlier in warmer springs, but also that individual females varied in the strength of their response to warmer temperatures, and that this variation in plasticity was heritable. Furthermore, the degree of plasticity was correlated with lifetime reproductive success, especially in the second two decades of their study (**Figure 2**). The presence of both selection and heritable variation in plasticity predict an adaptive response, however, an evolutionary change in plasticity has not yet been detected in this population. The researchers in this study used quantitative genetic animal model to estimate genetic variation. This approach is powerful, because it specifically quantifies genetic shifts while controlling for plasticity (Kruuk, 2004). However this approach also requires pedigree data, which is usually available only when animals can be individually marked and followed through multiple generations.

Shifting Allele Frequencies in Australian *Drosophila*

Many organisms exhibit geographic clines in allele frequencies at particular loci, presumably as a result of local adaptation. If clines in allele frequencies are driven by latitudinal variation in temperature, we can expect a shift in those clines through time with climate warming, so that pole-ward populations shift toward the allele frequencies previously found in equator-ward populations. Umina *et al.* used molecular markers to characterize allele frequencies at the alcohol dehydrogenase locus along the coast of Australia in 2002 and 2004, and compared their results to previous studies documenting allele frequencies in the same populations 20 years earlier. They found that the cline had shifted by about 4° latitude, so that southern populations had come to resemble the allele frequencies that had been found about 4° further north 20 years earlier (Umina *et al.*, 2005). A benefit to this approach, in terms of documenting evolutionary change, is that the use of sequence data eliminates the need to confirm that the observed change had a genetic basis. A drawback to this approach is that the connection between DNA sequence data and the actual phenotype under selection is typically unclear.

Prospective Studies: What Is the Potential for Future Adaptation?

Given evidence that evolution has already occurred in response to climate change, researchers would also like to understand whether adaptation will play a role in increasing some species' resilience to future change. Evolution can occur on relatively short timescales and may decrease extinction risk during periods of rapid environmental change (Bell and Gonzalez, 2009; **Box 1**). However, evolution does not always occur rapidly enough to outpace population decline, and current rates of environmental change may dramatically exceed rates of niche evolution that have occurred in the past (Quintero and Wiens, 2013). The key question then is how rapidly contemporary evolution will occur. Evolution over short timescales can occur from preexisting variation or from new mutations. Predicting the likelihood of new beneficial mutations is difficult, as it involves estimating rates of events that are extremely rare. Although quite labor intensive, the process of quantifying existing genetic variation for a trait is relatively straightforward. Three methods for assessing the capacity for future adaptation include quantitative genetic breeding experiments, artificial selection, and experimental evolution (**Table 2**). Importantly, these three methods also allow researchers to estimate correlated responses to selection and trade-offs, which may alter the rate of adaptation to a changing environment (Chirgwin *et al.*, 2015; Duputié *et al.*, 2012; Etterson and Shaw, 2001).

Box 1 Evolutionary Rescue

Evolutionary rescue can be defined as a species' ability to evolve quickly enough to adapt to a rapid change in the environment, thereby preventing its extinction (Gonzalez *et al.*, 2013). Understanding evolutionary rescue depends not just on understanding adaptation, but also its demographic effects (Tallmon *et al.*, 2004; **Figure B1**).

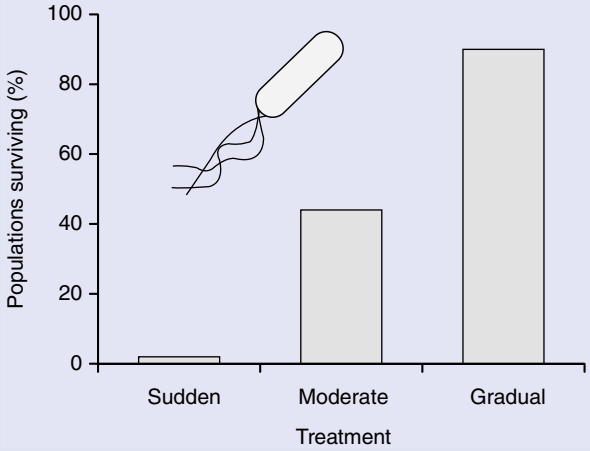

Figure B1 Percent of *E.coli* populations surviving, when given sudden, moderate, and gradual increases in an antibiotic treatment. Redrawn from Lindsey, H.A., Gallie, J., Taylor, S., Kerr, B., 2013. Evolutionary rescue from extinction is contingent on a lower rate of environmental change. Nature 494, 463–467.

Evolutionary rescue depends on the presence of some genotypes able to grow sustainably under the strong selective stress provided, and therefore on absolute, rather than relative fitness. Rescue is complicated by the fact that a response to selection comes with demographic costs. For example, Haldane showed that the number of deaths required for a single allele to be fixed in the population could be 10–30 times the size of the population. Thus, adaptation may not occur if a population cannot replenish its lost individuals fast enough, or if juveniles with the favorable allele do not survive to reproduce (Haldane, 1957). As a result, for both genetic and demographic reasons, evolutionary rescue is more likely in large populations (which will contain more variation) and when populations are exposed to gradually increasing stress (Bell, 2013; Bell and Gonzalez, 2009).

Lindsey *et al.* (2013) studied the precise effect of the rate of environmental change on populations of *Escherichia coli*. An original population was subcultured into three groups, which were treated with the antibiotic rifampicin. The 'sudden' stress group was immediately given the lowest lethal concentration of rifampicin, the gradual group was given doses in increments up to the maximum, and the medium group was given the maximum in half the time of the gradual group. The overall survival of the sudden group was much lower than that of the medium and gradual group, and genetic analysis showed that the mutations shown by the small surviving population were both radically different and smaller in number than the gradual and medium groups. A slow rate of change of environment allowed the accumulation of adaptive mutations, whereas a sudden one did not (Lindsey *et al.*, 2013).

Quantitative Genetics

The degree to which a population can respond to selection depends on the amount of additive genetic variation for a particular trait. Therefore, to predict evolutionary responses to climate change, researchers must estimate the additive variance present for the trait(s) under selection. One way to do this is through quantitative genetic breeding experiments (Shaw and Etterson, 2012). Quantitative genetics is the study of continuous traits and the statistical analysis of the relative contributions of genetic and environmental effects to phenotypic variation. For example, Kelly *et al.* measured the capacity to adapt to ocean acidification in the purple sea urchin (*Strongylocentrotus purpuratus*) by rearing 64 families (individual male–female crosses) under both ambient and elevated CO_2 conditions (Kelly *et al.*, 2013; **Figure 3**). Families varied in their sensitivity to high CO_2, and this allowed the researchers to estimate the amount of genetic variation present for the high CO_2 response. When the researchers incorporated this estimate into models of future population growth under high CO_2, they found reductions in population growth rates that were less severe than those predicted under the 'no evolution' scenario, suggesting that adaptation might ameliorate (but not erase) future effects of high CO_2 on this species.

Experimental Evolution

Experimental evolution probably provides the most realistic glimpse into potential evolutionary responses to high CO_2. In these studies, experimental populations are exposed to future conditions, such as warming temperatures, or increasing CO_2. After multiple (sometimes thousands) of generations of evolution under these conditions, populations are compared to controls under common conditions to quantify any genetically based phenotypic change. Interestingly, after 1000 generations of exposure to elevated CO_2, the green alga *Chlamydomonas* failed to evolve any specific adaptations to these conditions, suggesting a constraint on the response of photosynthesis to increased CO_2 (Collins and Bell, 2004). By contrast, 500 generations under high CO_2 conditions led to substantial adaptive evolution in the calcification response of the coccolithophore alga *Emiliania huxleyi* (Lohbeck *et al.*, 2012). Although calcification rates were not completely restored under high CO_2 conditions, they were still up to 50% higher in adapted as compared to nonadapted strains. A major strength of experimental evolution is that it can demonstrate capacity for evolution in response to a specific environmental factor; a limitation is that its application is typically limited to small organisms with short generation times.

Artificial Selection

Because the response to selection is proportional to the amount of genetic variation, another way to estimate capacity for adaptation is to expose a laboratory population to a predefined amount of selection and measure the response in the next generation. To measure the capacity to adapt to increasing temperatures, Kelly *et al.* exposed populations of a tide pool

Table 2 Methods for measuring potential for future change

Approach	*How it works*	*Examples*
Quantitative genetic breeding experiments	Researchers rear offspring from many families (single male–female crosses) under experimental conditions. By measuring variation among and within families, researchers can use statistical techniques to estimate additive genetic variance in traits important for responses to future environmental change	Purple sea urchins (*Strongylocentrotus purpuratus*) were shown to have substantial capacity for adaptation to ocean acidification (Kelly *et al.*, 2013) Sea urchins (*Centrostephanus rodgersii*) are not constrained in their ability to adapt to ocean warming and acidification simultaneously (Foo *et al.*, 2012)
Experimental evolution	Experimental populations exposed to future conditions, such as warming temperatures, or increasing CO_2. After multiple (sometimes 1000s) generations of evolution under these conditions, populations are compared to controls under common conditions to quantify any genetically based phenotypic change	500 Generations under elevated CO_2 led to partial recovery of calcification rates in the coccolithophore alga *Emiliania huxleyi* (Lohbeck *et al.*, 2012) Green algae failed to evolve specific adaptations to take advantage of high CO_2, after 1000 generations of evolution under high CO_2 conditions in the lab (Collins and Bell, 2004)
Selection experiments	Researchers expose a population of organisms to artificial selection in the laboratory. The response to selection in the next generation is proportional to the amount of genetic variation present for that trait	A marine crustacean showed limited ability to evolve increased heat tolerance, after 10 generations of selection in the laboratory (Kelly *et al.*, 2012) The rainforest endemic *Drosophila birchii* showed variation in desiccation resistance among populations, but the most tolerant population lacked the ability to evolve any further resistance after 30 generations of laboratory selection (Hoffmann *et al.*, 2003)

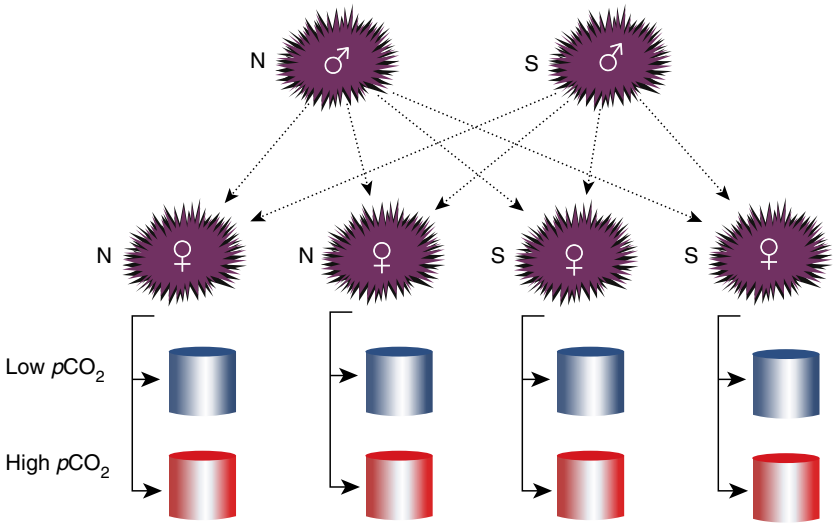

Figure 3 Controlled crosses raised under experimental conditions can be used to estimate genetic variation for traits involved in the response to environmental change. Modified from Kelly, M.W., Hofmann, G.E., 2012. Adaptation and the physiology of ocean acidification. Functional Ecology 27, 980–990.

copepod to 10 generations of selection for increased heat tolerance (Kelly *et al.*, 2012). After five generations of selection, populations evolved up to half a degree of additional heat tolerance. However, the response to selection plateaued rapidly, with no additional increase in heat tolerance between generations five and ten of selection in most populations. Although populations varied in their heat tolerance across the species, individual populations effectively 'ran out' of genetic variation after five generations of selection, suggesting limited capacity to adapt to increasing temperatures without gene flow from more tolerant populations.

Will Evolution Matter?

Theoretical models suggest that evolution might buy time for carbon emissions standards to take effect. For example, theoretical models that do not incorporate evolution predict the

collapse of coral reefs by the middle of this century, while models that incorporate adaptation predict the persistence of reefs into the next century under moderate greenhouse emissions scenarios (Baskett *et al.*, 2009). Incorporating evolutionary change into theoretical models also changes predictions about the probability of negative events. In Australia, climate change is expected to increase habitat suitability for *Aedes aegyptii,* the mosquito that carries dengue fever. Accounting for the potential evolution of higher desiccation resistance in expanding populations increases the projected risk that dengue fever will become established in a major urban area (Kearney *et al.*, 2009).

Incorporating Evolutionary Thinking into Management Decisions

There are a number of ways that evolutionary thinking can be incorporated into management efforts aimed at minimizing biodiversity losses from climate change. If populations of a species are locally adapted to a current climatic gradient, management efforts might focus on maintaining corridors of gene flow among populations, with the understanding that populations currently adapted to the warmest/driest conditions within a species range are an important source of variation for adaptation to future conditions in other populations. By contrast, in highly panmictic species, management efforts might focus on maintaining large local population sizes, to maximize potential for evolutionary adaptation *in situ.* Evolutionary thinking may also lead to changes in assessments of species' relative vulnerabilities to climate change. For example, evolutionary change in some populations may render them less vulnerable than would have been predicted from that populations' current range of environmental tolerances (Lohbeck *et al.*, 2012; Kelly *et al.*, 2013). On the other hand, in species with high levels of natural fragmentation, each population may contain a small subset of the environmental tolerances present in the species as a whole, so that individual populations will be more vulnerable to environmental change than would be predicted from the species-level range of tolerances (Kelly *et al.*, 2012; Schiffers *et al.*, 2013).

At this point, relatively few studies have measured evolutionary responses to climate change or the potential for future change in natural populations. Even fewer empirical studies have addressed the relative magnitudes of plastic versus evolutionary changes or the potential rate of evolution relative to the expected rate of environmental change. Evolutionary thinking can make important contributions to management decisions aimed at minimizing biodiversity losses, but more data are needed to better understand the role that evolution will play in species' responses to climate change.

Ring Species

DE Irwin, University of British Columbia, Vancouver, BC, Canada
DB Wake, University of California, Berkeley, CA, USA

The perfect demonstration of speciation is presented by the situation in which a chain of intergrading subspecies forms a loop or an overlapping circle, of which the terminal forms no longer interbreed, even though they coexist in the same localities. (Mayr, 1942, p. 180)

With the above quote, the great evolutionary biologist Ernst Mayr concisely described the phenomenon now termed 'ring species' (Cain, 1954) and pointed out their importance to the study of speciation, the process by which one species evolves into two or more. Ring species are fascinating to biologists because they illustrate in geographic space a central principle of evolutionary biology that we usually conceive of occurring in time: that species can evolve via small, stepwise changes into new species (**Figure 1**). In a ring species, two distinct forms can be found in the same geographic region, such that most biologists would consider them different species; yet these forms are connected by a chain of populations through which traits change gradually from one species to the other (Mayr, 1942; Cain, 1954; Moritz *et al.*, 1992; Wake, 2001; Irwin *et al.*, 2001b). The two forms can be considered simultaneously as members of the same species (if one looks at the chain of intergrading populations) and as two distinct species (if one looks at the reproductive isolation in the overlapping region). As Mayr (1942, p. 180) stated, ring species are "disturbing to the orderly mind of the cataloguing systematist, but they are welcome to the student of speciation." The ring species concept has inspired much thought about speciation, both with regard to specific case studies (see below) and in development of theory (Gavrilets *et al.*, 1998; Ashlock *et al.*, 2010; Martins *et al.*, 2013).

A wide variety of ring species have been proposed (reviewed by Mayr, 1942, 1963, 1970; Irwin *et al.*, 2001b; Irwin and Irwin, 2002; see also Bowen *et al.*, 2001; Bensch *et al.*, 2009; Mulcahy and Macey, 2009; Patten and Pruett, 2009; Cacho and Baum, 2012; Eastwood *et al.*, 2014), but there is controversy over whether specific cases should be described as ring species. This is a result of wide variation among biologists in concepts both of what a ring species is and of how they form, and ultimately in the ways ring species are used as evidence for various evolutionary processes. Here we review these distinct uses of the ring species concept, discuss the various types of ring species and the ways they could form, examine two ring species in depth, and then look toward future investigations of ring species.

Uses of the Ring Species Concept

The literature reveals a striking characteristic of the history of thought on ring species: the basic concept has been used as illustrations of and support for evolutionary processes in at least four distinct ways:

Illustrating the Fact that Species Evolve

Ring species are often used as a simple yet powerful illustration that distinct species can be connected by a series of small stepwise changes. While ring species provide a taxonomic conundrum (should we call a ring species a single species or two (or more) species?), they in fact illustrate in space the fundamental way that a single species can evolve into two over time (**Figure 1**). It is primarily for this reason that ring species are used so often in textbooks on evolution: they illustrate the continuity between evolution within species and between species so clearly.

Showing the Importance of Geography in Speciation

In the earliest apparent clear articulation of the ring species concept, in a quote attributed to Leonhard Stejneger (as reported by Jordan, 1905), the concept is used to explain how two closely related forms might come to live in the same area,

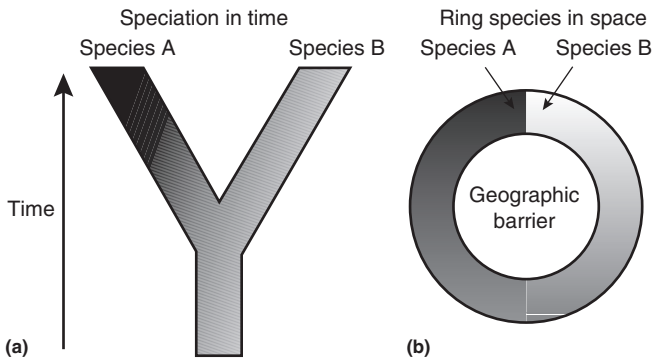

Figure 1 Speciation (a) is the process by which a single species diverges into two (or more) over time. Ring species (b) show a similar pattern over space, allowing geographic variation to serve as a possible proxy for divergence from a common ancestor over time.

by expansion from an ancestral area in two directions around a geographical barrier, the end points coming into contact and behaving as distinct species. In this context, the concept was first developed as support for the idea that geographic differentiation plays a key role in speciation: closely related species may be found living in the same area, but they diverged in different geographical areas and then expanded into the same region. Mayr (1942, 1963, 1970), who did much to popularize the concept, also emphasized this aspect of ring species, writing that "a more dramatic demonstration of geographic speciation than cases of circular overlap cannot be imagined" (Mayr, 1970, pp. 292–293; see also Cain, 1954). More recently, Newton (2003), Price (2008), and Coyne and Orr (2004) also emphasized ring species as illustrating various forms of geographic speciation.

Reconstructing the History of Changes During Speciation

Geographic variation in a ring species can sometimes be used to reconstruct how speciation occurred in time (Wake, 2001; Irwin *et al.* 2001a,b). This requires several assumptions: (1) the ancestral population is well represented by one of the intermediate forms in the ring, (2) we have a good idea which population is that source ancestral population, and (3) the current pattern of variation well represents the changes that occurred in time. A variety of genetic and biogeographic analyses can in some cases provide support for these assumptions, increasing confidence that such reconstruction of the history of speciation is valid.

Illustrating that Speciation Can Occur Despite Gene Flow

Finally, and more controversially, the ring species concept has sometimes been considered to demonstrate that speciation can occur without complete geographic and genetic isolation. The standard model of 'allopatric speciation' holds that speciation occurs following division of a single population into two geographically separated populations that do not exchange genes. Another theoretical possibility is 'speciation by distance,' in which divergence to the point of species occurs between the end points of a long chain of populations – gene flow can occur between neighboring populations, but the distance between the end points is so much greater than the movement of individuals that the two end populations are effectively isolated. Mayr (1942) initially emphasized both the geographic-speciation and speciation-by-distance aspects of the ring species concept, but later abandoned the speciation-by-distance idea as an important part of his concept of circular overlaps, given the "major gaps in nearly all of these chains of populations or at least evidence for the former existence of such gaps" (Mayr, 1970, p. 320). Nonetheless, he continued to hold up circular overlaps as prime examples in which "the process of geographic speciation can be followed step by step" (Mayr, 1970, pp. 292–293).

Dobzhansky went further than Mayr in emphasizing gene flow as an important feature of ring species, describing the chain of populations as a 'genetic bridge' between forms that are otherwise reproductively isolated (Dobzhansky, 1958; Dobzhansky *et al.*, 1964). His prime example, however, was based on various forms within the *Drosophila paulistorum* complex, in which gene flow was inferred using laboratory breeding experiments, and he acknowledged that "it is questionable whether [gene flow] is actually taking place" (Dobzhansky *et al.*, 1964).

Given these varying ways that the ring species concept has been used, it is unsurprising that there is debate over proposed cases in terms of whether they can be described as ring species. The debate can be simplified by clearly separating questions about pattern from questions about process. We can organize our thinking by considering two basic questions: First, what patterns have been described as ring species? Second, what processes lead to their formation?

Types of Ring Species

Scenarios described as circular overlaps or ring species come in a wide variety of flavors. The ideal case is illustrated in Figure 2(a), in which there is a complete ring of gradually varying populations, the end points of which (in blue and red) act as reproductively isolated species where they meet. There have never been actual proposed examples that fit such an ideal scenario; rather all cases that have been proposed (reviewed by

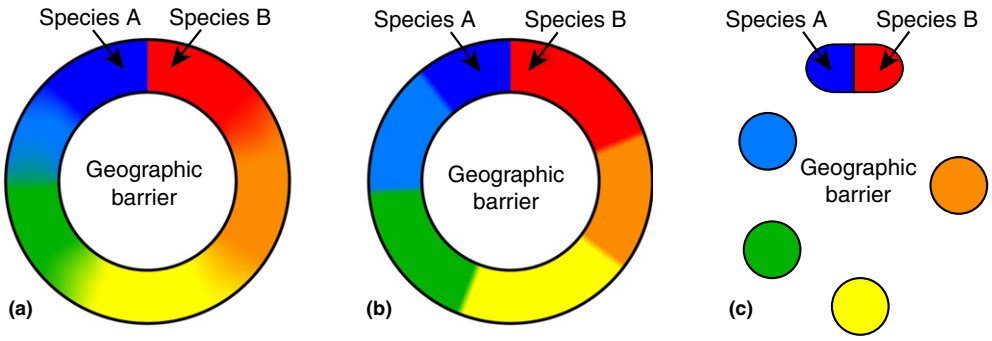

Figure 2 The types of situations that have been described as ring species. The ideal situation (a) is one in which a continuous ring of populations, through which traits and genes change gradually, except at a single location where distinct forms live side-by-side. All known cases of ring species fit less ideal situations in which there are stepwise, rather than completely gradual changes around the ring (b) and/or large gaps in distribution around the ring (c). Nonetheless, those situations illustrate the central concept of a ring species: a single species boundary through a ring of populations.

Mayr, 1942, 1963, 1970; Stebbins, 1949; Irwin *et al.*, 2001b; see also Bowen *et al.*, 2001; Bensch *et al.*, 2009; Mulcahy and Macey, 2009; Patten and Pruett, 2009; Cacho and Baum, 2012; Eastwood *et al.*, 2014) have imperfections of one sort or another. These real-world cases usually have a mixture of two other patterns, illustrated in **Figures 2(b)** and **2(c)**. In these cases, variation around the ring is not completely gradual (2(b)) and/or continuous (2(c)). Nonetheless, the overall pattern is one in which a series of progressively intermediate forms is arranged in a rough geographic order between the co-occurring and most divergent terminal forms (shown in blue and red). Another common complication is that reproductive isolation between the terminal forms can be incomplete, with some direct hybridization and introgression occurring between them (Brown, 1974; Wake *et al.*, 1989; Devitt *et al.*, 2011; Alcaide *et al.*, 2014). However, it is now generally accepted that reproductive isolation between distinct species is often incomplete (Coyne and Orr, 2004), such that a small amount of direct introgression is not inconsistent with the ring species description. The unifying characteristic common to all of these types of ring species is that there is a single species boundary around the ring: species A and B are considered two species where they meet, but there is no species boundary through the chain of populations connecting them around the ring (Cain, 1954).

How Do Ring Species Form?

Because ring species have generally been used as evidence for evolutionary processes, we have a fairly good understanding of various authors' ideas regarding how ring species form. In the ideal scenario (**Figure 3(a)**), which could be used for all of the purposes referred to above, an ancestral form expands from one side of the ring along two pathways around a geographic barrier, with progressive differentiation occurring before the terminal forms meet each other on the other side of the ring, where they are reproductively isolated. During this differentiation process, individuals can move a short distance during their lives in any direction, such that gene flow is continuous, although low in magnitude, throughout the ring. As mentioned above, we have no good examples of fully gap-free and completely gradual rings, so empirical evidence for such an ideal scenario is lacking. However, there is much evidence for cases in which populations expanded from a common ancestor along two pathways, colonizing a series of habitat patches in each pathway, with the final colonization event in each chain bringing the end points together again (**Figure 3(b)**). Such a scenario was outlined for many of the examples provided by Mayr (1942, 1963, 1970), as well as the recently proposed example in plants (Cacho and Baum, 2012). Finally, such a colonization process can be followed by expansion of each population into the gaps in the ring (**Figure 3(c)**), resulting in contact between previously separated populations and resulting in broad blending (**Figure 2(a)**) or the formation of narrow hybrid zones (**Figure 2(b)**).

In reality, most species complexes have had very complex histories, involving periods of geographic isolation and re-expansion as well as divergence-with-gene-flow (Mayr, 1942, 1963, 1970; Wake, 1997; Alcaide *et al.*, 2014), such that particular ring species may have formed via a complex mix of the processes illustrated in **Figure 3**. Regardless, the resulting pattern of two mostly reproductively and co-occurring forms being connected by a chain of progressively intermediate forms illustrates the evolutionary continuity between species and in some cases allows the inference of processes important in the generation of reproductive isolation.

Example Ring Species

There have been a large number of proposed ring species, but evaluating many of them is difficult due to lack of detailed research on specific cases as well as to the variety of ring species concepts. We propose that the emphasis should be not on declaring whether particular cases are or are not ring species, but rather on understanding the particulars of each proposed case and what we can learn from it. Specific cases should be viewed as lying somewhere on a spectrum between the ideal ring species (**Figures 2(a)** and **3(a)**) and clear examples of non-ring species.

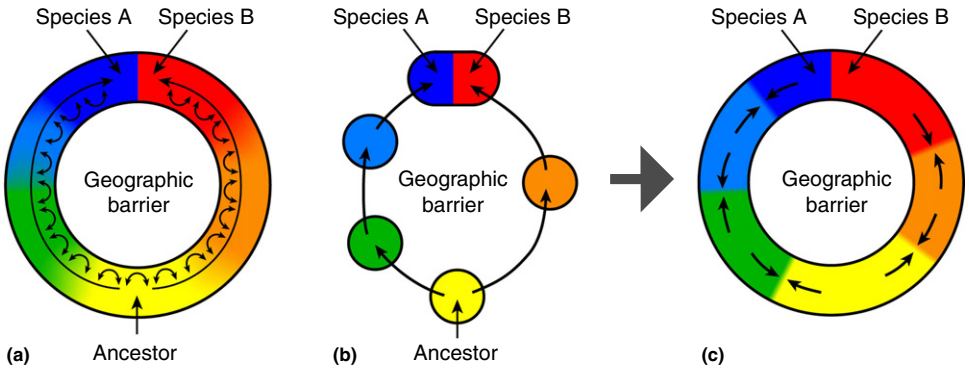

Figure 3 Scenarios by which ring species might form. In (a), an ancestral form expands around a geographic barrier, diverging gradually despite continuous gene flow at all stages of the process. In (b) populations colonize new areas and differentiate in a stepwise manner but there are major gaps in distribution, and divergence eventually proceeds through the chain of populations to the level of distinct species. In (c), the populations expand to meet each other again in narrow zones of intergradation. In each case, divergence to the level of distinct species has occurred only between the terminal forms.

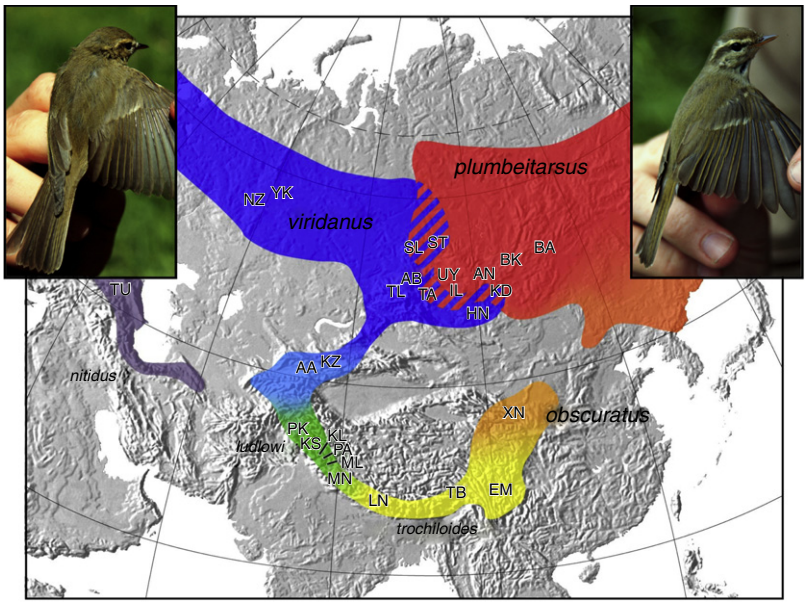

Figure 4 The breeding range of greenish warblers (*Phylloscopus trochiloides*) in Asia. Subspecies designations according to Ticehurst (1938) are shown with different colors: *viridanus* in blue, *ludlowi* in green, *trochiloides* in yellow, *obscuratus* in orange, *plumbeitarsus* in red, and *nitidus* (outside of the main ring) in purple. Photos show the difference in wing bars between *viridanus* (upper left, with a single wing bar) and *plumbeitarsus* (upper right, with two wing bars).

Of all of the cases that have been proposed, two in particular, the greenish warblers in Asia and the *Ensatina* salamanders in California, have stood out as meeting the ring species definition fairly well in terms of being a chain of intergrading forms with distinct coexisting terminal forms. We discuss each in some detail, before mentioning other proposed cases.

Greenish Warblers

In 1938, Claude Ticehurst conducted a detailed taxonomic reassessment of the *Phylloscopus* genus of Old World warblers (Ticehurst, 1938), based on examination of morphological variation in museum skins (e.g., body shape and size, as well as plumage color variation). He provided an intriguing description of six subspecies within the greenish warbler (*Phylloscopus trochiloides*) species complex: two subspecies, *viridanus* in west Siberia and *plumbeitarsus* in east Siberia, differed in plumage but co-occurred in central Siberia without intermediates there, suggesting reproductive isolation. But these forms were apparently connected by a ring of progressively changing forms: *viridanus* extended south into central Asia, where it met *ludlowi*, which Ticehurst described as a transitional form leading to *trochiloides*, the southern form spanning across the Indian and Nepali Himalayas and into southern China. Next came *obscuratus* in central China, which appeared intermediate between Himalayan *trochiloides* and east Siberian *plumbeitarsus*. Based on this description, Mayr (1942) featured the greenish warblers as an illustrative example of circular overlap. Ticehurst hypothesized that the situation arose when an ancestral species in the Himalayas (i.e., in the south) expanded along two pathways northward, separated by the high-altitude Tibetan Plateau.

Both the ring-species description and the proposed parallel northward expansion have now been tested by examining a variety of genetic, morphological, and behavioral traits, and the patterns are broadly consistent with Ticehurst's hypothesis (**Figure 5**; Irwin, 2000; Irwin *et al.*, 2001a, 2005, 2008; Wake, 2001; Alcaide *et al.*, 2014). Vocalizations (both songs and calls), plumage characteristics (mainly wing bar size), and genetic markers (including mitochondrial DNA, microsatellites, AFLPs, and genomic SNPs) differ strongly between *viridanus* and *plumbeitarsus*, supportive of there being strong reproductive isolation between them in central Siberia. Genetic data are supportive of two northward expansions into Siberia, as west Siberian *viridanus* is most related genetically and phenotypically to central Asian *viridanus* and *ludlowi*, and east Siberian *plumbeitarsus* is most related to *obscuratus* in China and *trochiloides* in the eastern Himalayas. Phenotypic traits such as songs, plumage, and migratory behaviors show gradual change around the ring (**Figure 5**). The pattern of song variation is particularly interesting: songs are simple in the south but become increasingly long and complex toward the north, but the form of complexity that has evolved during the two northward expansions differs dramatically between them, resulting in highly divergent songs in west and east Siberia (Irwin, 2000; Irwin *et al.*, 2008), where songs appear to play a role in reproductive isolation (Irwin *et al.*, 2001a).

Complicating the ring species scenario is evidence for a zone of steep genetic transition in the western Himalayas near the boundary between Kashmir and Himachal Pradesh, in a region where there is little change in song or plumage. This genetic transition was first observed as a narrow overlap area between the two major mitochondrial clades (Irwin *et al.*, 2001a). Later, patterns in AFLP markers were interpreted as supportive of gradual genetic variation through this region as

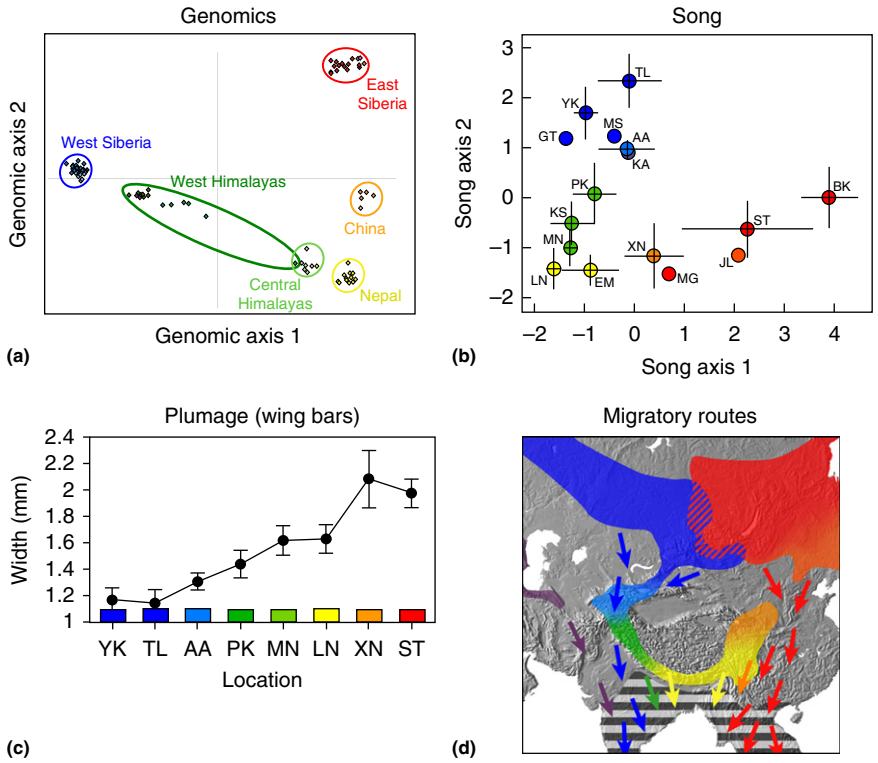

Figure 5 Patterns of genomic and phenotypic variation in greenish warblers. Colors correspond to the subspecies groups in **Figure 4**. Genomic variation (based on 2334 single nucleotide polymorphisms; Alcaide *et al.*, 2014), songs (Irwin, 2000; Irwin *et al.*, 2008), wing bars (Irwin *et al.*, 2001a,b), and migratory routes (Irwin and Irwin, 2005) all show strong differences between the two Siberian forms (*viridanus* and *plumbeitarsus*), but gradual or stepwise variation through the chain of populations to the south. These patterns are supportive of Ticehurst's (1938) and Mayr's (1942) description of the greenish warbler as a ring species, with two separate expansions northward into Siberia.

well as the entire ring, except between the highly divergent *viridanus* and *plumbeitarsus* (Irwin *et al.*, 2005), and this interpretation of isolation-by-distance was confirmed in subsequent analyses of the same data by Novembre and Stephens (2008), Zhang *et al.* (2009), and Martins *et al.* (2013). Finally, analysis of thousands of markers spread throughout the genome has revealed strong evidence for secondary contact in the western Himalayas of previously separated populations (**Figure 5(a)**; Alcaide *et al.*, 2014), within the range that Ticehurst described as the subspecies *ludlowi*. A further complication is that the genomic data shows strong evidence for a small amount of hybridization and introgression between *viridanus* and *plumbeitarsus*, such that reproductive isolation between those forms is not absolute (Alcaide *et al.*, 2014). There is also evidence for some individuals in central Siberia singing songs that mix elements of the songs of *viridanus* and *plumbeitarsus* (Irwin *et al.*, 2012b; Kovylov *et al.*, 2012). Nonetheless, those forms display highly divergent genetic clusters, indicating that the limited hybridization has not blended the two forms and suggesting that there is selection against introgressed genes.

The greenish warblers display the essential characteristics of a ring species: two highly differentiated forms that co-occur in one region (central Siberia) while being connected by a long chain of forms through which traits change gradually (e.g., song) or in a more stepwise fashion (e.g., genetics). However, the evidence for periods of geographic separation and secondary contact implies that greenish warblers do not provide a clear example of speciation by distance (Alcaide *et al.*, 2014), counter to a previous interpretation based on more limited genetic data (Irwin *et al.*, 2005).

Ensatina Salamanders

In 1949 R.C. Stebbins at the University of California, Berkeley, published a monograph on the *Ensatina* genus of salamanders that had a surprising conclusion: what had been treated as a genus with four distinctively colored species distributed along the west coast of North America was reduced by Stebbins to a single species comprised of 7 subspecies distributed in the form of a geographic ring (**Figure 6**; Stebbins, 1949). The subspecies all occur in California, where they are wrapped around the inhospitable Great Central Valley and extend southward both along the coast and inland into northern Baja California, Mexico. A form with the most generalized color pattern occurring in the historically most stable part of the overall range, in northwestern California, was hypothesized to have spread inland and southward through the Sierra Nevada, in one leg of its distribution, and separately along the coast southward through diverse coastal uplands. The forms were thought to have adapted to local and regional habitats and climates as they migrated southward, with coastal forms becoming more or less uniformly, and brightly, colored, and in the central coastal area they became aposomatically colored as part of a mimicry complex involving the dangerously poisonous news, *Taricha* (Kuchta, 2005; Kuchta *et al.*, 2008). In contrast, in the inner mountains

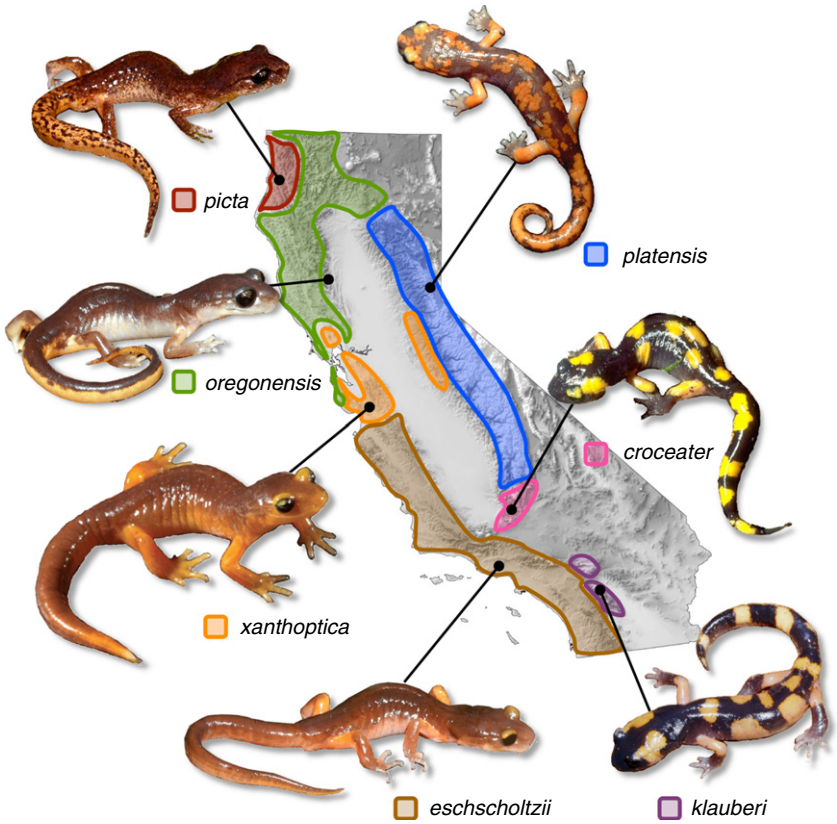

Figure 6 Geographic variation among races in the *Ensatina eschscholtzii* ring species in California. Reproductive isolation is stronger between the southern forms *klauberi* and *eschscholtzii* than elsewhere around the ring. Reproduced from Pereira, R.J., Monahan, W.B., Wake, D.B., 2011. Predictors for reproductive isolation in a ring species complex following genetic and ecological divergence. BMC Evolutionary Biology 11, 194, with permission from BMC Evolutionary Biology.

the salamanders evolved cryptic coloration and behavior, becoming spotted and blotched (such that they match the leaf litter well). The end points of these adaptively divergent pathways appeared to be different species.

Stebbins, who was renowned for his artistic abilities as a painter as well as being a serious scientist, argued that the forms intergraded with each other at various points in the ring. His critical insight was that the two major types came into near sympatry in Southern California, and he recognized signs of hybridization and intergradation between forms elsewhere around the ring. Nowhere was the ring hypothesis seen in more vivid detail that in the central Sierra Nevada, where two remarkably distinct forms, the aposematically colored *Ensatina eschscholtzii xanthoptica* and the cryptically colored, blotched, *Ensatina eschscholtzii platensis*, met and hybridized extensively, the result of a 'mid-valley leak' that had brought coastal forms into contact with Sierran forms (essentially a 'test' of the ring species concept mid-way through the ring); this contrasted with the much stronger reproductive isolation between distinct forms *Ensatina eschscholtzii klauberi* and *Ensatina eschscholtzii eschscholtzii* at the southern end of the ring. Stebbins did not think that the ring resulted from smooth expansion without any geographic breaks in continuity around the ring, but rather as something that had developed in fits and starts, with many interruptions and long periods during which regional adaptation occurred.

Subsequent research has added much detail and texture to the *Ensatina* example, and in recent years a heavy emphasis on molecular traits has shown that the ring of forms is old (millions of years) and deeply differentiated (Wake and Yanev, 1986). Both intergradation (based originally on color analysis, now backed up by allozyme data) and hybridization are well documented at various places around the ring (Wake and Schneider, 1998; Kuchta *et al.*, 2009). It is now thought (Jackman and Wake, 1994; Pereira and Wake, 2009; Pereira *et al.*, 2011) that the blotched forms were separated from other members of the complex for a long time before moving back northward and meeting the unblotched forms in secondary intergradations north and west of Lassen Peak, in northeastern California. Some hybridization has been observed between the terminal forms in southern California (Brown, 1974; Wake *et al.*, 1989; Devitt *et al.*, 2011), but it is more restricted than in the central Sierra Nevada (Alexandrino *et al.*, 2005), and at the southern-most possible point of meeting of the two main lineages, in the Cuyamaca Mountain of inner San Diego County, California, there is sympatry with no evidence of local hybridization (Wake *et al.*, 1986). While some have questioned the ring species description of the *Ensatina* complex (e.g., Highton, 1998) no primary researchers focused on the group has felt their results constituted a refutation of Stebbins' original hypotheses concerning intergradation, hybridization, and sympatry at different places within the ring,

nor, especially, of his broad biogeographical hypothesis. Despite the complexities, there is a single place in the ring where genetic and phenotypic differentiation are much stronger than elsewhere around the ring.

Other Proposed Cases

At least two dozen species complexes have been described as 'circular overlaps' or 'ring species' at one time or another (Mayr, 1942, 1963, 1970; Bowen *et al.*, 2001; Irwin *et al.*, 2001a,b; Patten and Pruett, 2009; Cacho and Baum, 2012; Eastwood *et al.*, 2014), but many of these are far from the ideal. Most of them are cases cited by Mayr (1942, 1963), containing large geographic gaps in distribution (e.g., similar to **Figure 2(c)**). Several cases that have been commonly used as example ring species in the popular literature have recently been called into question; these include the herring gull (*Larus argentatus*) complex surrounding the Arctic Ocean (Crochet *et al.*, 2002; Irwin and Irwin, 2002; Liebers *et al.*, 2004), the great tit (*Parus major*) complex (Kvist *et al.*, 2003; Päckert *et al.*, 2005), and the crimson rosella (*Platycercus elegans*) complex (Joseph *et al.*, 2008; Ribot *et al.*, 2009). In each of these cases, molecular analysis has revealed sizeable discontinuities and a lack of support for previously articulated biogeographic scenarios, leading some authors to declare that they are not ring species. During the same period of time that these classic cases were being called into question, a few other potential cases have been proposed. These include the first convincing example of a possible ring species in plants, in the Caribbean slipper spurge (*Euphorbia tithymaloides*; Cacho and Baum, 2012), the ring-like evolutionary pattern described for Night Snakes (*Hypsiglena*) around the Gulf of California (Mulcahy and Macey, 2009), an apparent 'incipient ring species' in willow warblers (*Phylloscopus trochilus*) surrounding the Baltic Sea (Bensch *et al.*, 2009; Irwin, 2009), a possible although complex example in song sparrows (Patten and Pruett, 2009), and a case in trumpetfish (*Aulostomus* sp.), although in the latter case the terminal forms of the ring appear to be blending together (Bowen *et al.*, 2001). Particularly intriguing is the first proposed case of a ring species in a pathogen (Eastwood *et al.*, 2014), in beak and feather disease virus infecting the crimson rosellas, which have themselves been proposed as ring species (see above). Most of these cases have strong discontinuities around the ring, such that the cases recently proposed as ring species ironically have many of the characteristics of those recently declared not to be ring species. This is a reflection of the fact that biologists use a variety of meanings of the word 'ring species,' and why we advocate that the term be used for any current situation in which a loop of populations has a single species boundary, avoiding definitions that include a statement about the process of formation of such a situation.

Conclusion

Both the greenish warblers and *Ensatina* salamanders are ring species in the sense that two forms that have diverged to the species level are connected by a chain of populations in which there is gradual or stepwise change, such that there is no clear species-level boundary through that chain. They both beautifully illustrate the first two purposes for which ring species have been used: as demonstrations that species differences are a result of evolution and that geography often plays an important role in the evolution of separate species. Species are not fixed entities, and the barriers between them are fluid and context-dependent. These cases also have been used to infer the history of changes during speciation. This is perhaps most clear in song variation of greenish warblers (**Figure 5(b)**), which provoked the working hypothesis that short, simple ancestral songs gradually evolved into the long, complex, and divergent songs of the two Siberian species. Both cases are however not good examples of speciation by distance, and the quest will have to continue for any examples that fit the ring species concept in that most ideal form (**Figures 2(a)** and **3(a)**). We note however that there is strong evidence from a variety of other sources for divergence-with-gene-flow (Pinho and Hey, 2010), and increasing evidence for speciation-with-gene-flow (Martin *et al.*, 2014), such that evidence for these phenomena from ring species is not essential to the validity of those ideas. In most of the literature on speciation-with-gene-flow, however, reproductive isolation is envisioned as evolving directly within the chain of populations connecting the diverging forms. The ring species concept differs in that reproductive isolation evolves not within the chain but rather between the overlapping end points.

One reason that the ideal ring species scenario (**Figures 2(a)** and **3(a)**) has proven so elusive is that it requires an unusual geographic arrangement of ecologically suitable and unsuitable areas of just the right geographic sizes, such that the central barrier is large enough to prevent movement of individuals across it while the ring is small enough for gene flow to keep neighboring populations similar. Furthermore, a period of ecological stasis long enough for the ring to form is necessary. It is likely this last requirement that is not often satisfied on this complex Earth with its frequent climatic shifts. Divergence to the level of species tends to occur on a scale of hundreds of thousands to millions of years, whereas climate shifts occur on a scale of hundreds to thousands of years, such that species distributions are undergoing frequent shifts. Hence it may be unlikely that we will find any cases that fit the most ideal scenario, but the search should still go on, as the Earth is filled with many possible barriers around which ring-like distributions may form (Irwin, 2012a; Monahan *et al.*, 2012).

RNA Viruses, Evolution of

EC Holmes, The University of Sydney, Sydney, NSW, Australia

Glossary

Capsid Protective protein coat that surrounds the viral genomic nucleic acid and possessed by all true viruses.
Clonal interference Competition (interference) between advantageous mutations as they go to fixation in asexual populations.
Complementation Where a defective virus particle is rescued by utilizing the functional genes/proteins of a virus that co-infects the same cell.
Defective interfering (DI) particle Defective virus genome, usually because of deletion mutations, that can compete (interfere) with co-infecting functional viruses.
Endogenous virus element (EVE) Partial (usually) or complete (occasionally) viral genome that is integrated into the host genome and transmitted through the germ line. RNA, DNA, and retroviruses all give rise to EVEs.
Epistasis Mutational effects that are different in combination than individually. Antagonistic epistasis reduces the fitness effect of combined mutations, whereas synergistic epistasis increases this effect.
Incomplete lineage sorting It occurs when there has been insufficient time for allele fixation (in the viral genome) between host speciation events and can lead to a mismatch between virus and host phylogenies.
Molecular clock A model in which molecular evolution proceeds at an approximately constant rate.
Muller's ratchet Progressive decrease in fitness due to the accumulation of deleterious mutations in asexual populations of finite size.
Multiplicity of infection (MOI) Technically defined as the ratio of viruses to the number of infected cells, but can more simply be thought of as the number of viruses infecting an individual cell.
Overlapping reading frame (overprinting) Translation starts on different positions within a codon leading to more than one protein product from a single codon region.
Persistent infection A relative term, that usually reflects an RNA virus infection that lasts for many months or years, or for most of the life span of the host. In contrast, acute infections may only last for a few days.
Phylodynamics Subject describing how the combination of evolutionary, epidemiological, and immunological processes determines the structure of phylogenetic trees.
Polymerase Essential, but error-prone, replication protein common to all RNA viruses. RNA viruses employ an RNA-dependent RNA polymerase, while retroviruses employ reverse transcriptase in which DNA is made from an RNA template.
Reassortment Form of recombination in segmented viruses in which viruses with different ancestries are packaged into the same virion leading to hybrid progeny.
Robustness The ability to maintain phenotype in the face of deleterious mutation.
Segment Independently replicating genomic molecule. Some RNA viruses carry a single segment (such that they are unsegmented), while others possess multiple segments. Viruses with multiple segments are able to reassort.
Sequence space All possible mutational combinations in a nucleotide or amino acid sequence.
Virion The mature virus particle containing the RNA genome and the full set of proteins.
Viroid Small circular RNA molecules that cause a variety of plant diseases and which do not encode proteins. Because they do not possess a coat protein they are not considered true viruses.

The Origins and Evolutionary History of RNA Viruses

The Origins of RNA Viruses

Determining when and how viruses originated is one of the most difficult topics in the study of viral evolution. The central challenge is that viruses likely originated so long ago that the signal of evolutionary history has been largely eroded and there is no fossil record. Despite this intrinsic difficulty, two theories dominate discussions of viral origins: that viruses have a pre-cellular origin, such that they arose before the last universal cellular ancestor, or that they evolved later as 'escaped' host genes that acquired protective capsid (coat) proteins and the ability to replicate autonomously.

According to the pre-cellular theory, RNA viruses are likely to be descendants of replicating elements that existed in a hypothetical and primordial 'RNA world.' Modern day viroids from plants, which share many similarities with RNA viruses, have been proposed to be remnants of this ancient time in earth's evolution (Flores *et al.*, 2014). Similarly, DNA viruses would be remnants of the first DNA replicators, with retroviruses' descendants of the first molecules that made the major evolutionary transition from RNA to DNA. Although difficult to test, there is growing support for the pre-cellular theory, particularly in the guise of protein structures that are conserved among highly divergent viruses (Koonin and Dolja, 2014). One of the most compelling examples is the jelly-roll capsid, a protein structure that forms the major capsid subunit of viruses with icosahedral shaped virions. Remarkably, the jelly-roll capsid is found in diverse RNA and DNA viruses that exhibit no clear sequence homology (Bamford *et al.*, 2005), which is strongly suggestive of ancient common ancestry.

In contrast, the escaped gene theory proposes that viruses originated from host cells on multiple occasions, and perhaps

 doi:10.1016/B978-0-12-800049-6.00240-7

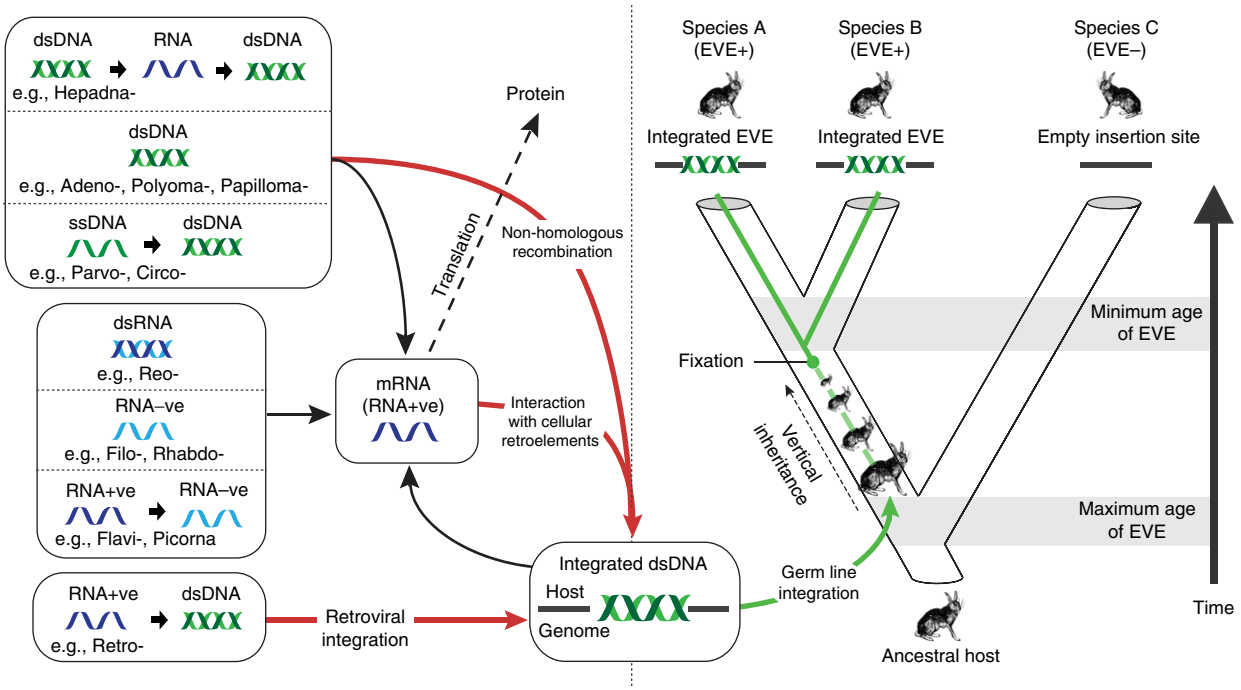

Figure 1 The evolution of endogenous virus elements (EVEs), which can occur in both RNA and DNA viruses, of which different types are shown. Importantly, EVEs allow estimates of the timescale of viral evolution. The presence of orthologous EVEs in host species A and B means that this EVE integration event occurred prior to the divergence of these two species, but subsequent to species C, such that its age can be estimated if the divergence time of the host species is known. Reproduced from Katzourakis, A., Gifford, R.J., 2010. Endogenous viral elements in animal genomes. PLoS Genetics 6, e1001191. Freely available through Creative Commons.

from cellular lineages that are now extinct. Hence, it is possible that RNA, DNA, and retroviruses represent independent episodes of host gene escape, which may also be the case for single-stranded (ss) and double-stranded (ds) RNA and DNA viruses. However, many escapes are proposed, the underlying theory is that a host gene that possessed or acquired the ability to self-replicate escaped from the cell, acquiring a protein coat on the way, eventually evolving into an independently replicating entity. A simple prediction of this theory is that key virus proteins (capsid, polymerase) have a host origin, although high levels of sequence divergence make this theory difficult to test. Although the escaped gene theory has fallen out of favor, it may have happened on occasion, with human hepatitis delta agent a possible example (Salehi-Ashtiani *et al.*, 2006).

The Timescale of Virus Evolution

Although RNA viruses are likely to be ancient replicators, it has proven difficult to provide a resolved timescale of their evolution because high divergence and frequent host jumping, and there are ongoing debates over the time of origin of major virus groups. Some information is provided by the match between the phylogenies of viruses and those of their hosts, which suggests that they have experienced long-term co-divergence (Sharp and Simmonds, 2011). A well studied example is that of the retrovirus simian foamy virus which has co-diverged with primates for at least 30 million years (Switzer *et al.*, 2005). More evidence for the deep timescale of virus evolution comes from the presence of endogenous viral elements (EVEs) that are a common component of eukaryotic genomes, particularly in the form of endogenous retroviruses (Katzourakis and Gifford, 2010). Once integrated into the host germ line they assume the low evolutionary rates of their hosts and can be used to estimate divergence times, particularly if orthologous ERVs are shared between species (**Figure 1**). Molecular clock dating using EVEs suggests that some human retroviruses diversified relatively early on in mammalian evolution. For example, there is evidence of endogenous foamy viruses in mammals for more than 100 million years (Katzourakis *et al.*, 2009).

Evolutionary Relationships among RNA Viruses

The evolutionary relationships of RNA viruses that are classified into different families have proven equally difficult to resolve. This problem is exasperated by the fact that viruses are likely the most common type of nucleic acid on earth and with the greatest genetic diversity, but where only a tiny fraction of the virosphere has been sampled. In addition, it is likely that lateral (horizontal) gene transfer events have occurred between diverse RNA viruses so that aspects of viral evolution may be better represented by an interconnected network of genes than a bifurcating phylogenetic tree (Liu *et al.*, 2012).

Many studies in this area have relied on phylogenetic analyses of the sequences that encode the RNA-dependent RNA polymerase (RdRp), the most conserved RNA virus protein. However, RdRp phylogenies are often highly uncertain, especially at the inter-family level, where there is

sometimes no more sequence similarity across the protein as a whole than expected by chance alone (Zanotto *et al.*, 1996). Despite this, different RNA virus families still share a number of short amino acid motifs in the RdRp, some of which are also found in the RT used by retroviruses, again arguing for the ancient common ancestry of these replicase proteins (Koonin, 1991).

RdRp phylogenies, combined with information on genome structure, have also been used to construct higher level classification schemes, manifest as 'orders' of viruses that represent assemblages of multiple viral families. At the time of writing, four such orders exist: the *Mononegavirales*, comprising multiple families of unsegmented negative-sense RNA viruses, and three orders of positive-sense RNA viruses – *Picornavirales*, *Nidovirales*, and *Tymovirales*. Despite the apparent limits to phylogenetic analysis, it is likely that more orders will be identified in the future, and that apparent 'gaps' in the RNA virus phylogeny will be filled by more in-depth sampling of the virosphere.

RNA Virus Emergence

There are two ways in which RNA viruses become associated with their hosts: co-divergence in which viruses diverge (speciate) along with their hosts, perhaps over many millions of years (as in the case of the foamy viruses described above), and cross-species transmission, in which viruses jump between host species and which can happen on very short timescales. Cross-species transmission is the major process driving viral emergence, and hence is essential in understanding the origins of infectious disease. However, most 'emerging viruses' only cause sporadic (dead-end) infections with no onward transmission in the new host, such that ongoing viral evolution is needed to ensure full host adaptation. A simple rule of thumb in this context is that the closer the phylogenetic relationship among the host species, the more likely viruses will be able to successfully jump between them, and which is supported by large-scale comparative studies (Kitchen *et al.*, 2011). Indeed, as the ability to recognize, infect, and be released from host cells is central to cross-species transmission (Parrish *et al.*, 2008), then viruses should be better able to jump between closely related host species as these will usually harbor similar cell receptors. Other key adaptive barriers that need to be breached to ensure successful host adaptation include the evasion of host immunity and successful transmission to other individuals in the population.

The principal evidence for co-divergence is a match (congruence) between the tree topologies of host and virus, and which may be relatively commonplace in the case of persistent viral infections (Sharp and Simmonds, 2011). Although co-divergence may occur across long-evolutionary timescales, and has been relatively commonly documented in some DNA viruses, it is possible that some of the match between virus and host phylogenies may in fact be due to preferential host switching in which viruses jump to related hosts (Hoyal Cuthill and Charleston, 2013). More cases of host jumping will doubtless be discovered when our sampling of the viral world increases. Conversely, host and virus phylogenies may appear to be more different than they are because of incomplete lineage sorting (Sharp and Simmonds, 2011).

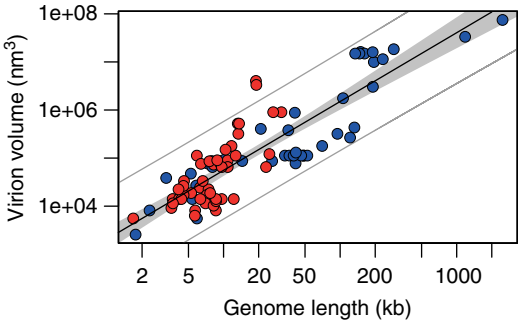

Figure 2 The relationship between the genome and virion sizes of viruses. RNA viruses are shown in red and DNA viruses in blue. Virion sizes, displayed as volume (nm^3) on a log scale, are shown on the *y*-axis, while genome length (kb) on a log scale is shown on the *x*-axis. The black line depicts the linear regression between log–log transformed data. The gray area shows the 95% confidence interval for the linear regression, while the outer gray lines represent the 95% prediction interval. Reproduced from Cui, J., Schlub, T., Holmes, E.C., 2014. An allometric relationship between the genome length and virion volume of viruses. Journal of Virology 88, 6403–6410.

Genome-Scale Evolution

The Evolution of Genome Structure and Size

RNA viruses exhibit a huge diversity of genome structures, including those with positive- and negative-sense orientations, those with single or double strands of RNA, and those with single or multiple segments. Despite such diversity, it is possible that all these forms of genome organization have evolved as ways of controlling gene expression (Holmes, 2009a). Interestingly, recent studies have revealed important phylogenetic links between segmented and unsegmented RNA viruses (Qin *et al.*, 2014), and shown that genome segmentation may allow RNA viruses to explore a greater proportion of sequence space than when only a single segment is present (Moreno *et al.*, 2014).

In contrast, the genome sizes of known RNA viruses exhibit relatively little variation, from less 2500 nucleotides (nt) in the case of some mitoviruses to approximately 32 Kb in the *Nidovirales*, with a mean value of approximately 10 000 nt. One theory is that genome sizes are constrained by the maximum size of the genomic material that can be contained within a virion. However, there is a remarkably strong (allometric) relationship between viral genome and virion sizes that covers viruses of all sizes and types (including RNA and DNA), indicating that viral genomes expand in size along with their virions (Cui *et al.*, 2014; **Figure 2**). A more plausible explanation is therefore that genome sizes are set by (high) background mutation rates, particularly as there is a strong relationship between mutation rate and genome size (see below; Gago *et al.*, 2009).

Mechanisms of Genome Evolution

Whatever the reasons for the genomic diversity in RNA viruses, a number of major evolutionary processes have been at play, although at uncertain frequencies and with complex patterns.

For example, while gene duplication must be responsible for some of the genomic and functional diversity seen in RNA viruses, particularly in the creation of different viral families, it has been relatively rarely documented (Simon-Loriere and Holmes, 2013). Importantly, more refined homology searching has revealed additional examples (Kuchibhatla *et al.*, 2014). It is possible that the relatively low frequency of gene duplication may reflect the major fitness costs (i.e., deleterious mutation load) associated with increases in genome size (see below). Lateral gene transfer (LGT) also appears to be a relatively rare event in RNA viruses (Song *et al.*, 2013), perhaps because it will similarly result in larger genomes. However, LGT has now been shown to have played a key role in the genesis of some virus groups (Liu *et al.*, 2012), and so may have generated important biodiversity. In addition, LGT can occasionally occur among between viruses and hosts with, for example, reports of RNA viruses incorporating host genome sequences (Megens *et al.*, 2014). A related theory is that of 'modular evolution,' in which viral genomes are proposed to comprise functional modules that can be exchanged through recombination to create novel viruses (Botstein, 1980), although its role in RNA virus evolution remains uncertain.

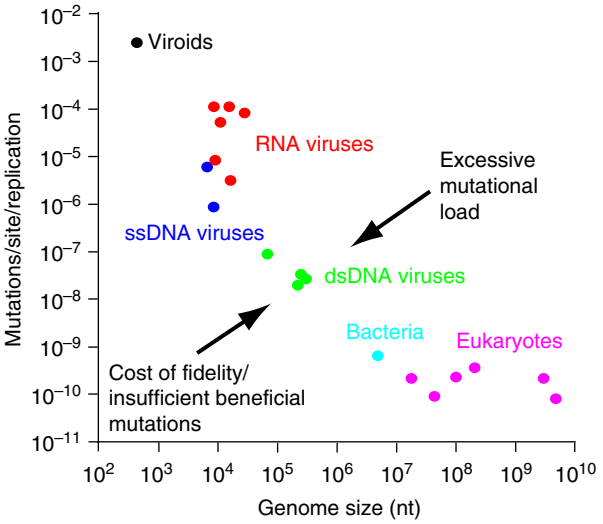

Figure 3 The fundamental relationship between log mutation rate (mutations/site/replication) and log genome size in diverse organisms, including RNA viruses and viroids. The evolutionary forces that might be responsible for the observed range of genome sizes and mutation rates are shown. Modified from Holmes, E.C., 2011. What does virus evolution tell us about virus origins? Journal of Virology 85, 5247–5251 and Gago, S., Elena, S.F., Flores, R., *et al.*, 2009. Extremely high mutation rate of a hammerhead viroid. Science 323, 1308.

Processes of RNA Virus Evolution

Rates of Viral Evolution

One of the most important facets of RNA virus biology is the rapidity with which these infectious agents evolve. Indeed, such is the pace of viral evolution that it can often be measured within the time-frame of human observation, providing the foundation for the science of phylodynamics (Holmes and Grenfell, 2009). This rapid evolution dictates much of the life history of RNA viruses and, in turn, evolutionary rates are a useful metric by which to compare RNA viruses.

Although complex to measure, current estimates of mutation rates in RNA viruses range from 10^{-3} to 10^{-6} mutations/nucleotide/cell infection (Sanjuán *et al.*, 2010). Lower rates, ranging from 10^{-8} to 10^{-6} mutations/nucleotide/cell infection, are observed in DNA viruses and reflect the higher fidelity of DNA polymerases, although ssDNA viruses mutate more rapidly than dsDNA viruses for reasons that are currently unclear (Holmes, 2009a). Importantly, these mutation rate estimates are compatible with the idea that there is an inverse relationship between mutation rate and genome size that applies to all living systems (Gago *et al.*, 2009; Holmes, 2011), such that mutation rates that are either too high or too low are selected against (**Figure 3**). Accordingly, mutation rates in RNA viruses are likely to be close to their maximum possible values (about one per genome replication; Drake *et al.*, 1998), with higher rates causing an excess of deleterious mutations, but where lower rates are also associated with significant fitness costs (Vignuzzi *et al.*, 2005).

Rates of nucleotide substitution show similar levels of variation (Duffy *et al.*, 2008), reflecting differences in both mutation and replication rates, including those associated with the host cell type infected as these turnover at different rates (Hicks and Duffy, 2014). Despite this variation, most substitution rates in RNA viruses fall between 10^{-3} and 10^{-4} nucleotide substitutions per site, per year (Duffy *et al.*, 2008). These rates are orders of magnitude higher than those seen in dsDNA viruses and cellular organisms (Holmes, 2009a), and are a major reason why RNA viruses are often able to adapt to new hosts and evade our attempts to control them through vaccines and antivirals.

Processes of Molecular Evolution in RNA Viruses

As with other organisms, understanding the major processes of evolutionary change in RNA viruses is of central importance. Because of the intimate evolutionary 'arms race' with their hosts, RNA viruses provide some of the very best examples of natural selection in action, with examples involving immune evasion, antiviral resistance, and the adaptation to new host species (Holmes, 2009b; Stapleford *et al.*, 2014). In turn, RNA viruses have exerted some of the strongest selection pressures on host genes (Daugherty and Malik, 2012).

Because the genomes of RNA viruses are small, with frequent epistasis (see below) and multifunctionality, it may be that very few mutations are strictly neutral. One study of mutational fitness in an experimental viral population revealed that nearly 40% of random mutations were lethal, 29% deleterious, a further 27% neutral, and only 4% beneficial (Sanjuán *et al.*, 2004). Broadly similar results have obtained using next-generation sequencing with, as expected, more synonymous than nonsynonymous mutations falling into the neutral class (although some were also advantageous), and with more lethal mutations nonsynonymous falling in nonstructural than structural genes (Acevedo *et al.*, 2014; **Figure 4**). Importantly, however, these measures are performed within a single cell, and many more deleterious

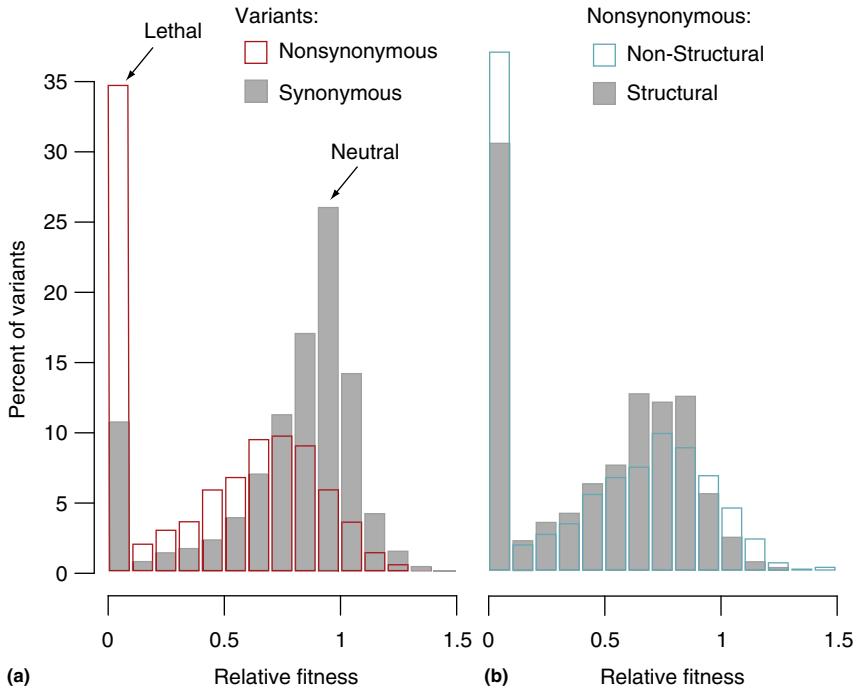

Figure 4 The fitness distributions of mutations in poliovirus as revealed by a next-generation sequencing approach. (a) The fitness of synonymous (gray) and nonsynonymous (red) mutations; (b) The fitness of nonsynonymous mutations in structural (gray) and nonstructural (blue) genes. Adapted from Acevedo, A., Brodsky, L., Andino, R., 2014. Mutational and fitness landscapes of an RNA virus revealed through population sequencing. Nature 505, 686–690.

mutations (and few neutral ones) are expected to accumulate across the entire virus life cycle, including inter-host transmission. Indeed, true measures of viral fitness must include the propensity for onward transmission within a population.

Similarly, RNA viruses possess very few, if any, pieces of functionless noncoding sequence, such as pseudogenes, and the common occurrence of overlapping reading frames (also known as 'overprinting') means that synonymous sites in one reading frame will often be nonsynonymous in another. As well as changing selective pressures, overprinting may lead to the creation of new viral proteins (Sabath *et al.*, 2012). The likelihood of neutral evolution will also be reduced by the presence of the RNA secondary structures that are a common feature of many RNA viruses, and which may contain control signals for such processes as replication and translation.

Codon usage may likewise have a profound effect on fitness. For example, there is growing evidence that the alteration of synonymous codon usage results in major fitness losses (Coleman *et al.*, 2008). This is supported by observations that synonymous sites can contain the signals for transcription and encapsidation (Marsh *et al.*, 2008). Many RNA viruses utilize synonymous codons that tend to match the nucleotide composition of the viral genome as a whole, suggesting that codon choice is either set by background mutational pressure, or that there is selection on overall nucleotide composition (Jenkins and Holmes, 2003). In other cases, there is evidence for direct selection on codon choice (Aragonès *et al.*, 2010), and codon choice has been suggested to influence the trajectory of virus evolution (Lauring *et al.*, 2012). Despite the mounting evidence that synonymous mutations can have important fitness consequences, it is also the case that levels of synonymous variation at the genomic scale are consistently higher than those at nonsynonymous sites, indicating that the fitness effects of synonymous mutations are usually less than those of nonsynonymous mutations (Acevedo *et al.*, 2014).

Another factor that influences the relative potency of natural selection is the virus effective population size (N_e), which is itself linked to the occurrence and strength of population bottlenecks. Large values of N_e are likely to occur within individual hosts following multiple rounds of replication and at the epidemiological (inter-host) scale if many hosts are infected. Natural selection is expected to be an efficient force in these cases. Conversely, low values of N_e, when genetic drift will be strongest, will occur during inter-host transmission and which may involve a major population bottleneck (Stapleford *et al.*, 2014). In some cases, such as certain forms of HIV-1 transmission, it is possible that infections are even initiated by a single virus particle (Keele *et al.*, 2008), although looser bottlenecks are seen in other viruses (Ghedin *et al.*, 2009).

Interactions between Virus Mutations and Genomes

Virus genomes and the mutations therein may interact in a variety of ways. Epistasis appears to be a common occurrence in RNA viruses, and most of the epistatic interactions determined to date are antagonistic rather than synergistic (Sanjuán *et al.*, 2004). Importantly, epistatic effects also vary between hosts, and therefore may be central to virus emergence (Lalić and Elena, 2013). The type of epistasis also impacts the level of genetic robustness seen in RNA viruses, itself a key aspect of adaptability. The high error rates of RNA viruses, combined with their highly compact genomes with little

redundancy, mean that mutations will repeatedly damage the same functions, resulting in antagonistic epistasis (Elena *et al.*, 2006). To overcome this, RNA viruses have evolved various mechanisms that provide them with some genetic robustness (Elena, 2012), and are in part protected by large population sizes.

Virus genomes can interact through the presence of defective interfering (DI) particles and complementation, both of which require a high multiplicity of infection. DI particles are a common observation in RNA viruses (Saira *et al.*, 2013), often harbor large genomic deletions, and have interesting evolutionary consequences. The shorter genomes of DI particles mean that they can replicate more rapidly than full-length viral genomes, and hence may theoretically inhibit the spread of the advantageous mutations. DI particles are likely to be maintained in virus populations through complementation, which is predicted to be a common occurrence when multiple viruses are able to infect a single cell (García-Arriaza *et al.*, 2004). Complementation is of evolutionary significance because it allows deleterious mutations to persist for extended periods (Aaskov *et al.*, 2006), but may also increase robustness (Gao and Feldman, 2009).

RNA Virus Recombination

Although RNA viruses are in some sense defined by their high mutation rates, recombination may also be a major contributor to their evolution. Recombination rates vary from effectively clonal (i.e., asexual) to cases in which the recombination rate per nucleotide exceeds that of mutation. There are two main forms of recombination in RNA viruses (**Figure 5**). 'True' RNA recombination occurs when two viruses co-infect a single host cell and a hybrid molecule is produced, most likely through 'copy-choice replication' in which the RNA polymerase jumps templates during replication (Simon-Loriere and Holmes, 2011). In contrast, reassortment occurs in segmented RNA viruses, and takes place when a virus packages segments with different ancestries.

The importance of recombination in viral evolution reflect its association with such key traits as host range, host immunity, antiviral resistance, and creating new viruses (Holmes, 2009a). For this reason it is commonly thought that recombination functions as a form of sexual reproduction to create advantageous genetic configurations. In addition, recombination may disassociate advantageous from linked deleterious mutations, and prevents clonal interference. Similarly, recombination facilitates the efficient removal of deleterious mutations. A related theory is that of Muller's ratchet, which has been observed in some laboratory viral populations (Chao, 1990). Although the rate of deleterious mutations (approximately one per genome replication) may be sufficient to provide a selective benefit to recombination in RNA viruses, this theory also requires that mutations interact through synergistic epistasis, for which there is currently little good evidence (Sanjuán *et al.*, 2004). In addition, because high rates of recombination are relatively infrequent in RNA viruses they are unlikely to be universally advantageous. It is also apparent that recombination rates vary across viral genomes, with distinct hot-spots and cold-spots, which may in part reflect patterns of RNA secondary structure (Runckel *et al.*, 2013).

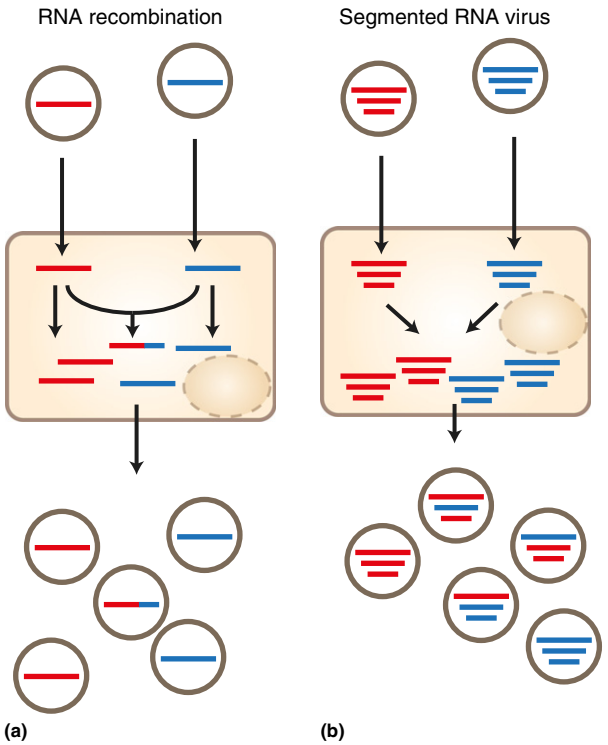

Figure 5 RNA recombination and reassortment in RNA viruses. (a) RNA recombination. This occurs following co-infection of a cell by different virus strains and can lead to the generation of recombinant viruses through copy-choice replication. RNA recombination can occur in both unsegmented viruses (as shown) or within the segment of a segmented virus. (b) Reassortment. This occurs following co-infection of a cell by different strains of a segmented virus, and can generate different combinations of reassortant progeny. Adapted from Simon-Loriere, E., Holmes, E.C., 2011. Why do RNA viruses recombine? Nature Reviews Microbiology 9, 617–626.

An alternative theory is that recombination rates simply reflect differing types of genome architecture and replication strategy (Simon-Loriere and Holmes, 2011), particularly because there is a general association between recombination frequency and virus genome structure. For example, the low recombination rates in (unsegmented) negative-sense RNA viruses may reflect the fact that their genomic and anti-genomic RNA molecules are bound to proteins to form ribonucleoprotein complexes that reduces the frequency of template switching.

Robustness and Evolvability in Molecular Evolution

A Wagner and JL Payne, University of Zurich, Zurich, Switzerland

Glossary

Evolvability The ability of organisms to bring forth novel, beneficial phenotypes through DNA mutations.
Folding The process by which the linear amino acid strings of proteins and the linear nucleotide strings of RNA molecules adopt a planar or three-dimensional shape that helps them perform their function.
Genotype network, neutral network A set of genotypes with the same broadly defined phenotype, represented as a network where vertices correspond to genotypes and edges connect vertices if their genotypes are separated by a single small mutation.
Genotype space A collection of genotypes that is usually large. For example, the genotype space of proteins with 500 amino acids comprises all possible 20^{500} amino acid strings of this length.
Mutational distance The number of mutations required to transform one genotype into another.
Neighborhood Comprises all those genotypes that differ from a given genotype through a small genetic change, for example, all neighbors of a protein that are derived from it through a single amino acid change.
Neighbors Two genotypes that differ in a small genetic change, such as a single amino acid change in a protein.
RNA secondary structure A planar shape that linear RNA molecules form through internal base pairing of their nucleotides.
Robustness The persistence of a phenotype in the presence of genetic mutation (the focus of this article) or environmental change.

Life is tough. Environments change, nutrients fluctuate, and mutations perturb. Yet life persists. What is more, it innovates. From the photoreceptors and lens crystallins that facilitate vision to the eyespots of butterfly wings that protect against predation, the natural world brims with examples of evolutionary innovation. Understanding how life balances its robustness, the ability to withstand perturbations and especially DNA mutations, with its capacity to exploit these mutations to create new and beneficial phenotypes – evolvability – is a central theme of biological research (Masel and Trotter, 2010) and is the subject of this article.

Any evolving population can be viewed as exploring a large space of possible genotypes, where each member of the population occupies one location in this space and moves through this space via random DNA mutation. Natural selection facilitates the survival or reproduction of those genotypes (individuals) that are best adapted to the environment they live in. Several decades of research have shown that genotypes with the same phenotype often form large and far-reaching networks in this space (**Figure 1**). These networks are a consequence of mutational robustness, and have been called neutral networks or genotype networks (Lipman and Wilbur, 1991; Schuster *et al.*, 1994; Ciliberti *et al.*, 2007a,b; Rodrigues and Wagner, 2009; Wagner, 2011a,b).

We here discuss evidence from the evolution of proteins, RNA, and gene regulatory circuits (**Figure 2**), which suggests that robustness can facilitate evolvability. The reason is that a genotype network allows an evolving population to explore genotype space while preserving well-adapted phenotypes, and in doing so, permits the exploration of novel phenotypes in different regions of this space. Some of these phenotypes may become evolutionary adaptations and innovations. We also discuss circumstances where the organization of a genotype network may reduce evolvability.

Proteins

In a 1970 article in the journal *Nature*, evolutionary biologist John Maynard Smith speculated on the existence of networks of proteins in the space of all possible proteins (Maynard Smith, 1970). In 1991, a computational analysis of a simple

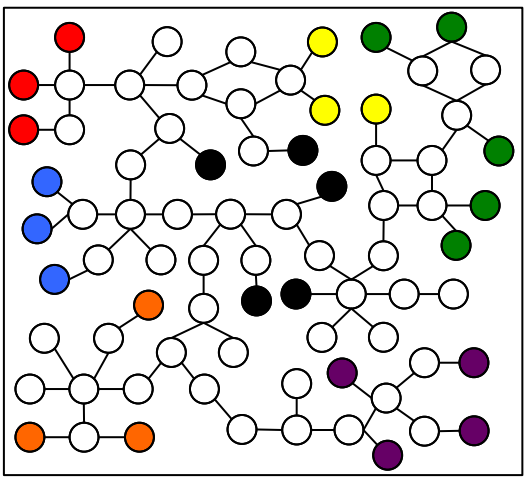

Figure 1 Mutational robustness facilitates evolvability via the formation of large genotype networks. This schematic shows how genotypes (open circles) in genotype space (rectangle) can be organized as a genotype network, where edges connect vertices if their corresponding genotypes differ in a single small mutation. Since most of these genotypes have more than one neighbor in the genotype network, they are to some extent robust to mutation. This schematic also illustrates how, by extending throughout genotype space, a genotype network provides access to a variety of phenotypes (filled circles; color indicates phenotype).

 doi:10.1016/B978-0-12-800049-6.00182-7

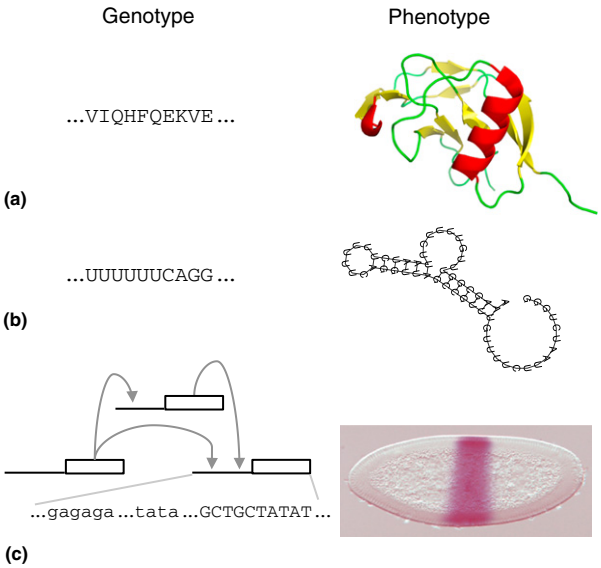

Figure 2 The genotype and phenotype of proteins, RNA, and regulatory circuits. (a) A protein genotype is its amino acid sequence and a protein phenotype is its tertiary structure and associated function. (b) An RNA genotype is its nucleotide sequence and an RNA phenotype is its spatial fold, of which the planar secondary structure is shown. (c) A gene regulatory circuit genotype is the DNA sequence encoding the circuit's constituent transcription factors and regulatory regions. For illustration, we show a hypothetical three-gene circuit and the DNA sequence of the transcription factor binding sites (lower case) and a part of the protein-coding region (upper case) of one of the genes in the circuit. The phenotype of a gene regulatory circuit is a spatiotemporal gene expression pattern. As an example, we show the expression pattern of *Krüppel* – one of the gap genes – in the developing embryo of *Drosophila melanogaster*.

model of protein folding first demonstrated the existence of such networks (Lipman and Wilbur, 1991). This model used a simplified amino acid chain consisting of two different kinds of amino acids (hydrophobic or hydrophilic) that fold on a two-dimensional lattice, such that the number of energetically favored interactions among amino acids is maximized. Each vertex in such a network corresponds to a single amino acid sequence, and two vertices are adjacent if they differ in a single amino acid. More specifically, this article demonstrated that proteins that fold into the same structure form connected networks in genotype space (Lipman and Wilbur, 1991). Each member of such a genotype network has one or more neighbors with the same phenotype, which means that each protein is to some extent robust to mutations that cause single amino acid changes. Mathematical work has shown that genotype networks are a consequence of robustness to mutations (Reidys *et al.*, 1997; Wagner, 2011a,b).

Genotype networks and robustness do not just exist in model proteins. For example, phylogenetic analyses of proteins such as oxygen-binding globins have demonstrated that proteins with the same tertiary structure and function can diverge in the vast majority of their amino acids (Aronson *et al.*, 1994). Proteins with highly diverged amino acid sequence yet preserved structure or function are the rule rather than the exception in biology (Rost, 2002; Todd *et al.*, 1999). In addition, random mutagenesis studies that alter a single or multiple amino acids in proteins such as lysozyme, or β-lactamase (Huang *et al.*, 1996; Rennell *et al.*, 1991), have shown that most single amino acid changes do not affect protein function detectably.

Such robustness can also facilitate the origin of proteins with novel functions. For example, laboratory experiments that engineer proteins such as cytochrome P450 toward increased robustness have demonstrated that robustness can facilitate the origin of novel enzymatic functions through point mutations. The reason is that mutations that create novel enzymatic functions often destabilize a protein. Increased robustness can counteract this destabilization effect, and thus help preserve mutations that create new functions (Bloom *et al.*, 2006). Another way of increasing protein robustness involves chaperones, proteins that help other proteins fold, and that can mitigate the detrimental effects of mutations on a protein's stability. By increasing the expression of a chaperone, mutations that would otherwise have destabilizing effects on proteins can become neutral, and this buffering of mutational effects can help new catalytic activities emerge. For example, in an *Escherichia coli* laboratory evolution experiment, overexpression of a chaperone enhanced the ability of a phosphotriesterase to cleave the novel substrate 2-naphtylhexanoate (Tokuriki and Tawfik, 2009). This link between robustness and the emergence of novel enzymatic functions also exists on evolutionary timescales. Specifically, the more robust a protein fold's tertiary structure is, the greater is the number of novel enzymatic functions that this fold has acquired in its evolutionary history (Ferrada and Wagner, 2010).

RNA

As in proteins, the earliest analyses of the genotype–phenotype relationship in RNA used a simplified computational model of phenotype formation. Specifically, they focused on RNA secondary structure, because it can be computationally predicted, and because proper RNA secondary structure is usually a necessary prerequisite for RNA function. Pioneering computational work identified extended networks that RNA genotypes with the same minimum free energy secondary structure form in RNA genotype space (Schuster *et al.*, 1994). These networks – which have also been called neutral networks – exist because individual RNA molecules typically have many neighbors in sequence space that have the same secondary structure phenotype. Large neutral networks harbor more RNA molecules, which are also on average more robust to mutations than RNA molecules from smaller neutral networks. Although experimental work shows that not all RNA molecules form neutral networks that are as extended in genotype space as computational work suggests (Jiménez *et al.*, 2013), biological RNA molecules often diverge greatly in sequence while preserving structure and function (Parsch *et al.*, 2000), suggesting that they do indeed show substantial robustness to genetic change. Large neutral networks can facilitate the discovery of novel RNA phenotypes by populations that evolve on them. The reason is that such populations experience fewer deleterious mutations, and can thus spread more rapidly through genotype space, which increases their chances to find novel

phenotypes (Wagner, 2008). The fact that these chances vary amongst genotypes raises the intriguing possibility that evolvability is itself evolvable. Because there is at present very little experimental data to support this notion, we do not discuss it further here.

Experimental work on ribozymes showed that genotype networks of RNA molecules can play an important role in the creation of RNA molecules with novel functions (Hayden *et al.*, 2011; Schultes and Bartel, 2000). One pertinent study designed a 'walk' in sequence space to interconvert the hepatitis delta virus self-cleaving ribozyme and a synthetic ligase ribozyme, which have different catalytic activities, folds, and sequences. During most of the individual steps (nucleotide changes) along this walk, ribozyme function did not change. At about half the distance between the two ribozymes in genotype space, a small number of key mutations were sufficient to change one evolving ribozyme's catalytic functions into that of the other ribozyme (Schultes and Bartel, 2000). This suggests that genotype networks and their proximity in genotype space can facilitate evolutionary transitions between ribozymes with different functions. Another experiment showed that genotype networks can facilitate the origin of new adaptations in an evolving population (Hayden *et al.*, 2011). To this end, it compared two evolving populations of the Azoarcus ribozyme, a self-splicing intron from proteobacteria of the genus *Azoarcus*. The first population was concentrated in a small region of genotype space, whereas the second population was spread out on the genotype network of the ribozyme's ancestral phenotype. The second population adapted faster to a new and challenging chemical environment, in which the ribozyme's native RNA substrate for a self-ligation reaction was replaced by a chemically modified substrate that required the population to adapt evolutionarily (Hayden *et al.*, 2011). In sum, these experiments demonstrate that genotype networks in RNA molecules can facilitate the origin of novel enzymatic phenotypes.

Gene Regulation and Gene Regulation Circuits

Gene regulatory circuits drive fundamental physiological, developmental, and behavioral processes in organisms across the tree of life (Carroll *et al.*, 2001). Examples include chemotaxis in bacteria (Alon *et al.*, 1999), mating behavior in yeast (Tsong *et al.*, 2006), and developmental patterning in the fruit fly (Lawrence, 1992). Such circuits comprise a set of genes – typically encoding DNA-binding proteins known as transcription factors – that regulate the expression of other genes in the circuit. The genotype of a regulatory circuit comprises the DNA encoding transcription factor genes, as well as DNA-binding sites for these factors near circuit genes. It encodes two aspects of circuit behavior, namely the interactions between genes (i.e., 'who-regulates-whom') and the signal-integration logic used by each gene to interpret the signals provided by its regulating gene products. The former aspect is encoded by the presence or absence of transcription factor binding sites near a gene, whereas the latter is encoded by the number, spacing, and binding affinity of these sites (Sharon *et al.*, 2012; Smith *et al.*, 2013). The phenotype of a regulatory circuit is its spatiotemporal gene expression pattern, which specifies when, where, and to what extent each gene in the circuit is expressed. A classical example of such a circuit is that formed by the gap genes of *Drosophila melanogaster*, which interprets a maternally deposited morphogen gradient along the anterior–posterior axis of the developing embryo to create precise expression bands, which are fundamental to defining the segmented body plan of the fly and constitute the phenotype of this gene circuit (Lawrence, 1992).

Each circuit genotype with a given expression phenotype can be viewed as a member of a genotype network. Vertices in such a network represent entire circuits and edges connect vertices if their corresponding circuits differ in a single regulatory interaction, or in the regulatory logic of a single gene. Most of what we know about the genotype networks of regulatory circuits come from computational models. For example, Ciliberti *et al.* (2007a,b) used such a model to demonstrate that for any given gene expression phenotype, the vast majority of genotypes form a single, connected genotype network. Similar observations were made using model regulatory circuits inspired by *Drosophila* development, in which a morphogen gradient is interpreted along a spatial domain to form a single, centralized band of gene expression (Cotterell and Sharpe, 2010). There too, stripe-forming circuits form genotype networks. In both models, individual genotypes typically have many neighbors with the same phenotype. Such genotypes are thus to some extent robust to mutations that cause small genetic changes. Moreover, such networks extend far throughout the space of possible genotypes. For instance, two circuits from the same genotype network can be as different from one another as are two circuits chosen at random from genotype space (Ciliberti *et al.*, 2007a). Empirical evidence that circuits with very different genotypes can have the same phenotype exists for circuits that regulate galactose metabolism, mating type, and ribosomal protein expression in fungi (Martchenko *et al.*, 2007; Tanay *et al.*, 2005; Tsong *et al.*, 2006).

Genotype networks not only confer mutational robustness to the expression phenotypes of gene regulatory circuits, they also facilitate evolvability. Ciliberti *et al.* (2007a) demonstrated this by sampling pairs of circuits from genotype networks and determining the sets of novel expression phenotypes that could be realized via regulatory mutations to each circuit in the pair. They found that these sets became increasingly distinct as the difference between the sampled circuits increases. In other words, because genotype networks extend far throughout the genotype space of regulatory circuits, they permit access to a large diversity of novel gene expression phenotypes and thus facilitate evolvability.

While computational analyses have allowed for the characterization of entire spaces of regulatory circuits, experimental data from protein-binding microarrays (Berger *et al.*, 2006) have permitted characterizing the smallest units of circuit organization, transcription factor binding sites, and the spaces they form. These short DNA sequences define the regulatory interactions of a circuit, and mutations to these sequences can affect a circuit's gene expression phenotype (Wray, 2007; Prud'homme *et al.*, 2007), either by altering binding affinity or by abolishing binding. Understanding the robustness of transcription factor binding sites is therefore important to understanding the robustness of regulatory circuits. A recent study

using protein-binding microarray data from 89 yeast and 104 mouse transcription factors analyzed the genotype networks of each of these factors' binding sites (Payne and Wagner, 2014). For 99% of the 193 factors, the majority of sequences bound by the factor are part of a single genotype network. Moreover, these networks are densely connected, implying that individual binding sites are to some extent mutationally robust. Some networks are larger than others – they comprise more binding sites – and individual binding sites in larger networks are more robust than binding sites in smaller networks.

For each of the 193 transcription factors that Payne and Wagner (2014) examined, they also sampled pairs of sites from the same genotype network and determined the sets of transcription factors that bind sites that neighbor those in the pair. As the mutational distance between sites increases, so does the diversity of transcription factors that bind neighboring sites. Moreover, the larger a genotype network is (and the more robust its binding sites are on average), the greater the number of unique transcription factors that bind sites adjacent to the genotype network. In sum, these observations suggest that robustness and evolvability exhibit a synergistic relationship in gene regulatory circuits and their transcription factor binding sites, made possible by the existence of large genotype networks that spread throughout genotype space.

Caveats

Although robustness facilitates evolvability in general, exceptions to this rule may exist. First, theoretical arguments suggest that certain topological properties of genotype networks, together with a population's location in a genotype network, can hinder evolvability. For example, if a genotype network has a dense interconnected core where many neighbors preferentially connect with one another, a population may become entrapped in this core such that it is no longer able to explore many novel phenotypes (Manrubia and Cuesta, 2014). Empirical evidence for this phenomenon can be found in the genotype network formed by four key amino acids of the PhoQ protein interface of *E. coli* (Podgornaia and Laub, 2015), in which each vertex represents a combination of amino acids capable of binding the protein PhoP. This PhoQ genotype network is expansive and includes 13 residue combinations found in natural PhoQ orthologs. All of these orthologs are contained in the genotype network's dense interconnected core, indicating that the structure of the genotype network may have constrained the evolutionary exploration of alternative PhoQ variants.

A second caveat is that the genotype networks of different phenotypes may be biased in their connectivity to one another, such that a random mutation may be more likely to allow evolving genotypes to enter a larger genotype network than a smaller genotype network. Computational work has shown that this connectivity bias may lead to an 'ascent of the abundant,' where populations evolve phenotypes with large genotype networks, even if these phenotypes do not provide adaptive advantages (Cowperthwaite *et al.*, 2008). The secondary structure phenotypes of multiple short noncoding RNA molecules have genotype networks much larger than expected by chance alone, i.e., based on randomly sampled phenotypes, suggesting that this ascent of the abundant is more than a theoretical possibility (Jorg *et al.*, 2008).

A third exception exists in situations where a genotype network is fragmented into multiple components or subnetworks (Jiménez *et al.*, 2015). For example, in stripe-forming regulatory circuits, there are several dynamical mechanisms by which a single, centralized band of gene expression may form (Cotterell and Sharpe, 2010). Even though each mechanism yields the same phenotype, the genotypes that encode these mechanisms form distinct genotype networks that are isolated from one another in genotype space. These genotype networks differ in their evolvability, because each provides mutational access to the genotype networks of different sets of novel gene expression phenotypes (Jiménez *et al.*, 2015). Here, individual circuits may be to some extent robust to genetic change, but because their genotype networks are fragmented, each circuit can access only a limited repertoire of novel phenotypes. Similar fragmentation has been observed for the secondary structure of RNA genotypes (Aguirre *et al.*, 2011; Schaper *et al.*, 2012). The extent to which such fragmentation hinders evolvability depends on multiple factors. For example, if population sizes are sufficiently high or mutation rates sufficiently large, populations can 'tunnel' between different components of fragmented genotype networks (Weinreich and Chao, 2005).

In sum, with possible exceptions, robustness can facilitate evolvability by virtue of genotype networks that allow evolving populations to preserve well-adapted phenotypes, while exploring distant regions of genotype space and the novel and potentially beneficial phenotypes they contain. As high-throughput technologies for phenotyping macromolecules and regulatory circuits continue to advance, it will become possible to experimentally probe the genotype networks of biological systems at ever-greater resolution, further elucidating when, how, and to what extent robustness and evolvability exhibit a synergistic relationship.

Rooting Trees, Methods for

T Kinene, J Wainaina, S Maina, and LM Boykin, The University of Western Australia, Perth, WA, Australia

Rooted versus Unrooted

Phylogenetic trees are either rooted or unrooted, depending on the research questions being addressed. The root of the phylogenetic tree is inferred to be the oldest point in the tree and corresponds to the theoretical last common ancestor of all taxonomic units included in the tree. The root gives directionality to evolution within the tree (Baldauf, 2003). Accurate rooting of a phylogenetic tree is important for directionality of evolution and increases the power of interpreting genetic changes between sequences (Pearson *et al.*, 2013).

Many techniques such as molecular clock, Bayesian molecular clock, outgroup rooting, or midpoint rooting methods tend to estimate the root of a tree using data and assumptions (Boykin *et al.*, 2010). However, Steel (2012) discusses root location in random trees and points out that information in the prior distribution of the topology alone can convey the location of the root of the tree. These results show that the tree models that treat all taxa equally and are sampling consistently convey information about the location of the ancestral root in unrooted trees (Steel, 2012).

Why Do We Need a Rooted Tree?

We are interested in rooting a phylogenetic tree in order to show the path of evolution of biological species. Therefore most users of phylogenetic trees want rooted trees because they give an indication of the directionality of evolutionary change. The root of phylogenetic tree is crucial in evolutionary interpretation of the tree (Williams, 2014), because an unrooted tree species shows only the relationships among the taxa and does not define the evolutionary path (**Figure 1(a)**).

When Do We Need an Unrooted Tree?

An unrooted tree is desired when we do not have a distantly related group (sequence) for comparison or when primary interest is focused only on relationships among the taxa rather than on the directionality of evolutionary change. Unrooted trees are beneficial in depicting clusters of related sequences. Unrooted gene trees have also become more prevalent within the multispecies coalescent phylogenetic framework, leading

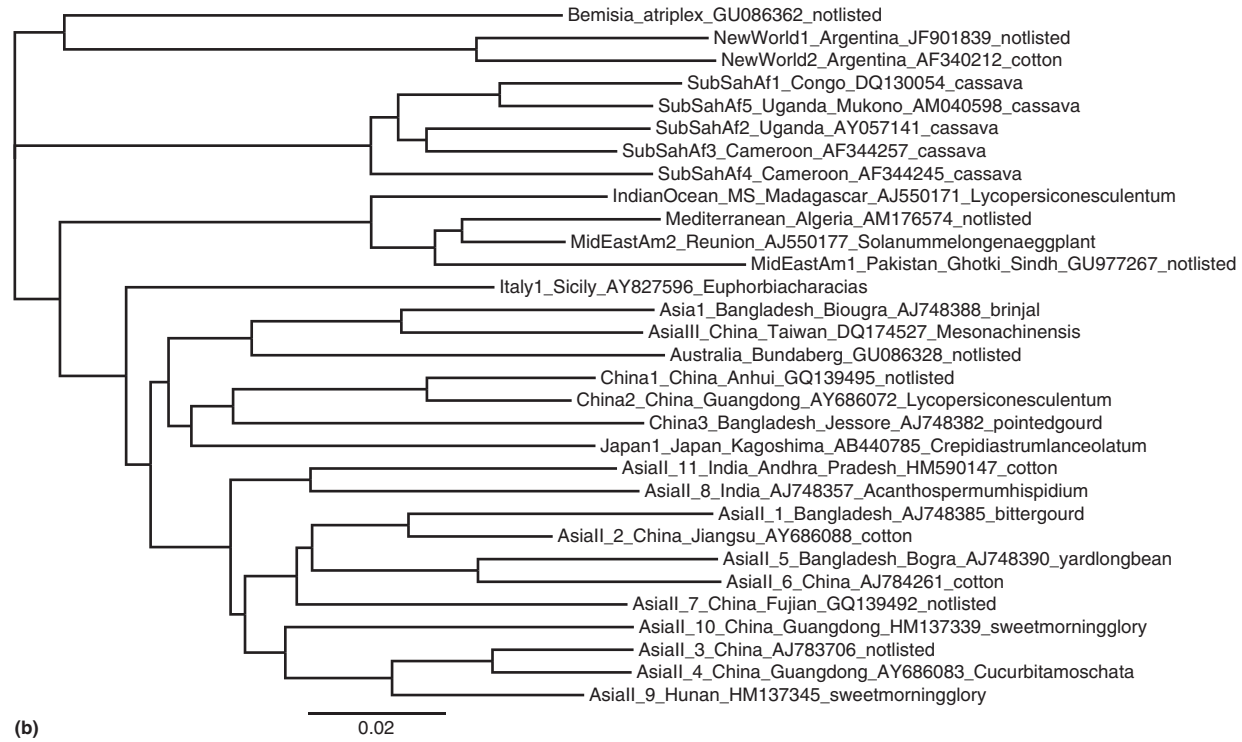

Figure 1 Continued.

to systematic approaches for inferring unrooted species trees from unrooted gene tree topologies (Liu and Yu, 2011). Gene trees and species trees can have similar topologies but often there is considerable discordance between gene tree and species trees (Degnan, 2013). For this reason, understanding how to root gene trees will have implications for accurate species tree inference (**Figures 1(b)** and **1(c)**).

How Do You Root a Phylogenetic Tree?

Outgroup Rooting

There are several rooting methods (**Table 1**), however the most popular and widely used is the outgroup method (Wheeler, 1990; Tarrío *et al.*, 2000; Hess and De Moraes Russo, 2007; Boykin *et al.*, 2010). Outgroup method assumes that one or more of the taxa are divergent from the rest of the taxa (ingroup). The branch linking the ingroup and outgroup becomes the starting point, and defines all subsequent evolutionary events within the tree (Brady *et al.*, 2011; Williams, 2014). In addition to providing evolutionary information of the ingroup, the outgroup has other additional functions. It allows the identification of distinct features within ingroup sequences (Wheeler, 1990). An important aspect of outgroup method is the need for a priori knowledge on the appropriate outgroup to use for the set of sequences (Wheeler, 1990; Hess and De Moraes Russo, 2007). However, this is also the main bottleneck for this method, especially within higher taxonomic groups such as angiosperms, birds, and mammals where a consensus outgroup is lacking (Qiu *et al.*, 2001). As a consequence, many authors are forced to choose between different sorts of outgroups that are either phylogenetically close or phylogenetically distant (Rota-Stabelli and Telford, 2008).

Lack of an appropriate outgroup results in drawbacks such as the long branch attraction (LBA). LBA occurs mainly when the outgroup taxa are distantly related to the ingroup due to either large divergence time and/or increased rate of evolution (Tarrío *et al.*, 2000). This results in homoplastic changes occurring at rapidly evolving sites thus resulting in artifactual rooting (random rooting) (Wheeler, 1990; Hendy and Penny, 2011; Maddison *et al.*, 1984). Several criteria have been proposed to prevent LBA within phylogenetic trees, through a multistep process as proposed by Rota-Stabelli and Telford (2008) to assist in outgroup selection especially in the case of arthropod classes. They include: (1) low substitution rate; (2) ingroup like G + C composition; (3) new strand bias estimators 'skew index'; (4) the tendency of the outgroup to avoid 'random branding effect'; and (5) phylogenetic proximity to the arthropod.

An alternative approach to assess the importance of an outgroup in rooting the tree is explored by Graham *et al.* (2002); this is by establishing whether the outgroup provides sufficient signal in response to root location, indicative of historic linkage or due to LBA. Using Pontederiaceae, an aquatic monocot, as the case study they assessed how the nearest outgroup provides for rooting Pontederiaceae compared to those less closely related relatives and further investigate the role of LBA when determining the optimal rooting of Pontederiaceae. However, they concluded that LBA may influence rooting, and may be supporting the wrong outgroup. To further reduce LBA and to ensure robustness of the outgroup rooting method they recommend multiple sampling of outgroups within the sister group rather than sampling within less closely related taxa.

Figure 1 Continued.

Midpoint Rooting

Midpoint rooting calculates tip to tip distances and then places the root halfway between the two longest tips (Swofford *et al.*, 1996). The ancestral point will be identified if the tree has constant rates of evolution. The method is exclusively dependent on the branch length of the phylogenetic tree and the assumption of the molecular clock (Holland *et al.*, 2003). Homogeneity is assumed across the branch and that the two most divergent taxa evolved at equal rates (Holland *et al.*, 2003; Swofford *et al.*, 1996). If the tree is balanced, midpoint rooting works well. However, a major limitation of midpoint rooting is the dependence on having clocklike data and a balanced topology.

The midpoint rooting method is often applied to viral genetic datasets because in many cases outgroups are unknown. For example, Stavrinides and Guttman (2004) utilize midpoint rooting to establish the evolutionary relationship of severe acute respiratory syndrome (SARS) coronaviruses. They carried out phylogenetic analysis of the viral genes encoding for viral structural proteins specifically, envelope matrix (M) and nucleocapsid (N) proteins. The midpoint rooting of the

Table 1 Four methods for rooting phylogentic trees

Rooting method	*Pros*	*Cons*	*Software*
Outgroup	Accurate	Must have an outgroup Long branch attraction	PAUP Figtree R package: ape (http://www.inside-r.org/packages/cran/ape/docs/unroot)
Midpoint	Fast No outgroup needed	Dependent on clocklike data Not good with unbalanced trees	PAUP R package: phangorn (https://cran.r-project.org/web/packages/phangorn/phangorn.pdf)
Molecular clock	No outgroup needed Robust to violations of the clock	Computationally intense	PAUP PAML
Bayesian molecular clock	Alternative rootings uncovered No outgroup needed	Must customize the prior	Post Root (http://www.stat.osu.edu/~lkubatko/software/phyl_util.html) Root annotator (http://sourceforge.net/projects/rootannotator/)

trees generated using the M protein data shows two groups, one that consisted of porcine, feline, and canine and one that contained bovine and murine coronaviruses (*Coronaviridae*). On the other hand, the N protein tree is midpoint rooted on the branch leading to the group 1 coronaviruses. Moreover, the appropriateness of midpoint rooting is supported by the results of Tajima's relative rate test (Tajima, 1993), indicating no rate heterogeneity among the coronavirus groups (Stavrinides and Guttman, 2004).

This method should be used as an alternative to the outgroup rooting method and could be adopted as the default method when the outgroup method is difficult to apply either due to problems with available outgroups, such as LBA or lack of a priori knowledge of the outgroup (Hess and De Moraes Russo, 2007).

Molecular Clock Rooting

The molecular clock rooting method has one assumption: the rate of evolution is constant for the sequences of interest (Yang and Rannala, 2012). The rate is typically expressed in substitutions per site per year or substitutions per site per million years (Brown and Yang, 2011). The strict clock is often used in analyses of sequences sampled at the intraspecific level, for which usually there is an exceptionally low rate of variation (Brown and Yang, 2011; Ho and Duchêne, 2014). The molecular clock assumption becomes problematic for distantly related species because there is a linear relationship between the genetic distances and approximate divergence. The slope of the line directly corresponds to the evolutionary rate variation among species especially among divergent taxa (Welch and Bromham, 2005). Before utilizing the molecular clock method for rooting a phylogenetic tree users should test if a molecular clock is appropriate to describe the data. Testing for the molecular clock entails generating two maximum likelihood trees, one computed with the molecular clock enforced and one without the molecular clock enforced and then utilizing the likelihood ratio test (Felsenstein, 1983; Holder and Lewis, 2003).

Bayesian Molecular Clock Rooting

Huelsenbeck *et al.* (2002) proposed the use of Bayesian inference under the molecular clock assumption to infer the root of a phylogenetic tree. After obtaining the posterior distribution of trees under Bayesian inference, the root of the tree is inferred to be the root position with the highest posterior probability. This method also provides the posterior probability that the root lies on any branch of the ingroup topology. Another advantage of the Bayesian method is that it allows the user to evaluate alternative rootings. Other rooting methods only return one rooting for a particular dataset, without any numerical assessment of confidence in that rooting. A Bayesian molecular clock analysis successfully identified the root of Orcuttieae (Poaceae) (Boykin *et al.*, 2010) when all other methods failed. Post_root was developed to analyze the output from MrBayes (Ronquist *et al.*, 2012) or ExaBayes (Aberer *et al.*, 2014) runs. The output from Post_Root will give the number of unique roots and also the most probable root position.

Most recently, Calvignac-Spencer *et al.* (2014) have further developed Post_Root to a web-based interface in their quest to identify the branch root posterior probability (RPP) of the most recent Ebola outbreak in West Africa. They were forced to rely on Bayesian molecular clock rooting because there is no known outgroup for Ebola. It is often the case when analyzing viral sequences that no outgroup is known; therefore the Bayesian molecular clock rooting is a very useful alternative, especially when rooting is crucial for viral outbreaks.

Glossary

Floras Enumerations of the plants of particular areas.

Keys Sequence of questions about features of an organism which when answered lead the user to its correct name.

Monophyletic A group containing all and only the descendants of a common ancestor.

The history of what today we could call taxonomy, the description of organisms and the construction of a hierarchical classification, and systematics, the study of the relationships between organisms, is complex. Understanding the connections between 'botany,' 'natural history,' 'zoology,' and 'biology' is central to this history and to that of the history of biology as a whole. It should also be remembered that most of the authors mentioned below distinguished rather simply between plants and animals, algae and fungi being considered to be plants (Box 1). In the middle of the seventeenth century, many, like Aristotle 2000 years before, believed in a nature that could be represented as some version of the scala naturae, a linear sequence of organisms arranged according to ideas of 'highness' and 'lowness,' in which man was above all organisms (and often not part of nature), and angels and ultimately god might be above him. There were many other ways of representing nature, and as the geologist Francis Bather observed in 1927, "not a single naturalist had a clear idea of what he meant by 'natural'. All he knew was that the other fellow's classification was unnatural" (Bather, 1927). In early usage, natural history itself for the most part had no historical element; 'history' meant 'story' or 'description.' In the nineteenth century in particular, men and women and amateurs and professionals studied different parts of natural history. Below authors may be referred to as being 'naturalists.' This is not always true, but it is the only general term that can be used. I carry the story through to the late 1980s, but do not attempt to other than outline some of the major issues, and these may play out in different ways in different countries as well as in different parts of natural history.

Box 1 Ambiguous names

The relationships between botany, natural history, zoology, and biology after Linnaeus published his *Systema naturae* in 1735 have been little studied. Indeed, throughout the nineteenth century, particular words that are in common use today like system, method, and organization were used with sometimes very different connotations than those they have today. 'Nature' and 'natural' are particularly ambiguous (e.g., Atran, 2008).

Classifications before Linnaeus

Members of cultures worldwide name the organisms that they commonly encounter, and detailed studies have been made of these folk taxonomies (Atran, 1999). They tend to include relatively few members, often under 500, perhaps reflecting limitations of human memory. Here the hierarchy is shallow (there are few ranks), and the taxonomies are partly shaped by the relationships between organisms and society. These may be other than simply utilitarian – hence the title of a paper, 'Why the cassowary is not a bird,' which explains why cassowaries are not included with other birds in some New Guinea local classifications.

Aristotle (384–322 BCE), Plato's student, is noted for his *History of Animals*, *Parts of Animals*, and *Generation of Animals*. Importantly, the *History of Animals* starts off with a discussion of the different relationships – excess, defect, and analogy – between similar structures in different organisms. These books include many quite accurate observations, and Aristotle is known to have dissected animals (but not humans). The botanical works of Theophrastus (ca. 381–287 BCE), also Plato's student and Aristotle's successor, include information about exotic organisms encountered by Alexander the Great's armies. Rather later Dioscorides in his *De materia medica* of ca. 60 CE discussed the uses of plants in medicine. His work, in particular, remained well known and the close association of plants/botany and medicine persisted into the nineteenth century.

In Europe, in the sixteenth to eighteenth centuries in particular, cabinets of natural curiosities, or natural history cabinets, were very popular. These might include everything from

 doi:10.1016/B978-0-12-800049-6.00002-0

geological and anthropological artifacts such as crystals and Eskimo canoes to animals and plants, skeletons, fibers, and the like. At the same time naturalists like Leonhart Fuchs in his much-reprinted *The Great Herbal* (1542) and Conrad Gesner and his five-volume *Historiae animalium* (1551–1558) produced very popular profusely illustrated volumes that in part integrated classical literature with European knowledge of plants and animals. Subsequently, organisms unknown to classical authors, particularly those newly encountered by Europeans in the course of their travels, were described and illustrated.

Particularly important in the questioning of classical knowledge was the anatomical work of Andreas Vesalius, whose *De humani corporis fabrica* (1543) consisted of superb dissections of the human body. Prior to this Galenic ideas of human anatomy predominated; Galen, born in 120 CE, seems to have based his ideas of human anatomy on dissections of Barbary apes and other animals. In 1555, Pierre Belon illustrated human and bird skeletons side by side, similar bones in the two being indicated by the use of the same letter, an early example of comparative anatomy. Microscopes became popular with the work of Robert Hooke and his *Micrographia* of 1665, while in the 1670s, Antoine van Leeuwenhoek discovered the teeming world of minute animals and plants in water.

Linnaeus

There had been many classifications before Linnaeus. For example, John Ray in his *Historia plantarum* (1686–1704) drew important distinctions between major groups of plants. Ray's friend Francis Willughby wrote the important *Ornithologia libri tres* of 1675. However, there was no generally accepted classification for organisms. This is what Linnaeus provided in successive editions of his *Systema naturae*, *Species plantarum*, and *Genera plantarum*. The first edition of the *Systema naturae* (1735) includes inventories of the three kingdoms of nature, plants, animals, and minerals, and is a linear listing of all natural phenomena according to the number, shape, position, and proportion of their parts (Koerner, 1999). Linnaeus brought order to previous work, bringing together different citations of the same species by earlier naturalists. In the first edition of the *Species plantarum* (1753) he introduced binomials. Binomials like *Canis familiaris* are noun–adjective combinations, as is the domesticated dog, to which that name refers, the only difference being that the first is in Latin, the *lingua franca* of the time. Naturalists worldwide soon found binomials indispensable. They were unambiguous and much shorter and more convenient than the descriptive phrase or polynomial that had previously been used. The 10th edition of *Systema naturae* of 1758 is the starting point of most zoological nomenclature, and that of plant (and bacterial) nomenclature is the *Species plantarum* of 1753.

Linnaeus's hierarchy had five main ranks, and he acknowledged that his higher groupings were for the most part artificial, and he recognized groups like 'worms,' 'fish' (which initially included whales), and so on. However, Linnaeus thought his genera and species were more or less natural and represented ranks in nature. There are also elements of the *scala naturae*, or chain of being, in how he arranged animals and plants in his classification. Species at the end of one genus might be more similar to a species at the beginning of the next than to some of the other species in its own genus; Aristotle had called such organisms dualizing, showing relationships in two directions.

Linnaeus had many students, and in some of their theses, which for the most part Linnaeus himself wrote, he did outline one or two more 'natural' groups of plants.

Although Linnaeus classified both plants and animals, he was more interested in the former, and most naturalists since have worked largely on plants or animals, rarely on both. Indeed, the histories of botanical and zoological systematics are rather different, partly because of the apparent simplicity of many plants and greater complexity of many animals.

Developments Immediately after Linnaeus

In botany, names such as J.E. Smith, Antoine-Laurent de Jussieu, and Augustin-Pyramus de Candolle were prominent in the late eighteenth and early nineteenth centuries, the last two being members of dynasties of scientists/botanists. J.E. Smith early acquired most of Linnaeus's collections and library and the prestige associated with them. Smith and de Candolle in particular distinguished between the various parts of natural history. Thus the 'philosophical' botany of Smith included physiology, while de Candolle distinguished between plant physics, which included Smith's philosophical botany, applied botany, the use of plants by humans, and botany 'strictly speaking,' botany as classification, i.e., taxonomy and systematics. Indeed, botany became synonymous with classification and naming.

Jussieu and Candolle are both noted for constructing natural systems, and this became common in the nineteenth century. Jussieu recognized precisely 100 families, surely hardly by chance, and if his system is examined in detail, it represents a modified chain of being. Candolle's revisions of plant families also showed continuity in relationships, genera being arranged in circles, these circles touching adjacent circles. In both cases the plant features used were largely those of external form, but they included features of the plant embryo and Candolle in particular was interested in anatomical information (Stevens, 1994).

As the century wore on, flora-writing became ever more important in botanical work, and these floras might cover large areas of the world – usually colonial posessions – and could take half a century or more to complete. Keys allowed the plants to be identified. Thus, Carl Friedrich Philipp von Martius's *Flora brasiliense* came out in 130 fascicles between 1840 and 1896 (Martius was then long dead). Martius also wrote the great *Historia naturalis palmarum* (3 vols, 1823–1850), which included remarkable anatomical studies by Hugo von Mohl.

Hugo von Mohl was basically an anatomist-physiologist, and the name of Robert Brown, 'botanicorum facile princeps,' who was active in the first half of the nineteenth century, is also prominent here (Mabberley, 1985). Initially Brown's work was more floristic and taxonomic, but he also carried out detailed microscopic work on pollen, plant cells, etc., naming

the nucleus and noticing what is now called Brownian motion. At this time, 1820–1850, a number of botanists took up physiological and anatomical studies, a shift particularly evident in Germany. However, anatomical work was not commonly carried out by taxonomic botanists, but not because of any limitation of early microscopes. The remarkable *Traité d'organogénie comparée de la fleur* (1854–1857) by Jean-Baptiste Payer includes engravings that show as much detail as early electron micrographs.

Naturalists working on animals had taken up anatomical studies earlier. George-Louis Leclerc, Conte du Buffon, wrote a 36-volume *Histoire naturelle, générale et particulière* (1749–1788) in which the accounts of quadrupeds were accompanied by drawings of dissections by Louis-Jean-Marie Daubenton. In the first part of the nineteenth century, Georges Cuvier in France and Richard Owen in England, both also paleontologists, were the foremost vertebrate anatomists. Buffon developed evolutionary ideas, while Cuvier was a catastrophist, organisms appearing anew after life had been wiped out. Although Owen is often remembered for being anti-evolutionary, his anatomical work led him to make clear distinctions between homology, largely determined by the relative position and connection of parts, and analogy, largely functional similarity. From his detailed comparative studies he abstracted an archetype, which, although it looks like a primitive fish, depended not on evolutionary ideas but more to German Romantic thought.

Darwin and Ideas of Relationships

A goal of many naturalists was to discover the relationships between organisms, and many diagrams showing relationships – some tree-like – were published before 1859 (Winsor, 1991).

The publication of Darwin's *On the Origin of Species* (1859) did not much affect the practice of systematics, since it did not suggest any obvious way to detect phylogenies or promote new ways of describing species, although it did explain why there might be uncertainty over species limits. However, after 1859, diagrams showing relationships became more common.

In these diagrams there was often an attempt to convey both ideas of relationships and of evolutionary advancement. Ernst Haeckel's thought that ontogeny recapitulated phylogeny (oversimplified!), and embryology was considered to provide the most important evidence about relationships. The default arrangement in many early evolutionary works was for organisms to be arranged in a series from simple to more complex, and there was much talk of lowness (simple) versus highness (more complex), primitive versus advanced.

Comparative anatomy also became very popular among some botanists in the latter part of the nineteenth century, and subsequently features like chromosome numbers and plant chemistry were all at least briefly popular. Karl Mez and Hermann Ziegenspeck studied the serological reactions of plant proteins, publishing the very controversial 'Konigsberg Stammbaum' in 1926. Rather later, and also quite controversial, was the technique of DNA hybridization used by Charles Sibley and Jon Ahlquist in the early 1980s to determine the relationships of birds.

But how were naturalists to evaluate differing ideas of relationships? How does – or even can – the mind analyze all the observations made on a group when deciding on its limits, the limits of the species it contained, and its relationships? What characters were important in evolution and so important in determining relationships? Naturalists as far back as Aristotle had claimed to use many characters in their classifications, but close analysis of earlier classifications suggests that often only one or two conspicuous features were used, while the reason particular characters were thought to be evolutionarily important often seemed to be based on circular arguments. Some classifications were structured in such a way as to make them easy to memorize.

The 1960s saw the short-lived but important flowering of phenetics or numerical taxonomy, in which Peter Sneath and Robert Sokal were prominent names. Sneath and Sokal developed methods to enable the analysis of many characters simultaneously to produce estimates of overall similarities between organisms, methods facilitated by the use of early computers. The emphasis was on objectivity; subjective opinions as to which features were important took second place to the analysis of large numbers of carefully defined characters. However, it was unclear how the branching diagrams produced in these analyses related to phylogeny, and understanding phylogeny remained important for most systematists. Nevertheless, techniques that began to be developed at this time are used when describing the shapes of organisms, analyzing data to determine species limits, as well as in ecology and elsewhere.

When it came to constructing evolutionary trees, the philosophy of the entomologist Willi Hennig, popular in the 1970s and afterwards, had a profound effect. Methods were developed to determine what character states (e.g., scales versus feathers) are plesiomorphic ('primitive': scales) and what are apomorphic ('derived': feathers). The phylogenetic trees that were constructed minimized the number of evolutionary steps between these character states, the principle of parsimony, and this led to quite different ways of reconstructing relationships. Classifications also changed, only monophyletic groups being given names, and groups like reptiles and dicotyledonous plants began to disappear from the vocabulary of biologists. As always, claims were made that the groups recognized were 'natural.'

Species

However, the way species were described changed only little. The usual procedure was to assemble specimens and write a description, in consultation with the earlier literature. No more, no less. It is hardly surprising that Darwin in the *Origin* said that species were what competent naturalists said were species, largely because taxonomic practice was so opaque to the observer.

This 'authoritarian' approach persisted in much of botany, for example. However, in the latter half of the nineteenth century Spencer Baird of the Smithsonian Institution listed specimens and measurements taken from those specimens. The ornithologist Robert Ridgway wrote 8 of the 11 volumes of the monumental *The Birds of North and Middle America* (1901–1950). There we find maxima, minima, and means of

measurements, analyses of variation broken down geographically, etc. Indeed, absent such studies, one could argue taxonomy, often described as being a cumulative science, integrating and building on the work of naturalists since the time of Linnaeus, accumulates very little other than names and specimens.

Of course, what species represent in the mind of the taxonomist certainly changed. For Linnaeus, species were divinely created; for Darwin, they were the result of evolution. With the advent of evolutionary ideas and still more the rediscovery of the rules of inheritance at the end of the nineteenth century, the study of variation became more important. One issue was how evolution occurred, gradually, or in fits and starts, and another was whether natural selection drove evolution, or not. Biometricians, who primarily studied continuous variation at the infraspecific level and rejected mutation, took the first position on these two issues, while Mendelians took the second position.

At about this time Karl Jordan, a curator of Walter Rothschild's collections in Tring, England, began working on various insect groups (Johnson, 2012). He developed a species concept similar to the biological species concept later championed by Ernst Mayr, that is, a species is a population of group of populations reproductively isolated from other such populations. Indeed, the Mendelian and biometrician approaches were reconciled in the evolutionary synthesis of the middle of the last century (Mayr, 1982). But the biological species concept signals a shift away from describing species to thinking about their origin, and Mayr, although he described species early in his career, thought of himself as an evolutionary biologist. The emphasis in ornithology had long been changing, from descriptive work ('scientific ornithology' for Ridgway) to behavioral studies and the like ('popular ornithology'), a major shift.

Collecting and Collections

Much collecting in the nineteenth and early twentieth century in particular was on expeditions that had geopolitical or colonial implications. Thus Darwin circumnavigated the world in H.M.S. *Beagle* (1831–1836) while Hooker sailed on H.M.S. *Erebus* (1839–1843), both were surveying trips that collected information about geography, ocean currents, etc., important for British Empire and its commerce.

In the early days of natural history possession of a personal collection was the mark of a serious naturalist. Perhaps the largest collection was accumulated by Baron Walter Rothschild; at its peak it contained approaching three million specimens, of which about two-thirds were insects. Much of his collection is now in the Natural History Museum, London, funded by the government, and his birds are largely in the American Museum of Natural History, a private institution; most natural history collections are now in institutions. Many Universities had collections, although these have tended to be dispersed as priorities shifted within biology.

Biology, Natural History, and Botany

The term biology had come into use intermittently by the end of the eighteenth century. Both Lamarck and Gottfried Reinhold Treviranus, early proponents of biology, thought that biology had to do with the understanding of the 'organization' of organisms, how they were put together and what made them function; classification was not central to this endeavor, particularly for Lamarck. How they and others saw biology, botany, and natural history proved very important in shaping what became the subdisciplines of biology.

By late in the eighteenth century, women and botany had become associated; Linnaean botany was a subject fit for study by women, and could also be helpful in the education of their children. As translated, Jean-Jacques Rousseau's *Elementary Letters on Botany* (1782) conveyed a gendered idea of botany that emphasized an already dated Linnaean botany. Indeed, throughout the nineteenth century there was a botany that was a science of names, something suitable for study by women and children, healthy but not involving undue exertion, and that could be carried out in safety. In 1887 J.FA. Adams wrote a paper in *Science* protesting that the study of botany was indeed suitable for young men – although mainly because it was healthy.

Natural history was also gendered. An exchange in William MacGillivray's *History of British Birds* (1837) makes this clear: "It is a barbarous practice, this practical ornithology of yours" (it involved shooting and dissection), … "Ladies indeed cannot become practical ornithologists…". Natural history outside of museums involved strenuous outdoor activities and was the provenance of boys and men.

Thus, botanists and naturalists studied different parts of nature in different ways; furthermore, botanists who described species were very different kinds of botanists than those who botanized around their houses with their children. Botany did remain part of the medical curriculum, but its value there was often seen as being decidedly ambiguous.

With the advent of the tellingly named 'wissenschaftliche Botanik' or the New Botany, a more physiological, laboratory-based, and experimental botany was introduced from Germany to other parts of Europe and America by the end of the century. Early proponents were Julius Sachs, a physiologist, and Mathias Schleiden, a father of the cell theory. As the *Encyclopedia Britannica* of 1911 noted, Schleiden's work, "did much to shake the tyranny of the purely systematic Linnean school, whose accumulations he was accustomed irreverently to describe as 'hay.'" Proponents of the New Botany in North America like Charles Bessey and John Merle Coulter used a caricature of a gendered and discredited 'old' botany to support the New Botany, Coulter noting that botany had been "[r]ecommended especially to the ladies as a harmless pastime, not overtaxing to the mind" (Coulter, 1895).

The new-style biologist studied internal characters and used a compound microscope. However, in North America the nineteenth century closed with a vitriolic debate about 'Sham biology' – should biology include botany, particularly classificatory botany? Zoological natural history with its history of comparative anatomical studies fared better in such debates. Classificatory botany was close to being marginalized, and through the next century there were fears that botany might be replaced by a zoology wearing the mask of biology, that botany departments would disappear from universities (many did), and that taxonomists would disappear (not yet, at least).

Searching Tree Space, Methods for

A Stamatakis, Scientific Computing Group, Heidelberg Institute for Theoretical Studies, Heidelberg, Germany

Glossary

Approximation algorithm An algorithm for an NP-hard problem that has a guaranteed worst case performance.

Heuristic search An ad hoc algorithm for an NP-hard problem that has no guaranteed worst case performance.

NP-hard Term from theoretical computer science, referring to a combinatorial optimization problem for which no efficient algorithm is known, that is, all combinations need to be scored to find the best one.

Topological alteration mechanism An operation for changing a tree topology.

Introduction

The reason why a substantial amount of research effort has been invested into designing tree search algorithms is that the problem of finding the optimal tree according to criteria such as parsimony or likelihood (see 'See also' section on these topics) that indicate how well the sequence data (e.g., a multiple sequence alignment) fits a given tree is NP-hard. Consider, for instance, that one intends to find the optimal tree under parsimony for a set of 50 species (taxa). For 50 taxa there exist approximately 2.83×10^{74} different binary unrooted tree topologies (see, for instance, Yang (2014) for a derivation of the number of possible trees); the exact number is:

28380632508077991283772917269612815092062858799810511441573766775415039062

Now, consider that calculating the parsimony score on one of those trees requires 1 s. To find the best tree, one would need to evaluate all 2.83×10^{74} tree topologies which will require a total of about 9×10^{65} years, which is in turn roughly 9 times the age of the universe. Hence, finding the best tree for just 50 taxa is simply not feasible, which means that a workaround is required.

Heuristic search strategies that traverse the tree space in a 'clever' way to find a tree with a 'good' score are therefore typically used to address this problem. Note that, most of these heuristics are ad hoc heuristics, that is, they do not offer any guarantees of how close or far away (with respect to the score) the trees they will find are from the globally optimal tree. To this end, the inexact terminology that is often used in evolutionary biology papers should be avoided. Authors often refer to 'the Maximum Likelihood tree,' whereas this is simply the best tree that could be found with the ad hoc heuristic search strategy that was used.

In this context a digression on how Bayesian methods (see 'See also' section) are affected by the enormous size of the tree space is in place. When introducing Bayesian methods to students the equation for the posterior probability can be written as follows:

$$P(T|D) = P(T) \times P(D|T)/\text{ouch}$$

where T is the tree, D the data, $P(T)$ is the prior probability, and $P(D|T)$ the standard phylogenetic likelihood (as used for maximum likelihood-based inferences; see 'See also' section) score of the tree. The term 'ouch' represents the marginal probability. Note that, for calculating this probability exactly one needs to evaluate the likelihood scores of all possible trees which, as explained before, is extremely painful.

Hence, it is impossible to compute the posterior probability $P(T|D)$ exactly, and thus it needs to be approximated via Markov-Chain Monte-Carlo (MCMC) methods (see 'See also' section). So-called MCMC chains are guaranteed to converge to the true posterior distribution if run for infinity. Since this is typically not feasible, the convergence of the chains is assessed using a plethora of methods (e.g., Nylander *et al.* (2008)). However, such convergence diagnostic methods can never ever tell the user that the chains have converged; they will merely indicate that they have not converged or that they might have converged. Therefore, in analogy to parsimony and maximum likelihood and the respective best-found trees, the inexact terminology authors frequently use when referring to converged MCMC chains should be avoided. One may state that one believes that they have converged or that they have reached apparent convergence.

In the following tree search algorithms will be introduced in a top-down manner. Initially, it will be outlined how search algorithms work in principle, that is what they have in common. Then the standard and most widely used tree alteration mechanisms will be discussed. Thereafter, it will be described how these standard alteration mechanisms are used in current tree search tools. Then, some advanced issues pertaining to the optimization of tree moves and terraces in tree space will be outlined. This part concludes with a short discussion and summary of the most important issues users should be aware of when using such algorithms. The main focus is on search algorithms under the parsimony and ML criteria, but commonalities with Bayesian inference methods will be emphasized where appropriate.

Top-Level View of Search Algorithms

Here, the design of most search algorithms will be outlined, before describing some strategies in further detail. In general, search algorithms comprise two steps:

1. Build a starting tree containing all taxa.
2. Change the topology of that starting tree to find a tree with a better score.

Building Starting Trees

To build a starting tree (often also called comprehensive tree), there exist three main options. One can either build a random starting tree, build a tree using a simple, that is, fast-to-compute tree building method (e.g., Neighbour Joining: NJ (see 'See also' section)), or build a randomized stepwise addition order starting tree.

Building a random tree or a tree using an existing NJ implementation is straightforward. Below, the construction of a randomized stepwise addition tree, given n taxa (see Figure 1) is outlined:

1. Select three taxa at random and build the one and only possible unrooted binary tree containing these three taxa.
2. Select the next taxon i at random.
3. Insert that taxon into every branch of the tree with $i-1$ taxa, calculate and store the score (using parsimony or likelihood) and remove the taxon from the tree again.
4. Insert taxon i into the branch that yielded the best score.
5. If $i<n$, increment i by 1 and go to step 2, otherwise the algorithm terminates and can return the comprehensive starting tree.

There are two things worth noting here: Firstly, this algorithm already uses a criterion to select among trees when adding taxa, that is, it will typically have a better score than a pure random starting tree. Secondly, depending on the randomized order by which taxa are added, one might obtain topologically distinct starting trees.

The fact that a randomized stepwise addition order starting tree already has a 'good' score helps to reduce the inference times for optimizations of the tree topology because the search already starts in a 'good' or reasonable region of the search space.

The fact that different random addition orders might produce distinct starting trees allows to start topological optimizations for finding the best-known tree from different good points in the tree space and might thus help to avoid some local optima (see below and Figure 2). However, under parsimony and for large phylogenomic datasets (e.g., in the analyses conducted for Misof *et al.* (2014)) with strong signal it has been repeatedly observed that different random addition orders can yield exactly the same starting tree. Hence, users should not implicitly assume that randomized addition order starting trees will be distinct, but perform appropriate tests (e.g., using the Robinson–Foulds distance, see 'See also' section) to verify that this is the case.

Note that, Bayesian inference programs usually start from a random tree, but some implementations also offer the option to start the MCMC procedure on a randomized stepwise addition order parsimony tree.

Changing Topologies

Given a comprehensive starting tree, one can then try to further improve its score by changing the tree topology and subsequently re-evaluating the score of the new tree using likelihood or parsimony. Here, one needs to distinguish between topological alteration mechanisms, that is, operations to change the tree topology and search strategies, that is, how and in which sequence those mechanisms are applied. Initially, the three basic tree search mechanisms that are used in every parsimony or ML search algorithm and also in every Bayesian MCMC implementation are introduced. Examples of search strategies are provided in the next section.

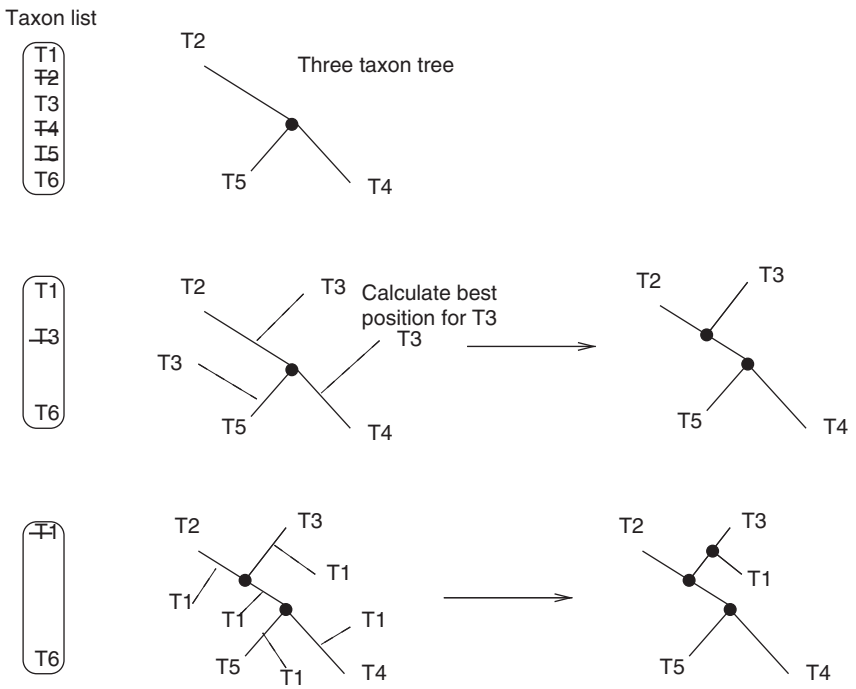

Figure 1 Schematic outline of randomized stepwise addition order algorithm for constructing starting trees.

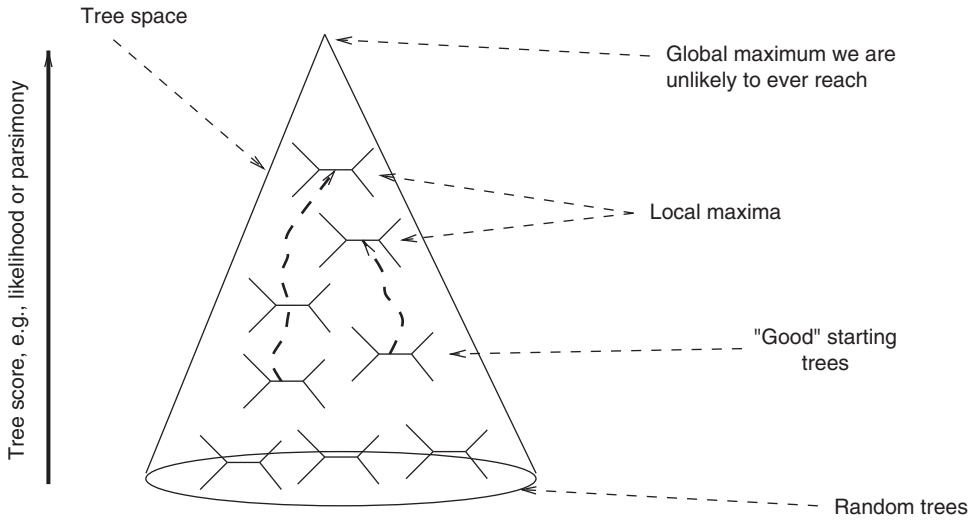

Figure 2 Schematic outline of the maximum likelihood tree search space.

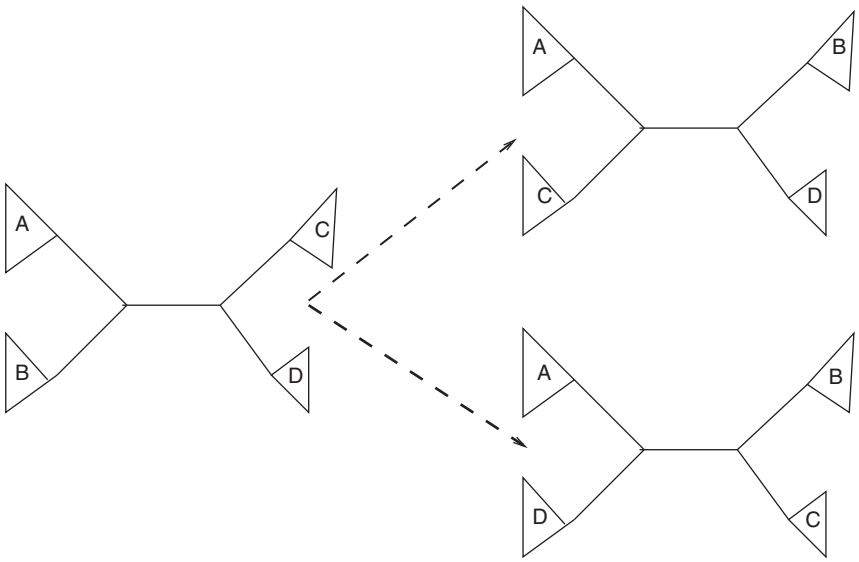

Figure 3 Schematic outline of NNI moves.

There exist three basic topological alteration mechanisms:

1. NNI: Nearest Neighbour Interchange (see **Figure 3**).
2. SPR: Subtree Pruning and Re-grafting (see **Figure 4**).
3. TBR: Tree Bisection and Reconnection (see **Figure 5**).

The most simple move is the NNI move. To execute an NNI move one selects an inner branch of the tree that defines four subtrees *A*, *B*, *C*, and *D*. Assume that *A* and *B* are located on one side of the branch and *C* and *D* on the other side of the branch (often denoted by *AB*|*CD*). One can then flip subtrees over that branch to construct two alternative topologies (*AC*|*BD* and *AD*|*BC*) and evaluate their respective scores.

A slightly more complex move is the SPR move. Here, one initially selects a subtree root in the comprehensive tree. Next, the selected subtree is removed (pruned) from the branch (called pruning branch) in the comprehensive tree to which it was attached. Thereafter, one can insert (and remove again) the subtree successively into all branches of the remaining tree and calculate the score for each subtree attachment. A frequently used variant of the SPR move is to limit the size of the region where the subtree will be reinserted into the remaining tree instead of reinserting it into all branches. Usually, a so-called rearrangement radius is used that specifies up to how many nodes away from the pruning branch the subtree shall be inserted.

The most complex or powerful move is the TBR move. Here, one initially chooses a branch and removes it from the comprehensive tree such that it is bisected, that is, two subtrees are obtained. These subtrees are then reconnected by using a new branch to connect any pair of branches in the two disjoint

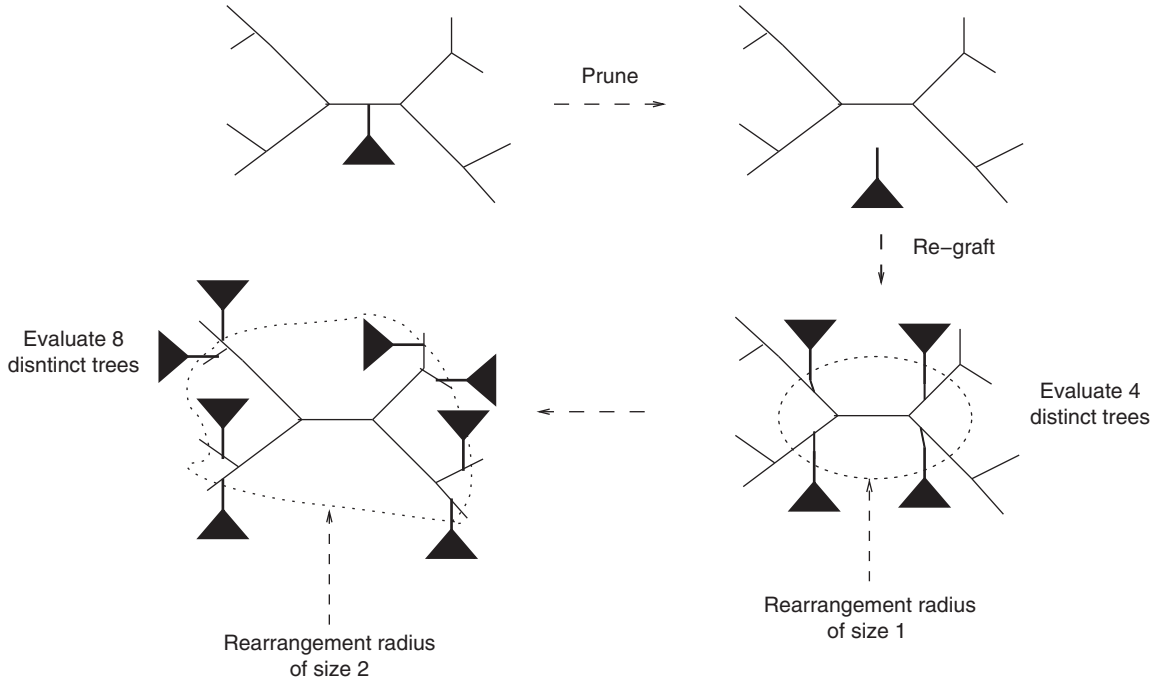

Figure 4 Schematic outline of SPR moves.

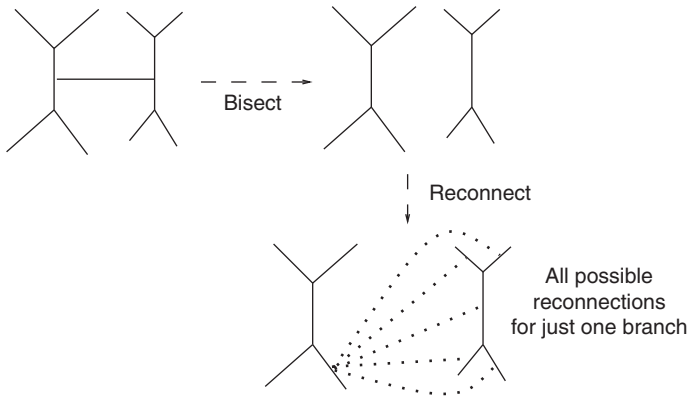

Figure 5 Schematic outline of TBR moves.

subtrees. In analogy to SPR moves, one can once again limit the size of the regions (number of branches) in the two disjoint subtrees that are considered for reconnecting the subtrees.

Search Strategies

Given these topology alteration mechanisms, they can be used to devise tree search algorithms or strategies. Most algorithms apply such topological moves until there is no move that yields a tree with a better score. In this case one says that the search algorithm has converged and the tree can be returned.

A simple example algorithm might initially build an NJ starting tree and subsequently apply NNI moves. For applying NNI moves it can repeatedly visit all inner branches of the tree. At each branch it will evaluate the two alternative NNI topologies and apply an NNI move if one of the two alternative topologies yields a better score. It will terminate if for none of the inner branches there is an improving NNI move.

The main problem one faces with such approaches is that, upon convergence, the search algorithm is most likely stuck in a local maximum (see **Figure 6**) that it cannot leave again via an NNI, SPR, or TBR move. There exist different approaches to alleviate this problem.

As mentioned before, one can initiate tree searches on distinct starting trees (e.g., RAxML, Stamatakis (2014)) in the hope of getting stuck in a more optimal local maximum. An extension of this approach is to use so-called genetic algorithms (e.g., GARLI, Zwickl (2006)) that also conduct searches on a set (population) of trees, but at some given points exchange information between trees to include, for instance, specific subtrees with good scores in most trees (e.g., tree fusion option in TNT, Goloboff *et al.* (2008)).

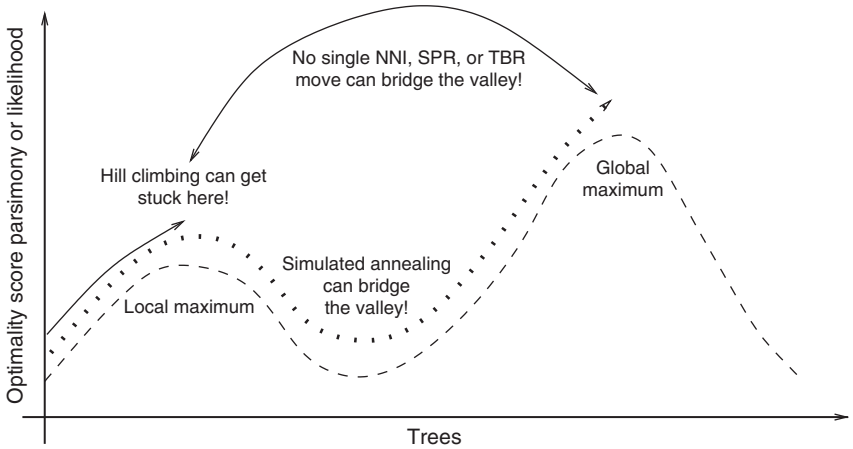

Figure 6 Outline of local maxima in tree searches.

The recently introduced IQ-Tree (Nguyen *et al.* (2015)) program tries to quickly navigate out of local optima by randomly perturbing the current locally optimal tree and then re-optimizing it. A similar idea for quickly navigating out of local optima by means of random perturbation is the ratchet method that has been applied to parsimony and ML searches (Nixon (1999) and Vos (2003)).

Another option is to use simulated annealing algorithms that sometimes, randomly, but not arbitrarily allow for backward steps, that is, moving to trees with lower scores which might in turn allow to navigate out of local maxima (e.g., Barker (2004) or Stamatakis (2005)). Note the connection between simulated annealing methods and Bayesian MCMC sampling methods that also sometimes allow for randomly but not arbitrarily accepting downhill steps toward trees with lower posterior probability. In addition, MCMC-based implementations typically also deploy Metropolis-Coupled chains to facilitate moving between and sampling of different local maxima (e.g., MrBayes by Ronquist *et al.* (2012) or ExaBayes by Aberer *et al.* (2014)).

Finally, a rather distinct approach for designing tree search heuristics relies on the quartet puzzling idea as implemented in Tree-Puzzle (Schmidt *et al.* (2002), see 'See also' section).

Advanced Topics

Computational Costs of Tree Moves

All tree search algorithms spend the largest fraction of overall run-time in evaluating scores on trees. Note that, as ML methods, Bayesian methods also spend between 90% and 95% of their time in evaluating likelihoods on changed trees or for altered model parameters. Thus, from an engineering point of view, ML and Bayesian inference face the same underlying computational problems.

Despite the fact that search heuristics are already being used, some moves and in particular SPR as well as TBR moves are still computationally very expensive such that further shortcuts need to be taken. In the following, the main focus will be on likelihood-based methods (Bayesian and ML) that require substantially more computational resources than parsimony. For instance, a parsimony search using a standard laptop computer on a DNA dataset with 125 taxa and around 30 000 sites takes 2.25 s under parsimony and 4464 s under maximum likelihood.

One common approach in ML-based inference is to deploy so-called lazy NNI or SPR moves. To calculate the ML score of an altered tree one normally needs to re-optimize all branch lengths of the changed tree which is a highly compute-intensive step. To avoid this, one may choose to pre-score and sort alternative SPR moves using parsimony which is substantially faster and subsequently simple to evaluate the most promising candidate moves under ML as done in PHYML (Guindon *et al.* (2010)). Alternatively, one can choose to only optimize a small set of branches around the new subtree insertion point of an SPR move as done in GARLI (Zwickl (2006)) and RAxML (Stamatakis (2014)).

MrBayes and ExaBayes use similar parsimony-based pre-scoring techniques to conduct topological SPR and TBR proposals in order to achieve a good proposal acceptance rate. Note that the implementation of such biased (i.e., non-random) proposals in the Bayesian framework is non-trivial because the reverse move (e.g., undoing a TBR) must have the same probability to be carried out. For an in-depth introduction to Bayesian phylogenetic inference, see 'See also' section.

Terraces in Tree Space

An issue whose existence for likelihood-based methods was only recently discovered and that yields tree searches even more challenging is that of terraces in tree space. For parsimony, the issue was already known by design of the criterion since researchers were aware of the existence of equally parsimonious trees, that is, trees with different tree topologies that have the same parsimony score. Such a set of topologically distinct trees with identical optimal scores is called a terrace in tree space.

For likelihood-based methods, terraces may exist for partitioned phylogenomic alignments with missing data and unlinked branch lengths. Branch lengths are unlinked when a set of completely independent branch lengths is estimated for each partition (e.g., each gene) of the input dataset. Whether a

dataset gives rise to terraces depends on the structure of the missing data (Sanderson *et al.* (2011)). The two main problems one faces with terraces are the following: Firstly, one should avoid conducting tree moves that will just take the search to another tree located on the same terrace. Secondly, the presence of terraces can severely bias bootstrap and Bayesian support values (Sanderson *et al.* (2014), see 'See also section).

Discussion

Readers should keep in mind that most search heuristics are ad hoc methods that work well on the empirical and simulated datasets on which they have been tested and tuned. In contrast to so-called approximation algorithms that guarantee to always yield results that are, for instance, at most 50% worse than the optimal solution, current phylogenetic inference tools do not guarantee for anything whatsoever. This also holds for Bayesian inference, albeit there is a more solid theoretical underpinning that guarantees that the chains will converge to the true posterior distribution if run for an infinite amount of time, regardless of the quality (acceptance rate) of the proposal mechanisms that are being used.

Thus, development of tree search methods generally represents an engineering task. Engineering always entails tradeoff decisions. For instance, when designing a search algorithm, one needs to decide how much additional computing time one is willing to sacrifice in order to obtain trees with potentially only slightly better scores. In addition, program performance can be dataset-specific. Thus, users should try to run two or three ML and Bayesian inference codes to identify the search strategy that works best on their dataset.

EDITOR IN CHIEF

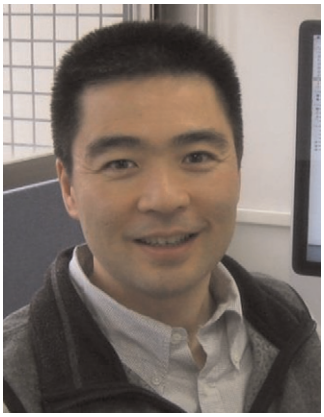
Richard M. Kliman, PhD, is Professor of Biological Sciences at Cedar Crest College in Allentown, Pennsylvania. He received his BA from Colby College in biology and music. His graduate work at Wesleyan University focused on quantitative genetics of circadian rhythms and photoperiodism in the Djungarian hamster, *Phodopus sungorus*. As a postdoctoral fellow at Rutgers University and Harvard University, he studied molecular evolution and population genetics. Prior to Cedar Crest College, he taught at Radford University in Virginia and Kean University in New Jersey. He has also served as a program director in the Division of Environmental Biology at the US National Science Foundation (NSF).

Kliman's research interests center on questions in molecular evolution, including the evolution of codon usage bias in a variety of organisms; speciation and natural history; and ecology and conservation. Much of this work has relied on population genetics/genomics and bioinformatics approaches. He has also collaborated with Cedar Crest colleague John Cigliano on an Earthwatch-supported "before-after-control-impact" study on the effects of a new marine reserve in Belize on queen conch populations. His research in evolutionary and ecological genetics has been supported by the US National Institutes of Health and by Conservation International.

Kliman has served on the editorial boards of *Genetica* and *The Journal of Molecular Evolution*. He has been deeply involved in evolution education, helping to coordinate "Undergraduate Diversity at SSE/SSB," an NSF-supported program to bring a diverse group of undergraduates to the annual Evolution research conference. He was a lead editor of population/quantitative genetics and evolutionary genetics for *Nature Education/Scitable* at its inception. He is a member of the Education and Outreach Committee of the Society for the Study of Evolution, and editor of the society's peer-reviewed educational resource, the *EvoEd Digital Library*.

SECTION EDITORS



Hiroshi Akashi is a Professor of Evolutionary Genetics at the National Institute of Genetics, Japan. He worked with Marty Kreitman for his PhD in Ecology & Evolutionary Biology from the University of Chicago (1996) and with John Gillespie as a postdoctoral fellow at UC Davis. He has been a faculty member at the University of Kansas (1998–2000), Penn State University (2000–2008), and NIG (2009–present). Akashi's research focuses on inferring causes of genome evolution, especially weak selection, from within and between species sequence variation. His studies of codon usage employed population genetic methods to detect natural selection acting at its limit of efficacy and identified a phenotypic basis of natural selection (translational accuracy) from sequence comparisons in *Drosophila*. Extensions of this work revealed constraints related to biosynthesis that act globally on compositional properties of microbial proteins. The interplay of weak evolutionary forces appears to shift frequently among closely-related species and current interests include tests of adaptive changes in protein/DNA composition.

Tim Coulson's primary interest is in creating better links between the fields of ecology and evolution. He does this by developing theory, parameterising models for field and laboratory systems, making predictions from these models, and, where possible, testing these predictions with experiments. He works on a range of systems, from bulb mites within the laboratory, to guppies living in streams in Trinidad, to wolves in Yellowstone. His motivation to do this comes from observations that ecological and evolutionary change can be observed occurring on similar time scales, yet ecological theory typically ignores evolutionary processes and vice versa.

Tim was awarded his PhD in plant ecology from Imperial College, London, in 1994. He moved on to research genotype-by-environment interactions as Natural Environment Research Council (NERC)-funded post-doc at the Institute of Zoology in London. He remained at the Institute on a fellowship where he developed models to investigate the economic and life history consequences of a range of population management strategies. In 2000 he moved to the University of Cambridge, where he briefly lecturered in the Zoology department. In 2004 he moved back to Imperial College London as a senior lecturer where he started developing models that allow the simultaneous investigation of the dynamics of life history, populations, and quantitative characters. In 2007 he became Professor of Population Biology at Imperial College London. He left Imperial in 2013 to take up his current position as Professor of Zoology at the University of Oxford. He is also a Professorial fellow of Jesus College, Oxford.

Andrew Forbes

Rosemary Gillespie is a Professor at the University of California, Berkeley, where she also holds the Schlinger Chair in Systematics. She is Past President of the *International Biogeography Society* and Trustee and Fellow of the *California Academy of Sciences*, and serves as Associate Editor for *Molecular Ecology*. Gillespie was born and educated in Scotland, receiving her BSc in Zoology from Edinburgh University in 1980. She came to the US to conduct graduate work on the behavioral ecology of spiders at the University of Tennessee. After her PhD she spent several months at the University of South in Tennessee, and then started work at the University of Hawaii in 1987, initially as a postdoc, and then in 1992 as Assistant Professor in Zoology and Researcher in the Hawaiian Evolutionary Biology Program. It was during her first year in Hawaii that she discovered an adaptive radiation of *Tetragnatha* spiders. She left Hawaii in 1999 to join the faculty at the University of California in Berkeley, where she continues her research focus on the islands of the Pacific, Hawaii in particular, using islands of known age and isolation to assess the combined temporal and spatial dimension of biogeography and determine patterns of diversification, adaptive radiation, and associated community assembly.

David Guttman received his PhD from Stony Brook University in 1994 working with Daniel Dykhuizen on questions related to the role and importance of recombination in structuring genetic diversity in bacterial populations. He followed this with a postdoc in molecular evolution with Brian and Deborah Charlesworth at the University of Chicago, and a second postdoc at the University of Chicago with Jean Greenberg to gain experience in the fields of molecular plant pathology and plant-microbe interactions. He started his faculty position at the University of Toronto in 2000, and is currently a Professor in the Department of Cell & Systems Biology (CSB). He is also the Associate Chair for Research in CSB, founder and Director of the University of Toronto Centre for the Analysis of Genome Evolution & Function, and Canada Research Chair in Comparative Genomics. He has served as the Chair of the American Society for Microbiology, Division R (Evolutionary and Genomic Microbiology), and was the *PLoS Pathogens* Section Editor for Bacterial Evolution & Genomics.

Dr. Guttman runs a highly diverse research program generally focused on bacterial evolutionary genomics, with three major foci: (1) the evolution of host specificity and virulence in plant pathogenic bacteria; (2) microbial comparative genomics; and (3) studies of the human and plant-associated microbiome. He is best known for elucidating and linking evolutionary and mechanistic processes that determine the course and fate of bacterial infections, and characterizing the impact of genetic variation on the balance between disease and immunity.

Norman A. Johnson, the section editor for Applied Evolution, is an evolutionary geneticist and author. He received his PhD from the University of Rochester in 1992 and did postdoctoral research at the University of Chicago. His research interests have generally focused on aspects of speciation, specifically those related to the genetics and evolution of hybrid incompatibility: sterility, inviability, or other reduction of fitness in hybrids between species. Dr. Johnson, an adjunct professor in the Biology Department at the University of Massachusetts at Amherst, has taught classes there, as well as at Hampshire College, the University of Texas at Arlington, and the University of Chicago.

Dr. Johnson also has a long-standing commitment toward improving the communication of science in general and evolutionary biology in particular to other scientists, educators, and the public at large. He is the author of *Darwinian Detectives: Revealing the Natural History of Genes and Genomes* (Oxford University Press: 2007), a book geared to general audiences that shows how biologists use DNA sequence data to make inferences about evolutionary processes. He also was the lead organizer for a working group on communicating human evolution at the National Evolutionary Synthesis Center (NESCent).

Laura Kubatko received a PhD in Biostatistics from The Ohio State University (OSU) in 1999. After seven years on the faculty at the University of New Mexico, she returned to OSU in the Fall of 2006, and is now Professor of Statistics and of Evolution, Ecology, and Organismal Biology at OSU. Laura served as an Associate Director of the Mathematical Biosciences Institute at OSU from 2013–2015. At OSU, she is a Faculty Affiliate of the Initiative in Population Research, and a Faculty Affiliate in Translational Data Analytics (TDA@OSU). She holds appointments as an Affiliate Faculty Member at the Battelle Center for Mathematical Medicine at Nationwide Children's Hospital in Columbus and as an Adjunct Research Scientist at Lovelace Respiratory Research Institute in Albuquerque, NM. Laura's research interests are in statistical genetics, with a focus on the development of statistical methods for inferring phylogenies from molecular data. Her recent work in this area concentrates on bridging the gap between traditional phylogenetic techniques and methodology used in population genetics analyses, primarily through the application of coalescent theory to species-level phylogenetic inference. She develops and distributes several software packages for phylogenetic inference, and has been an active member of the *Society of Systematic Biologists*. She has served as an Associate Editor for the journal *Systematic Biology* since 2007.

Amy Litt has been studying plant evolution and diversity since her PhD on floral structure and evolution in the neotropical plant family Vochysiaceae, known for its beautiful but unusual flowers many of which have only one petal and one stamen. While completing her PhD in plant systematics and morphology in the joint City University of New York/New York Botanical Garden Plant Sciences program under Scott Mori and Dennis Stevenson, she became interested in the molecular basis of plant diversity. She did her post-doc in the developmental genetics lab of Vivian Irish at Yale University on the evolution of a family of transcription factors involved in flower development, and she continues to study the functional evolution of this gene family currently. After one year on the faculty of University of Alabama, she moved back to The New York Botanical Garden as Director of Plant Genomics, where she developed her research program studying the evolution of plant form along two paths: studying evolutionary changes in genes to see how those changes affected flower and fruit form; and identifying the genes that underlie differences in form among closely related species. Dr. Litt also served as a program director in Plant, Fungal, and Microbial Development and Evolutionary Development at the National Science Foundation. She recently moved to the University of California at Riverside, where she continues to study the genetic basis of plant diversity.

Maria E. Orive is a professor of evolutionary genetics in the Department of Ecology and Evolutionary Biology at the University of Kansas. Her research in theoretical population genetics aims to develop mathematical models that provide a conceptual framework for exploring important questions in evolutionary biology and analytical tools for demographic and genetic data. Her work has considered levels of selection and mutation in organisms that reproduce both sexually and asexually, the relationship of population structure and life-history attributes to gene flow and genetic diversity, and models of within- and between-host pathogen and symbiont population dynamics. Orive received her BS from Stanford University and her PhD from the University of California at Berkeley. After spending two years as a postdoctoral researcher in genetics at the University of Georgia, she was an NSF-NATO Postdoctoral Fellow at the University of Edinburgh. Her research has been funded by multiple grants from NSF and NIH. In 2007–2008, she was the Carl and Lily Pforzheimer Foundation Fellow at the Radcliffe Institute for Advanced Study (Harvard University), and has served as the University Faculty Ombudsman for the University of Kansas since 2007.

Daniel Ortiz-Barrientos is an Associate Professor in evolutionary genetics in the School of Biological Sciences at The University of Queensland, Brisbane, Australia. During his scientific career he has investigated the ecological and genetic basis of speciation both in plants and animals. His current research program explores the early stages of speciation, the molecular basis of parallel speciation, and the interplay between recombination and natural selection during the origin of new species. His research funds come from The Australian Research Council. He is married to Antonia Posada, and is the father of three energetic and beautiful kids.

Claudia Russo was born in Leeds, England, but has lived in Rio de Janeiro, Brazil since she was two years old.

Claudia has an academic major in Ecology from Universidade Federal do Rio de Janeiro completed in 1989, and finished her Master's thesis in 1991 on population genetics of two actiniid species of sea anemones with different reproductive strategies, under the supervision of Associate Professor Antonio Mateo Sole-Cava. Her PhD dissertation was on the diversification of drosophilids and on the use of a known phylogenetic tree to estimate the reliability of tree building methods. The dissertation was completed in 1995 under the supervision of the Evan Pugh Professor Masatoshi Nei who recently received the prestigious Thomas Hunt Morgan Medal. Her graduate degrees were obtained as a student at the Genetics Program from the Universidade Federal do Rio de Janeiro and as a visiting scholar at the Pennsylvania State University (1992–1995).

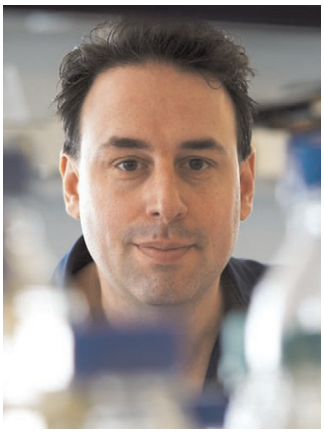
Claudia is currently the Head of the Genetics Department at the Federal University of Rio de Janeiro, having been a member since 1997. Claudia has supervised 13 Master's dissertations, eight PhD theses and seven post-docs, of which eight are now Assistant Professors at universities in Brazil and abroad. She has published 42 academic papers that have been cited over 1,200 times. Her *h-index* is 14. Since 2012, Claudia has been a member of the editorial board, and an associate editor of the *Molecular Biology and Evolution* journal. Since 2012 she has been a council member for the Pan American Association of Computational Interdisciplinary Sciences and since 2009 for the Brazilian Association for the Advancement of Science.

Claudia's general academic interests are on key aspects of animal phylogenetics, including their diversification patterns in time and space. She has worked with various metazoans groups but more prominently on marine sponges, sea anemones, arthropods, passerine birds, and mammals. Claudia has also published on the use of known phylogenetic trees to estimate the efficiency of phylogenetic methods in recovering and rooting those trees. More recently, she has developed some interesting *hands-on* educational tools for evolutionary biology practices in the classroom.

Karen E. Sears is an evolutionary developmental biologist whose primary research goal is to determine how developmental variation within a species produces congenital malformations in humans, and among species generates new evolutionary forms in mammals. Dr. Sears earned her PhD from the University of Chicago, did postdoctoral research at in the Howard Hughes Medical Institute (HHMI) lab of Dr. Lee Niswander, and joined the faculty of the University of Illinois at Urbana-Champaign. At Illinois she holds positions as an Associate Professor in the Department of Animal Biology, a Faculty Member in the Institute of Genomic Biology, and an Affiliate of the Program in Ecology, Evolution and Conservation Biology and the Department of Cell and Developmental Biology. She is also the President of the Pan American Society for Evolutionary Developmental Biology. She has authored or co-authored over 35 publications including first-authored publications in *Nature*, *Proceedings of the National Academy of Sciences*, and *Evolution*. She has served as a principal investigator on multiple, nationally-funded research projects, and presented invited seminars at more than 30 institutions and symposia. She is routinely ranked among the top 10% of Illinois professors for her teaching, and was a featured scientist in the PBS/HHMI documentary "*Your Inner Fish*."

Vassiliki "Betty" Smocovitis is Professor of the History of Science in the Department of Biology and in the Department of History at the University of Florida. Her areas of expertise include the history of evolutionary biology, genetics and systematics and the history of botany. She is best known for her contributions to understanding the historical event known as the "evolutionary synthesis" and in gaining greater understanding of the origins of the discipline of evolutionary biology. She has published extensively on both the intellectual and social aspects of the history of evolutionary biology including a history of the Society for the Study of Evolution, a history of the Darwin Centennial of 1959, and the integration of botany, genetics, and anthropology into the evolutionary synthesis. She was the contributor to the *Oxford Bibliographies* entry on Charles Darwin at over 25,000 words and the entry on the modern synthesis. She is the author of *Unifying Biology: The Evolutionary Synthesis and Evolutionary Biology* (Princeton: Princeton University Press, 1996).

Nina Wedell is a professor of evolutionary biology with research interests focused on the evolutionary ecology of sex. She has worked extensively on various aspects of sexual selection and sexual conflict, in particular on the role of selfish genetic elements in reproductive biology. Nina is the Academic lead for the Behaviour research group at the University of Exeter.



Jason Wolf is Professor of Evolutionary Genetics in the Department of Biology & Biochemistry and The Milner Centre for Evolution at the University of Bath. His research is unified with a special focus given to understanding the influence that frequently ignored or under-appreciated sources of genetic variation have on the genotype-phenotype relationship and how this, in turn, influences evolutionary processes. He integrates theoretical, computational and empirical quantitative and population genetic techniques to achieve this goal. He is particularly interested in understanding the evolutionary consequences of various types of interactions, including gene interactions (epistasis), parent-offspring interactions and social interactions. He received a PhD from the University of Kentucky, after which he was a postdoctoral researcher at Indiana University and a US National Science Foundation Postdoctoral Fellow at Washington University School of Medicine. Prior to moving to the University of Bath he held positions at the University of Tennessee and the University of Manchester. He won the Dobzhansky Prize from the Society for the Study of Evolution, a Young Investigator's Prize from the American Society of Naturalists and the Scientific Medal from the Zoological Society of London.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Alphabetical Contents List

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

All articles within the encyclopedia have an extensive list of cross-references which appear at the end of each article, for example:

Adaptive Mutation Controversy

> *See also*: Directional Selection and Adaptation. Microbial Experimental Evolution. Mutation, Population Genetic Models of. Natural Selection, Introduction to. Recombination in Bacterial Populations

3. Subject Classification List

A subject classification list has been developed by the editors to group articles under broad topics. This index is useful for making broad connections between articles and locating the relevant article for a topic that is covered in more than one article.

4. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

5. Contributors

A full list of contributors appears in the front mater of each volume.

Subject Classification List

Animal Diversification

Amniotes, Diversification of
Amniotes, the Origin of
Animal: What is an Animal?
Bird Flight Origins
Birds, Diversification of
Cambrian Explosion: A Molecular Paleobiological Overview
Complexity, the Role of Oxygen in Evolution of
Homo, Diverification of
Insects and Ecdysozoa, Diversification of

PREFACE

The *Encyclopedia of Evolutionary Biology* was developed to provide an authoritative overview of the current state of evolutionary biology. It was an ambitious goal, especially given that the field did not pause for the two and a half years needed to complete the project. The encyclopedia's 15 section editors collaborated to ensure that content gaps were kept to a minimum, and their efforts show. When the project was completed, we had compiled 256 entries, covering a broad range of topics selected by the editors to ensure a comprehensive resource. It was a privilege to read every one of these entries, and I was truly humbled by the collective efforts of hundreds of authors to communicate the excitement and sophistication of a field of study that touches on every conceivable topic in biology today.

There are many ways to envision an encyclopedia of evolution, and we had to choose an approach that would lead to a cohesive resource. Readers will note that, in the more organismal-focused entries (edited by David Guttman, Amy Litt, and Claudia Russo), there is an emphasis on *diversification* of life. We did not set out to provide an overview of the diversity of life, as such a goal would be untenable; rather, we focused on the evolutionary processes and key events responsible for diversity. Numerous entries deal with speciation, life history evolution, evolutionary biogeography, and coevolution. These entries (edited by Daniel Ortiz-Barrientos, Tim Coulson, Rosemary Gillespie, and Andrew Forbes) bring to light how the evolution and diversification of life is intimately entwined with ecology. Of course, there is extensive coverage of population genetics, quantitative genetics, evolutionary developmental biology, the evolution of sex and mating systems, molecular/genome evolution, and phylogenetic analysis (edited by Maria Orive, Jason Wolf, Karen Sears, Nina Wedell, Hiroshi Akashi, and Laura Kubatko), all fundamental to our understanding of evolutionary processes. And as thematic bookends, several entries (edited by Betty Smocovitis and Norman Johnson) cover the history of evolutionary biology and applications of evolutionary biology.

Readers of the encyclopedia will find that entries are generally pitched at a somewhat advanced level, although with great effort by authors to make entries as accessible as possible to a broad audience. Encyclopedias, like living organisms, are compromises. If all entries could be readily understood in their entirety by first-year university students, this encyclopedia would be of limited value to experts. At the other extreme, if entries were extremely technical – and our authors were undoubtedly capable of producing such entries – the encyclopedia might be inaccessible to students. While there is, by necessity, variation among entries in this regard, we settled on a general target: the majority of an entry should be accessible to a motivated, advanced undergraduate. Readers are, of course, directed to additional resources, with authors providing bibliographies and lists of further reading.

As with any undertaking of this scale, there are many individuals who should be recognized for their roles in the development of this encyclopedia. Special thanks go to Norman Johnson for early discussions that helped us develop the general structure of the encyclopedia. The dedicated and distinguished team of section editors deserves the credit for drafting the table of contents, recruiting authors, and working extensively with authors to ensure the highest quality product. It should go without saying that the high quality of this encyclopedia ultimately reflects the efforts of the editors and authors. Finally, the project management and development teams at Academic Press were always ready to assist, and while it is not possible to name everyone who contributed to the effort, I am particularly indebted to Simon Holt, Will Bowden-Green, Paula Davies, and Justin Taylor.

Richard Kliman
Editor in Chief

FOREWORD

What is life, how did it originate, and what accounts for its great diversity? These are fundamental scientific questions that have and will always be the source of endless fascination and wonderment. Charles Darwin and Alfred Russel Wallace provided an answer to the latter question through the grand idea of evolution and the process of natural selection. Darwin also speculated on the where question of the origin of life by hypothesizing it originated long ago in a warm lagoon. Most importantly, however, Darwin shattered the notion that the natural world is static and replaced it with a biology that is dynamic and continually changing. Species are not fixed, typological entities. Rather, they are related by common descent in a great tree of life. Analogous to tracing one's ancestors back in time in a pedigree, one can climb down the tree along its branches and boughs that connect species in a hierarchy of phylogenic relationships until reaching the base of its trunk and the common ancestor of us all. One can also climb up the tree and quickly realize that evolution produces a seemingly endless array of new forms (and sometimes extinction). Thus, as the tree of life grows, populations are continuously evolving and diverging from one another, creating novel varieties and races (showing slight differences) that eventually evolve into new species (separated by distinct gaps). And natural selection – the differential survival of individuals in populations possessing heritable traits favorable for their survival and reproduction – is the primary materialistic process causing evolutionary change and the origin of new species.

The *Encyclopedia of Evolutionary Biology* chronicles our current state of understanding of the dynamics of evolution and its product, Darwin's great tree of life. A diversity of seminal topics are covered including overviews of the history of the field, the origin of life, the history of life (including the phylogentic methods used to reconstruct life's history), the myriad ways and means (including mechanisms other than natural selection) that evolution is affected, and the important roles that conflict versus cooperation, and mergers and acquisitions, occurring within across varying levels of biological organization, play in the narrative of life. In so doing, the *Encyclopedia* highlights the grandeur in Darwin's view of life. We are not separate, but rather a twig along a branch of life, a twig that has evolved the ability to comprehend the existence of and our connectedness to the tree, and climb around its branches to see what has been and think about what may come. It is a wonder of life that it can look at and understand the meaning of itself.

But Darwin's grand view has even larger ramifications, going beyond providing a materialist basis for organismal change and putting us in our place. The reality of evolution also answers the question of what life is. If pressed to define life, most of us would reply with a list of the things that living organisms do. For example, living organisms metabolize, grow, develop, move, behave, mutate (are variable), and reproduce with inheritance. One can investigate these different characteristics of life separately and discern the mechanistic basis for the different processes that constitute life – the "how" of life. And such studies represent the basis for many fields of the life sciences. However, these are only the components of life and, in isolation, produce a static view of the natural world. Rather, the seminal insight is that populations of living beings possessing these characteristics have the emergent property that they evolve. Darwin's "*On the Origin of Species*" therefore not only describes how populations evolve, and as a logical extension how new species form, but also conveys the essence of what life itself is – evolution. Thus, as Theodosius Dobzhansky famously stated "nothing makes sense except in the light of evolution." The Encyclopedia wonderfully brings this view of life to light, providing the reader with the breadth of knowledge and overview of the current state of the field of evolution needed to appreciate and participate in the next major ongoing synthesis in our understanding of life, the so-called "Omics Revolution."

The study of evolution is in an accelerated phase of discovery brought about by major technical advances in our ability to DNA sequence whole genomes (genomics), and to generate profiles of mRNA transcription (transcriptomics), protein levels and enzymatic activity (proteomics), and metabolic products (metabolomics) at varying stages in the life cycle and development of organisms. This "Omics Revolution" may not change foundational evolutionary principals, per se. Our understanding of evolution has been heightened by a series of such advances in the past, including the "Modern Synthesis" when Mendelian genetics was wedded to Darwinian thinking and the "Molecular Revolution" in which genetic technology increasingly allowed allele frequencies in natural populations to be analyzed. The Omics Revolution is an extension of these pervious advances, but one in which the workings of whole organismal systems and the composition of entire communities can be gleaned at once.

Perhaps, the most important discoveries in Omics will come from linking an understanding of the process occurring at the cellular and microevolutionary level with large scale patterns and trends at the macroevolutionary scale. Previously, processes occurring within and interactions occurring among cells could be studied in at least some detail. Omics is providing an opportunity to fully understand how all of these processes interact simultaneously to result in the development and functioning of integrated, multicellular systems of life. At the other end of the spectrum, fossils attest to the evolution of new life forms through time and the creation of great and observable morphological diversity. Genomic sequencing is providing a powerful means to help accurately place these fossils within the framework of a fully resolved molecular phylogenic tree to better understand the history of life, including major trends, themes, and variation in the tempo and mode of evolutionary change. But it is the middle of the micro and macro at the branching points in the tree of life that Omics may prove most insightful. Now it is possible to not only DNA sequence large numbers of individuals within populations, but to equate these genetic differences within and between populations to morphological, physiological, and behavioral phenotypes, and discern the developmental

and physiological mechanisms by which these genetic changes produce organismal variation, diversity, and reproductive isolation – the stuff of evolution and speciation itself. Thus, we will be able to not only understand the everyday processes responsible for how the tree of life grows, but be able to translate this into a mechanistic appreciation of how these processes result in new branches on the tree forming and others dying out, giving shape to the history of being on our planet.

The field of evolution is currently inundated with a mass of Omics data and the bottleneck is the development of bioinformatic analytical tools to edit, analyze, and interpret the results. However, it is clear that many new insights are on the horizon, and even if they do not affect the root principles of evolution, soon a deep connection of the how and why of life will emerge to help forge a truly integrative evolutionary biology: The *Encyclopedia of Evolutionary Biology* is an excellent guide to prepare readers to assimilate these new findings, keeping bioinformatics grounded in the bio and providing a valuable source for seeing the tree through the forest to understanding the grand synthesis of life that is flowering.

Secondary Metabolites, the Role in Plant Diversification of

M Wink, Heidelberg University, Heidelberg, Germany

Glossary

Allelopathy SM produced by one plant which inhibit germination and growth of other plants.
Aposematic coloration Animals with warning colors are termed aposematic.
Callose A polysaccharide used by plants during a variety of processes in their development and/or in response to multiple biotic and abiotic stresses.
Ectomycorrhiza Symbiotic relationship between a fungal symbiont and the roots of various plants.
Elicitors Compound which can induce a defense reaction in plants.
Endomycorrhiza Symbiotic relationship between an internal fungal symbiont of various plants.
Endophyte Bacteria or fungi, living endosymbiotically within a plant.
Lignin Polymer from phenylpropanoids used to support tissues and structures of vascular plants and some algae.
Phytoalexins Antimicrobial substances synthesized *de novo* by plants at areas of a microbial infection.
Tonoplast Membrane surrounding the vacuole of a plant cell.

What are Secondary Metabolites?

Diversity of Secondary Metabolites

Whereas primary metabolites occur in all plants and are essential for survival, secondary metabolites (SM) have a more restricted distribution. Plants can live without them, as can be seen from some of our cultivated crop plants (Kadereit *et al.*, 2014) from which they have been removed by breeding. Nevertheless, SMs, which occur in great structural diversity, count as typical traits of plants (Seigler, 1998; Wink, 2010a,b; Kadereit *et al.*, 2014). More than 200 000 chemical structures have been isolated and described so far, and these can be divided into SM with and without nitrogen in their structures (**Table 1**). Among nitrogen containing SM, the class of alkaloids is the largest with over 27 000 structures (Roberts and Wink, 1998), followed by 700 non-protein amino acids (NPAA). Cyanogenic glucosides, glucosinolates, and amines are less diverse, with fewer than 100 structures in each class. The largest group of SM do not contain nitrogen in their structures; among them terpenoids (mono-, sesqui-, di-, tri-, and tetraterpenes, saponins, iridoid glucosides) are most numerous, followed by the widely distributed phenolics (phenylpropanoids, flavonoids, catechins, tannins, lignans, coumarins, furanocoumarins, anthraquinones) (**Table 1**). It has been estimated that only 20% of all plants have been studied phytochemically using mass spectrometry and NMR; therefore, it is likely that the real number of SM will exceed 200 000 by far when all plant taxa have been analyzed one day.

Biosynthesis and Storage of Secondary Metabolites

The more than 200 000 SM structures might irritate a student of botany, but the underlying biosynthetic pathways are less diverse (**Table 2**; Dewick, 2002; Wink, 2010b). SM derive from precursors of primary metabolism. Certain amino acids (especially lysine, arginine, ornithine, phenylalanine, tyrosine, tryptophan) are precursors for alkaloids, cyanogenic glucosides, glucosinolates, and amines. Precursors of phenolics are the aromatic amino acids phenylalanine and tyrosine, the latter being synthesized in the shikimate pathway. Acetyl-CoA is a universal precursor for terpenoids, fatty acids, waxes, and polyketides. The polyketide pathway leads to quinones and partially to flavonoids, catechins, and anthocyanins (details in Wink, 2010b; Krauss and Nies, 2014). The main skeletons, which are generated by these key pathways, are further modified by oxidations or reductions, and by introduction of functional groups, such as carboxyl, aldehyde, hydroxyl, and SH-groups. Furthermore, via the functional groups, SM can be esterified, glycosylated, or polymerized. Each SM with its unique 3D structure represents a unique biologically active compound that has been shaped during evolution by natural selection, which can interfere with molecular targets in herbivores, microbes, and even other plants. SM show a

Table 1 Estimated number of described secondary metabolites and their main functions for the plants producing them[a]

Class	*Numbers of structures*	*Toxic or repellent for herbivores*	*Antimicrobial activity*	*Attraction of pollinators or fruit dispersers*
With nitrogen				
Alkaloids	27 000	++++	++	−
Non-protein amino acids (NPAA)	700	++++	+++	−
Cyanogenic Glucosides/HCN	60	++++	+	−
Mustard oils (Glucosinolates)	150	++++	++++	+/−

considerable turnover during normal metabolism, after wounding or after an infection. Whereas the enzymes of SM formation are highly substrate specific, the degrading enzymes (glucosidases, esterases, phenolase) exhibit a much broader substrate spectrum.

The genes which encode key enzymes of several pathways have been identified, so that the SM of plants can be manipulated by gene technology (Kutchan, 1995; Facchini, 2001; Memelink, 2005; Schäfer and Wink, 2009; Wink, 2010b). This technology offers the opportunity to knock out genes and analyze how this event changes the phenotype and more importantly the survival of a plant in nature. SM-free mutants produced by this technology can help to elucidate the functions of the SM. Furthermore, it is now possible to breed crop plants resistant to microbial pathogens or herbivores, as SM are important contributors to these traits (Wink, 1988). In the future, it will probably be possible to produce valuable plant SM (morphine, vinblastine) in recombinant microorganisms (Memelink, 2005; Schäfer and Wink, 2009; Wink, 2010b).

The cytoplasm is usually the site for SM synthesis. Hydroxylations via cytochrome oxidases are carried out at the smooth endoplasmic reticulum. A few biosynthetic pathways or parts of them can take place in chloroplasts (some terpenoids via the pyruvate – glyceraldehyde pathway; a few alkaloids, such as quinolizidine and steroid alkaloids), mitochondria (some amines, the alkaloid coniine), or vesicles (some isoquinoline alkaloids) (Kutchan, 2005; Zenk and Jünger, 2007; Wink, 2010b; Krauss and Nies, 2014).

SM are not only synthesized but they need to be stored to fulfill their ecological functions (see Section Function of Secondary Metabolites as Defense and Signal Compounds). This is a challenge for a plant because most of the SM constitute active agents which may also disturb the metabolism of the plant producing them. The large central vacuole of most plant cells is not a site for biosynthesis but rather for the sequestration of defense, signal, and storage compounds (Boller and Wiemken, 1986; Kutchan, 2005; Wink, 1997). The vacuole is a storage compartment for many of the hydrophilic SM, such as alkaloids, cyanogenic glucosides, glucosinolates, betalains, flavonoids, anthocyanins, saponins, cardiac glycosides, anthraquinone glycosides, NPAAs, and organic acids (**Table 1**). Lipophilic SM (especially terpenoids, phenylpropanoids, polyacetylenes) (**Table 1**) are not stored in the vacuole, but in dead cells or compartments, such as resin ducts, oil cells, glandular scales, trichomes, or on the cuticle. In Papaveraceae (poppy family), some Asteraceae (aster family), Euphorbiaceae (spurge family), and some Apocynaceae (dogbane family) we find latificers (latex ducts) filled with milky juice containing toxic alkaloids, sesquiterpenes, or diterpenes (Wink, 2008a,b, 2010b; Krauss and Nies, 2014).

Vacuoles often contain high concentrations of an SM. In order to reach the vacuole, the mostly polar and hydrophilic SM have to pass the tonoplast (a biomembrane around the vacuole) against a concentration gradient. A few SM can diffuse across the tonoplast and are later trapped in the vacuole as charged molecules (e.g., nicotine and some other alkaloids)

Table 2 Biosynthetic origin of secondary metabolites: overview of the main biosynthetic pathways

Precursor in primary metabolism	*Class*	*Group of SM*
Acetyl-CoA (cytoplasm); Alternatively in chloroplast: Pyruvate + 3-phosphoglyceraldehyde	Terpenes	(C10) Monoterpenes, iridoid glucosides (C15) Sesquiterpenes (C20) Diterpenes and phorbolesters (C30) Triterpenes and saponins (C27) Steroids and steroid saponins (C40) Tetraterpenes Polyterpenes
Acetyl-CoA/malonyl-CoA	Quinones (polyketides)	Anthraquinones Naphthoquinones (plumbagin)
	Fatty acids	Polyacetylenes Thiophenes
	Conium alkaloids	Coniine
Phenylalanine/tyrosine	Phenols	Phenylpropanoids, phenolcarboxylic acids, lignin Coumarins and furanocoumarins Lignans
	Alkaloids	Isoquinoline alkaloids (papaverine) Morphinane alkaloids (morphine) Protoberberine alkaloids (berberine)
	Glucosinolates	Benzylisothiocyanates
	NPAA	Mimosine
	Cyanogenic glucosides	Prunasin, amygdalin
Phenylalanine + polyketide units	Phenols	Flavonoids, isoflavones Anthocyanins Catechins and catechin tannins
Tryptophan	Alkaloids	Tryptamine Simple indole alkaloids Ergot alkaloids
	Glucosinolates	Glucobrassicin
Tryptophan + secologanin	Alkaloids	Monoterpene indole alkaloids
Ornithine	Alkaloids	Tropane alkaloids (atropine) Pyrrolizidine alkaloids Pyrrolidine alkaloids (nicotine)
Lysine	Alkaloids	Quinolizidine alkaloids Piperidine alkaloids
Glucose	Glucosides	
Quinic acid	Gallic acid	Gallotannins Ellagitannins

(so-called ion-trap mechanism). In most other cases, active transporters are required, which can be energy-dependent ABC transporters or proton-dependent antiporters (Wink, 1997; Kutchan, 2005; Yazaki, 2006; Rea, 2007). ABC transporters are better known from cancer cells, parasites, or drug-resistant bacteria where they pump out any lipophilic substance that has entered a cell via free diffusion (Wink *et al.*, 2012). Genomic studies have revealed that plants also have several ABC transporter genes and that some of them apparently govern the import of polar SM into the vacuole (Yazaki, 2006; Rea, 2007).

The site of synthesis of an SM is not always the site of its accumulation. Some SM, such as nicotine or tropane alkaloids, are made in the root but are stored in all other plant tissues. Lupines and other related legumes (Fabaceae) produce quinolizidine alkaloids in photosynthetically active tissues (mostly leaves) but store them in other tissues, especially seeds (Wink, 1992, 2013). While nicotine and tropane alkaloids are transported via the xylem (which transports water) to the other plant organs, quinolizidine, pyrrolizidine alkaloids, and some glucosinolates follow the route of other assimilates (amino acids, sugars) in the phloem (Wink, 2003, 2010b).

Plants always produce and store mixtures of SM, which are usually produced by differing pathways. For example, an alkaloid-producing plant often produces phenolics and terpenoids at the same time. The composition of such mixtures differs between organs and developmental stages: the SM profile usually differs among the root, leaves, flowers, and seeds. Furthermore, a seedling differs from a young, mature

Table 3 Examples of protoxins, which are activated after an attack by an herbivore or microbe

SM in intact tissues (occurrence)	*Enzyme*	*Active metabolite*
Cyanogenic glucosides (many Rosaceae)	β-Glucosidase	HCN
Glucosinolates (Brassicaceae)	Myrosinase	Isothiocyanates
Alliin (a NPAA from *Allium*)	Alliinase	Allicin
Arbutin (Ericaceae)	β-Glucosidase	Hydroquinone
Gein (*Geum urbanum*)	β-Glucosidase	Eugenol
Ranunculin (many Ranunculaceae)	β-Glucosidase	Protoanemonin
Bidesmosidisic saponins (widely distributed)	β-Glucosidase or Esterase	Monodesmosidic saponins
Coumaroyl glucoside (Apiaceae, Fabaceae)	β-Glucosidase	Coumarins
Iridoid glucosides (Lamiaceae, Plantaginaceae)	β-Glucosidase	Active dialdehydes

and flowering, or old senescent plant. In addition, SM patterns differ among individual plants and populations in nature. This apparent variability has hardly been addressed by phytochemists or plant physiologists but is probably important as a strategy against adaptation of herbivores and microbial pathogens (Wink, 2008b).

SM is dynamic and several SM undergo a regular turnover. Because some SM may be inactivated by a spontaneous racemization or polymerization process, the degradation of these SM and continuous new synthesis ensures that SM are always present in an active form. Furthermore, plants can actively react when challenged by an herbivore or microbe, by either activating a preexisting SM (**Table 3**) or by stimulating the synthesis of existing SM or new types of SM (called phytoalexins). Many SM are stored as inactive prodrugs which become activated in emergency by hydrolysis with glucosidases or esterases which come in contact with their substrate after tissue decompartmentation (**Table 3**). Well-known examples are cyanogenic glucosides, which release the toxic hydrogen cyanide, or glucosinolates that produce the pungent isothiocyanates (Wink, 2003, 2008a, 2010b; Krauss and Nies, 2014).

Production, transport, and storage of SM are energetically costly. Costs occur for the synthesis of precursors and subsequently the SM themselves (in the form of ATP and/or NADPH), but also for the synthesis of proteins, genes, and morphological structures that are involved with SM formation (Wink, 2010b).

Function of Secondary Metabolites as Defense and Signal Compounds

Secondary metabolites as defense compounds

Plants survive in an environment full of enemies. Plants cannot run away from herbivores (roughly 60% of animals are herbivores) nor do they have a powerful immune system with antibodies against infection from bacteria, fungi, and viruses, as used by animals with high success. Similar to the situation of other sessile or slowly moving organisms (such as nudibranchs, jelly fish, corals, sponges) or toxic organisms such as many amphibians, plants began early in their evolution to produce and store a diversity of toxic, deterring or repellent SM (**Table 1**; Levin, 1976; Harborne, 1993; Hartmann, 2007; Wink, 1988, 1993, 2003, 2010a). Using deterrent, pungent, bitter, or toxic SM, plants can defend themselves against most herbivores, such as arthropods, worms, and vertebrates. Plants use some of their SM not only against herbivores and microbes but also against other plants, competing for light, water, and nutrients (termed allelopathy) (**Figure 1**).

In some instances, plants have developed structural specialties, which help to deter herbivores. They include stinging hairs of nettles (filled with formic acid, acetylcholine, and histamine) which hurt after contact and cause an inflammation. Thorns, spines, thick cell walls, leaf hairs, and inert bark also serve as barriers against herbivores and microbes.

If a plant becomes wounded or infected, pathways are activated in which jasmonic acid (made from α-linolenic acid) and salicylic acid are important signaling molecules. Both substances regulate the expression of genes of SM metabolism or proteinase inhibitors. In addition, the volatile ethylene also stimulates the expression of defense genes. Plant cells carry receptors on their surfaces that can detect elicitors, which derive from cell walls of bacteria and fungi. The elicitors are released when plants undergo an infection by microbes, and prompt the plant to initiate its defense strategies (Harborne, 1993; Kadereit *et al.*, 2014; Krauss and Nies, 2014).

The structures of SM have been shaped during evolution, enabling plants to cope with a multitude of herbivores and microbes. In analogy to the 'molecular modeling' of pharmaceutical chemists we could term the process for the selection of SM as 'evolutionary molecular modeling' (Wink, 1988, 2008a,b). SM have been optimized to interact with a multitude of molecular targets in animals and microbes (**Tables 1** and **4**). Many SM attack more than a single target; we can consider them as multi-target agents. As a consequence, many of the anti-herbivore SM (such as many phenolics, terpenoids, and some alkaloids) can also attack microbes (Wink, 2007b, 2008b). On the other hand, some SM appear to have been selected solely as antimicrobials (some saponins, antimicrobial peptides) and contribute to the innate immune system of plants. After an infection, plants not only use their antimicrobial SM, they also produce enzymes which degrade bacterial or fungal cell walls, accumulate callose or stabilize their walls through incorporation of lignin (Kadereit *et al.*, 2014).

Evolution apparently tried to attack several enemies with one stone when developing SM, because in addition to defense some SM serve for UV protection (some phenolics), antioxidants (many phenolics, some terpenoids) and as mobile but toxic nitrogen storage compounds (some NPAAs, alkaloids, peptides, and lectins) (Wink, 2008a, 2010a; **Figure 1**).

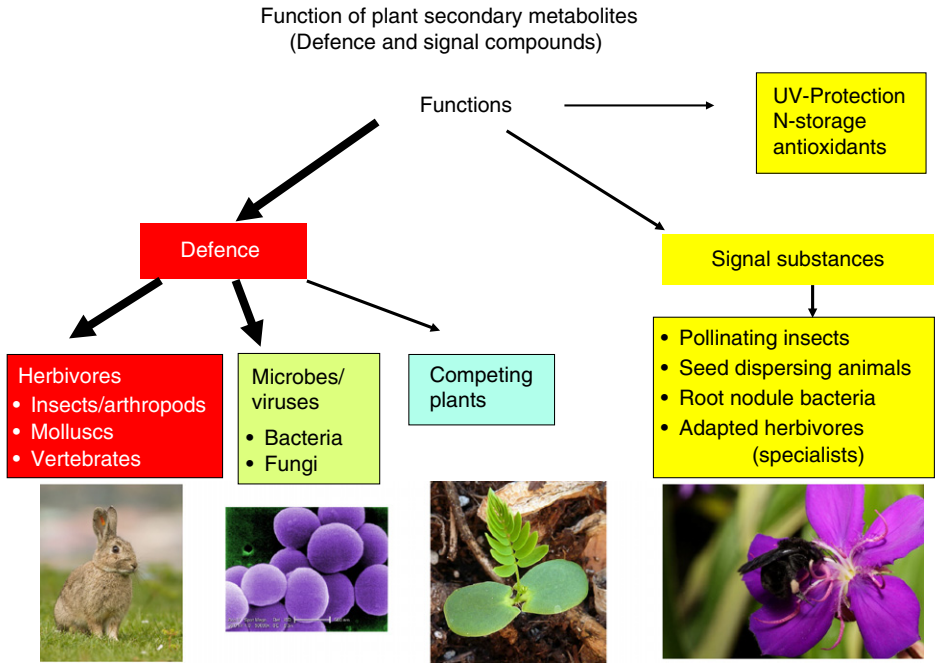

Figure 1 Functions of plant secondary metabolisms (pictures from WikiCommons).

Table 4 Targets of SM and their modes of action

Main target	*SM class*	*Mode of action*
Proteins	Quinone	Reaction with amino-, hydroxyl-, and SH-groups
	Phenolic	Reaction phenolic OH groups with amino groups of proteins; formation of hydrogen and ionic bonds
	Sesquiterpenes, polyacetylenes	Reaction with SH-groups of proteins and glutathione
	Epoxides	Reaction with amino-, hydroxyl-, and SH-groups
	Aldehydes	Reaction with amino- and imino groups
	Alkaloids	Neurotoxins:
		– Binding to neuroreceptors
		– inhibition of acetylcholine-esterase, MAO
		– Modulation ion channels
		– Modulation of ion pumps
		– Modulation of signaling pathways
	Vinblastine, colchicine, podophyllotoxin	Inhibition of microtubule assembly
	Paclitaxel	Inhibition of microtubule disassembly
	Cardiac glycosides	Inhibition of Na^+/K^+ ATPase
	Cyanogenic glucosides/HCN	Inhibition of cytochrome oxidase in respiratory chain
	NPAA	Disturbance of protein synthesis; 3D structure of proteins
	Isoflavones	Modulation of hormone receptors and tyrosine kinases
Biomembrane	Monodesmosidic saponins	Complexation of cholesterol; disturbance of membrane fluidity and permeability
	Terpenes, isothiocyanates	disturbance of membrane fluidity and permeability, modulation of ion channels
	AMPs	Pore formation in biomembranes
DNA/RNA	Alkaloids	DNA-intercalation: Sanguinarine, berberine, Harman alkaloids; DNA-alkylation: Pyrrolizidine alkaloids, aristolochic acids, cycasine
		Inhibition of topo-isomerase: camptothecin
	Furanocoumarins	DNA-intercalation, DNA-alkylation
	Epoxides, aldehydes	DNA-alkylation

Secondary metabolites as signaling compounds

Although defense is the most important function of SM for plants, it should not be overlooked that many plants sometimes use the same SM as signaling compounds to attract animals for pollination (especially insects, sometimes small rodents, fruit bats, humming birds, sunbirds) or seed dispersal (many frugivorous birds, fruit bats, primates) (Harborne, 1993; Wink, 2010b; Kadereit *et al.*, 2014; **Figure 1**). The attraction is mediated by the color of some SM in flowers (anthocyanins, chalcones, aurones, betalains, and carotenoids) and/or volatile and aromatic terpenoids, alcohols, aldehydes, ketones, amines, and phenylpropanoids. However, pollinators should only be attracted to flowers, and not eat them. Therefore, SM serve as signal compounds from a distance and as a deterrent when an animal has settled on a flower, where it is rewarded by nectar, oils, or energy-rich pollen.

Fruits store a number of SM and are therefore often unpalatable or even toxic when they are not mature. Upon maturation, they incorporate attractive colors (anthocyanins, carotenoids, aurones), perfumes (many volatile mono- and sesquiterpenes), and sweet sugars (glucose) (Harborne, 1993; Wink, 2010b; Kadereit *et al.*, 2014). Plants follow the strategy to attract frugivores, which eat the pulp, but leave the seeds unharmed. After passage through the gastrointestinal system, the seeds are later deposited in the feces at sites generally distant from the mother plant. Using this strategy frugivores employ some SM for seed dispersal. In the complex interaction of symbiotic nitrogen-fixing rhizobial bacteria and their host plants, SM (especially flavonoids) serve as signal substances (Harborne, 1993; Krauss and Nies, 2014).

SM can only serve as defense and signal compounds if they are present at the right time and in the right location. Many SM are stored in epidermal cells, hair cells, or the bark. This makes sense, considering the role as defense compounds, as these cells and tissues have to ward off intruders in the first place (Roberts and Wink, 1998; Wink 1988, 2003). As discussed above, SM are biologically active agents which may also interfere with the metabolism of the plants producing them. The production of SM as inactive prodrugs (**Table 3**) or of SM which affect targets that are only present in animals (e.g., alkaloids which modulate neuroreceptors) (Roberts and Wink, 1998; Wink *et al.*, 1998; Wink, 2000, 2007b) has probably been stimulated by this selection pressure. In addition, the sequestration of SM in cellular compartments, by which SM do not interfere with the cell's metabolism, appears to be another relevant strategy. The question of how plants protect themselves against their own toxins is not fully understood although interesting adaptations can be expected.

Exceptions to the rule

If you walk with open eyes in the field you will certainly find plants which are affected by herbivores or microbes. Very often these are crop plants that have been domesticated by humans during the last 10 000 years. With regard to SM, crop plants (except spices) usually do not contain toxic, bitter tasting or pungent SM; these traits have often been selected away (Wink, 1988). As a consequence, most crop plants produce only few SM and are more susceptible to herbivores and microbial pathogens than their wild ancestors. Modern agriculture employs synthetic pesticides instead, which replace the originally present defense compounds. Because agriculture often uses single substances (instead of mixtures as the plants do) and grows plants in large monocultures, resistant herbivores and pathogens quickly develop, resulting in the need for new pesticides. An alternative approach would be to cultivate crops with high concentrations of defensive SM and to remove the compounds later during food processing.

It should be remembered that for defense, plants use complex mixtures of SM, the composition of which varies in a time-, site-, and development-specific fashion. This phenomenon can be regarded as a strategy to reduce the risk that herbivores and microbes develop resistance or tolerance against the toxic SM. As a mixture contains dozens of bioactive SM which affect different targets, it is more difficult for a herbivore or microbe to develop resistance than if a single compound were present (Wink, 2008a,b). However, even highly protected plants have their adapted enemies. A close analysis of these herbivores or pathogens will reveal that they often represent specialists which attack a single or few often phylogenetically related host plants (Harborne, 1993; Bernays and Chapman, 1994; **Figure 1**). What allows a specialist to attack these highly protected plants? With the tools of genetics and chemical ecology, a number of these adaptations have been explored.

Larvae of the monarch butterfly (*Danaus plexippus*) feed on *Asclepias* (milkweed) plants, which produce cardiac glycosides (CG) which are highly toxic for most herbivores (Harborne, 1993). We demonstrated that the target of cardiac glycosides, the Na^+/K^+ ATPase in *D. plexippus*, has been inactivated by a point mutation, so that CG are no longer toxic to them (Holzinger and Wink, 1996). As the larvae sequester CG and pass them on to the adult butterflies, both of them become toxic to avian and other predators. Monarch butterflies are a good example of adapted insect herbivores, which can not only tolerate a plant toxin but use it for their own defense. Similar cases are known for insects which sequester pyrrolizidine, quinolizidine alkaloids, and aconitine, but also for iridoid glucosides and glucosinolates (Harborne, 1993; Wink, 1993, 2010a,b; Brown and Trigo, 1995; Krauss and Nies, 2014; Wink, 2010a). These insects often bear aposematic warning colors.

Furthermore, herbivores and microbes have developed a series of general adaptations and detoxification strategies against plant SM. These include ABC transporters, which can export a wide variety of lipophilic SM that enter cells via free diffusion. If a food is rich in such toxins, the expression of ABC transporter genes is often upregulated (Wink *et al.*, 2012). Animals have mechanisms by which lipophilic SM become conjugated with a hydrophilic component (often glucuronic acid, sulphate, or amino acids) which facilitates their elimination via the urine (Krauss and Nies, 2014). Many herbivores cultivate microbes in their digestive system which can inactivate SM. These adaptations enable herbivore generalists to feed on SM containing plants.

When Did the Secondary Metabolism Evolve?

The first land plants developed in the Silurian/Devonian about 420 million years ago from green algae. These algae had survived in a world full of animals (mostly arthropods) and

microbes (bacteria, fungi) that were ready to attack these aquatic plants (Kadereit *et al.*, 2014; Wink, 2003, 2008b). It is therefore highly likely that the early land plants already used SM for chemical defense, especially against microbes. The SM profiles of extant mosses, horsetails, lycopods (club mosses) and ferns – all plants that reproduce by spores and that had their prime time in the Carboniferous about 320 million years ago – show that they produce a diversity of phenolics and terpenoids that occur with similar chemical structures in seed plants. Only a few spore-bearing plants produce alkaloids (except for some lycopods and horsetails), cyanogenic glucosides or glucosinolates. Whereas phenolics and terpenoids are still dominant in gymnosperms, N-containing SM are more common in modern angiosperms, which started to evolve about 140 million years ago (Roberts and Wink, 1998; Wink, 2010b). Plants with wind pollination (many grasses, trees) often produce terpenoids and phenolics for defense, but plants which actively attract pollinators and frugivores (plants with attractively colored flowers or fruits) often use toxic alkaloids, cyanogens, and isothiocyanates, which affect the nervous system of animals.

How Did Plants Acquire the Genes for Secondary Metabolism?

When we analyze the distribution of SM across the plant kingdom, we see that a number of classes, such as phenolics and terpenoids occur throughout. Other SM occur in restricted genera or families, for example, glucosinolates are common in the order Brassicales (mustards and relatives) but not anywhere else. However, several alkaloids (quinolizidine and pyrrolizidine alkaloids) or terpenoids (iridoids, cardiac glycosides) dominate a few genera or families but also occur in exactly the same chemical structure in nonrelated families (Wink *et al.*, 2010; Wink, 2013, 2014). For example, quinolizidine alkaloids are dominant in a clade of Fabaceae (legumes) but are also found in Ranunculaceae (buttercup family) and Amaranthaceae (amaranth family), and cardiac glycosides are found in several unrelated families including Asparagaceae (asparagus family), Apocynaceae (dogbane family), Brassicaceae (mustard family), Ranunculaceae, and more. This is an argument why SM pattern should not be used naively for reconstructing phylogenies (as is sometimes done in chemosystematics).

Monoterpene indole alkaloids (MIA) occur in many members of the Apocynaceae. Therefore, one would expect that the key enzymes of MIA biosynthesis, such tryptophan-decarboxylase (TDC) and strictosidine synthase (STS) and the corresponding genes would only be present in plants which produce MIA (Wink, 2010a,b). However, genome analyses have revealed that TDC and STS genes are present in most plants (Facchini *et al.*, 2004; Wink *et al.*, 2010); because we find MIA only in the Apocynaceae we assume the corresponding genes are downregulated or inactivated in the other plant families (Wink *et al.*, 2010). When genomes of bacteria, fungi, and animals are included in the search for MIA genes, we find homologues in microbes and even animals. This finding not only applies for TDC and STS but also for a number of key genes of other pathways (overview Wink *et al.*, 2010b; Wink, 2014). One conclusion would be that many genes of plant SM have a ubiquitous distribution but are only locally expressed (Wink, 2003, 2008a,b). This assumption does not rule out that specific plant groups have developed a set of their own SM genes.

How to explain the patchy distribution of SM?

It is well established that bacteria and fungi produce a wide variety of SMs showing identical or similar chemical structures to plant SM. Also some key genes of bacteria, fungi, and plants are closely related, such as polyketide synthetases and terpene cyclases (Krauss and Nies, 2014).

According to the endosymbiont hypothesis, about 1.8 billion years ago early eukaryotic cells acquired protobacteria which later became the mitochondria. It is likely that these protobacteria carried several genes for SM pathways in their genome and that these genes were incorporated into the nuclear genome of the host cell. This was an early event of horizontal gene transfer (HGT) which occurred several times during evolution (**Figure 2**). When photosynthetically active protists and algae evolved, another symbiosis took place by incorporating cyanobacteria, which later became the chloroplast of modern plants. Cyanobacteria are known for extensive synthesis of SM; thus we can assume that they introduced a further set of SM genes into the plant genome. We postulate that early land plants used these microbial genes for the synthesis of phenolics and terpenoids. These genes were later modified to produce the diversity of SM we know today. This scenario would help to explain the occurrence of SM and SM genes described above (Wink, 2008a,b, 2010a,b, 2013, 2014).

About 90% of plants live together with symbiotic fungi, such as ecto- and endomycorrhiza, which help plants to obtain nutrients and water (Kadereit *et al.*, 2014). Fungi also produce a high diversity of toxic and repellent SMs. Do fungi support their host plants with SM? For a long time phytochemists have wondered about the occurrence of ergot alkaloids: Ergot alkaloids are known SM of the fungus *Claviceps purpurea*, which occurs on rye and other grasses. Ergot alkaloids function as neurotoxins, affecting the neuroreceptors of serotonin, noradrenaline, and dopamine (Wink, 2000). In grasses that are infected with *Claviceps*, the alkaloids serve as defense compounds against herbivores (Wink, 2008b). The interaction of *Claviceps* with their host plants is no longer regarded as parasitic but symbiotic. Ergot alkaloids of similar chemical structures have also been detected in some North American species of Convolvulaceae (morning glory family). Formerly, it was assumed that these plants produced these alkaloids themselves. A close analysis of the Convolvulaceae revealed that some of them carry endophytes related to *Claviceps* which produce the ergot alkaloids. The insular distribution of ergot alkaloids in the plant kingdom is thus not a function of a wide distribution of SM genes (as discussed above) but can be explained by symbiotic endophytes.

The example of ergot alkaloids is apparently not an exception, but might represent a widespread phenomenon (**Table 5**). Several instances have been documented in which certain SMs of a plant, which had been considered to be a typical plant SM, are produced by endophytes. Very likely, many more examples of this kind will be discovered in the future. In some instances, apparently endophytes but also the

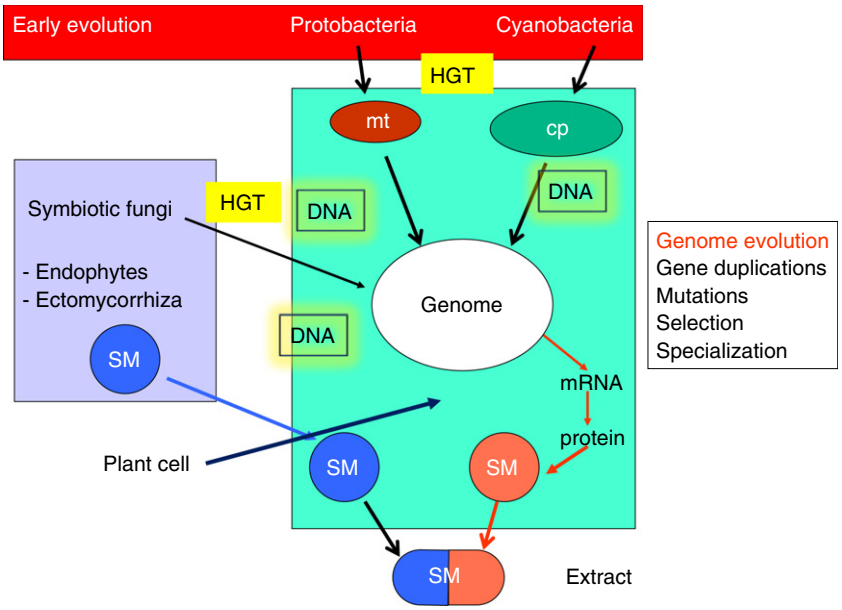

Figure 2 Putative origins of genes encoding biosynthesis enzymes of secondary metabolites and the SM found in a plant.

Table 5 Examples for SM from endophytes

Host plant	Fungal SM, accumulating in host plant
Astragalus spec.; *Oxytropis* spec.	Swainsonine and other indolizidine alkaloids
Hypericum perforatum	Hypercin
Ipomoea tricolor	Ergot alkaloids
Lolium pratense	Loline (PA)
Maytansia	Maytansinoids
Nothapodytes foetida	Camptothecin
Podophyllum peltatum	Podophyllotoxin
Taxus brevifolia	Paclitaxel

plant without endophytes produce identical SM. We may speculate that fungal genes might have been transferred into the genome of their host plants by HGT (**Figure 2**; Wink, 2008a,b, 2010b, 2014).

Considering the diversity of plant SM, we may speculate that a large proportion of genes which govern plant SM have been transferred by HGT from protobacteria, cyanobacteria, and endophytes into the plant genome during evolution (**Figure 2**). Future genome analyses will reveal the dimension of such gene transfers.

Evolutionary Pharmacology and Phytotherapy

As discussed above, plants have evolved a wide set of bioactive SM (Wink and Schimmer, 2010), whose bioactivities were discovered by humans a long time ago. Toxic alkaloids and cardiac glycosides have been used as arrow poisons for hunting and war. Other plants were used to poison wild animals, rivals, or enemies (Mann, 1992; Wink, 1988; Wink and van Wyk, 2008). Aromatic SM (mono- and sesquiterpenes, phenylpropanoids) were employed as perfumes, colored SM for dyeing of clothes or skin. Neurotoxins (mostly alkaloids and amines) were (and still are) widely selected as stimulants, intoxicants, and hallucinogens (Wink, 2000; Wink and van Wyk, 2008). For thousands of years humans have used plants and plant extracts to treat infections, inflammations, pains, and health disorders. About 2000 years ago Dioskorides published a Materia medica in which 400 medicinal plants and their applications were described; several of these plants are still in use in present day phytomedicine (overview in van Wyk and Wink, 2004; van Wyk *et al.*, 2015).

Plants that produce powerful poisons affecting a single or few targets are often still in use today. Mostly, isolated SM, such as morphine, colchicine, vinblastine, paclitaxel, galanthamine, huperzine, or emetine, are applied in medicine as registered drugs (Schmeller and Wink, 1998; van Wyk and Wink, 2004; **Table 3**). In addition, traditional medicines and phytotherapy employ extracts from medicinal plants that contain complex mixtures of phenolics, terpenoids, saponins, and polysaccharides. These extracts affect a multitude of targets and are therefore often prescribed to treat more than one health problem (**Table 3**). Such multi-target drugs also affect molecular targets in diseases, for which the relevant targets have not yet been identified. An advantage of the extracts is the presence of components which potentiate each other in a synergistic matter (Wink, 2008, 2015).

In the time of genome analyses modern medicine more and more discovers the molecular causes of diseases and health disorders. In consequence, the number of disease-relevant molecular targets, towards which the pharmaceutical industries will develop modulators or inhibitors, will increase substantially. From a perspective of evolutionary pharmacology it is obvious that SMs of plants, but also of microbes and sessile marine organisms (Proksch and Ebel, 1998), represent a treasury of potential active agents which only waits to be discovered by bioprospection (Wink, 2007a,b). This treasury of potential drugs is an important aspect of ecosystem services of biodiversity and it is evident, that it is important to preserve the diversity of plants and animals so that future

generations have the chance to find new drugs for medical and other applications.

Key Definitions

Escalation An evolutionary process where enemies are the predominant selective agents.
Evolutionary security (synonyms: natural security, Darwinian security) Field of study that applies the principles of evolutionary biology to problems in human security.
Operational adaptation Research on how to achieve effective adaptation in war.

Introduction

Security affairs in human society are often discussed in the context of geopolitics, religious and ideological conflict, and human history. Conflicts and the resulting security challenges they create also may have environmental drivers, though conclusive evidence is mixed (Homer-Dixon, 1994; Stewart, 2002; Barnett and Adger, 2007; United Nations Environment Programme, 2009; Forsyth and Schomerus, 2013). Although there have been scattered efforts in the past, since the 9/11 attacks, there has been more concerted and interrelated attempts to examine human security within an evolutionary context. These efforts come from a vast range of fields and viewpoints and accordingly this review cannot be exhaustive but attempts to highlight key areas and to provide a general framework to organize the body of evolutionary security works and illustrate how they might be applied to address human security concerns.

Evolution provides a potentially valuable framework for looking at security for several reasons. From a practitioner standpoint, there is a feeling that the old methods and lenses with which to look at security had either failed (e.g., the 9/11 attacks) or were inadequate to address the complexities and nuances of today's security environment (Sagarin and Taylor, 2008). Evolution provides a lens to look at security broadly and across a number of different gradients. For example, evolution provides insights into the relative role of technology (phenotypic trait variation) and tactics (behaviors) in adapting to security threats. Evolution helps us consider the origin and maintenance of offensive weaponry vs. defensive structures or behaviors. Evolution helps us think about the relative role of cooperation vs. conflict. And, a functional and historical approach can help us think about ways to better prevent and respond to security breaches.

Individual scholars from within and outside biology have raised parallels between security in natural and human systems for many years. Most notably Warder Clyde Allee applied his studies of cooperation among organisms to questions about international conflict and cooperation, including the nascent idea of a United Nations, in several works (Allee, 1943, 1951). Ecologist Ed Ricketts (a student of Allee) frequently referred to evolution and ecology in his essays (Rodger, 2006), and he attempted to apply his studies to the intelligence efforts of the US in World War II, with disappointing results (Steinbeck, 1986). Economist Kenneth Boulding has described his 1962 book *Conflict and Defense* as the 'beginning of an evolutionary theory of conflict, seeing conflict as merely one element in the vast process of evolutionary and ecological interaction' (Boulding, 1962 [1988], p. ix). Paleobiologist Geerat Vermeij created a grand synthesis of paleobiological research suggesting that increasing capacities of organisms to obtain resources leads to increasing dangers in the environment, thus driving an escalation of offensive and defensive capacities for all organisms that interact strongly with their environment (Vermeij, 1987). Later, Vermeij applied this synthesis to human military escalation, making a pointed criticism of missile defense programs in noting that the inevitable evolutionary escalation of weaponry obviates the "false claim that weapons provide absolute security in the event they are used" (Vermeij, 2004, p. 300).

These and other individual efforts have been augmented in recent years through interdisciplinary collaborations and working groups dedicated to evolutionary security studies. Sagarin, for example, convened in 2005 a 'Darwinian Security' working group comprised of biologists and security experts at the National Center for Ecological Analysis and Synthesis. Dominic Johnson convened in 2010 an international workshop on 'Operational Adaptation' featuring biologists, anthropologists, civilian and military security experts and informed by evolutionary models, which was sponsored by the US Office of Naval Research Global. These efforts have resulted in books, collaborative papers and briefings to security agencies, although their ultimate effect on security policy is unknown (see below).

Approaches

There are several basic approaches that have been used in applying evolutionary thinking to security issues. Briefly, these include using analogies from nature to illuminate what appear to be similar situations in human security struggles, or the inverse approach in which direct observation of human security situations are contextualized in evolutionary terms.

[†]Deceased.

An alternative approach is developing models, including but not limited to those previously used in ecological and evolutionary studies, to simulate or elucidate underlying causes of behaviors and patterns in human security. All of these approaches have been used in either an analytic/explanatory sense to shed light on past or ongoing security situations, or in a pro-active/prescriptive sense to make predictions or warnings about potential future security scenarios (examples in Sagarin and Taylor, 2008).

Direct Analogies from Nature

Analogies from nature provide rich ground for examining security in society. While simple 'biomimicry' has turned up numerous 'products' of evolution (e.g., the fusiform shape of a tuna, camouflage mechanisms in cuttlefish) that may be effectively used in security situations (Armstrong and Warner, 2003), there is far richer ground to explore in the 'process' of evolution and the activities of biological organisms, when put into the context of security studies.

Perhaps the most obvious area to look, because it is so apparent in the phenotype of many organisms, is in studies of development and escalation of armaments and defensive structures of conflict. A recent review of this topic, particularly focused on modern fauna and making a number of direct analogies to human weaponry, is Emlen's *Animal Weapons* (Emlen, 2014). Whereas behavioral changes may be an initial, and reversible defense, animals also can add morphological defenses. Thus, the ecological interest in constitutive vs. inducible defenses in plants and animals (Harvell, 1990; Poitrineau *et al.*, 2004) is another potential analogy to human security, regarding to what extent we invest in a baseline level of security vs. maintaining the capacity to quickly ramp up defenses when necessary.

Looking at predator–prey relationships has been used to provide insight into warring sides in conflict. The relative costs of predation can also be examined in societal terms. Applying the 'life-dinner' principle (in which one side is running for its life where the other is merely trying to obtain a single meal) (Dawkins and Krebs, 1979) to conflict can illuminate the relative motivations of terrorists vs. states (Guerra-Pujol, 2012).

These differential benefits and costs relate to a larger and growing field of security studies – that of asymmetric conflict – that have relevant analogies in evolved systems. Parasite–host interactions, for example, resemble many features of asymmetric conflict among human societies where one side at relatively low energetic cost can have enormous effects and even modify the behavior of a typically larger and better-resourced host. The analogy of viruses, in particular, has been used widely to describe the actions of terrorists, the relatively lower cost of terrorist action vs. counter-terrorism by a 'host' country, cybersecurity threats, and surprisingly, the roots of cooperation (Villarreal and DeFilippis, 2000; Stares and Yacoubian, 2005; Lafferty *et al.*, 2008; Villarreal, 2008). Likening crime to an infectious disease and examining spatial and temporal patterns of its spread has also been an effective analogy (Zeoli *et al.*, 2012; NPR, 2015).

Intraspecific competition also has lessons for human security. 'Arms races' among species (particularly due to sexual selection on armaments such as antlers or oversized claws) are apt descriptors of some types of human conflicts and thus can be analyzed for their underlying causes and long-term trends. Fiddler crab males, for example, have been likened to both the posturing of both sides of the cold war, as well as the stability conferred by the concept of 'mutually assured destruction' (Sagarin, 2012; **Figure 1**). Such analogizing is more than descriptive because it allows a mechanistic view of the conditions in which symmetrical conflict can lead to stability or escalation. For example, Emlen (2014) argues that certain conditions, including competition for limited resources, resources that are localized and defensible, and opportunities for face-to-face conflict, make escalation of armaments more likely.

Figure 1 The Cold War arms race between the Soviet Union and the US was similar to male fiddler crabs competing with each other for mates. Crabs wave their oversized claws at each other but actually don't use them in battle, and analogously, superpowers assume that the threat of using strong nuclear weapons against the enemy prevents the enemy's use of those same weapons. https://upload.wikimedia.org/wikipedia/commons/5/5f/Fiddler_crab_4.jpg.

More subtle linkages between evolution and human security have been elucidated within the behaviors and life histories of organisms. Threat detection and alarm calling are particularly apt areas of study. On this question, a concern for the natural and human social realm is how can threats be detected accurately, and alarms about these threats be conveyed clearly and with enough urgency to get a population to react appropriately. The issue of habituation to alarm calls (or ignoring false alarms) is particularly worrisome in the human security realm (Blumstein, 2008), where it has been estimated that 21 million Americans don't keep batteries in their smoke detectors and even residents of areas hard hit by the 2005 Boxing Day tsunami soon dismantled newly installed tsunami warning alarms because of the high rate of false alarms (Sagarin, 2012). Accordingly, analogies from the natural world tend to focus on 'honest signaling,' which is expected to be costly when used (Blumstein *et al.*, 2012). Yet we should expect many situations where honest signaling is rare and individuals are trying to provide mis-information to modify the behavior of another individual. Understanding the value of information is key and to properly interpret information, knowledge about the signaler's reliability is often essential. For instance, Blumstein revealed that some individuals in-groups of marmots make alarm calls only when there is a clear and present danger, whereas others make abundant

alarm calls, even to non-consequential threats (Blumstein and Armitage, 1997; Blumstein, 2008). Marmots use their estimates of caller reliability when making decisions about how to respond to these vocalizations.

Observing human conflict, cooperation, and other security-related behaviors and then reaching back for evolutionary causation represents the inverse approach of using evolutionary analogies. The field of evolutionary psychology attempts to identify ultimate drivers of human behavior (Barkow *et al.*, 1992) and may be useful in helping to explain seemingly irrational or maladaptive behaviors (such as suicide bombing or the inability to properly weigh the relative risk of terrorism relative to other more common threats) which may have been adaptive (or neutral) in humans' ancestral environments (Liddle *et al.*, 2011). Nonetheless, because our own deep evolutionary history is intertwined with a more modern social evolution that itself may feedback on our evolution, seminal works in the areas of evolutionary psychology, 'sociobiology' (Wilson, 1975), and 'biopolitics' (Somit and Peterson, 1997) have generated considerable controversy that continues to be debated (e.g., Wilson, 1998; Corning, 2001; Somit and Peterson, 2001; Goetze and James, 2004).

Much aggressive and cooperative behavior among humans has been linked to human cultural biases, including deep seeded ethnocentrism (Hammond and Axelrod, 2006) and favoring in-group members against out-group members, which are reinforced through cultural norms and religion, as portrayed in a rich evolutionary literature (Henrich and McElreath, 2003; Ehrlich and Levin, 2005; Sosis and Alcorta, 2008). Villarreal examined the deep evolutionary roots of in-group/out-group biases, suggesting they are a human manifestation of self/non-self recognition systems that date back to the earliest bacterial and viral interactions (Villarreal and DeFilippis, 2000; Villarreal, 2008). Hatemi and colleagues (2013) links this out-group bias directly to fear of out-group members and discuss the conflict it creates in a political context. Because many of these biases are expressed through religious identification, global assessments of common features of religion can helpfully point out likely development-related points of entry and exit from radical religious beliefs (e.g., adolescence) (Sosis and Alcorta, 2008).

Peeling back a layer from strong out-group biases in humans reveals that cooperation among in-group members is an essential and somewhat enigmatic process (Henrich and Henrich, 2006) when contrasted to self-interest, and this is particularly debated in the context of altruism. Altruism in humans has been explained through basic evolutionary mechanisms such as kin selection (Davis, 1997; West *et al.*, 2011) as well as more nuanced explanations such as the role of empathy (which likely goes back deeper than the human lineage; de Waal, 2008), costly displays that reinforce group identity (Henrich, 2009), potential for group punishment of defectors (Fehr and Gachter, 2002) and even 'supernatural' punishment (acknowledged in a religious sense) of defectors (Johnson and Kruger, 2004).

Dominance hierarchies are a particular set of behaviors that have been viewed for many years of having direct linkages between human and nonhuman analogs. Allee (1938), for example, carefully considered the 'pecking order' in hen houses as a direct lesson for human cooperation and conflict. Silk (2002) used studies of primates to suggest that random acts of aggression may effectively discourage subordinates from defecting in a hierarchical society. More recently, the work of Robert Sapolsky and colleagues has linked dominance hierarchies in primates to factors that maintain cooperation or foment conflict, with commensurate lessons for humans (Sapolsky, 2006). Individuals (or nations) may have special roles in stabilizing societies. For instance, Flack *et al.* (2006) showed that the removal of especially powerful dominant male pigtail macaques (*Macaca nemestrina*) led to increased conflict and group fragmentation. Especially powerful entities can have a stabilizing effect on groups. Related to dominance hierarchies, with important implications for warfare and peace building, are studies on the evolution of leadership (King *et al.*, 2009).

Emergent Properties

The most intriguing and complex view of evolution in security comes through examining the widespread or in some cases emergent properties of evolutionary systems. Chief among these properties is that of adaptability – the capacity of a biological system to cope with (adapt to) the unexpected disturbances of the environment, internal or external. Especially after 9/11, many security agencies and advisors talked of the need to be more adaptable, and the process and outcomes of adaptable biological systems likewise became a unifying theme of evolutionary security work (Sagarin and Taylor, 2008).

While adaptability is an attractive conceptual framework for security, it needs to be broken down into processes that can be emulated if it is to be useful in an applied security context. One such process is symbiosis, which is both universal and emergent in evolutionary systems (Margulis, 1998). Symbiosis can be seen as an appropriate model for the kinds of partnerships necessary in security practice because in nature it is not a simple *quid pro quo*, and it includes relationships between unlikely partners including partners that once had an antagonistic relationship (Allee, 1951; Margulis, 1998). Corning (2005) suggested that synergistic (cooperative) effects have played an important role in the emergence of more complex natural and social systems and conversely that a global security system might emerge through the selective advantages of cooperative interactions. Analogous symbioses in human affairs have resulted in health provisioning partnerships between Israeli, Palestinian, and Jordanian health practitioners (Gresham *et al.*, 2009), and likely led to a rapid reduction in deaths due to improvised explosive devices in Iraq for US forces (Sagarin, 2012).

Redundancy is another general feature of adaptable systems that appears universal in biology (Vermeij, 2004). At the upper end of biological complexity, redundancy (of functional types) seems to provide resiliency to ecosystems (Levin, 1999). In human terms, redundancy can provide a 'hedge' against the uncertainty of unpredictable security situations. Indeed, individuals often seek to reduce uncertainty about the true risk of predation and using different modalities of stimuli to assess risk is likely favored in noisy, dynamic, and uncertain situations (*sensu* Munoz and Blumstein, 2012).

Finally, adaptable systems often rely on decentralized abilities to sense change in the world (Vermeij, 2008). The adaptive vertebrate immune system is an exemplar, wherein

immune cells search for, identify, and neutralize invading pathogens throughout a body with very little contact with the central nervous system. In the realm of human security, the last decade has seen an explosion of decentralized sensory systems – particularly those facilitated by cell phone networks – aimed at security-related concerns such as mapping disease outbreaks or areas needing immediate assistance following a natural disaster.

Evolutionary and Ecological Models

The descriptive approaches above have been augmented by modeling approaches that capitalize on the enormous body of existing evolutionary and ecological models made for situations analogous to those that are found in human security concerns. Examples of models used in studies of conflict are especially rich in game theory with Axelrod's *The Evolution of Cooperation* being a key early contribution (Axelrod, 1984, 2006). Many games focus particularly on the conditions under which cooperation between people or groups arise. Interpretations of games have relied on both economic and evolutionary models, which may lead to conflicting conclusions about root causes for the observed behaviors (Hagen and Hammerstein, 2006), suggesting that there is still need to reconcile the relative roles of cultural and biological evolution in determining peoples' willingness to cooperate with or punish other people.

Ecological models stemming from various levels of biological complexity have been used to draw light on terrorism and conflict. Turchin and collaborators (2003) have used various spatial ecological models of animal movement and population cycles to draw conclusions about seemingly synchronous events in economics and international relations. Drapeau *et al.* (2008) used heuristics of predator–prey and competition models to outline potential counter-terrorism strategies. Bohorquez and colleagues (2009) developed models that treat insurgent populations as part of an ecology of dynamically evolving, decision-making groups to identify commonalities in the timing and size of violent events within conflicts. Keohane and Zeckhauser (2003) used an ecosystem model of stocks and flows to examine how individuals might respond to terrorism.

More recently, food web and network models have been manipulated for use in security studies. For example, using the medium of TED talks, Eric Berlow applied food web theory to an overly-complex map of the US war strategy in Afghanistan and showed that it could be simplified to just a small number of key actions. Ferenc Jordan used network theory to analyze the July 7, 2005 London subway terrorist attacks and determined that terrorists chose the second-most destructive combination of stops to attack (out of 3.2 million possible combinations) (Jordan, 2008).

Finally, natural selection models can be used to study conflict. Johnson (2009), for example, studied coalition vs. insurgency success across several years of combat in Iraq using the three pillars of natural selection theory (variation, selection, replication) as metrics. He found that insurgent organizations had several characteristics favoring faster rates of adaptation under all three of these components of selection. However, the battlefield creates strong selective forces and the creation of 'hillbilly armor' illustrates that even coalitionary forces can adapt (**Figure 2**).

Figure 2 Operational adaptation on the battlefield. When US forces were caught off-guard by the development of improvised explosive devices (IEDs) in Iraq, active duty personnel up-armored their vehicles with whatever spare parts and scrap metal was available. It took years for the military to develop and deploy better-armored vehicles, but such hillbilly armor provided an interim solution. https://en.wikipedia.org/wiki/Improvised_vehicle_armour#/media/File:HillbillyArmor5tonCargo.jpg.

Targets and Prospects

There is always a concern that analogies from nature can be overstretched or inappropriately applied and most recent works on evolution and security acknowledge this directly. For example, Ehrlich and Levin (2005) explicitly discuss differences between human social evolution and biological evolution *via* natural selection. Likewise, a discussion of the ethics of applying evolutionary models to societal concerns graces most extended works on this topic (e.g., Vermeij, 2004). The misuse of 'social Darwinism' and adoption by proponents of eugenics has left scars on the academic community that are still felt today.

There are numerous fields of security studies and practice that have been examined from a functional and historical perspective, including crime analysis and policing strategies, homeland security, and natural disaster prevention (Felson, 2006; Sagarin, 2012; Roach and Pease, 2013). Cyber and information security, which already commonly uses the biological language of viruses, still suffers from a relatively static, firewall-based approach to security (Wulf and Jones, 2009), a situation that may benefit from an evolutionary treatment (Sagarin and Taylor, 2012; Sagarin, 2013).

Conflict between states might also be examined in an evolutionary context. From a behavioral point of view, Thayer attempted to reexamine various theories in international relations with an evolutionary lens and then applied this viewpoint to warfare and ethnic conflict (Thayer, 2004). Dietl, taking a macro-level approach, used concepts from selection theory to strengthen the idea that structural changes in world politics can be viewed in evolutionary terms (Dietl, 2008). While scholars have debated the role of environmental conditions in leading to conflict or hampering peace building (Crocker *et al.*, 2014), actual applications of evolutionary theory to peace building have been limited (Sagarin, 2014).

Likewise, an area of security that would seem to most naturally lend itself to lessons from adaptable natural systems is the growing field of climate change adaptation, but thus far

this field has primarily focused on social sciences approaches to stakeholder engagement (Willows and Connell, 2003), rather than viewing adaptation as a biological process. One of the key lessons from nature here is to understand whether there is sufficient adaptive flexibility (i.e., phenotypic plasticity) in a particular system or whether evolutionary changes are necessary. While there is extensive work studying the phenotypic plasticity of plants and animals, we need to know much more about human societal plasticity, its drivers, and the adaptive consequences of it.

While we can retrospectively identify the logic of evolution being applied to security policy, it is hard to identify particular cases where evolutionary approaches have been used at the outset to solve a security problem. A renewed focus on identifying both security problems amenable to applying evolutionary logic as well as identifying mechanisms underlying potential evolutionary responses may be helpful in developing concrete case studies of successful natural security.

There is a worry that although evolutionary approaches to security have been relatively welcome within academic circles, the pathway to incorporating them in practice may follow the delayed and incomplete application of 'Darwinian Medicine' to the practice of medicine (Armbruster, 2008). Indeed, one lesson from Darwinian Medicine is that it may take decades to develop an effective change model that becomes widely adopted. Thus, we should not be too concerned that it may take time to develop a catalog of successful natural security case studies.

Certainly, government and military officials have been briefed by some scientists in these works through individual meetings, staff briefings, seminars at military and homeland security departments and research academies (e.g., Sagarin lectured in evolutionary security at the Naval Postgraduate School) and conferences. There have also been calls for proposals from military organizations specifically looking at biomimetic technologies. How influential these inroads have been on policy remains to be seen and may never be fully quantifiable as policy arises from a complex mix of underlying science and research (which may come from many different fields), ideological struggles, and the particularly political environment surrounding law makers.

Regardless of the pathway to application, there is abundant basic research to be done in this field, which is very much in its infancy. Identifying key security questions that are amenable to an evolutionary approach will be a needed step in properly evaluating the tremendous potential of applying lessons from 3.5 billion years of successful life on Earth to increase the security of its diverse set of global citizens.

NS Nagalingum, Royal Botanic Gardens & Domain Trust, Sydney, NSW, Australia

Glossary

Allopolyploid A polyploid that formed between individuals of two different species (interspecific).
Arborescent (arborescence) Having a tree-like growth form.
Autopolyploid A polyploid that formed between individuals of the same species (intraspecific).
Bryophytes Lineage including mosses, liverworts, and hornworts. All reproduce via spores, lack vascular tissue, and the gametophyte stage is dominant. Current evidence is unclear whether bryophytes are monophyletic or not.
Cryptospore The first spores found in the fossil record. They lack features indicating they were connected to other spores (compare with trilete spore). They are given the prefix 'crypto' because of the ambiguous configuration with other spores, and the poor knowledge of their parent plants and affinities.
Dichotomous Describes a bifurcation resulting in two equal and symmetric branches.
Epipetric Growing on rock.
Epiphytic Growing on another plant.
Euphyll (also megaphyll) Leaf of a euphyllophyte. The leaves are produced by the apical meristem (a region of active division at the apex of the plant). In the central vascular tissue, in the area where a euphyll arises, there is a distinct region with nonvascular cells (called a leaf gap). Compare with lycophyll.
Euphyllophytes Lineage of plants that bears vascular tissue and leaves that are termed euphylls or megaphylls. It includes all vascular plants except the lycophytes; that is, ferns, horsetails, and seed plants.
Leaf gap A distinct region in the vascular tissue where there are nonvascular cells, and is linked to the formation and position of a megaphyll. Occurs only in euphyllophytes.
Lepidodendrids An extinct lineage of the lycophytes. They formed tall trees with thick trunks, and were particularly common in Carboniferous coal swamps.
Lycophyll (also microphyll) Leaf of a lycophyte. The leaves are produced by an intercalary meristem (a region of active division occurring in the stem, at the base of a leaf). In the central vascular tissue, in the area where a lycophyll arises, the vascular tissues are continuous and uninterrupted, thus lacking a leaf gap. Compare with euphyll.
Lycophytes Lineage including plants in the Lycopodiaceae, Selaginellaceae, and Isoetaceae. The plants reproduce via spores, and leaves are referred to as euphylls or megaphylls.
Megaphyll See euphyll.
Meristem A region of active cell division.
Microphyll See lycophyll.
Monilophytes Lineage including horsetails and ferns. The plants reproduce via spores, and in the central vascular tissues, the first xylem cells (protoxylem) are confined to lobes of the xylem strand.
Tracheophytes Lineage of plants that possesses vascular tissue. It includes lycophytes, ferns, horsetails, and seed plants; that is, lycophytes and euphyllophytes.
Trilete spore Spore that bears a Y-shaped mark. The Y-shape is derived from contact among four spores (tetrad) that were the product of meiosis.
Vascular cambium Actively dividing ring of tissue in the stem, which produces the vascular tissues. A type of meristem.

A large proportion of land plant history has been occupied by spore-bearing plants, that is, plants that reproduce via spores and not seeds. The earliest land plants were spore-bearing plants. These first plants are recovered in the fossil record almost 100 million years before the appearance of seed plants and about 330 million years before the earliest evidence for flowering plants.

This article reviews the evolutionary history of spore-bearing plants (Figure 1) – ferns, lycophytes, mosses, liverworts, and hornworts (the latter three are known as bryophytes). It incorporates knowledge from the fossil record, morphology of living taxa, and analyses of molecular DNA data. This article is not intended to be exhaustive, rather it offers some starting points for further exploration of these fascinating plant groups.

Bryophytes

Bryophytes as the Earliest Land Plants?

The earliest plant life on land reproduced via cryptospores, but there is uncertainty about the taxonomic affinity of these plants. They were thought to be bryophytes (Kenrick *et al.*, 2012; Wellman, 2004), but more recently, they have been called 'cryptophytes' – an extinct assemblage of land plants (a non-monophyletic grade) predating the various modern bryophyte lineages of land plants (Edwards *et al.*, 2014). The affinity or affinities of cryptospore-producing plants and their exact morphology are unclear because the fossils are fragmentary; nonetheless, they were only several millimeters tall with a unique combination of features that are not found in living taxa.

 doi:10.1016/B978-0-12-800049-6.00255-9

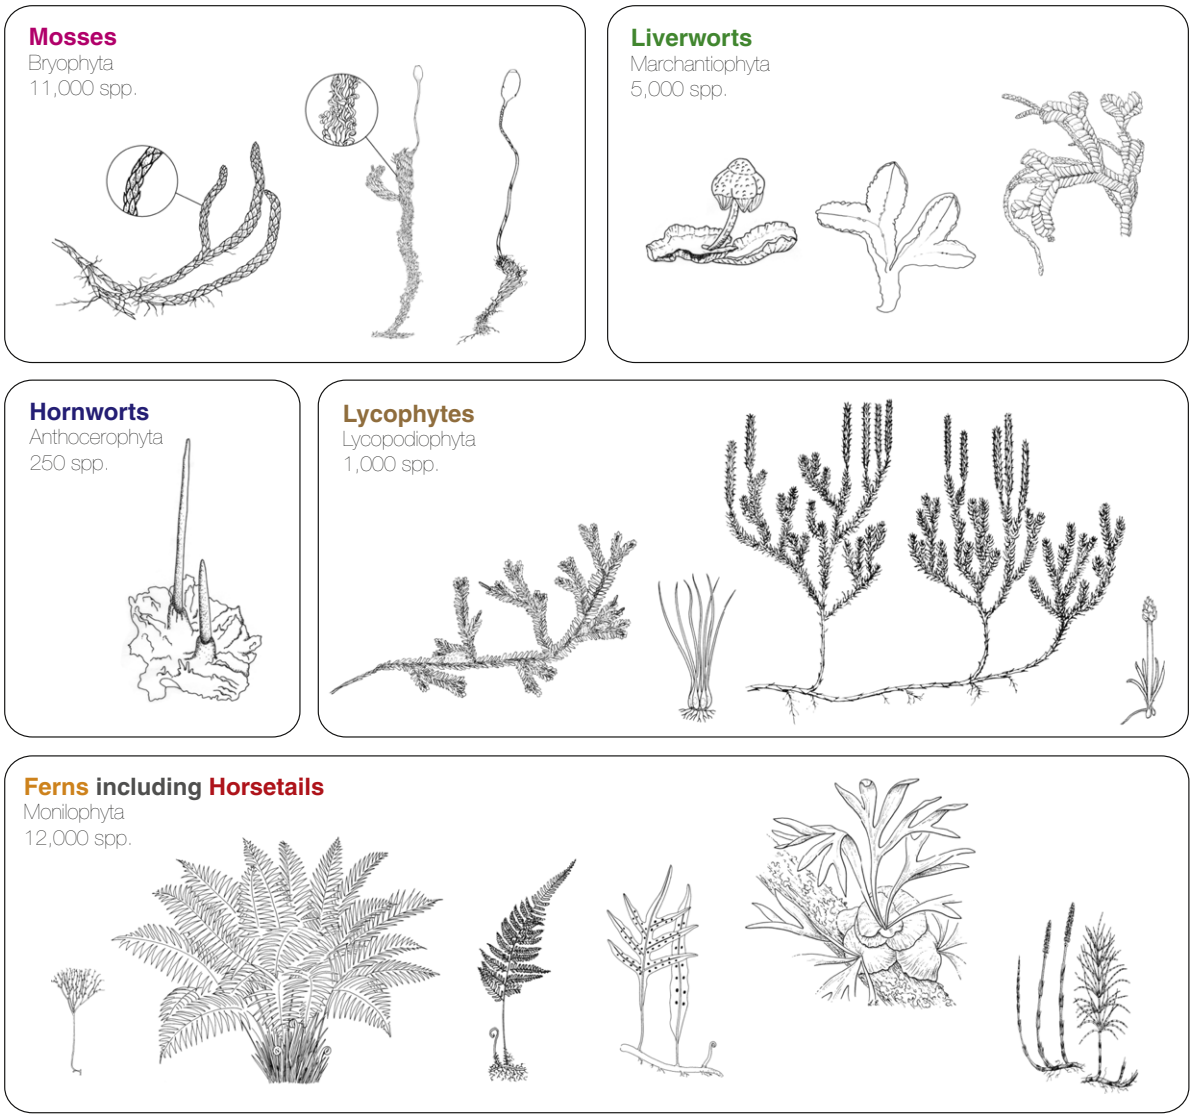

Figure 1 The five living spore-bearing plant lineages. Each box gives the common name, the division, number of species (Chapman, 2009), and representative illustrations of plants in each lineage. Illustrations are not to scale. All images from the Royal Botanic Gardens and Domain Trust archive accessed by Lesley Elkan, except for hornwort and thalloid liverworts images provided by D. Christine Cargill, and *Selaginella* from Stina Weststrand.

The first cryptospores appeared in the Middle Ordovician (roughly 470 mya (million years ago)) and increased in morphological diversity shortly after. For the next 30 million years, from the Middle Ordovician to Early Silurian, the cryptospores were globally distributed, but showed little variation suggesting an evolutionary stasis (Kenrick *et al.*, 2012; Gensel, 2008; Wellman, 2004). A major change in spore floras occured in the Early Silurian when cryptospore diversity decreased and trilete spore diversity increased. By the Devonian, ca. 420 mya, cryptospores virtually disappeared, possibly because trilete spore-producing plants outcompeted the cryptophytes. The plants that produced the early trilete spores were land plants, possibly from bryophyte-like organisms as well as vascular plants.

Alternating Generations and the Haploid Lifestyle

Living bryophytes comprise three groups: mosses, liverworts, and hornworts (**Figure 1**). They are mostly diminutive plants, and share one significant aspect of their life cycle – the haploid stage, in which they have a single copy of each chromosome, is the dominant phase (Shaw *et al.*, 2011; Niklas and Kutschera, 2010). In vascular plants, the diploid stage, in which there are two copies of each chromosome (or more), is dominant. All land plants alternate between these two phases of the life cycle, the haploid and diploid stages (gametophyte and sporophyte, respectively); however, the difference between vascular plants and bryophytes is that the dominant stage differs.

Because the dominant bryophyte plants have only a single copy of each chromosome and each gene, bryophyte evolution is quite different from plants with multiple copies of each chromosome. Every deleterious or beneficial mutation in a haploid plant is immediately expressed. This allows for a rapid spread of beneficial alleles, as well as the rapid elimination of any disadvantageous alleles, ultimately resulting in increased fitness (Otto and Gerstein, 2008).

Ambiguity in Relationships Among Bryophytes

The relationships among the three bryophyte lineages remain controversial. One hypothesis predicts that the three are monophyletic, thus, all sharing a single ancestor, and together are sister to all vascular plants (**Figure 2(a)**). Alternative hypotheses suggest that mosses plus liverworts are sister to vascular plants (**Figure 2(b)**), or that hornworts are sister to all vascular plants, with mosses plus liverworts as the first branching lineage in the land plant phylogeny (**Figure 2(c)**). There is another hypothesis that each group within the bryophytes evolved separately and they do not share a common ancestor, therefore, forming a grade rather than a monophyletic group (**Figure 2(d)**). Furthermore, in some analyses liverworts are the first diverging lineage and are sister to all other land plants (mosses and hornworts can be monophyletic or not) (**Figure 2(d)**). The results depend on the method of phylogenetic analysis used (Cox *et al.*, 2014), and studies using either whole chloroplast genomes or almost a thousand genes have failed to converge on an answer (Wickett *et al.*, 2014; Ruhfel *et al.*, 2014).

Understanding the relationships among bryophytes is critical to interpreting the evolution of land plants and development of morphological innovations (Renzaglia *et al.*, 2007). For example, if mosses are most closely related to vascular plants (Kenrick and Crane, 1997; Kenrick, 2000), the water-conducting cells in the mosses could be precursors to vascular tissue. However, if bryophytes are monophyletic or if hornworts are sister to vascular plants, then these cells in the mosses are an autapomorphy, suggesting vascular tissues arose *de novo* in vascular plants (Kenrick and Crane, 1997). The evolution of vascular tissues was a major evolutionary innovation allowing plants to become larger and explore new habitats.

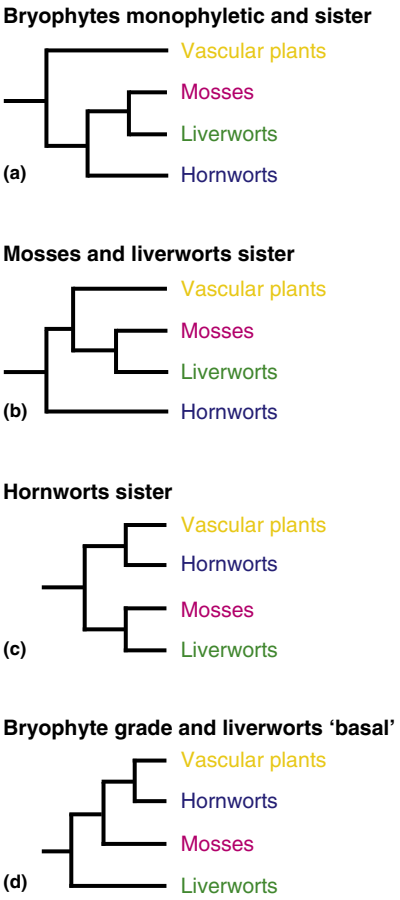

Figure 2 Phylogenetic relationships of bryophytes and vascular plants. (a) Bryophytes are monophyletic and together are sister to vascular plants; (b) hornworts are the first diverging lineage, and mosses plus liverworts are sister to vascular plants; (c) hornworts are sister to vascular plants, and mosses are sister to liverworts; (d) liverworts are the first diverging lineage or 'basal,' and the three bryophyte lineages form a grade with each arising from separate ancestors. The figure depicts the four principal relationships, although alternative relationships have been recovered from various studies. For relationships within vascular plants see **Figure 3**.

Ancient Origins Followed by Later Diversifications

Because of the delicate nature of bryophytes, there are very few macro fossils preserved in the fossil record. This absence of data has hampered our understanding of bryophyte diversification through time. The fossils that are known appear highly similar to extant species and, combined with the persistence of some ancestral morphological features, suggest bryophytes have 'limited evolutionary capacities' (Laenen *et al.*, 2014; Shaw *et al.*, 2011). The available fossils indicate that the modern lineages are ancient in origin, dating from the Paleozoic (although there is no record for hornworts until the Cenozoic) (Heinrichs *et al.*, 2015; Kenrick *et al.*, 2012).

Molecular timetrees are increasingly revealing a more complex history. These timetrees indicate that living diversity is the result of later radiations in the mid- to late Mesozoic and even during Cenozoic (Feldberg *et al.*, 2014; Laenen *et al.*, 2014; Cooper *et al.*, 2012; Fiz-Palacios *et al.*, 2011). For mosses and leafy liverworts, diversification was probably due to the new forest floor and forest canopy habitats created by angiosperms; a similar pattern is also observed for ferns (Schneider *et al.*, 2004; Schuettpelz and Pryer, 2009). Diversification analyses further suggest that mosses and liverworts experienced bursts of diversification from the mid-Mesozoic to the Cenozoic (Laenen *et al.*, 2014), while the hornworts did not (Villarreal *et al.*, 2015). The relatively low extant species richness in the groups appears to be the result of substantial extinction (Laenen *et al.*, 2014).

Lycophytes

Diversity in Morphology and Habitat Preferences

The three lineages, Lycopodiaceae, Selaginellaceae, and Isoetaceae, which collectively form the lycophytes, have divergent

morphologies and habitat preferences (Figure 1). The Lycopodiaceae or lycopods, are the most diverse of these lineages, having species that are epiphytic, terrestrial and creeping with a rhizome, terrestrial and climbing with a rhizome, or terrestrial with a subterranean tuber (Wikström, 2001). Selaginellaceae are prostrate and mat-forming, creeping, or erect, whereas their sister group Isoetaceae are aquatic to semi-aquatic and grow from a corm (Rydin and Wikström, 2002; Korall and Kenrick, 2002; Pigg, 2001).

The First Branch in Vascular Plants

The lycophytes occupy a special position in vascular plant (tracheophyte) phylogeny (Figure 3). They are the first branching lineage of tracheophytes, and consequently, they are sister to all other vascular plants (the euphyllophytes: ferns including horsetails, gymnosperms, and angiosperms) (Pryer *et al.*, 2001; Ruhfel *et al.*, 2014; Wickett *et al.*, 2014; Qiu *et al.*, 2006; Kenrick and Crane, 1997). Using the phylogeny as a framework, the lycophytes are critical to understanding the steps involved in the evolution of plants (Banks *et al.*, 2011; Floyd and Bowman, 2007; Ambrose, 2013). For example, we can compare genomes across the phylogeny to identify genes responsible for evolutionary changes between the major lineages. Comparing a lycophyte genome to genomes of bryophytes and of euphyllophytes reveals that three times as many genes were needed for the lycophyte–euphyllophyte transition as compared to bryophyte–vascular plant transition (516 vs. 1350 genes) (Banks *et al.*, 2011). On a genetic level, this indicates that there is greater complexity involved in becoming a euphyllophyte compared to transitioning to the vascular plant lifestyle.

Converging on the Leaf and Tree Habit

The lycophytes show two remarkable examples of convergence in plants – the evolution of the leaf and of the tree habit. Both have arisen independently in the lycophytes and in their sister group, the euphyllophytes (Figure 3). The earliest evidence of true leaves is in fossil lycophytes, as narrow elongated leaves called microphylls. Microphylls, also termed lycophylls, are quite different from the euphyll, or megaphyll, leaves of the euphyllophytes (Gifford and Foster, 1989; Pryer *et al.*, 2004). Lycophylls arise from an intercalary meristem (a region of active division occurring in the stem at the base of a leaf), whereas euphylls grow from an apical meristem. Also the central vascular tissues in lycophytes are continuous and uninterrupted, whereas those of euphyllophytes have a leaf gap when leaves form (a leaf gap is a distinct region in the vascular tissue where there are nonvascular cells). Such differences in development and morphology indicate that land plants have converged on leaf structures at least twice (Schneider *et al.*, 2002; Donoghue, 2005; Pryer *et al.*, 2004; Ambrose, 2013).

Another example of convergence between lycophytes and euphyllophytes is the ability to grow into large trees, also termed arborescence (Donoghue, 2005; Niklas, 1997). In the lycophyte lineage, the now extinct lepidodendrids were the main components of forests in the Carboniferous, around 320 mya. These plants were up to 35 m tall with trunks 2 m in diameter, dichotomous branches at the crown, and leaves that were 1 m long (Niklas, 1997). They formed enormous stands in swamps, and their decayed, preserved organic matter is the basis of modern coal deposits. One of the many remarkable features of these plants is that they formed tall trees; however, the mechanism by which they attained their height differs from that of most living seed plant trees, indicating separate evolutionary origins. The lepidodendrids and the living seed plants both possess an actively dividing ring of tissue in the stem (a meristem called the vascular cambium) that allows for increased girth and height; however, the divisions of the cells in the ring differ. In the lepidodendrids, the cambium divided in only one direction toward the inside of the stem, while in extant trees, the cambium cells divide in two directions to the inside and outer side of the stem. The tree habit has also evolved within other extinct and living groups, including ferns, horsetails, cycads, and monocots, but in quite different ways (Niklas, 1997).

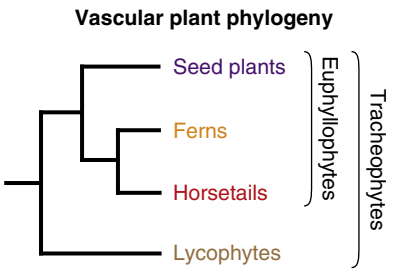

Figure 3 Phylogenetic relationships of the vascular plants. Relationships are based on the consensus from multiple studies (see text).

Ferns

Fern Distributions and Diversifications

In ferns, there are a range of forms and habitat preferences. They can be terrestrial, climbing, aquatic, epipetric (growing on rocks), epiphytic (growing on trees), xerophytic (growing in arid conditions), and also arborescent (Figure 1). Like many other plant groups, ferns are taxonomically diverse in the tropics (Nagalingum *et al.*, 2015; Kessler *et al.*, 2011; Kessler, 2010; Moran, 2008; Kreft *et al.*, 2010). High fern diversity correlates to high rainfall and montane regions (Nagalingum *et al.*, 2015; Kessler, 2010). Ferns share this preference for wet conditions with bryophytes, as shown by the strong correlations between bryophyte and fern diversity (Nagalingum *et al.*, 2014).

The majority of living fern diversity is the result of a relatively recent radiation starting in the mid-Cretaceous about 130 mya, occurring as a response to the diverse and complex forest niches created by the evolution of angiosperms (Schneider *et al.*, 2004; Schuettpelz and Pryer, 2009; Lovis, 1977; Rothwell, 1987; Crane, 1987; Nagalingum *et al.*, 2002). Part of this radiation included diversification of the epiphytic ferns in the Cenozoic (Schuettpelz and Pryer, 2009). Prior to this radiation, there were two earlier periods of fern diversification. The previous radiation was in the late Paleozoic

(approximately 250 mya), resulting in many lineages including some that persist today (such as the Osmundales, Schizaeales, and Gleicheniales) (Tidwell and Ash, 1994; Lovis, 1977; Rothwell, 1987; Pryer *et al.*, 2004). The oldest fern radiation occurred in the early Paleozoic (ca. 360 mya) following the evolution of ferns in the Devonian; however, this radiation produced fern families that are all now extinct (Rothwell, 1987).

Rearranging the Family Tree: Horsetails Among the Ferns

As a result of DNA analyses, fern phylogeny and classification have undergone significant reorganization over the past years, although many groups inferred through morphology have been confirmed (Christenhusz *et al.*, 2011; Smith *et al.*, 2006). There is a general consensus about the major groups in the ferns and their relationships (Rothfels *et al.*, 2012; Schuettpelz and Pryer, 2007; Pryer *et al.*, 2004, 1995; Hasebe *et al.*, 1995; Rothfels *et al.*, 2015; Lehtonen, 2011). However, there have been some outstanding questions, including the relationship of *Equisetum*, the horsetails, within the monilophytes (horsetails and ferns, **Figure 1**; Pryer *et al.*, 2001, 2004; Karol *et al.*, 2010). In some analyses, horsetails are recovered as sister to the Ophioglossales (adder's-tongues, grape ferns, and their allies) and Psilotales (whisk ferns) (Grewe *et al.*, 2013), or as sister to Psilotales alone (Ruhfel *et al.*, 2014). Recent analyses are converging on the position of horsetails as sister to all ferns, making them the first diverging monilophyte lineage (**Figure 3**; Rothfels *et al.*, 2015; Knie *et al.*, 2015; Wickett *et al.*, 2014).

Understanding Why Rates of DNA Evolution Vary

Molecular phylogenies depict the relationships among taxa, and in addition, the length of the branches represents the extent of molecular evolution, usually as substitutions per site. Branch lengths can differ, signifying there have been variable molecular evolutionary rates among the taxa (as well as indicating different ages). Understanding the causes of variation in molecular rates is an intriguing biological question. In animals, generation time is often suggested as a cause of variation, with long-lived species having slower rates simply because there are fewer generations to accumulate mutations. Alternatively, species that have shorter generation times have more generations to acquire mutations. In flowering plants, this phenomenon seems to be echoed by larger plants that take a longer time to reach maturity and so have slower rates, whereas smaller herbaceous plants have shorter generation times and have faster rates (Smith and Donoghue, 2008; Lanfear *et al.*, 2013). But is this true across the plant tree of life, and for plants that have a very different life history, such as ferns that reproduce via spores and undergo a period as a free-living gametophyte?

Ferns have substantial morphological diversity and so it is not surprising that the rates of molecular evolution are not uniform. Phylogenetically, the tree ferns have significantly shorter branches than their nearest relatives (Korall *et al.*, 2010). Analyses clearly indicate that the short branches are due to a slowdown or deceleration in rates in tree ferns. The possible cause is the tree habit, which is associated with a delayed time to maturity as compared to other ferns, mirroring the pattern in animals and in flowering plants (generation time effect).

Polyploidization and the Origin of Species

Polyploidization, the duplication of the whole genome, is prevalent in plants (Otto and Whitton, 2000; Soltis *et al.*, 2003; Soltis and Soltis, 1999; Wood *et al.*, 2009). Polyploid individuals have multiple copies of each set of chromosomes. Humans are diploid with two sets of chromosomes, while taxa with three sets are called triploids, four sets are tetraploids, and so forth. An exceptionally high ploidy level occurs in the adder's tongue fern, *Ophioglossum reticulatum*, which is a 96-ploid with 1440 chromosomes (Khandelwal, 1990).

These polyploids can be categorized to indicate the history of the polyloidy event. Allopolyploids form between two different species (interspecific), whereas autopolyploids occur within the same species (intraspecific). Therefore species are described by the ploidy level as well as the category of polyploidy. For example, *Polypodium hesperium* is tetraploid, and is the result of a cross between the diploids *Polypodium amorphum* and *Polypodium glycyrrhiza*. Thus it is called an allotetraploid (Sigel *et al.*, 2014).

To further complicate matters, allo- and autopolyploids can have repeated origins, where the polyploidization/hybridization event can occur multiple times. Following on from the example above, the chloroplasts of the allotetraploid *P. hesperium* differ across its range (Sigel *et al.*, 2014). This indicates that *P. hesperium* originated from multiple hybridization events between *P. amorphum* and *P. glycyrrhiza*. Based on DNA evidence, it was inferred that *P. amorphum* was the maternal parent (donating its chloroplast) in some cases, and in other cases, *P. glycyrrhiza* was the maternal parent. These different origins occurred in different geographical regions in North America, resulting in populations north and south of 42°N latitude having different plastid genomes. Such recurrent polyploid origins lead to higher genetic diversity, compared to a single origin (Soltis and Soltis, 1999).

Polyploidy allows duplicated, extra gene copies to mutate and explore new functions (Otto and Whitton, 2000; Otto, 2007; Soltis *et al.*, 2003; Soltis and Soltis, 1999, 2000). These new functions potentially enable polyploids to acquire new biochemical properties and expand into ecological niches, resulting in increased adaptability. Given these advantages, it is not surprising there are many polyploid ferns. In the Australian fern and lycophyte flora, 38% of all species are polyploids, with polyploids more common in particular families (Tindale and Roy, 2002). These numbers match estimates for ferns and lycophytes in general, such that 31% of species derive from polyploidy (Wood *et al.*, 2009). Interestingly, some ferns do not appear to have undergone polyploidization, with fossil nuclei showing the same genome size as living plants (Bomfleur *et al.*, 2014). As data from the first sequenced fern genomes are assessed (Sessa *et al.*, 2014), and with further studies investigating differing expression of parental genomes in a polyploid (Sigel *et al.*, 2014), it is likely that we will gain even further insights into the role that polyploidization has played in the evolution of ferns.

Selective Sweeps

ZA Szpiech and RD Hernandez, University of California, San Francisco, CA, USA

Glossary

Ancestral allele The allele previously fixed in an ancestral population.

Composite likelihood function A simplified version of a likelihood function that treats certain data points as independent even if they are not.

Composite likelihood ratio test A likelihood ratio test (see below) using composite likelihood functions.

Derived allele An allele segregating in a population that differs from the ancestral allele.

Folded site frequency spectrum A site frequency spectrum (see below) based on the minor allele frequency instead of the derived allele frequency. For a sample of n chromosomes, there are n/2 entries if n is even, otherwise there are $(n-1)/2$ entries.

Fst A measure of population differentiation calculated as the amount of genetic variance attributable to population subdivision.

Hard selective sweep The process by which a single adaptive allele arises and spreads through a population to fixation.

Likelihood function A function that gives the probability of the data under a given parametric model.

Likelihood ratio test A statistical test based on the ratio of the likelihood function for an alternative model divided by the likelihood function for a null model, where the null mode is a special case of the alternative model.

Maximum likelihood estimate The parameter values that maximize the likelihood function for a given model and set of observed data.

Minor allele The least frequent allele at a biallelic locus.

Site frequency spectrum (SFS) The random vector $\xi=(\xi_1,\xi_2,\ldots,\xi_{n-1})$, where ξ_i is the number of loci at which i chromosomes carry the derived allele and $n-i$ chromosomes carry the ancestral allele.

Soft selective sweep The process by which multiple adaptive haplotypes rise in frequency, either due to selection acting on a previously segregating allele or selection acting simultaneously on multiple alleles at a locus.

Introduction

A fundamental process in the evolution of species is natural selection. When a novel genetic variant confers a reproductive advantage to an individual in a population, it can undergo positive selection, possibly 'sweeping' through the population by rising quickly in frequency generation over generation. Although the time-course from origin to fixation of an adaptive variant will be faster than a neutral variant, in many cases an adaptive variant will still take hundreds to thousands of generations to achieve a large change in population frequency. It is therefore difficult to directly observe an adaptive variant's frequency trajectory over time.

There are at least two instances where it may be possible resurrect the true dynamics of an adaptive allele. The first is the case of experimental evolution, such as the Lenski Long-Term Evolution Experiment (Lenski, 2011). Here, by following an experimental population subject to a stimulus, it is possible to identify when, where, and how adaptive innovations occur (e.g., Blount *et al.*, 2012). Another case has recently emerged as a result of the development of ancient DNA sequencing (Pääbo *et al.*, 2004), whereby DNA is extracted from the preserved ancestors of a species. Such a technology potentially enables the reconstruction of the natural time-course of adaptive mutations throughout history (Pickrell and Reich, 2014).

However, there are many instances when neither of these cases is possible. In such situations, we may only have genetic data from an extant population. Over the last several decades, population geneticists have devoted much work toward the development of statistics designed to infer where and when positive selection may have occurred from such data collected at a single time point. In this article, we will discuss some basic models of selective sweeps, along with their expected patterns and methods for inferring their historical action from modern sequence data. We will then discuss complications with the selective sweeps model, as well as alternative models of adaptation.

Examples of Selective Sweeps

While selective sweeps are thought to have been rare in human evolutionary history (Hernandez *et al.*, 2011), there are a few strong candidates in the human genome. A now classic example of a selective sweep in humans is the region around the lactase gene (LCT; Bersaglieri *et al.*, 2004; Tishkoff *et al.*, 2006). Ancestrally, adult humans are lactose intolerant – losing their childhood ability to digest lactose – and endure severe intestinal distress should they consume fresh milk. However, certain regulatory variants around *LCT* confer a phenotype that maintains intestinal lactase activity at childhood levels into adulthood, thus allowing adult carriers to digest fresh milk safely (Swallow, 2003). This lactase persistence phenotype may have been advantageous during the development of agricultural pastoralism, allowing adult carriers an additional source of nutrition.

Other species across the great ape phylogeny may have experienced different rates of selective sweeps, both across the autosomes as well as the sex chromosomes. One recent study found a high rate of selective sweeps on the X chromosome across all great apes (Nam *et al.*, 2015). On the autosomes, selective sweeps are thought to be much more common in other organisms such as *Drosophila*, where ~13% of amino acid substitutions are thought to have resulted in selective sweeps (Sattath *et al.*, 2011).

Inference of selective sweeps often informs our understanding of the natural history of species. However, given the putative location of a selective sweep, careful sleuthing is required to understand what the precise adaptive variant may have been (e.g., in the lactase example given above). In domesticated species, we can often use our understanding of the phenotypic diversity across breeds or varieties in conjunction with signatures of selective sweeps to better understand the basic biology governing phenotypic variation. For example, in dogs (the species with the greatest diversity in body size of any terrestrial vertebrate), researchers sought to identify selective sweeps between the smallest and largest breeds (Sutter *et al.*, 2007). They found strong evidence for a selective sweep across a single gene that was nearly exclusive to small breeds compared to large breeds. This gene encodes insulin-like growth factor 1 (*IGF1*), which is thought to influence body size in both mice and humans (Wit and Walenkamp, 2013). Similar study designs have been applied in several different domesticated species such as cattle (Qanbari *et al.*, 2014), rabbits (Carneiro *et al.*, 2014), and rice (Xu *et al.*, 2012) with mixed success.

Basic Population Genetic Models of Natural Selection

The basic model of allele frequency change under selection assumes an autosomal locus in a diploid hermaphrodite species that cycles through a process of random mating and then selection each generation. For two alleles A_1 and A_2 with frequencies p and q, let the absolute fitness of individuals with genotypes A_1A_1, A_1A_2, and A_2A_2 be given by w_{11}, w_{12}, and w_{22}. At the end of random mating, the expected genotype frequencies are given by their Hardy–Weinberg proportions p^2, $2pq$, and q^2. After undergoing selection the expected genotype frequencies are changed to $p^2w_{11}/\overline{w}$, $2pqw_{12}/\overline{w}$, and $q^2w_{22}/\overline{w}$, respectively. The normalizing factor $\overline{w}$ is the mean population fitness and is given by $\overline{w} = p^2w_{11} + 2pqw_{12} + q^2w_{22}$. It is then a simple exercise to derive the expected post-selection allele frequency $p' = (p^2w_{11} + pqw_{12})/\overline{w}$ as well as the change in allele frequency

$$\Delta p = p' - p = \frac{(pq[p(w_{11} - w_{12}) + q(w_{12} - w_{22})])}{\overline{w}} \quad [1]$$

Often, for the sake of simplicity, we consider the relative fitness of genotypes by dividing each individual's fitness by the fitness of one genotype. Thus, under an additive model of selection, if we divide each genotype fitness by the absolute fitness of the A_1A_1 homozygotes, we obtain relative fitnesses of $w_{11}/w_{11} = 1$, $w_{12}/w_{11} = 1 + hs$, and $w_{22}/w_{11} = 1 + s$ for the A_1A_1, A_1A_2, and A_2A_2 genotypes, respectively. Here s is the selection coefficient, and h is the dominance coefficient. Given this reformulation, we can now write eqn [1] as

$$\Delta p = p' - p = \frac{pqs[q(h-1) - hp]}{\overline{w}} \quad [2]$$

with $\overline{w} = 1 + 2pqhs + q^2s$. In the case of $0 \le h \le 1$, we have directional selection, and the most fit genotype will tend toward fixation. For a *de novo* mutation this is referred to as a 'hard selective sweep.'

When $\alpha = 2N_es$ is large (where N_e is the effective population size) the adaptive allele's frequency trajectory over time ($x(t)$) is essentially deterministic (satisfying the differential equation $\frac{dx(t)}{dt} = -\alpha x(t)(1 - x(t))$) when it is not close to 0 or 1 (Kaplan *et al.*, 1989). However, if the adaptive allele is close to 0 or 1 stochastic forces dominate. The frequency at which an adaptive allele transitions from the stochastic phase to the deterministic phase is referred to as the establishment frequency. While the adaptive allele is below the establishment frequency, there is a high likelihood (with probability $1 - 2s$) that the allele will be lost (Ewens, 1979). Kaplan *et al.* (1989) suggest an establishment frequency value of $\varepsilon = \frac{5}{\alpha}$ as a rule of thumb.

Expected Patterns

Under the model of a hard selective sweep, the frequency trajectory of an adaptive *de novo* mutation proceeds in three phases. It arises in a population and undergoes a period of stochastic fluctuations before (possibly) reaching the establishment frequency. The second phase, for large s, is essentially deterministic and the allele quickly rises in frequency. The final phase is a mirror of the first, where the adaptive variant undergoes a period of stochastic fluctuations at high frequency before ultimately reaching fixation. During this process, linked genetic material is also brought to high frequency unless a recombination event intervenes during the sojourn toward fixation. This hitchhiking effect has been the subject of much theoretical analysis (Maynard Smith and Haigh, 1974; Kaplan *et al.*, 1989; Stephan *et al.*, 1992; Barton, 1998), and the local effects on neutral segregating loci are well known, namely

1. a reduction in diversity surrounding the adaptive locus,
2. a skew in the 'site frequency spectrum' (SFS) toward rare variants,
3. a skew in the SFS toward high-frequency derived variants, and
4. long derived haplotypes extending from the adaptive locus.

The length of the physical region affected and the magnitude of the effect are related to the ratio of the selection coefficient to the recombination rate.

This process is illustrated in **Figure 1**. In **Figure 1(a)**, an adaptive mutation (red bar) arises on single haplotype in a population, and in **Figure 1(b)** it begins to rise in frequency. Occasionally a recombination or mutation event will occur during the sweep, but because this process happens on a faster timescale these events are relatively rare. The resulting genetic pattern immediately after fixation (**Figure 1(c)**) is greatly reduced diversity surrounding the adaptive locus. Finally, after the sweep has completed, recombination and mutation events continue to accumulate in the region (**Figure 1(d)**), thus

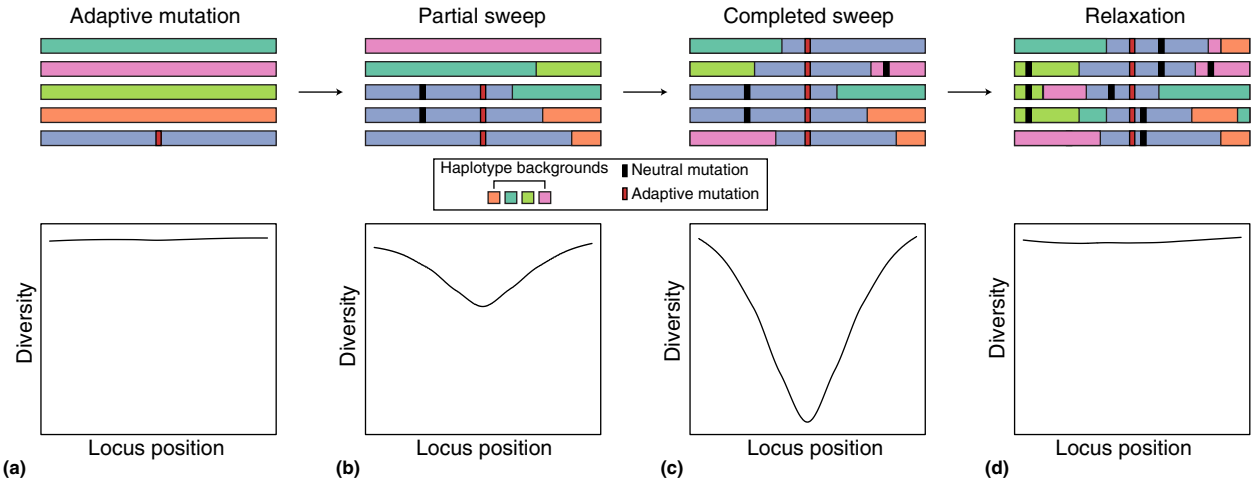

Figure 1 A cartoon illustration of a hard sweep showing haplotype and diversity patterns for (a) the initial adaptive mutation, (b) the hard sweep in progress, (c) the hard sweep at completion, and (d) after relaxation.

increasing diversity among haplotypes and causing a 'relaxation' of the reduced diversity footprint of a selective sweep.

The SFS – the number of observed variants segregating at a given frequency – is also affected by a sweep. As an adaptive allele sweeps toward fixation, linked variants on the adaptive haplotype will rise in frequency, while variants that reside on the nonadaptive haplotype will decrease in frequency. As such, we expect a skew toward rare and high-frequency variants during a sweep and at completion; if no further sweeps occur, the region will eventually relax back to a neutral SFS. Figure 2 demonstrates these patterns in the SFS.

Methods for Inference

Several studies have developed statistics designed to identify putatively selected regions by searching for deviations from neutral expectation of diversity and/or haplotype length (Lewontin and Krakauer, 1973; Tajima, 1989; McDonald and Kreitman, 1991; Fu and Li, 1993; Fu, 1997; Fay and Wu, 2000; Akey *et al.*, 2002; Ramos-Onsins and Rozas, 2002; Sabeti *et al.*, 2002; Kim and Nielsen, 2004; Nielsen *et al.*, 2005; Voight *et al.*, 2006; Jensen *et al.*, 2007; Sabeti *et al.*, 2007; Williamson *et al.*, 2007; Oleksyk *et al.*, 2008; Chen *et al.*, 2010; Pavlidis *et al.*, 2010; Alachiotis *et al.*, 2012; Liu *et al.*, 2013; Pavlidis *et al.*, 2013; Ferrer-Admetlla *et al.*, 2014). Some of these methods have been extended to multiple populations in the search of population-specific selective sweeps. Methods that extend the SFS to multiple populations often consider patterns of F_{st} (e.g., the Population Branch Statistic; Yi *et al.*, 2010), though cross-population extended haplotype homozygosity (*EHH*; see section 'Extended haplotype homozygosity') statistics have also been developed (Sabeti *et al.*, 2007). In this article we focus on two major classes of inference methods for hard sweeps, those based on examining the SFS and those based on examining haplotype patterns.

Site Frequency Spectrum Methods

A number of SFS-based statistics have been developed to test for departures from neutrality, and since the SFS deviates from neutrality during a sweep (Figure 2), these can be used to provide evidence of selection. Formally, we define the SFS of a sample of n chromosomes as ξ_i, the number of loci where the 'derived allele' is observed exactly i times. Similarly we define the 'folded SFS' as $\eta_i=(\xi_i+\xi_{n-i})/(1+\delta_{i,n-i})$ (where $\delta_{i,j}=1$ if $i=j$ and 0 otherwise), the number of loci where the 'minor allele' is observed exactly i times in a sample of size n chromosomes ($i\leq\lfloor n/2\rfloor$). Given the SFS, we can compute a number of useful statistics, including the number of segregating sites $S=\sum_{i=1}^{n-1}\xi_i=\sum_{i=1}^{\lfloor n/2\rfloor}\eta_i$ and the mean pairwise sequence differences $\pi=\binom{n}{2}^{-1}\sum_{i=1}^{n-1}i(n-i)\xi_i=\binom{n}{2}^{-1}\sum_{i=1}^{\lfloor n/2\rfloor}i(n-i)\eta_i$. A detailed treatment of the SFS and its statistical properties are given in Fu (1995).

Tajima's D *and others*

Under the standard neutral model population size is held constant and, in the absence of natural selection, genetic variation is only influenced by mutation and drift. Tajima (1989) devised a test for deviations from the neutral model by comparing the mean pairwise sequence differences (π) and the number of segregating sites (S). Under this model, $E[\pi]=E[S]/a_1=\theta$ (Watterson, 1975; Tajima, 1983), where θ is the population-scaled mutation rate and $a_1=\sum_{i=1}^{n-1}\frac{1}{i}$. Under the standard neutral model, $E[\pi-S/a_1]=0$. Therefore, Tajima (1989) proposed

$$D=\frac{\pi-S/a_1}{\sqrt{Var[\pi-S/a_1]}} \qquad [3]$$

where the denominator is the standard deviation of the difference $\pi-S/a_1$.

Tajima's D is expected to be 0 under the standard neutral model, and departures can shift D both positive and negative. D is roughly beta-distributed (Tajima, 1989), and a rule of thumb for determining significance (at the 5% level) is $|D|>2$, although Simonsen *et al.* (1995) explore this question in more depth. During a sweep, we expect an excess of rare alleles surrounding the adaptive locus sending $D<0$.

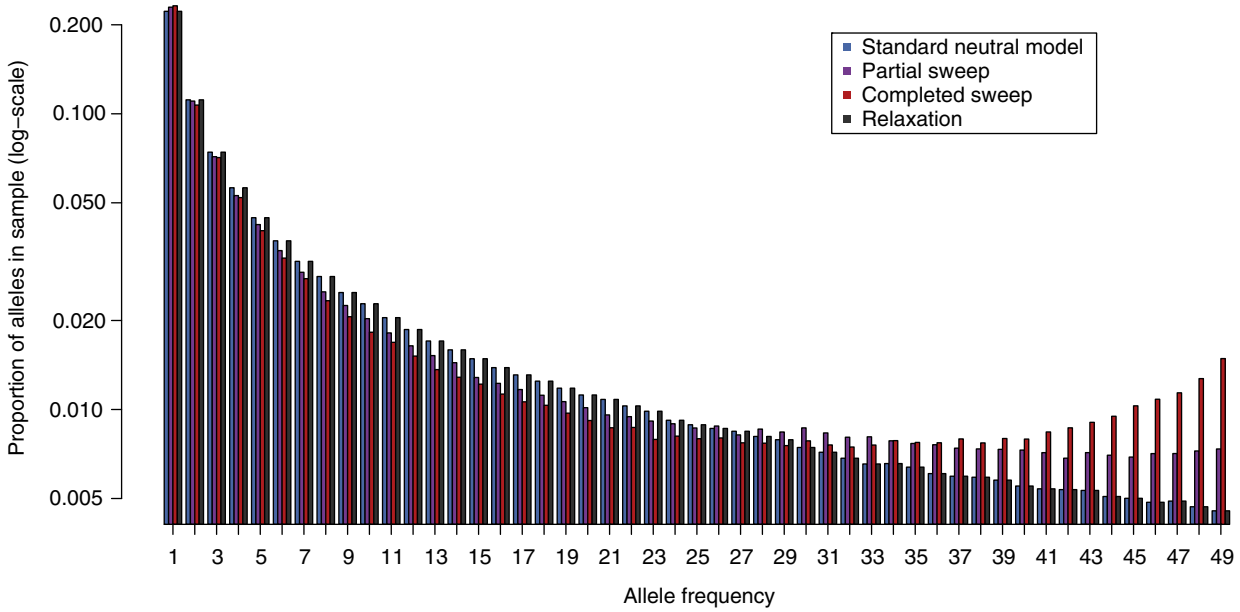

Figure 2 The expected site frequency spectrum for the standard neutral model (blue bars), for a hard sweep in progress (purple bars), for a hard sweep at completion (red bars), and after relaxation (black bars).

We illustrate the effect of a hard sweep on D with simulated genetic data using mssel, a version of the coalescent simulator ms (Hudson, 2002) modified to perform coalescent simulations conditional on an allele frequency trajectory (see Hudson and Kaplan, 1988; Kaplan *et al.*, 1988). We simulate 200 replicates of 50 haploid samples of 3 Mbp in a constant population size (effective population size $N_e = 10\,000$) with a recently fixed positively selected allele placed at the center of the region with a selection coefficient of $s = 0.02$ and a dominance coefficient of $h = 0.5$. We calculate D in a sliding window of 50 kbp with steps of 25 kbp. Figure 3 plots the mean D across replicates in each window along the simulated region and shows a clear dip below $D = -2$ (marked with a red dotted line) in proximity to the selected site indicating a significant departure from neutrality. Importantly, while Tajima's D can be used to detect a recent sweep, it also has power to detect other departures from the standard neutral model, including historical changes in population size that may affect D in ways similar to a hard sweep (Simonsen *et al.*, 1995).

A number of other statistics have been developed along similar lines as Tajima's D, including Fu and Li's D, D^*, and F^* (Fu and Li, 1993), and Fay and Wu's H (Fay and Wu, 2000). Indeed, these are each special cases of two generalized statistics derived by Fu (1997) and based on linear functions of the folded or unfolded SFS.

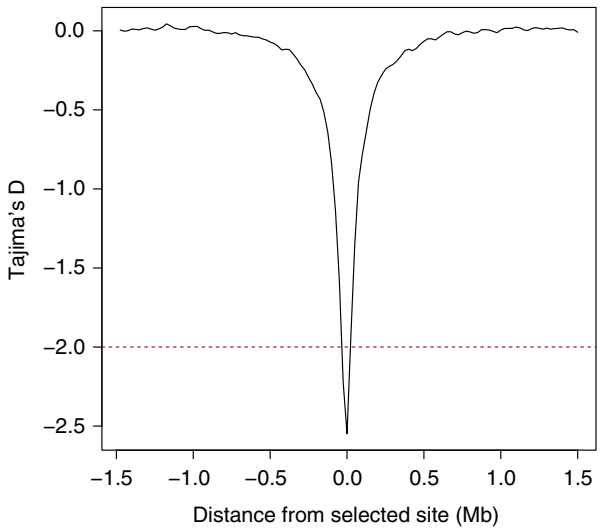

Figure 3 Mean Tajima's D across 200 replicates of 50 haploid samples of 3 Mbp calculated in a sliding window of size 50 kbp with steps of 25 kbps. As the window approaches the location of the simulated sweep, mean Tajima's D drops below 2, suggesting a significant departure from neutrality.

Composite likelihood of site frequency spectrum

A more sophisticated approach to detecting selective sweeps utilizes a 'composite likelihood ratio test' (CLRT) framework to analyze the SFS (Nielsen *et al.*, 2005). For a sample of n chromosomes, let the probability of observing a derived allele j times be p_j for $j \in \{1,2,\ldots,n-1\}$, and let $\mathbf{p} = (p_1, p_2, \ldots, p_{n-1})$. Then the 'composite likelihood function' is given by

$$\mathscr{L}(\mathbf{p}) = \prod_{j=1}^{n-1} p_j^{\xi_j} \qquad [4]$$

for which the 'maximum likelihood estimate' of $\mathbf{p}$ for k single nucleotide polymorphisms (SNPs) is given by $\hat{\mathbf{p}} = (\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_{n-1})$ where $\hat{p}_j = \xi_j / k$ for all $j \in \{1,2,\ldots,n-1\}$. Furthermore, let $\mathbf{p}_R$ represent $\mathbf{p}$ within some genomic region R containing k SNPs, such that $L(\mathbf{p}_R)$ is the composite likelihood for the region R and $\hat{\mathbf{p}}_R$ is the maximum likelihood estimate. A simple CLRT for an aberrant SFS in query region R

is then given by

$$\text{CLRT} = 2[\log\mathscr{L}(\hat{\mathbf{p}}_R) - \log\mathscr{L}(\hat{\mathbf{p}}_0)] \quad [5]$$

where $\hat{\mathbf{p}}_0$ is often computed genome wide. While this test does not specifically test for selection, it will identify regions with a SFS that are significantly different from the genome-wide average, including regions that have undergone a selective sweep.

To directly incorporate selection into this test, Nielsen *et al.* (2005) make two approximations. First, they assume that each ancestral lineage 'escapes' the sweep by recombination off of the sweeping haplotype and that this occurs independently with identical probability. Second, they assume that all recombinations during the sweep occur before any lineages coalesce. Under these assumptions, Nielsen *et al.* (2005) derive the distribution of site frequencies after a sweep and construct another CLRT.

This second test can be used to scan the genome to search for regions that have experienced a sweep and, simultaneously, infer selection strength. In order to determine significance of either of the CLRTs, scores must be compared to neutral simulations under an explicit demographic scenario. Alternatively, the empirical genome-wide distribution of scores can be used.

Using the program SweeD (Pavlidis *et al.*, 2013) to calculate CLR scores from a sample of 102 European human genomes (population code CEU), from The 1000 Genomes Project Consortium (2012), we examine a putatively neutral region of chromosome 2 and the *LCT* locus for evidence of positive selection. In order to determine significance, we use the 95% percentile of the genome-wide distribution of CLR scores.

Figure 4(a) shows CLR scores in a 2 Mbp putatively neutral window on chromosome 2. As expected for a neutral region, the vast majority of CLR scores are below the significance cutoff (CLR = 4.6643 marked with a red dotted line). However, if we examine a region containing the *LCT* locus (**Figure 4(b)**, *LCT* highlighted in blue), we find a substantial enrichment of CLR scores above the critical threshold, indicative of a sweep.

Haplotype Methods

If a hard sweep is in progress or recently completed, we should expect to find a large number of high-frequency variants in the vicinity of the adaptive locus that have hitchhiked to high frequency along with it. In particular, for a small window around the adaptive locus there will be low haplotype diversity as mutation and recombination events are unlikely to have occurred close to the locus during the sweep. However, if we successively widen this window to include more surrounding variants, the likelihood of observing mutation and recombination events increases and we should expect haplotype diversity to increase. Following this idea, a number of statistics have been designed to detect recent or ongoing positive selection by summarizing the decay of haplotype homozygosity away from a given locus. These statistics search for unusually long haplotypes given the putative age of the derived variant (using allele frequency as a proxy). A number of haplotype-based statistics have been implemented by Szpiech and Hernandez (2014) in the program selscan.

Extended haplotype homozygosity

The extended haplotype homozygosity (EHH) statistic was introduced by Sabeti *et al.* (2002) and is defined as the homozygosity of all haplotypes surrounding a core locus. For a sample of n chromosomes, the set C contains all possible distinct haplotypes at a core locus. For simplicity, we assume the core locus and all adjacent markers are biallelic SNPs, thus $C := \{0,1\}$, where 0 represents the 'ancestral allele' and 1 denotes the derived allele. The set $C(x_i)$ contains all possible distinct haplotypes extending from the core locus in one direction (upstream or downstream) to the i^{th} marker. Therefore, $C(x_1) := \{00,01,10,11\}$, $C(x_2) := \{000, 001, 010, 011, 100, 101, 110, 111\}$, etc. The EHH of a sample of haplotypes extending from the core locus to marker x_i is then

$$EHH(x_i) = \sum_{h \in C(x_i)} \frac{\binom{n_h}{2}}{\binom{n}{2}}, \quad [6]$$

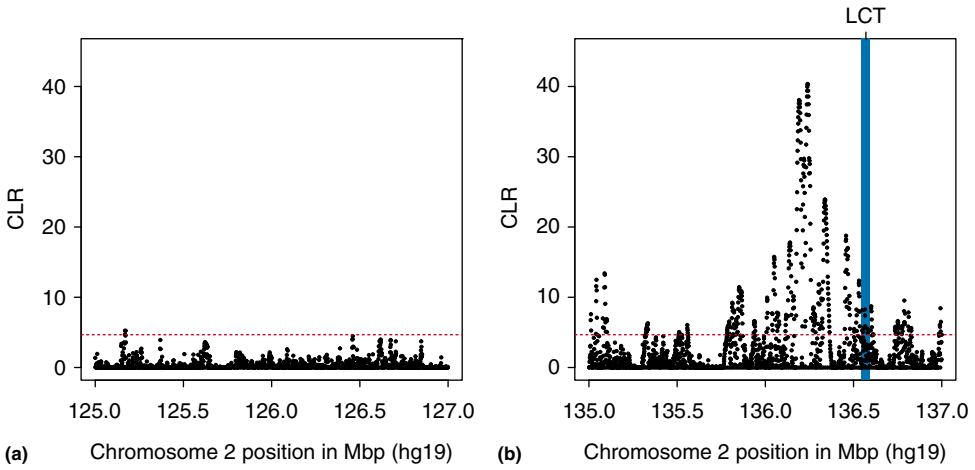

Figure 4 CLR scores calculated across 102 European human genomes for (a) a putatively neutral region of chromosome 2 and (b) a region surrounding the LCT locus (bounded by blue box) on chromosome 2.

where n_h is the number of observed haplotypes of type $h \in C(x_i)$ and by definition $\binom{x}{2} = 0$ for all $x < 2$. EHH(x_i) thus measures haplotype homozygosity within an interval extending from a core locus and is expected to be high for short intervals and monotonically decay as the interval widens since mutation and recombination events break up haplotypes. If the core locus contains an adaptive variant that is sweeping toward or has recently reached fixation, then we expect very long high-frequency haplotypes extending from the core and we should observe EHH(x_i) decay slower than around a neutral locus. In practice, we select a query locus in the genome to test for evidence of a selective sweep and compute EHH at this locus with successively wider genomic intervals. We then compare this to a null distribution of EHH that is computed around a large number of randomly selected, putatively neutral loci, with similar allele frequencies.

We illustrate this using mssel to simulate genetic data and the program selscan (Szpiech and Hernandez, 2014) to compute EHH curves. We simulate 200 replicates of 50 haploid samples of 3 Mbp in a constant population size (effective population size $N_e = 10\,000$) with a recently fixed positively selected allele placed at the center of the region with a selection coefficient of $s = 0.02$ and a dominance coefficient of $h = 0.5$. We also perform 200 replicate neutral simulations of 50 haploid samples in a constant population size ($N_e = 10\,000$). Each EHH calculation was centered on the middle of the simulated region and extended out 100 kbp on either side. **Figure 5(a)** shows the EHH decay curves for both neutral (blue) and non-neutral (red) simulations, demonstrating the slow decay of haplotype homozygosity around a positively selected versus neutral loci.

Integrated haplotype score

If a hard sweep has not reached fixation, the adaptive variant will be at intermediate frequency, and EHH values computed amongst the whole sample will be depressed because of higher overall diversity. In this case we may desire to compute EHH on a subset of haplotypes containing only the derived allele at the core or only the ancestral allele at the core. By separating the EHH computation between the ancestral and derived haplotypes, we can compare the relative size and diversity of ancestral and derived haplotypes at the same locus and search for unusually large differences between the two, thus implying a selective sweep in progress (**Figure 5(b)**). This is the basis for the development of the Integrated Haplotype Score (iHS; Voight *et al.*, 2006).

In order to compare the ancestral and derived EHH curves, Voight *et al.* (2006) proposed to integrate the curves with respect to genetic distance. Unstandardized iHS is then computed as the log-ratio of the ancestral and derived integrated values,

$$\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right) \qquad [7]$$

where iHH_1 is the integrated derived EHH curve and iHH_0 is the integrated ancestral EHH curve. In this formulation, positive values suggest long derived haplotypes relative to ancestral haplotypes and negative values suggest the converse. However, unstandardized iHS is correlated with derived allele frequency (see **Figure 4** in Voight *et al.*, 2006, note that their definition of iHS swaps the position of iHH_1 and iHH_0 in the log-ratio) as low-frequency variants are more likely to be young and therefore reside on longer haplotypes. Thus, unstandardized iHS scores are normalized in frequency bins to give

$$\text{iHS} = \frac{\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right) - E_p\left[\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right)\right]}{\sqrt{Var_p\left[\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right)\right]}} \qquad [8]$$

where $E_p\left[\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right)\right]$ and $\sqrt{Var_p\left[\ln\left(\frac{\text{iHH}_1}{\text{iHH}_0}\right)\right]}$ are the mean and standard deviation in frequency bin p.

Although large positive iHS scores suggest a long derived haplotype, in practice the adaptive variant may not be typed and neighboring ancestral alleles may hitchhike to high

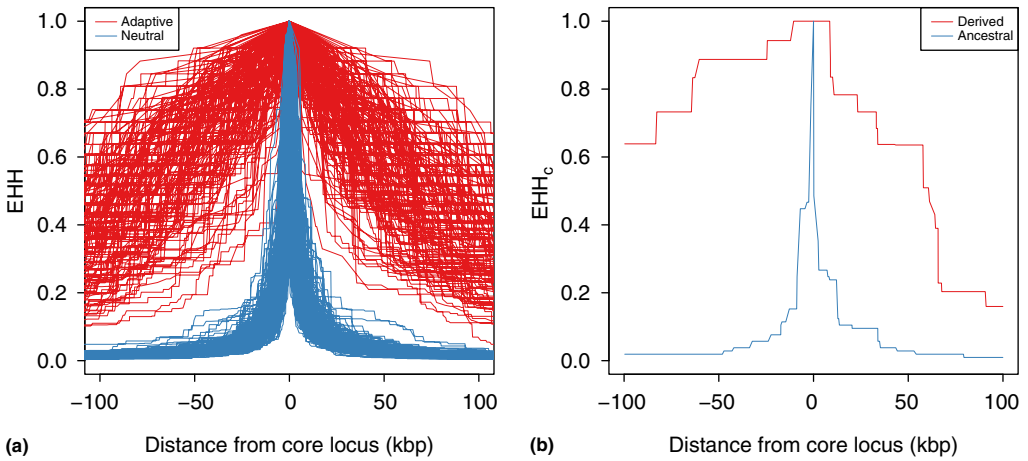

Figure 5 (a) Extended haplotype homozygosity (EHH) calculated from 50 haploid samples for 200 simulated replicates of a hard sweep (red lines) and 200 simulated replicates of neutrally evolving regions (blue lines), illustrating a slower EHH decay away from the adaptive locus as compared to neutral ones. (b) One example of EHH calculated on ancestral (blue line) and derived (red line) haplotypes separately in the vicinity of a hard sweep.

frequency, therefore it is common to search for extreme values of $|iHS|$ instead. Furthermore, Voight *et al.* (2006) note that extreme $|iHS|$ scores can occur under neutrality but tend to be randomly distributed, as opposed to a region undergoing a selective sweep where extreme scores tend to cluster together. With this in mind, Voight *et al.* (2006) devised a procedure to identify putative regions undergoing a sweep.

First, identify all core loci above a critical value, which is typically chosen as $|iHS| > 2$. As the standardized iHS scores are roughly distributed normally with mean = 0 and standard deviation = 1, this approximately represents the most extreme 5% of scores. Then divide the genome up into nonoverlapping windows of 100 kbp, and calculate the fraction of scores within each window that are above the critical value. To account for the variable number of scores within a fixed length window, bin windows based on the number of scores. Finally, examine the distribution of these fractions and select the top 1% (thus bounding the false positive rate to be $\leq 1\%$) from each window bin as putatively under selection. Using the program selscan (Szpiech and Hernandez, 2014) to calculate iHS scores from a sample of 102 European human genomes (population code CEU) from the 1000 Genomes Project (The 1000 Genomes Project Consortium, 2012), we examine a putatively neutral region of chromosome 2 and then the *LCT* locus for evidence of positive selection. **Figure 6(a)** shows $|iHS|$ scores in a 2 Mbp putatively neutral window on chromosome 2. As expected for a neutral region, nearly all of the iHS scores are below the critical threshold ($|iHS| = 2$ marked with a red dotted line). However, if we examine a region containing the *LCT* locus (**Figure 6(b)**, *LCT* highlighted in blue), we find a substantial enrichment of iHS scores above the critical threshold, indicative of a strong sweep in progress.

Cross-population extended haplotype homozygosity

The cross-population EHH (XPEHH) statistic introduced by Sabeti *et al.* (2007) is designed to detect local adaptation within a query population by comparing iHH with a reference population. To do this we use eqn [6], and calculate the integrated haplotype homozygosity of the entire haplotype sample separately for each population. For populations A and B, we have iHH_A and iHH_B, and the unstandardized XPEHH is given by

$$\ln\left(\frac{iHH_A}{iHH_B}\right) \quad [9]$$

which is typically normalized with respect to the genome-wide distribution of *XPEHH* scores. Here, positive scores suggest long haplotypes in population A with respect to population B and a potential sweep in A, whereas negative scores suggest long haplotypes in B with respect to A.

Alternatives to using a genetic map

In many species, recombination events do not occur uniformly across their genome. To accommodate this, the formulations above assume knowledge of a genetic map. When calculating integrated EHH scores, a genetic map is integrated over and acts to weight an extended haplotype based on prior knowledge of recombination rate in that genomic location. For example, if a sweep occurs proximal to a recombination hotspot, then it would be uncommon to observe an extended tract of haplotype homozygosity spanning the region, and thus it is a highly informative event. In genetic distance space, this hotspot will be represented as a long interval, and iHH scores will be upweighted. In contrast, proximal to a recombination coldspot, it would not be uncommon to observe an extended haplotype spanning the region. In genetic distance space this region will appear shrunken, and iHH scores will be downweighted. However, it is not always possible to obtain a genetic map or the map may be of questionable quality. In these cases one could use a physical map as a proxy.

Another alternative would be to use the nSL statistic introduced by Ferrer-Admetlla *et al.* (2014). nSL can be reformulated to conform to the notation given above and is calculated as a log-ratio of the SL statistic calculated for the ancestral and derived haplotype pools. The essential difference from iHS is the removal of genetic map information. Whereas previously we integrate with respect to a genetic map, for the calculation of nSL all gaps between markers are given a weight of 1. After calculating nSL, scores should be normalized in frequency bins as with iHS.

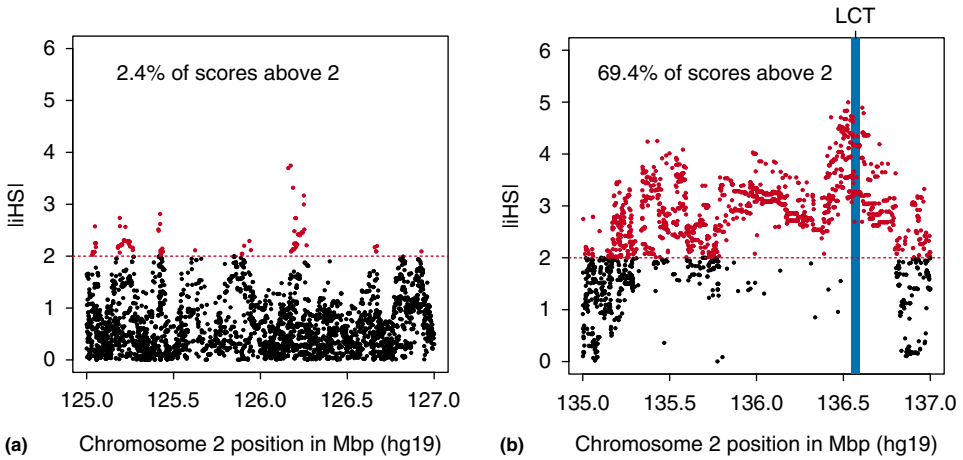

Figure 6 iHS scores calculated across 102 European human genomes for (a) a putatively neutral region of chromosome 2 and (b) a region surrounding the LCT locus (bounded by blue box) on chromosome 2.

Simulation Methods

Structured Coalescent

Kingman's coalescent model for neutral gene evolution (Kingman, 1982) provides a fast and flexible model for simulating neutral genealogies backwards in time and – in concert with a model of mutation, recombination, and migration – allows one to simulate genetic data under complex demographic scenarios. Although in its original formulation, only neutral data can be simulated under this model, theoretical work on the properties of neutral variation linked to a non-neutral variant suggest a way to incorporate selection at a single linked site (Kaplan *et al.*, 1988; Hudson and Kaplan, 1988). By conditioning on the selected site's allele frequency trajectory, $x(t)$, lineages linked to the adaptive derived allele are treated as coming from a population of size $2N_e x(t)$ and lineages linked to the ancestral allele are treated as coming from a population of size $2N_e(1-x(t))$. If a lineage from one background recombines onto the other, this is treated as a migration from one population to the other. A number of software programs exist to simulate this conditional coalescent process including mssel (a modified version of ms, Hudson, 2002), selsim (Spencer and Coop, 2004), mbs (Teshima and Innan, 2009), msms (Ewing and Hermisson, 2010), and cosi2 (Shlyakhter *et al.*, 2014).

Forward Simulations

The structured coalescent for simulating hard sweeps does suffer from some limitations, however. While the coalescent simulations are fast, only a single non-neutral allele can be considered at a time, and a frequency trajectory must also be simulated separately. It is also not possible to simulate the effects of multiple sweeps occurring simultaneously in a population. The primary alternative is a forward simulation, which can be made as flexible as desired (including demography, positive selection on multiple sites, linked negative selection, etc). There are many implementations of forward simulators (Hoban *et al.*, 2012). Some of the simulators that balance flexibility with computational efficiency across a range of parameters SFS_CODE (Hernandez, 2008), SLiM (Messer, 2013), and FWDPP (Thornton, 2014).

Some Caveats

Nonequilibrium Demography

The statistics described above for inferring the genomic location of a hard sweep are quite powerful, as they summarize patterns of polymorphisms that are expected to differ under a hard sweep versus under neutrality. However, the theory supporting these methods assumes a simple constant population size with no subdivision and no migration. Most, if not all, natural populations do not exist with such simple demographic histories and will likely have experienced numerous subdivisions, complex migration patterns, and population size expansions and contractions. These nonequilibrium demographies can create, under neutrality, very similar patterns as a hard sweep in a constant-size population. Indeed, population size contractions have the effect of reducing genetic diversity and generating long haplotypes. Contractions and expansions can create an excess of low- and/or high-frequency variants. Population subdivisions are subject to the Wahlund effect where genetic drift can cause an increase of homozygosity, and migrants between populations can introduce genetic material that has experienced a very different demographic history.

To mitigate these potentially confounding factors, these methods typically do one of two things. The first is to compare observed values to the distribution of values calculated from neutral simulations under an explicit demographic model. As a practical matter though, misspecification of the underlying demographic model could have a profound effect on the distribution of scores and could inflate the false positive rate. Alternatively, under the assumption that recent or ongoing hard sweeps are relatively rare throughout the genome at any given time point, many methods will compare observed scores in a particular region to the genome-wide distribution of scores, highlighting the most deviant ones as putative regions under selection. This, too, suffers from a similar problem of a possibly increased false positive rate. An extreme example would be a genome with absolutely no recent selection, but, through purely neutral deviations, some regions will always fall into the tails of the score distribution, which may then be marked as putative regions under selection.

Background Selection

While our attention has been focused on the action of positive selection, in many circumstances, linked negative selection can result in similar processes (known as background selection). Imagine a locus in the genome subject to frequent deleterious mutations. As natural selection acts to purge these deleterious mutations, linked neutral variation will also be eliminated. This can result in a local reduction in diversity around the deleterious locus, and in some cases result in an excess of both high- and low-frequency derived alleles (Charlesworth *et al.*, 1993). This pattern mimics some signatures of positive selection, and can cause an excess of false-positive inference for statistics that focus on these patterns. However, some of the effects of background selection are easily modeled, and can be incorporated into the statistical procedure for inferring the action of positive selection (Huber *et al.*, 2015).

Alternative Models

Throughout this article we have discussed the properties of hard sweeps and some methods for their detection. However, a selective sweep need not be 'hard.' A mutation that is intially neutral or mildly deleterious may become adaptive after an environmental change or during the colonization of a new niche. Depending on its frequency at the time it became adaptive, it may be segregating on several haplotype backgrounds, which then sweep to high frequency (Hermisson and Pennings, 2005). Similarly, if a locus has a high adaptive mutation rate, multiple adaptive alleles on different haplotype backgrounds could simultaneously sweep to high frequency (Pennings and Hermisson, 2006a). These scenarios result in

'soft selective sweeps,' and may generate different patterns of variation from what would be expected from a hard sweep (Pennings and Hermisson, 2006b; Messer and Petrov, 2013; Wilson *et al.*, 2014). Because of this, many of the statistics developed for detecting hard sweeps are under-powered to detect soft sweeps, although some efforts are being made to detect soft sweeps and distinguish them from hard sweeps (Peter *et al.*, 2012; Ferrer-Admetlla *et al.*, 2014; Garud *et al.*, 2015).

Sensory Systems: Molecular Evolution in Vertebrates

EA Gutierrez, A Van Nynatten, NR Lovejoy, and BSW Chang, University of Toronto, Toronto, ON, Canada

Introduction

Vertebrates are a strikingly diverse group occupying a wide variety of niches and environments, some astonishingly extreme. Because distinct environmental conditions pose different selective constraints, natural selection is expected to have influenced sensory evolution, shaping the way vertebrates perceive, interact, and respond to their natural surroundings. This has resulted in extraordinary examples of sensory adaptation, such as electroreception in fishes, thermoperception in snakes, and the echolocation abilities of whales and bats. The last few decades have been particularly fruitful in expanding our knowledge of how different sensory systems are structured and how they operate at the level of genes and proteins. Even more remarkable have been the advances in our understanding of the molecular mechanisms underlying sensory receptor physiology as well as the evolutionary processes driving sensory adaptation in vertebrates. This review summarizes our current knowledge of the molecular underpinnings of the diverse array of sensory systems found in vertebrates.

Photoreception

Amidst the diverse array of vertebrate sensory modalities, vision is among the best understood. At the molecular level, all of the components underlying the visual transduction cascade within the photoreceptors of the eye have been identified in model species. Comparative molecular studies have largely centered on visual pigments, light-sensitive receptors found within the highly specialized rod and cone photoreceptor cells of the retina. Visual pigments are G protein-coupled receptors that form the first step in visual transduction, and mediate vision under different light intensities. They are comprised of an opsin protein covalently bound to a vitamin A-derived chromophore in a region known as the binding-pocket. Upon stimulation by light, the chromophore isomerizes, leading to conformational changes in the opsin structure that initiates a biochemical cascade through activation of the G protein transducin.

Five classes of spectrally distinct visual pigments are present in vertebrates, and there is impressive variation in opsin complement across species (**Figure 1**). While rhodopsin (RH1) is expressed in rod cells and mediates vision under dim-light, up to four classes of opsins (RH2, SWS1, SWS2, and LWS) have been identified in cone cells, which are active under bright-light conditions and ultimately mediate color vision. Interactions between the chromophore and amino acids lining the binding-pocket affect the wavelength of maximal absorbance of a visual pigment, which may be shifted to different wavelengths of light as a result of amino acid substitutions in this region. In vertebrates, it is known that the proportion and number of spectral classes of photoreceptors in the eye, and the wavelengths at which they are maximally sensitive (λmax) can vary enormously (**Figure 1**), and are generally thought to represent adaptations to aspects of the light environment such as spectral composition and light intensity (Bowmaker, 2008).

Visual pigment genes evolved through successive duplications from a single ancestral gene. As a result, four classes of visual pigments were thought to be present in the lineage leading to ancestral vertebrates. *RH1* and *RH2* originated later in the evolutionary history of vertebrates emerging from a duplication event that probably occurred before the divergence of agnathans and gnathostomes (Pisani *et al.*, 2006). While several opsin genes were lost in cartilaginous fishes, visual pigments further diversified in bony fishes following a whole genome duplication (WGD) event. This may have spurred the evolution of additional spectrally distinct pigments, allowing bony fishes to explore more varied, spectrally complex environments, and to evolve in concert with sexually dimorphic coloration. For instance, six distinct copies of *LWS* have been found in the adult guppy (Weadick and Chang, 2007), a model system for the study of sexual selection and mate choice. Neotropical cichlids have a reduced number of cone opsin classes (Weadick *et al.*, 2012) relative to their African sister clade famous for their extravagance and diversity in coloration (Seehausen *et al.*, 2008; Miyagi *et al.*, 2012; Weadick *et al.*, 2012). However, ecological factors associated with spectrally distinct fresh water environments may underlie the evolution of *RH1* in both cichlid lineages (Schott *et al.*, 2014). In contrast, deep-sea teleost and cottoid fishes display a reduced visual pigment repertoire and blue-shifted RH1 pigments that match the wavelengths of available light at extreme depths (Hunt *et al.*, 1996; Hunt *et al.*, 2001).

In tetrapods, opsin genes underwent several major evolutionary events that resulted in extremely diverse distributions among lineages. In amphibians, frogs, and salamanders there persists two classes of rod cells, in which *RH1* and *SWS2* are expressed, whereas *LWS*, *SWS1*, and *SWS2* are expressed in cones (Hisatomi *et al.*, 1998; Hisatomi *et al.*, 1999; Ma *et al.*, 2001). Among reptiles, crocodiles and snakes have a reduced cone opsin repertoire while lizards and turtles have retained all five classes of visual genes. In birds, vision is known to have played an important role in the evolution of colored plumage and social communication. Single photoreceptor cells in birds express all five classes of vertebrate opsins, whereas LWS is also expressed in double cones. Interestingly, certain amino acid residues mediating ultraviolet (UVS) to violet sensitivity (VS) in birds may differ from those in other vertebrates. These amino acid substitutions account for large spectral tuning shifts in SWS1, the short wavelength-sensitive visual pigment, in birds, and have been suggested to underlie shifts from a VS ancestor to UVS in a number of bird lineages (Wilkie *et al.*, 2000; Carvalho *et al.*, 2007; Van Hazel *et al.*, 2013). While the influence of particular single amino acid substitutions mediating UVS and VS sensitivity in birds

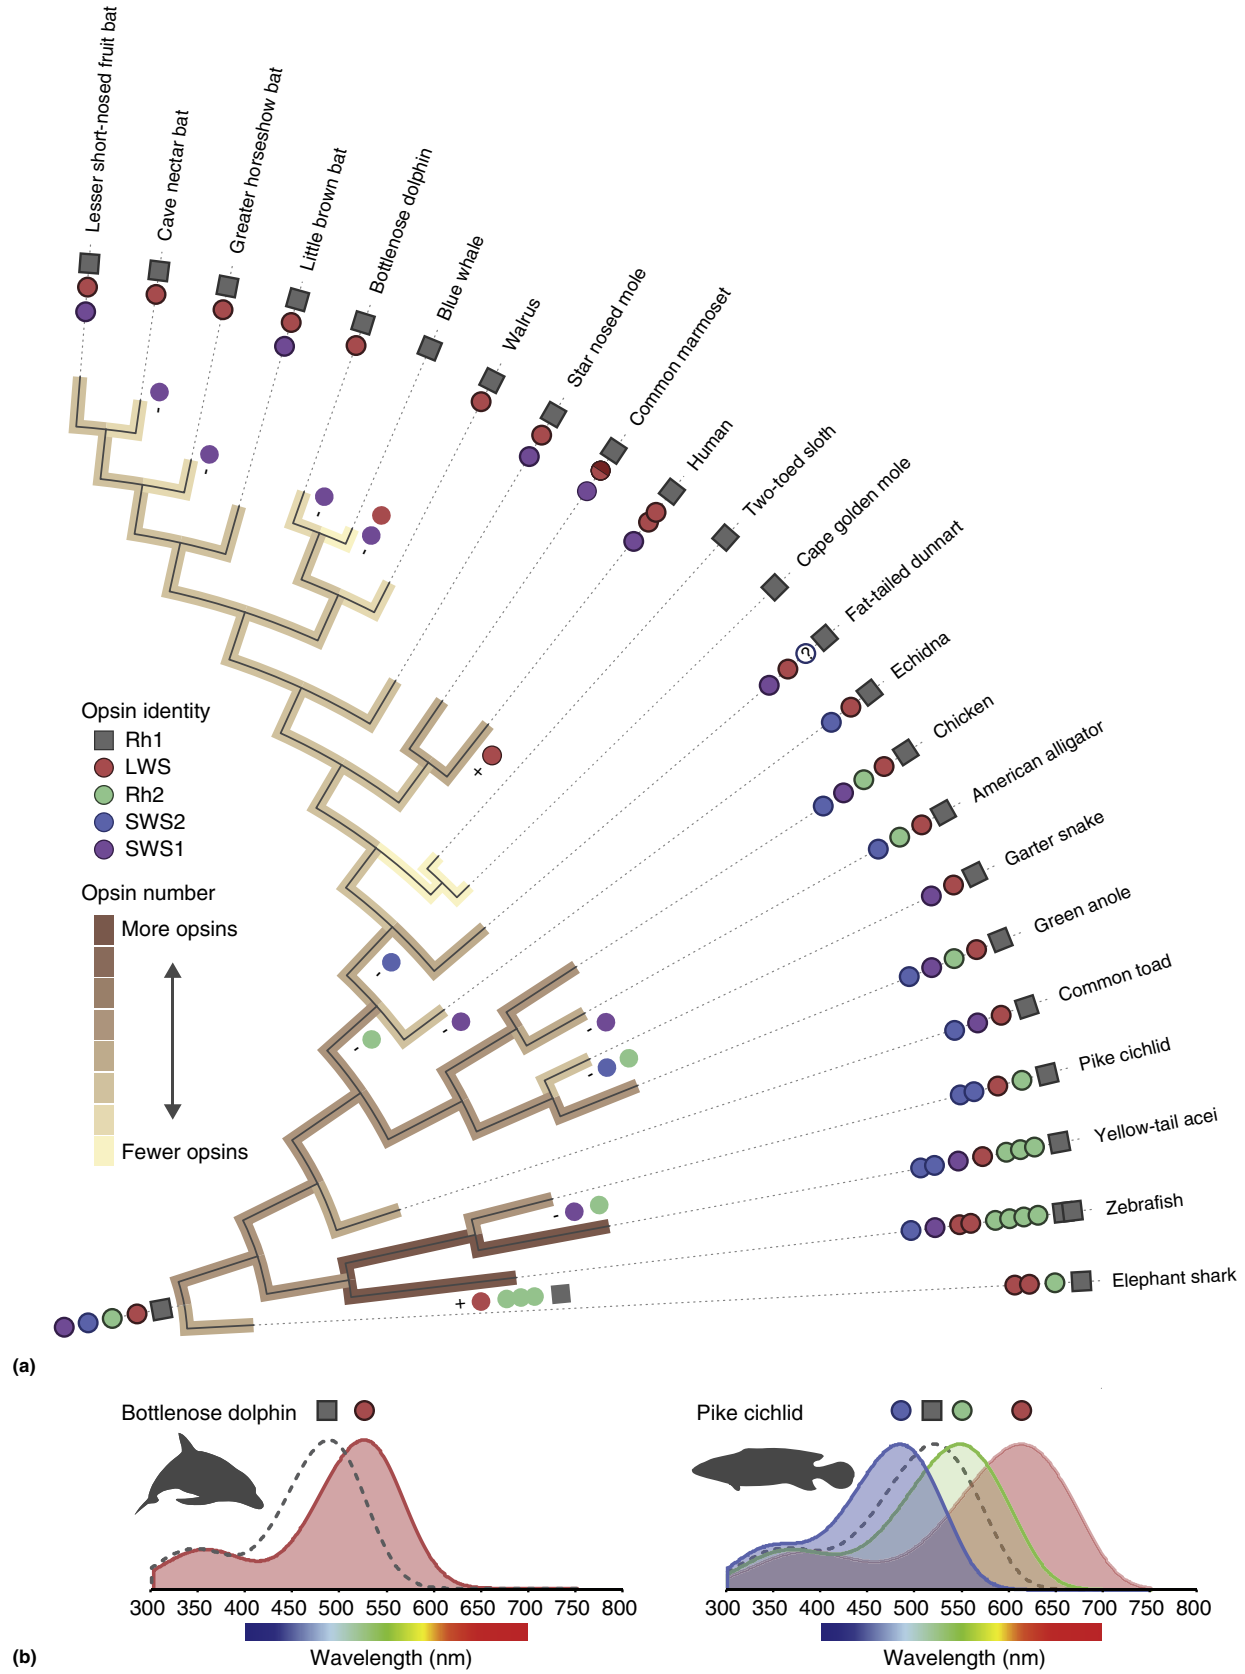

Figure 1 Diversity of vertebrate opsin complements. (a) Phylogeny depicting the gains and losses of specific opsin genes across vertebrate taxa. Branch length and color are indicative of opsin number, and duplications and losses are shown below branches. Cone opsins represented as circles, and rod opsins as squares. Cone opsins with question marks represent the yet-uncharacterized opsin classes, and bicolored cone opsins represent allelic variants providing distinct spectrally sensitive pigments. (b) Spectral sensitivity curves for the bottlenose dolphin (Fasick *et al.*, 1998) and pike cichlid (Weadick *et al.*, 2012).

has been well-characterized, in other vertebrate groups, such as mammals, these substitutions are much more variable and do not predictably shift λmax (Hauser *et al.*, 2014).

Relative to other vertebrates, mammals have a reduced set of opsin genes. While monotremes have functional copies of *LWS* and *SWS2* genes, the majority of marsupials and eutherians have only retained LWS and SWS1 cone pigments (Jacobs, 2009). Intriguingly, a third class of spectrally distinct cones has been identified in some Australian marsupials (Arrese *et al.*, 2002), although the molecular basis of this pigment remains unknown (Cowing *et al.*, 2008).

Within terrestrial eutherian mammals, nocturnality appears to play an important role in the evolution of visual pigments, particularly the *SWS1* gene, which has become pseudogenized in many nocturnal carnivores and nocturnal primates. Curiously, bats, which have long occupied the nocturnal niche, exhibit a complex distribution of the *SWS1* gene; though it is functional in most microbats, *SWS1* became pseudogenized in some megabats and a few related microbat lineages, likely as result of the evolution of refined high-duty cycle (HDC) echolocation as well as cave-roosting behavior (Zhao *et al.*, 2009a). Interestingly, RH1, which mediates dim-light vision, does not appear to have undergone adaptive evolution in bats as a consequence of the photic limited niche, although convergent evolution has occurred between lineages of highly visual bats (Shen *et al.*, 2010; Zhao *et al.*, 2009b).

Remarkably, subterranean eutherian mammals also exhibit variable opsin gene repertoires, ranging from the typical mammalian arrangement in the star-nosed mole to only a functional *RH1* copy in the Cape golden mole (Emerling and Springer, 2014). Nevertheless, a number of visual genes have become pseudogenized in phylogenetically distant lineages, which likely occurred after those lineages invaded subterranean environments (Emerling and Springer, 2014). In contrast, xenarthrans (armadillos, sloths, and anteaters), which diverged very early in the eutherian lineage and occupied a variety of ecological niches, have nonfunctional *SWS1* and *LWS* genes, probably the result of a subterranean lifestyle in the early history of the group (Emerling and Springer, 2015).

Aquatic environments are also thought to have shaped visual pigment evolution in mammals. Pinnipeds and cetaceans have independently lost functional *SWS1* genes, possibly due to relaxation of selective constraints (Levenson *et al.*, 2006). *LWS* is also pseudogenized in most baleen whales and in some deep-diving toothed whale lineages whose representatives inhabit depths in which light is dim and dominated by short-wavelengths (Meredith *et al.*, 2013). Curiously, the RH1 pigment is blue-shifted in most cetacean species (Bischoff *et al.*, 2012), showing functional variation that is likely associated with diving depth.

Unlike the majority of mammals, diurnal primates have regained a middle-wavelength sensitive (MWS) class of cone opsin through evolutionary modification of the *LWS* gene. While this occurred through gene duplication in Old World primates (Nathans *et al.*, 1986), in New World primates it evolved through a polymorphism of the *LWS* gene by allelic variants on the X-chromosome (Williams *et al.*, 1992). Thus, MWS is present in both male and female Old World monkeys, whereas only heterozygous female New World monkeys have a copy of the MWS pigment (Bowmaker, 2008). Opsin polymorphism linked to the X-chromosome has also been identified in diurnal and cathemeral prosimians (Jacobs *et al.*, 2002; Veilleux and Bolnick, 2009). Remarkably, MWS also evolved in Neotropical howler monkeys (Jacobs *et al.*, 1996), though through unequal crossover that allocated two different alleles of the polymorphic New World gene onto a single chromosome (Hunt *et al.*, 1998). Although the adaptive significance of a three-cone opsin system remains unclear, many have argued that it improves the detection and assessment of ripe fruits (Sumner and Mollon, 2000a,b), new leaves (Dominy and Lucas, 2001), and predators (Pessoa *et al.*, 2014) through a better discrimination of red and green signals.

Chemoreception

Odorant Perception

Although not as well studied as vision, the molecular mechanisms of odorant perception are starting to be revealed in detail. Three classes of odorant GPCRs have been identified in vertebrates: olfactory receptors (OR), vomeronasal receptors (V1R and V2R), and the recently discovered trace amine associated receptors (TAAR). Typically, ORs are expressed in the main olfactory epithelium (MOE), and are activated by volatile odorant molecules that enter the olfactory cavity, whereas VNRs are expressed in the vomeronasal organ (VNO) and respond to social odors such as pheromones (Niimura, 2012). The recently identified TAARs are also expressed in the MOE and have the ability to recognize volatile amines present in urine and molecules linked to stress (Liberles and Buck, 2006).

Olfactory receptors

Compared to other sensory receptors, which are tuned to respond to a specific stimulus, OR function in a combinatorial manner: multiple ORs may be sensitive to a single odorant or a single OR may detect multiple odorants. This makes the study of olfactory mechanisms very complex. Two types of ORs have been identified in vertebrates and are predicted to detect odorants with different chemical properties. While ORs that respond to water-soluble molecules are present in fishes and amphibians, ORs sensitive to airborne components have diversified predominantly in tetrapods. Interestingly, amphibians also exhibit a particular group of ORs that likely detect odorants that dissipate both in the air and water, such as alcohols (Niimura, 2012).

In mammals, *OR* genes form a surprisingly high proportion of the genome, but also contain a great deal of pseudogenization. It is broadly accepted that the numerous families of *OR* genes evolved through the process of birth-and-death evolution, in which gene duplication followed by mutation may result in fixation or deletion in the genome, varying the number of functional genes as well as pseudogenes (Nei *et al.*, 2008). Interestingly, expansion and retraction of the mammalian *OR* gene repertoire is thought to be closely associated with ecological factors. For instance, mammals that occupy similar ecological niches but are phylogenetically distant exhibit similar patterns of contraction or expansion of the OR gene families, such as in aquatic, terrestrial and flying groups

(Hayden *et al.*, 2010). Among bats, several *OR* gene families have been linked to frugivory in New World and Old World lineages, indicating another example of niche specialization in the *OR* gene repertoire (Hayden *et al.*, 2014). Primates, on the other hand, have *OR* gene repertoires that are markedly reduced compared to other terrestrial mammals, which has been linked to a trade-off between olfaction and the presence of three classes of cone opsins in some lineages (Gilad *et al.*, 2004; but see Matsui *et al.*, 2010).

Vomeronasal receptors

Unlike ORs, vomeronasal receptors are encoded by only two multigene families, *V1R* and *V2R*, and play an important role in pheromone detection. Upon activation, V1Rs and V2Rs couple with specific G proteins, which leads to the opening of TRPC2 channels, ultimately resulting in signal transduction (Nei *et al.*, 2008). While VNRs are expressed in the vomeronasal system, which is exclusive to tetrapods, genes of the vomeronasal-signaling pathway are expressed in the olfactory epithelium of fishes (Grus and Zhang, 2006).

V1R genes and *Trpc2* genes evolved early in the vertebrate lineage and are less diverse compared to *V2R* genes, which originated after the divergence of agnathans and gnathostomous (Grus and Zhang, 2009). Though *V1R* genes are under strong purifying selection among several fish lineages, sites at putative ligand-binding regions are under positive selection within African cichlids, suggesting an adaptive function of V1Rs for reproductive behavior or social communication (Nikaido *et al.*, 2014). Contrary to *V1R*s, *V2R* genes are much more diverse in teleost fishes and play important roles in feeding behavior and social communication. Although the ligand-binding region of V2Rs exhibits impressive sequence variation within several fish lineages, suggesting adaptation to different ligands, studies have failed to detect signals of positive selection, indicating that sequence variation likely emerges from relaxation of selective constraints or genetic drift (Nikaido *et al.*, 2013).

The transition from aquatic to terrestrial environments in tetrapod evolution was followed by the emergence of the VNO resulting in enormous expansion of VNR genes in some tetrapod lineages as well as numerous pseudogenization events in others. Frogs, which have a rudimentary VNO, display the largest *V2R* gene repertoire among tetrapods and only small number of *V1R* genes. In contrast, no *V1R* genes are observed in birds and the VNO is absent (Grus *et al.*, 2005). Within mammals, there is great variation in VNR gene repertoire. Generally, the *V1R* gene family expanded in lineages that exhibit a morphologically complex VNO, such as in monotremes and rodents where adaptive evolution likely contributed to gene diversification. Nevertheless, no functional V1Rs are observed in several bats, cetaceans, and humans, due to pseudogenization of *Trpc2* (Liman and Innan, 2003; Young *et al.*, 2010; Zhao *et al.*, 2011). Although most *V1R* genes also became pseudogenized in Old World monkeys, several functional copies are observed in New World monkeys and are even more numerous in prosimians. Interestingly, sites at the ligand-binding region of V1Rs in prosimians are under strong positive selection, indicating adaptation of the *V1R* gene repertoire and emphasizing the ecological importance of the VNS in this primate lineage (Hohenbrink *et al.*, 2012; Yoder *et al.*, 2014). Comparatively, *V2R* genes are less diverse and became pseudogenized in several mammalian lineages, likely through relaxation of selective constraints (Shi and Zhang, 2007).

Gustatory Perception

Taste receptors (TRs) are encoded by two multigene families that are in close phylogenetic proximity to *VNR* genes. TRs are expressed in cells located in taste buds on the tongue and palate and respond to organic compounds associated to the perception of sweet, umami (savory), and bitter taste. Similar to other GPCRs, stimulation of TRs mediates the activation of receptor-specific G proteins, leading to a biochemical cascade that ultimately results in the gating of a transduction channel, in this case TRPM5 (Chandrashekar *et al.*, 2006). Conversely, the perception of salty and sour taste is mediated by direct entry of Na^+ and H^+ in taste receptor cells (TRC) through specific ion channels, although molecular mechanisms underlying these gustatory modalities have just begun to be elucidated (Liman *et al.*, 2014). While great variability in TRs is observed among vertebrates, shifts in gene copies numbers, and pseudogenization of *TR* genes generally reflect adaptation to ecological niches and diet, as a way to better assess the quality and nutritional value of food.

T1Rs mediate the perception of umami and sweet taste through different sets of heterometric receptors. Subunits T1R1 and T1R3 form a receptor that detects L-amino acids and nucleotide enhancers (IMP, GMP, AMP), which are perceived as a savory taste known as umami (Nelson *et al.*, 2002), whereas the T1R2 + T1R3 heterodimer responds to simple sugars, artificial sweeteners, and D-amino acids, mediating sweet taste (Nelson *et al.*, 2001). *T1R* genes evolved in the ancestor of cartilaginous and bony fishes, along with the taste-transduction channel gene *Trpm5*. Whereas T1R1 and T1R3 are encoded by single copy genes in bony fishes, T1R2 further diversified through multiple gene duplications (Shi and Zhang, 2006). Interestingly, sites at ligand-binding region of T1R2 are positively selected, indicating that the duplicate genes likely adapted to respond to different tastants (Hashiguchi *et al.*, 2007). Relative to fishes, great divergence is observed in *T1R* genes among tetrapods. Amphibians, for instance, have lost all *T1R* genes and detection of amino acids is mediated by V2Rs, whereas *T1R2* genes were lost in all avian lineages, resulting in inability to perceive sweets (Shi and Zhang, 2006). Intriguingly, this ability was recovered in nectar-eating hummingbirds. In this group, the T1R1 + T1R3 umami receptor has been repurposed by substitutions at the ligand-binding domain of the T1R3 subunit, acquiring a new adaptive function (Baldwin *et al.*, 2014). Similarly, diet specialization and diverse ecological niches act as strong selective pressures on the evolution of T1Rs in mammals. The giant panda is related to carnivorous bears, but lacks the ability to perceive amino acids through umami receptors due to pseudogenization of *T1R1* gene, which occurred concomitantly to a dietary switch to bamboo in the evolution of the species (Zhao *et al.*, 2010b), though other molecular adaptations might also be involved in diet specialization in pandas (Jin *et al.*, 2011). Conversely, *T1R2* became pseudogenized in several carnivores, rendering them unable to detect carbohydrates, which is likely a result of a dietary specialization to obligatory carnivory (Jiang *et al.*,

2012). Curiously, *T1R2* has also undergone pseudogenization in hematophagous bats (Zhao *et al.*, 2010a), and loss of umami taste is widespread among bats, regardless of diet (Zhao *et al.*, 2012). The most striking example of gustatory loss is observed in sea lions and cetaceans, in which feeding behavior and niche specialization contributed to relaxation of selective constraints, resulting in pseudogenization of all *T1R* genes (Jiang *et al.*, 2012; Feng *et al.*, 2014; Zhu *et al.*, 2014).

Unlike other chemosensory receptors, several *T2R* genes are expressed at different levels in a single TCR, rendering taste cells sensitive to a variety of bitter molecules, which maximizes the ability to detect potentially harmful substances, characterized by bitter taste (Yarmolinsky *et al.*, 2009). Compared to T1Rs, T2Rs originated much later in the evolution of vertebrates, just before the divergence of teleosts and tetrapods, in which T2Rs became more diverse through lineage-specific gene duplications (Grus and Zhang, 2009). Amphibians, reptiles, and mammals have large *T2R* gene repertoires, though fewer copies are observed in some avian lineages (Dong *et al.*, 2009). Interestingly, T2Rs in some birds are broadly tuned to a variety of agonists, which compensates for the low diversity of bitter receptors (Behrens *et al.*, 2014). Within mammals, reintrogression into aquatic environments accompanied by a switch in feeding ecology led to pseudogenization of *T2R* genes in sea lions (Jiang *et al.*, 2012) and cetaceans (Jiang *et al.*, 2012; Feng *et al.*, 2014; Wang *et al.*, 2014). In terrestrial mammals, diet plays a major role in the evolution of T2Rs. Herbivorous and omnivorous mammals generally exhibit a larger *T2R* repertoire compared to carnivorous mammals, as a way to detect harmful bitter tasting compounds in plants. However, a large proportion of the *T2R* repertoire of cows and horses became pseudogenized, likely the by-product of extensive artificial selection in these lineages (Dong *et al.*, 2009).

Auditory Perception

Prestin (SLC26A5) is a voltage-sensitive membrane protein expressed in the outer hair cells (OHC) of the auditory system that underlies hearing sensitivity and frequency range through amplification of signal input. This is particularly relevant for bats and whales, in which the ability to acoustically sense the environment, known as echolocation, convergently evolved. The *Prestin* gene has undergone parallel evolution in echolocating bats and continued to undergo adaptive selection in the lineage leading to the more derived HDC echolocating bats (Li *et al.*, 2008). *Prestin* is also thought to have undergone adaptive evolution in toothed whales, suggesting that adaptive changes in *Prestin* are linked to the evolution of echolocation in this group (Liu *et al.*, 2010b). Remarkably, it appears that *Prestin* evolved convergently in HDC bats and echolocating cetaceans, as result of strong selective constraints to detect high-frequency sounds in both lineages (Li *et al.*, 2010; Liu *et al.*, 2010a). More recently, substitutions at two amino acid sites have been identified as critical for functional convergence among high-frequency echolocating mammals (Liu *et al.*, 2014). In addition to *Prestin*, several genes involved in OHC function (*Kcnq4*, *Pjkv*, *Cdh23*, *Pcdh15*), maturation (*Tmc1*) and signal transduction (*Otof*) also experienced adaptive selection and convergent evolution in echolocating bats and dolphins to account for high-frequency hearing (Liu *et al.*, 2011; Davies *et al.*, 2012; Liu *et al.*, 2012; Shen *et al.*, 2012a).

Electroreception and Electrogenesis

The ability to detect electric fields is conferred by electroreceptors, which exhibit a complex pattern of evolution across vertebrate lineages and achieved greater specialization following the evolution of the electrogenic organs in some taxa. Electroreceptors transduce electric signals into action potentials that are processed in the central nervous system, and can convey information of relevance for social communication, navigation, hunting, and defense (Albert and Crampton, 2005). Electroreceptors evolved in the common ancestor of all vertebrates as a submodality of the lateral line system, which also encodes mechanosensory information in fishes and amphibians through specialized neuromast hair cells. In some amphibians, cartilaginous fishes, and non-teleost bony fishes, electroreceptors are organized into ampullary organs that respond to passive low-frequency environmental electric fields (Jørgensen, 2005).

Electroreceptors were lost in amniote and teleost fish ancestors. Air is a poor conductor of electricity, explaining the absence of electroreceptivity in terrestrial taxa. Within amniotes, electroreception was independently regained in aquatic monotremes and river dolphins through neofunctionalization of mechanosensory organs (Pettigrew, 1999; Czech-Damal *et al.*, 2012). Multiple lineages of teleost fishes have independently regained electroreception. In two orders of electrogenic fishes, the South American Gymnotiformes and African Mormyriformes, a sophisticated electrosensory system is mediated by a second class of tuberous electroreceptors. These electroreceptors are sensitive to the higher frequency of self-generated electric fields, enabling fishes to covertly communicate and navigate using electric fields. The waveforms of the electric organ discharges (EODs) vary substantially across gymnotiform and mormyriform species. Avoidance of electroreceptive predators and sexual selection have likely contributed to the evolution of EOD diversity (Stoddard, 1999; Crampton *et al.*, 2013).

The waveform of an EOD is modulated by the rate of depolarization and repolarization of the stacked electrocyte cells forming the electric organ, which is in turn controlled by ion channels lining the anterior and posterior faces of each individual cell. The *scn4aa* and *scn4ab* genes (duplicates of the mammalian *Scn4a* gene), respectively encode the sodium channel proteins Nav1.4a and Nav1.4b, which play a role in determining properties of the EOD (Ferrari *et al.*, 1995). In most teleost fishes, *scn4aa* and *scn4ab* are expressed in muscle; however, in most Gymnotiformes and Mormyriformes, *scn4aa* is exclusively expressed in the electric organ (**Figure 2**; Zakon *et al.*, 2006). This phylogenetic pattern of expression is accompanied by increased rates of molecular evolution and elevated dN/dS values in *snc4aa* from electrogenic fish lineages (**Figure 2**; Arnegard *et al.*, 2010), likely due to natural selection associated with diversification of EODs. Sites found to be positively selected in these lineages likely affect the kinetics of channel activation and inactivation, and

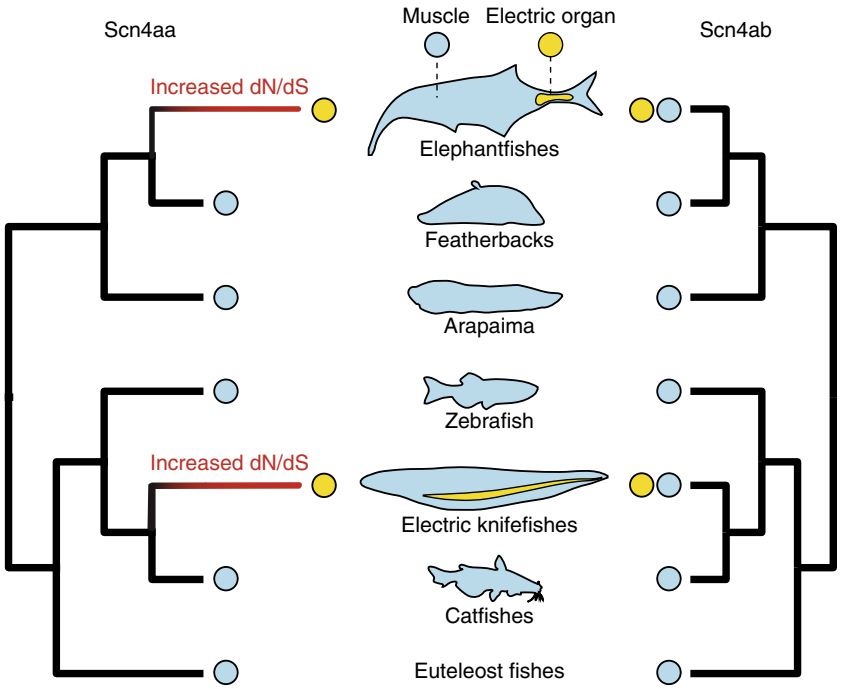

Figure 2 Expression of *scn4aa* and *scn4ab* in teleost fishes. Branch lengths and color are schematic representations of nonsynonymous to synonymous rate variation. Blue and yellow circles identify tissue type where the *scn4a* gene is expressed. Based on data presented in Zakon *et al.* (2006).

thereby EOD waveform parameters. Thus, convergent neofunctionalization of a duplicated sodium channel gene likely contributed to the evolution and diversification of independently derived electrosensory systems.

Thermoreception

The TRP superfamily of ion channels, expressed in neurons of the somatosensory system, responds to temperature changes in peripheral tissues. Remarkably, some *TRP* genes have gained a new function in specialized organs on the faces of snakes and bats, conferring infrared sensing abilities that are crucial for food acquisition. The TRPA1 calcium channel, expressed in the pit organs of snakes, detects infrared radiation, which is transduced into electric signals that are processed in the optic tectum, resulting in a 'thermal vision' (Gracheva *et al.*, 2010). This ability evolved independently in pythons, boas, and venomous snakes through adaptive selection of sites at different domains of the TRPA1 channel, becoming crucial for prey detection and predator avoidance (Geng *et al.*, 2011). Interestingly, infrared perception also evolved in vampire bats, though through a different mechanism. In the leaf pit organs located on the face of vampire bats, a shorter splice variant of the *Trpv1* gene is expressed. TRPV1-S is truncated at the C-terminus end, lowering the threshold to which the leaf pits respond, allowing vampire bats to detect areas where blood flows closer to the skin (Gracheva *et al.*, 2011).

Concluding Remarks and Future Research

Studies throughout the last decade have greatly developed our understanding of the diverse molecular mechanisms underlying the remarkable sensory adaptation observed in vertebrates. This outstanding progress has been particularly fruitful in identifying molecules that act as sensory receptors responsible for transducing a variety of environmental stimuli into neural signals that ultimately result in physiological and behavioral responses. Interestingly, the nature of vertebrate somatosensory mechanoreceptors that mediate our sense of touch remains largely puzzling, although much progress has been made in invertebrates (Schuler *et al.*, 2015). It is also important to note that although vision and particularly visual pigments have been studied in a comparative context (Shen *et al.*, 2012b; Lin *et al.*, 2013; Shen *et al.*, 2013; Emerling and Springer, 2014; Emerling and Springer, 2015), other sensory systems have not received the same degree of attention, and remain largely understudied from a molecular evolutionary perspective. The recent developments in next generation sequencing technologies provide an unprecedented opportunity to not only identify candidate genes that may play a role in sensory transduction pathways (Gracheva *et al.*, 2010, 2011; Gerhold *et al.*, 2013), but also to expand our understanding of the complex mechanisms underlying vertebrate sensory perception. Finally, future research should also be devoted to the intricate interactions among different sensory systems, many of which have likely coevolved to result in the exquisite examples of sensory adaptation observed in nature.

Sequential Speciation

GR Hood and JL Feder, University of Notre Dame, Notre Dame, IN, USA

Glossary

Cascading or sequential speciation A process by which ecological speciation of one organism creates a new niche for other organisms to potentially adapt to, leading to their speciation.

Co-speciation The simultaneous and interdependent diversification of host and parasite lineages.

Ecological speciation A process by which barriers to gene flow evolve between populations due to ecologically based divergent natural selection between environments or habitats.

Host races Geographically cooccurring populations that are partially reproductively isolated due to divergent ecological selection associated with differential host use.

Inquiline A parasitic relationship between two organisms whereby one species exploits the living space of another.

Niche construction/engineering Modification to the environment by one species in a manner that affects resource availability for other species and that can have lasting effects on the fitness of populations.

Parasitoid A specialized insect that feeds and develops within or on another insect host during the immature stages of its life cycle, typically killing its host in the process.

Reproductive isolation A reduced ability of individuals from different populations to court, mate, or produce viable, fertile offspring.

The Biodiversity Question and Sequential Speciation

'What determines species diversity?' is one of the most important questions in biology (Pennisi, 2005). Two key considerations in this regard involve the ecological adaptation of organisms to different environments and the coevolutionary interplay between organisms themselves. The hypothesis of sequential or cascading speciation attempts to unify these two considerations. Specifically, sequential speciation contends that as organisms diverge they create new niche dimensions for other organisms to exploit, and that if these other organisms experience novel selection pressures, they may speciate in kind. Here, we discuss how the idea of sequential speciation has been generally applied to a number of different questions in biology. We then explain how sequential speciation differs from strict co-speciation and examine the conditions thought to favor sequential speciation. Phytophagous (plant-eating) insects and their natural enemies represent systems where sequential speciation has been most commonly documented. As case studies, we examine evidence from two phytophagous insects–natural enemy systems where sequential speciation has been shown to be occurring. We then discuss several systems where a hypothesis of sequential speciation is not supported.

General Implications of Sequential Speciation

The idea that diversity begets diversity has been applied to several areas in biology. In paleontology, niche construction has been argued to help trigger diversification following mass extinctions, possibly facilitating major diversification events such as the Cambrian explosion (Erwin, 2005, 2008; **Figure 1(a)**). In community ecology, species richness is a strong predictor of diversification rates (Emerson and Kolm, 2005; **Figure 1(b)**). In systematics, sequential speciation may help explain why some clades of plant-feeding insects are more speciose than sister groups of non-plant feeders (Mitter *et al.*, 1988; **Figure 1(c)**). In each of these cases, diversification of organisms into new habitats and life histories may increase the rate of speciation among other species with whom they interact, thereby increasing total species richness in a community.

Distinguishing Sequential Speciation from Strict Co-speciation

Sequential speciation requires that divergent ecological selection pressures cascade across trophic levels to cause linked patterns of diversity. However, sequential speciation is just one process that can increase clade richness across communities. In this regard, it is important to distinguish sequential speciation from strict co-speciation. In co-speciation, concordant divergence across trophic levels is due to (1) host and parasite populations being jointly geographically isolated, resulting in parallel allopatric speciation, and/or (2) parasites being vertically transmitted and lacking a sexually reproductive adult stage independent of the host (de Vienne *et al.*, 2013). Strict co-speciation is therefore not driven by the creation of new biological niches that result in ecological diversification (i.e., by coevolutionary processes), but rather by the concordant geographic and reproductive separation of host and parasite populations (Feder and Forbes, 2010; de Vienne *et al.*, 2013). Distinguishing sequential speciation from strict co-speciation therefore requires study systems having appropriate natural histories (e.g., those possessing free-living reproductive life stages), known biogeographies (to rule out non-ecologically based reproductive isolation as the primary cause for divergence), and well-resolved phylogenies documenting histories of parasite host shifting. An additional consideration for phylogenetic tests of sequential speciation is that it must be shown that a degree of divergent ecological adaptation

accompanied (was required for) the host shift, and that parasites are not merely shifting between geographically separated hosts.

Conditions Conducive for Sequential Speciation

For organisms like phytophagous insects and their natural enemies, both of which partition and experience resources on a fine scale, the effects of new niche construction and engineering may be especially prone to cascading through the ecosystem (Bush, 1993). Not all insect systems possess attributes that are conducive to sequential speciation, however. The conditions most favorable for sequential speciation are similar to those important for host race formation via host plant shifting in phytophagous insects (Berlocher and Feder, 2002; Dres and Mallet, 2002 and sources therein). Specific conditions that should promote host race formation and sequential speciation between two or more trophically linked organisms are summarized by Abrahamson and Blair (2008) and Hood *et al.* (2015) and listed (with some modification) below:

1. Recent colonization of a new environment resulting in fitness tradeoffs that reduce gene flow and generate reproductive isolation between populations.
2. Populations at least partially overlap in their geographic ranges such that the opportunity for encountering alternative hosts/habitats exists, i.e., is not totally impeded by physical barriers or distance.
3. Courtship and mating occur on or near the host, linking host choice and mate choice, thereby generating prezygotic

reproductive isolation. A degree of host preference for natal habitats that is at least partly genetically controlled must also exist.

4. Phenology (life history timing) is associated with host habitat such that reproductive overlap between populations is temporally reduced, resulting in prezygotic isolation. This generally requires a univoltine (one generation per year) life cycle with an adult life span that is relatively short compared to the phenological difference between hosts (i.e., individuals cannot span the entire range of seasonal availability of alternate hosts).

Evidence Supporting Sequential Speciation

Empirical evidence for sequential speciation in phytophagous insects and their natural enemies is mixed, with results ranging from apparently negative (Cronin and Abrahamson, 2001; Baer *et al.*, 2004; Althoff, 2008; Lozier *et al.*, 2009; Dickey and Medina, 2012), to uncertain (Henter and Via, 1995; Althoff and Thompson, 2001), to probable (see several sources in Abrahamson and Blair, 2008). Below, we present results for two systems where evidence strongly supports the sequential speciation hypothesis.

Case 1: One Host, One Natural Enemy: The Goldenrod Stem Galler, *Eurosta solidaginis*, and the Tumbling Flower Beetle, *Mordellistena convicta*

Speciation of host

The fly *Eurosta solidaginis* (Diptera: Tephritidae) induces galls on the stems of two species of goldenrods, *Solidago altissima* and *Solidago gigantea*, that geographically overlap in the northern United States (Abrahamson *et al.*, 2003). The shift of *E. solidaginis* from its ancestral host *S. altissima* to *S. gigantea* is a classic example of host race formation via host plant shifting. Several factors contribute to reproductive isolation between host races of *E. solidaginis*. First, *E. solidaginis* emerges from galls induced on *S. gigantea* 10–14 days earlier than galls induced on *S. altissima* (Craig *et al.*, 1993). Second, *E. solidaginis* flies mate on the buds of their respective host plants and exhibit oviposition preferences for stems of their natal host plants. Moreover, if mating and oviposition occur between host races, F1 hybrids and backcrossed individuals suffer a reduction in fitness due to a decreased frequency of successful gall induction on either host plant (Craig *et al.*, 1997). Thus, the link between mate choice, habitat choice, and reduced hybrid fitness ecologically isolate populations of *E. solidaginis* on alternative hosts. Likely a result of these isolating barriers, the two *Eurosta* races exhibit host-associated genetic differentiation at five allozyme loci (Warring *et al.*, 1990) and posses distinct, although not highly diverged, mtDNA haplotypes on *S. altissima* versus *S. gigantea* (Smith *et al.*, 2002).

Sequential speciation of natural enemy

The formation of host races of the tumbling flower beetle, *Mordellistena convicta* (Coleoptera: Mordellidae) represents one of the only examples of sequential speciation that does not involve a host–parasitoid relationship. Beetles feed as inquilines on the gall tissue induced by *E. solidaginis* on goldenrods, resulting in levels of fly mortality >70% (Abrahamson and Blair, 2008). Evidence suggests that host-associated populations of beetles have ecologically and genetically diverged

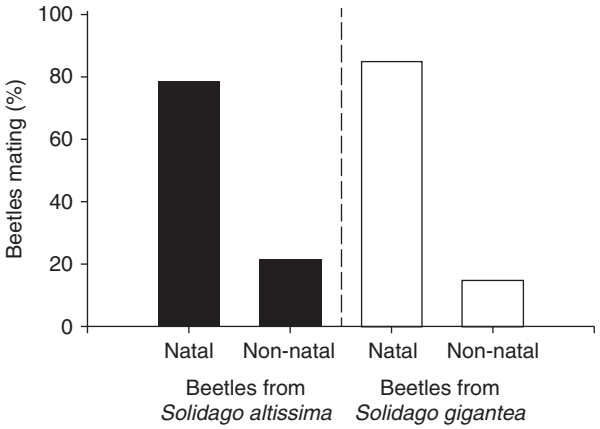

Figure 3 Percent *Mordellistena convicta* originating from *Solidago altissima* (black bars) and *Solidago gigantean* (white bars) goldenrod galls mating with individuals reared from natal and non-natal hosts (Eubanks *et al.*, 2003).

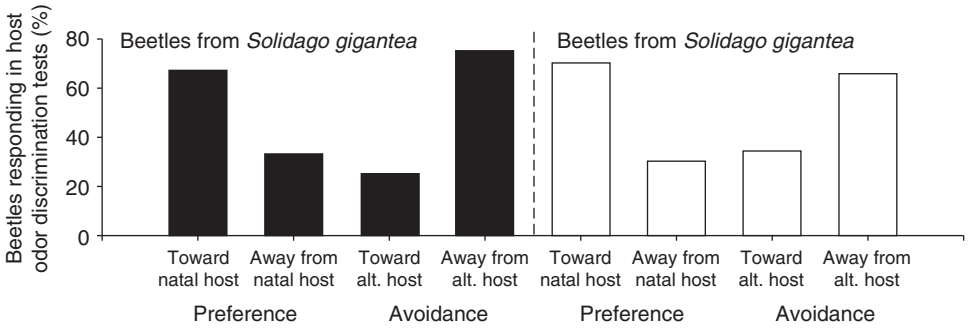

Figure 2 Percent of *Mordellistena convicta* originating from *Solidago altissima* (black bars) and *Solidago gigantea* (white bars) goldenrod galls that prefer and avoid the surface volatiles of galls in host odor discrimination tests. Adapted with permission from Rhodes, B.C., Blair, C.P., Takahashi, M.K., Abrahamson, W.G., 2012. Figure 4 Percent *Mordellistena convicta* offspring originating from *Solidago altissima* (black bars) and *Solidago gigantean* (white bars) recovered the following generation after being reared on natal (control) and non-natal host galls (Eubanks *et al.*, 2003).

due to differential gall formation on alternative host plants. Modest allele frequency differences exist at five allozyme loci between sympatric *M. convicta* inhabiting *S. altissima* and *S. gigantea* galls (Blair *et al.*, 2005). Additionally, a number of host-related ecological adaptations likely contribute to reproductive isolation in *M. convicta*. First, beetles prefer the volatiles emitted from natal galls and avoid non-natal galls in host odor discrimination tests (Rhodes *et al.*, 2012; **Figure 2**). Second, beetles exhibit sexual isolation via mate choice. Adults prefer to mate with individuals from their natal rather than non-natal host plant (Eubanks *et al.*, 2003; **Figure 3**). Third, when host races of *M. convicta* are exposed to the alternative gall habitat and allowed to oviposit, adult emergence the following generation is reduced (Eubanks *et al.*, 2003; **Figure 4**). The reduction in emergence could be due to either reduced survivorship and/or reduced oviposition into non-natal galls; regardless this result implies a degree of host specialization and ecological reproductive isolation. However, the site of mating of *M. convicta* is not known, so it remains to be

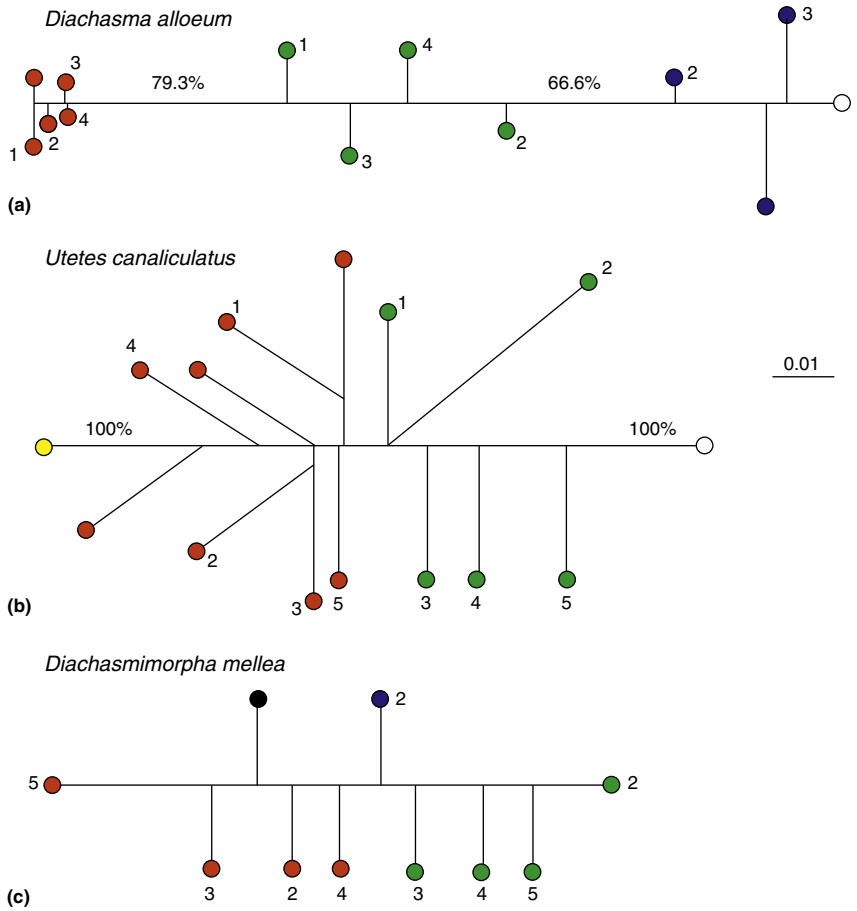

Figure 5 Genetic distance network based on microsatellite loci allele frequency depicting the relationship among (a) *Diachasma alloeum*, (b) *Diachasmimorpha mellea,* and (c) *Utetes canaliculatus* populations attacking apple (green), hawthorn (red), flowering dogwood (yellow) blueberry (blue), snowberry (white), and black cherry (black) flies. The black cherry infesting fly, *Rhagoletis cingulata*, is a more distantly related species to the *Rhagoletis pomonella* group. Populations with the same number represent wasp from the same field site. Adapted with permission from Forbes, A.A., Powell, T.H.Q., Stelinski, L.L., Smith, J.J., Feder, J.L., 2009. Sequential sympatric speciation across trophic levels. Science 323, 776–779 and Hood, G.R., Forbes, A.A., Powell, T.H.Q., *et al.*, 2015. Sequential divergence and the multiplicative origin of community diversity. Proceedings of the National Academy of Sciences of the United States of America. Online early. doi:10.1073/pnas.1424717112.

determined if the beetles experience some degree of prezygotic isolation due to differences in host preference (Abrahamson and Blair, 2008). In addition, *M. convicta* races do not seem to be temporally isolated, as emergence times for adults differ by only 1.1 day (Eubanks *et al.*, 2003; Blair *et al.*, 2005). Consequently, ecological specialization in *M. convicta* appears to be driven by host plant related survivorship and oviposition preferences, with some additional prezygotic isolation due to differential mate choice that is related to host-origin, but independent of host choice.

Case 2: One Host, Many Natural Enemies: The Apple Maggot Fly, *Rhagoletis pomonella*, and Three Parasitoids: *Diachasma alloeum*, *Diachasmimorpha mellea*, and *Utetes canaliculatus*

Speciation of host

The *Rhagoletis pomonella* (Diptera: Tephritidae) sibling species group is a model for ecological speciation-with-gene-flow. The group consists of the hawthorn (*Crataegus* spp.) and apple (*Malus domestica*) infesting host races of *R. pomonella*, as well as several sibling species including the undescribed flowering dogwood fly (host: *Cornus florida*), *Rhagoletis mendax* (host: blueberry; *Vaccinium* spp.) and *Rhagoletis zephyria* (host: snowberry; *Symphoricarpos* spp.). The close morphological similarity, distinct host affiliations, and broadly overlapping geographic ranges of these flies imply that they radiated by shifting and adapting to new host plants in sympatry. In particular, the recent shift (<160 ya) of *R. pomonella* from its native, ancestral host hawthorn to introduced domesticated apple is often cited as an example of incipient ecological speciation in action (Berlocher and Feder, 2002).

Two ecological adaptations are important in generating reproductive isolation among *R. pomonella* taxa. First, each of the flies attack a different, nonoverlapping set of host plants that all fruit at different times of the year (Dambroski and Feder, 2007). *Rhagoletis* uses host fruit as a rendezvous site for mating and oviposition. Eggs hatch and fly larvae feed in host fruit for 2–4 weeks. When fruit abscises, larvae leave fruit, burrow into the ground, and form puparia. Flies overwinter in a facultative diapause, eclosing the following summer as adults to complete their univoltine life cycle. Because adult longevity is short (~28 days), flies must time their diapause phenology to match the fruiting time of their host plant. As different hosts plants fruit at different times, *Rhagoletis* flies eclose at different times of the year, resulting in allochronic premating isolation, as well as a degree of post-zygotic isolation due to migrants and hybrids having diapause phenotypes suboptimal for attacking non-natal hosts (Feder *et al.*, 1994; Berlocher, 2000).

The second factor generating ecologically-based reproductive isolation in *Rhagoletis* is host-specific mating on or near the host fruit, coupled with host fruit discrimination. Differences in host preference lead to assortative mating between fly populations, resulting in prezygotic isolation. The most important long range cue that flies use to find and discriminate among alternative hosts is the volatile compounds emitted from the surface of ripening fruit (Linn *et al.*, 2003). Flies prefer the volatiles of their natal host fruits and avoid non-natal fruit odors (Linn *et al.*, 2003; Forbes *et al.*, 2006). Mark recapture studies have estimated that host fruit choice and habitat specific mating reduce migration 4–6% per generation

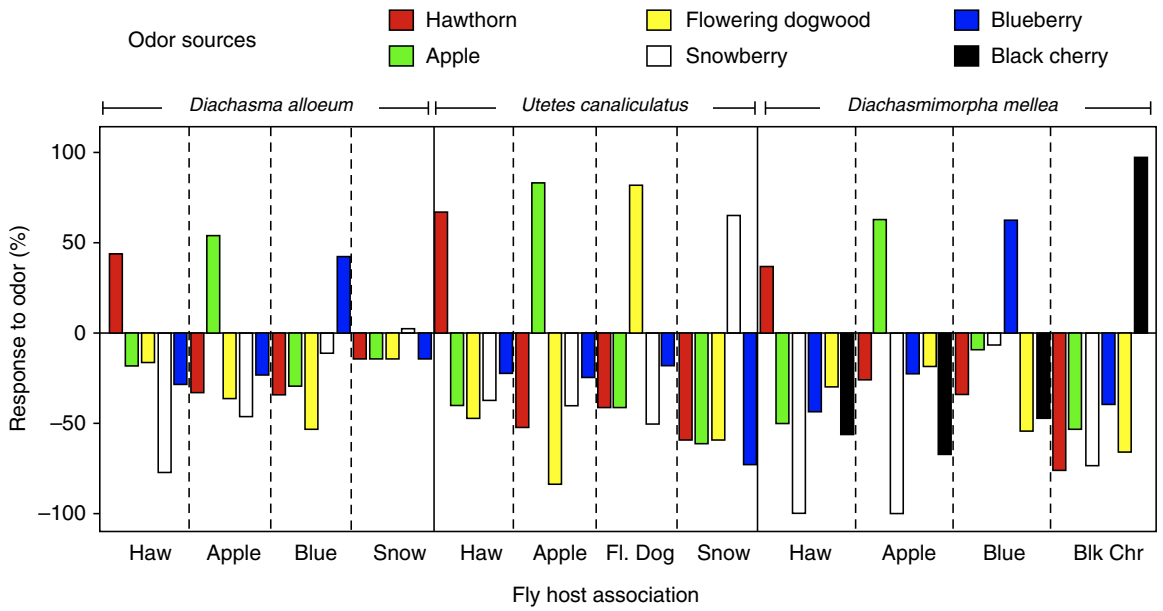

Figure 6 Preference for and avoidance of apple-, hawthorn-, flowering dogwood-, blueberry-, snowberry-, and black cherry-fly origin *Diachasma alloeum, Utetes canaliculatus* and *Diachasmimorpha mellea* to odors of natal and non-natal fruit compared to odorless controls (not shown) in host odor discrimination tests (Forbes *et al.*, 2009). Odor sources: apple (green), hawthorn (red), flowering dogwood (yellow), blueberry (blue), snowberry (white) and black cherry (black). Adapted with permission from Forbes, A.A., Powell, T.H.Q., Stelinski, L.L., Smith, J.J., Feder, J.L., 2009. Sequential sympatric speciation across trophic levels. Science 323, 776–779 and Hood, G.R., Forbes, A.A., Powell, T.H.Q., *et al.*, 2015. Sequential divergence and the multiplicative origin of community diversity. Proceedings of the National Academy of Sciences of the United States of America. Online early. doi:10.1073/pnas.1424717112.

between apple and hawthorn populations at sympatric sites (Feder *et al.*, 1994) and could completely isolate certain sibling species (Feder and Bush, 1989).

Flies in the *R. pomonella* group also display host-related genetic differentiation. Apple and hawthorn flies differ significantly in allele frequencies for 6 allozyme and 26 microsatellite loci, many of which are associated with diapause timing (Michel *et al.*, 2010). The immediate sister taxon to *R. pomonella* that infests flowering dogwood shows an even stronger pattern of allele frequency divergence than the apple and hawthorn hosts races (Powell *et al.*, 2013). Diagnostically fixed genetic differences also do not distinguish between *R. pomonella* and two other siblings attacking blueberry (*R. mendax*) and snowberry (*R. zephyria*) flies. However, these taxa are distinguished by moderate to strong allele frequency differences for a subset of loci (Xie *et al.*, 2008).

Sequential speciation of natural enemies

Rhagoletis pomonella group flies and their associated community of parasitoid wasps (Hymenoptera: Braconidae) represent a case where sequential speciation is multiplicatively amplifying biodiversity across an entire assemblage of species. The wasps, *Diachasma alloeum*, *Diachasmimorpha mellea*, and *Utetes canaliculatus* are each host-specific and attack various immature life stages of *Rhagoletis* developing within host fruit. As with *R. pomonella*, all three species display allele frequency differences for several microsatellite loci among sympatric populations attacking apple, hawthorn, blueberry, snowberry, and flowering dogwood flies, implying that each represents a complex of host races (**Figure 5**; Forbes *et al.*, 2009; Hood *et al.*, 2015). In addition, a lack of fixed differences and shared haplotypes for mtDNA suggests that host-associated wasp populations are of recent origin and/or there is some ongoing gene flow. Moreover, the same ecological adaptations that reproductively isolate *Rhagoletis* flies also isolate members of the parasitoid community. Wasps rendezvous on or near host fruit for mating and display similar host odor preference and avoidance responses to their natal versus alternative non-natal fruit volatiles in behavioral assays (**Figure 6**; Forbes *et al.*, 2009; Hood *et al.*, 2015). In addition, wasps show host-related differences in their mean eclosion times (10–27 days), matching the chronology of when host fruit ripen, and hence when fly larvae are available for oviposition (**Figure 7**; Forbes *et al.*, 2009; Hood *et al.*, 2015). Furthermore, microsatellites that differed significantly among host-associated populations are associated with the timing of adult eclosion in *D. alloeum* and *D. mellea*. Given that adult wasps live only ~2 weeks (half as long as flies), the effects of temporal isolation can be even more pronounced in reducing gene flow (15–100%). The concordant natural history, documentation of recent sympatric host shifting of flies, and evidence for genetic differentiation therefore all support the formation of new wasps host races community-wide and highlight the potential for sequential speciation to multiplicatively amplify diversity.

Systems Lacking Evidence

A number of studies have reported an apparent absence of sequential speciation (Cronin and Abrahamson, 2001; Baer *et al.*, 2004; Althoff, 2008; Lozier *et al.*, 2009; Dickey and Medina, 2012). A common theme among these systems is that the natural enemies in question have multivoltine life histories, a trait which reduces the potential for allochronic isolation (Althoff, 2008; Dickey and Medina, 2012). In addition, four studies investigating sequential speciation (Baer *et al.*, 2004; Althoff, 2008; Lozier *et al.*, 2009; Dickey and Medina, 2012) have attributed negative results to (1) host plant discrimination behavior that is learned, rather than genetically controlled and (2) external feeding of the host on their host plant, elevating the importance of visual cues and decreasing the significance of plant-associated chemical cues for locating and differentiating between hosts. An emphasis

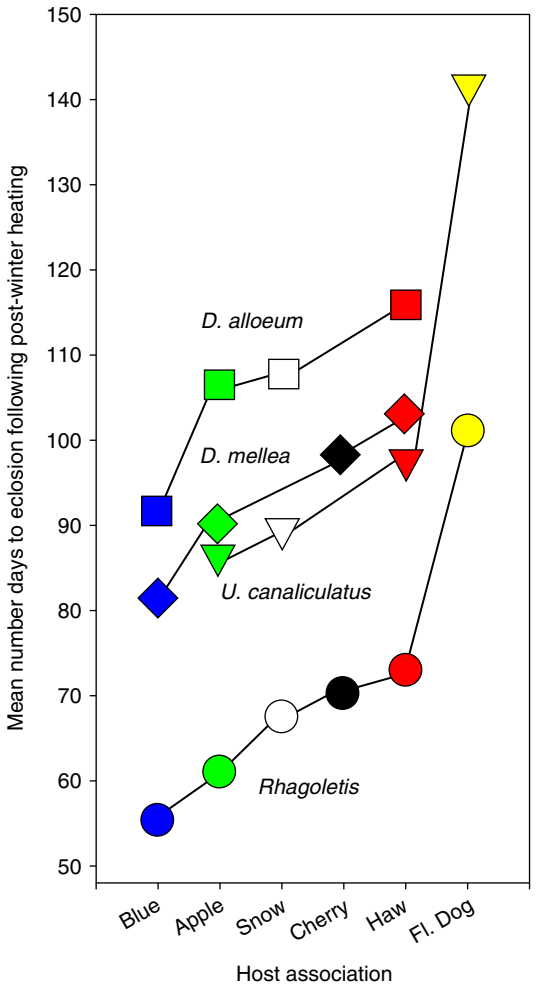

Figure 7 Mean number of days to adult eclosion for *Rhagoletis* (circles) infesting apples (green), hawthorn (red), flowering dogwood (yellow), blueberry (blue) and black cherry (black) flies and *Utetes canaliculatus* (triangles), *Diachasmimorpha mellea* (diamonds), and *Diachasma alloeum* (squares) attacking those fly hosts. Adapted with permission from Forbes, A.A., Powell, T.H.Q., Stelinski, L.L., Smith, J.J., Feder, J.L., 2009. Sequential sympatric speciation across trophic levels. Science 323, 776–779 and Hood, G.R., Forbes, A.A., Powell, T.H.Q., *et al.*, 2015. Sequential divergence and the multiplicative origin of community diversity. Proceedings of the National Academy of Sciences of the United States of America. Online early. doi:10.1073/pnas.1424717112.

on visual, rather than chemical, orientation toward host fly galls may also be a factor in the apparent lack of sequential divergence of the *Eurosta* parasitoid *Eurytoma gigantea* (Abrahamson and Blair, 2008).

Concluding Remarks: Future Directions

Until recently, most evidence for sequential speciation had been inferred from studies of adaptive radiations following mass extinctions, community level studies of species richness, and comparative phylogentic analyses of clade diversity. Here, we have highlighted two test cases from among several empirical studies that have identified candidate systems likely undergoing sequential speciation as well as several instances where no support has been found. To better understand if and how sequential speciation contributes to the genesis of biodiversity, several questions need attention. For example, what is the frequency of sequential speciation, both within and between systems? Is the community-wide amplification of diversity seen in *R. pomonella* more a rule or an exception? Similarly, how far up the trophic web can the effects of divergent ecological selection act to amplify biodiversity? In many systems, hyperparasitoids (parasitoids of parasitoids) are common and may experience the same divergent selection pressures as their lower trophic level hosts. We have focused our discussion on sympatric systems with the potential for high level of gene flow, the most difficult circumstances for divergent selection to drive ecological differentiation. However, sequential speciation may also be a factor in cases of parapatry and allopatry, although in the latter case it is more difficult to disentangle the consequences of divergent selection generated from new biotic opportunities from the effects of geographic isolation and limited or no gene flow. Lastly, while phytophagous insects and their natural enemies have attributes that *a priori* may make them more prone to sequential speciation, a more balanced view of the prevalence of sequential speciation requires study of other types of organismal interactions.

Sex and Recombination in Snails

JR Auld, West Chester University, West Chester, PA, USA
P Jarne, CEFE, CNRS, Université de Montpellier, Université P. Valéry, EPHE, Montpellier, France

Glossary

Apomixis Uniparental, asexual reproduction that occurs without meiosis; all offspring produced are genetically identical to each other and the parent (*cf.* automictic asexual reproduction which involved meiosis, hence the opportunity for recombination, but no fertilization).

Asexual reproduction Uniparental reproduction without fertilization; meiosis may occur (automictic) or may not occur (apomictic).

Cladistic A taxonomic perspective that groups organisms by shared evolutionary history; clades are groups of organisms that include the common ancestor and all of the descendants from that common ancestor.

Copulation A physical connection required for transfer of male gametes to the female.

Gonochore/gonochorism (i.e., dioecy/diecious) A sexual system in which males and females are separated into different organisms (i.e., different bodies); *cf.* hermaphroditism. The term 'gonochorism' is typically used by zoologists, while the synonymous term 'dioecy/diecious' is typically used by botanists.

Hermaphrodite/hermaphroditism A sexual system in which males and females are combined into a single organism (i.e., the same body); *cf.* gonochorism. Hermaphroditism can be simultaneous or sequential; simultaneous hermaphrodites express both sexes at the same time (they are simultaneously male and female), sequential hermaphrodites change from one sex to the other during their lifespan (see protandry/protogyny).

Imposex A disorder in some organisms where female individuals develop male sexual structures.

Inbreeding Mating with an individual that is genetically related; the extreme is selfing.

Inbreeding depression The decrease in fitness suffered by inbred offspring relative to outbred offspring.

Lecithotrophic A form of larval dispersal where the larvae are produced with a yolk sac or some other means of being nourished while they disperse. Lecithotrophic larvae may disperse further than direct developing larvae but not as far as planktotrophic larvae.

Life history The relative timing of key aspects of an organism's life, especially with regard to birth/survival/death, growth, sex and reproduction, and the quantitative investment in these aspects. This includes, for example, whether reproduction is attempted only once or in multiple rounds, and how long the reproductive period (and life itself) lasts.

Mating system The pattern of mating among individuals in a population; the mating system can be thought of in terms of the relative number of males and females mating with each other (e.g., monogamy, polygamy, polyandry, polygyny) or in terms of the level of inbreeding/outbreeding in a population.

Metapopulation A set of populations that are linked by migration/gene flow and experience extinction and colonization.

Outbreeding/outcrossing/cross-fertilization Mating with an individual that is not a genetic relative; can be used less strictly in comparison to self-fertilization in simultaneously hermaphroditic species.

Parthenogenesis Literally means 'virgin birth' (i.e., birth from a single female parent with no male involved (no fertilization)); asexual reproduction. Note that some fish species actually require copulation, but reproduce asexually (the sperm do not fertilize the eggs).

Phenotypic plasticity The phenotypic variation expressed by a given genotype (set of genes) across different environmental conditions.

Planktotrophic A form of larval dispersal where the larvae are capable of feeding while they disperse. Planktotrophic larvae may disperse further than both lecithotrophic larvae and direct developing larvae.

Ploidy The number of copies of homologous chromosomes (hence of alleles per gene) that are contained in the nucleus.

Polyphyletic A taxonomic grouping that does not reflect shared evolutionary history; a polyphyletic group may not include the common ancestor of a group, may contain organisms with a variety of different common ancestors, or may exclude some of the descendants from the most recent common ancestor.

Polyploidy Having >2 (e.g., 4, 8) copies of each chromosome. Uneven numbers of copies occur in animals.

Protandry A form of sequential hermaphroditism where an individual starts sexual maturity as a male and switches to female. Some organisms can start as male-only and convert to simultaneous hermaphroditism.

Protogyny A form of sequential hermaphroditism where an individual starts sexual maturity as a female and switches to male. Theoretically, some organisms could start as female-only and convert to simultaneous hermaphroditism, but this is probably rare.

Recombination The production of a new combination of genes in the offspring – different from either parent; primarily occurs through two processes during meiosis: crossing over between homologous chromosomes and independent assortment between nonhomologous chromosomes.

Selfing/self-fertilization Sexual reproduction wherein an organism independently produces male and female gametes (via meiosis) then facilitates their fusion (fertilization) to produce offspring; the most extreme form of inbreeding.

Sex Can refer to the type of gamete an individual produces or to a mechanism of reproduction that involves alternating rounds of meiosis and fertilization. Sexual reproduction may or may not require copulation.
Sex determination A mechanism whereby the sex (male or female) of an individual is determined; can be genetically based (e.g., via a sex chromosome system), environmentally based, or some combination of the two.
Sex ratio The relative number of breeding males to breeding females in a population.
Sexual conflict Any of numerous situations where males and females (or male and female functions in hermaphrodites) maximize their reproductive output by different means; can lead to antagonistic interactions between the sexes where what is good for one sex may actually be detrimental to the other sex.
Sexual dimorphism A consistent difference in phenotype between the sexes (in gonochoric organisms); may involve a size difference or any other ornament/armament/display trait.
Sexual reproduction Reproduction that involves alternating rounds of meiosis and fertilization.
Sexual system The arrangement of male and female gonads into individuals (e.g., gonochorism, hermaphroditism).
Uniparental reproduction Reproduction that only involves a single parent; can be asexual or sexual (self-fertilization).

Introduction

Snails and slugs (Mollusca: Gastropoda) are a very diverse class of single-shelled (or shell-less) mollusks occupying terrestrial, freshwater, brackish, and marine environments. Gastropods are a very old group, with fossils dating to 500 million years ago (Lindberg *et al.*, 2004; Lecointre and Le Guyader, 2006). Estimates for the number of extant snail species range from >100 000 (Lecointre and Le Guyader, 2006) to almost 150 000 (Lindberg *et al.*, 2004) making them second only to insects in terms of the number of animal species in a biological class. New species are very commonly discovered and described, especially in tropical forests and in the sea. Snails, like flowering plants, have long attracted the interest of evolutionary biologists, especially those considering/studying the evolution of reproductive systems, because of their amazing diversity in terms of sexual system, morphology, and behavior. Gastropods also serve as important model species in molecular biology and neurobiology, and they function as intermediate hosts for a number of human diseases (e.g., schistosomiasis). Gastropod reproductive systems have been reviewed in detail in Giese and Pearse (1977) and Wilbur *et al.* (1984); more recent reviews in Leonard and Cordoba-Aguilar (2010) have focused on the reproductive morphology of several major gastropod groups. Ponder and Lindberg (2008) provide an overview of Molluscan evolution including several chapters on gastropods.

All individual snails possess a single gonad (Aktipis *et al.*, 2008), but there is widespread variation in whether this gonad is used to produce one type of gamete or both. Most snails (>75%) are gonochoric (i.e., diecious), meaning that males and females exist as separate individuals. The separation of the sexes, and the mechanism by which this is achieved (e.g., sex chromosomes), brings up immediate questions regarding sex ratios, sexual selection, and sexual conflict – cases where male and female reproductive fitness are optimized in different ways. Some species have evolved radical sexual dimorphism where the males are extremely reduced in size and live within or attached to the females (i.e., dwarf males). Within gonochoric species, some snails utilize a very different form of reproduction – asexual reproduction, where no fertilization is involved (and hence males are not needed). Asexuality in snails is generally associated with an absence of genetic recombination (apomixis) and variation in ploidy level. In some species, asexual females coexist with sexual females and males, meaning that recombination is in competition with asexual reproduction. Some snails, especially the terrestrial and some freshwater ones, are simultaneous hermaphrodites, possessing both fully functional male and female sexual systems. These snails may have the capacity to self-fertilize or outcross (i.e., cross-fertilize) with partners. There are examples of species that prefer one strategy over the other, and there are some that seem to routinely do both (Jarne and Auld, 2006; Escobar *et al.*, 2011). When snails cross-fertilize, copulation is often (but not always) required, and this copulation might be bilateral, where both individuals play male and female at once, or unilateral, where one individual plays the male role and the other plays the female role. Some snails are sequential hermaphrodites, starting their reproductive life as one sex (e.g., male) and switching at some point to be the other (e.g., a fully functional female with no further male gametes produced); protandry seems to be much more common than protogyny (i.e., individuals beginning their life as female before switching to male). Therefore, snails vary from sexual to asexual and span the gamut of sexual reproduction, from self-fertilization to panmictic outcrossing. With all of this reproductive diversity, they serve as an excellent model system to study the evolution of reproductive systems, including sex itself. In this article, we review the diversity of sex and recombination in snails from a taxonomic (cladistic) perspective, highlighting particular examples of unique evolutionary outcomes (e.g., aphally, love darts, parasitic castration, and apophallation).

Gastropod Reproductive Systems

The vast majority of gastropods have separate sexes, which is the case in animals in general (Bell, 1982; Jarne and Auld, 2006). This means that issues bearing on the evolution of sexual systems are to a large part the same as in insects or mammals. For example, sex might be determined through sex chromosomes. However, most gonochoric gastropods are marine species, and our knowledge of these species lags behind, as is often the case when comparing marine and continental biology. No marine species has really been established

as a model system that can easily be manipulated in the laboratory. Much is therefore to be gained by further studies of sexual systems and sexual selection. It is also not clear whether the common ancestor of all gastropods was gonochoric or hermaphroditic. It has been argued, based on out-group comparisons, that the ancestral character state is gonochoric (Ponder and Lindberg, 1997); but until our understanding of the gastropod (and mollusc) phylogeny is settled, a conclusion seems premature. One thing does appear to be clear regardless of what the ancestral character state was: There have been numerous transitions in sexual systems within this group (i.e., several tens of transitions between hermaphroditism and gonochorism; Heller, 1993). Indeed the lability of sexual system is impressive, but so is the fact that several large groups show stasis in terms of sexual systems (e.g., the Hygrophila is almost completely hermaphroditic, see below).

Some gastropods also practice asexual reproduction, and a brief, but important clarification is pertinent. Sexual reproduction requires alternating rounds of meiosis and fertilization (Maynard Smith, 1978; Bell, 1982). Gametes are produced through the process of meiosis, which allows for genetic recombination and reduces ploidy; the normal ploidy level is then restored during fertilization when two gametes fuse to make a zygote. This process may be accomplished by a single individual (if that individual can produce both sperm and eggs) or two individuals (a male and a female in separate-sex species, or two cross-fertilizing hermaphrodites). While an individual may receive sperm from multiple sperm donors, only one spermatozoon is required to fertilize an egg. Asexual reproduction is a uniparental form of reproduction without fertilization. While some forms of asexual reproduction produce offspring that are exact replicas of the parent (i.e., cloning), some forms of asexual reproduction allow for meiosis (and therefore genetic recombination) to occur. Asexual reproduction is not extremely common in gastropods, occurring in a few tens of species, but offers fascinating models. Apomixis (i.e., clonal, where no recombination takes place) seems the norm, but detailed cytological/genetic studies are needed to distinguish automictic parthenogenesis from alternative forms of reproduction. These studies are not always available, and herein we will use 'asexual reproduction' and 'apomictic parthenogenesis' as synonymous.

Aside from variation in sexual systems and mating systems, gastropods also exhibit a great deal of variation in basic life-history traits that influence the evolution of reproductive traits (e.g., spawning, dispersal). While in many species copulation is involved and eggs are deposited either in gelatinous capsules/masses attached to a substrate or laid individually, there are examples of groups that have live birth, brooding, dispersing larvae (planktotrophic and lecithotrophic), and external fertilization (Wilbur *et al.*, 1984; Aktipis *et al.*, 2008). The extent to which the evolution of such life-history strategies is related to the evolution of the reproductive system is a topic ripe for future research. Eppley and Jesson (2008) explored the issue at the scale of all animal groups, and this could fruitfully be downscaled within groups exhibiting wide variety in sexual systems such as the gastropods.

We opt below for a presentation based on the taxonomic organization of gastropods in order to highlight the variety of issues across taxonomic groups and the fact that different questions are addressed in different groups. We used the purely cladistic system of classifying gastropods, recognizing six major clades, of Bouchet and Rocroi (2005). These clades are the Patellogastropoda, Vetigastropoda, Cocculiniformia, Neritimorpha, Caenogastropoda, and Heterobranchia; three of these clades (Vetigastropoda, Caenogastropoda, and Heterobranchia) are considerably larger than the other three, and the vast majority of studies have been on the latter two. The precise phylogenetic relationship among these clades is not clear, which complicates reconstruction of the ancestral sexual-system phenotype. Nonetheless, these clades can be thought of as six semi-independent groups within which the evolution of reproductive systems and strategies can be explored. **Table 1** provides an overview of the presence of hermaphroditism and sexual/asexual reproduction in these groups.

Patellogastropoda

The Patellogastropoda (Nakano and Ozawa 2007; Lindberg, 2008) are the true limpets, a marine group that is thought to be mostly gonochoric with sex ratios approximately 1:1 (e.g., Henninger and Hodgson, 2001), although some examples of protandrous (Lindberg and Wright, 1985; Gray and Hodgson, 2003; Collin, 2013) and even simultaneous (Cunha *et al.*, 2007) hermaphroditism exist. It is not clear whether this latter case is an anomaly, and even less whether self-fertilization occurs, as this species in particular seems to be normally gonochoric (Curdia *et al.*, 2005).

Vetigastropoda

The Vetigastropoda are another marine group of approximately 3700 species (Geiger *et al.*, 2008); they appear to be

Table 1 The prevalence of sexual systems (gonochorism vs. hermaphroditism), sexual reproduction (by outcrossing and selfing), and asexual reproduction among the six major gastropod clades.

Clade	*Sexual system*		*Sexual reproduction*		*Asexual reproduction*
	Gonochorism	*Hermaphroditism (type)*	*Outcrossing*	*Selfing*	
Patellogastropoda	Majority	Minority (sequential; some simultaneous)	Present	Not reported	Not reported
Vetigastropoda	Majority	Minority	Present	Not reported	Not reported
Cocculiniformia	Absent?	Minority (simultaneous)	Present	Not reported	Not reported
Neritimorpha	Majority	Absent?	Present	Not reported	Not reported
Caenogastropoda	Majority	Minority (sequential; some simultaneous)	Present	Not reported	Present
Heterobranchia	Minority	Majority (simultaneous; some sequential)	Present	Present	One species

predominantly gonochoric (e.g., Najmudeen, 2007) although hermaphrodites have been observed (Judge and Haszprunar, 2014). Thiriot-Quiévreux (2003) highlights that one species of *Monodonta* has evolved an X0–XX mechanism of sex determination.

Cocculiniformia

The Cocculiniformia is a group of approximately 130 species of deepwater limpets exhibiting simultaneous hermaphroditism where eggs and sperm are made in a single gonad (Strong and Harasewych, 1999; Lindberg, 2008; Hartmann *et al.*, 2011). Heller (1993) reported that 94% of the genera in this group are hermaphroditic, but noted that it is difficult to distinguish simultaneous and sequential hermaphrodites.

Neritimorpha

The Neritimorpha is primarily a marine group of deepwater limpets (Lindberg, 2008). It also contains some terrestrial and freshwater snails. The group appears to be gonochoric on the whole, but very little else seems to be known about its sexual and mating systems. Sex chromosomes (X0–XX) have evolved in the Neritidae (Thiriot-Quiévreux, 2003). Some species, for example, in the genus *Neritina*, are diecious and have marine larval forms, but freshwater adult forms.

Caenogastropoda

The Caenogastropoda is a very large and diverse group (~ 60% of the Gastropoda) containing marine, terrestrial, and freshwater species. Many snails formerly called Prosobranchs belong to this group; note that Prosobranchia is now considered to be a polyphyletic grouping.

Caenogastropods are almost entirely gonochoric. Studies on Caenogastropods (e.g., *Pomacea canaliculata*; Yusa, 2004a,b, 2006, 2007a) have explored the genetics of sex determination and the evolution of sex ratios. Yusa (2007b) reviewed this work, highlighting that while population sex ratios are often 1:1 the sex ratio within broods is often highly variable. This work, coupled with the discovery that environmental pollutants can cause female snails to develop male reproductive anatomy (i.e., imposex; e.g., Martin, 2002; reviewed in Sternberg *et al.*, 2010) has made Caenogastropod snails an important model for understanding the evolution of sex determination. More work on the ecological and evolutionary implication of imposex is needed. True sex chromosomes (i.e., stabilized gonochorism) have evolved in some species (e.g., Taguchi *et al.*, 2000; reviewed by Thiriot-Quiévreux, 2003). Interestingly, both ZW–ZZ and XX–XY mechanisms of sex determination have evolved in the genus *Viviparus*, while an X0–XX mechanism has been observed in other genera (Dillon, 2000; Thiriot-Quiévreux, 2003). In other groups, sex determination appears to be oligogenic (Yusa, 2007b). This variation suggests that future work on the evolution of Caenogastropod sex-determination mechanisms and transitions between states is likely to be very illustrative.

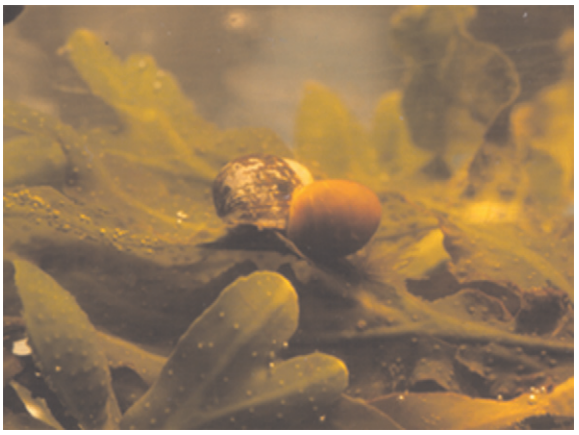

Figure 1 Copulation in *Littorina obtusata*. The diverse, marine genus *Littorina* has been widely studied in evolutionary ecology (Rolán-Alvarez *et al.*, 2015). Photo courtesy of E. Rolán-Alvarez.

Other Caenogastropods (e.g., *Littorina*; **Figure 1**) have served as models for studying the evolution of mate choice (Zahradnik *et al.*, 2008; Saltin *et al.*, 2013) and the process of sexual selection (Erlandsson and Johannesson, 1994; Rolán-Alvarez *et al.*, 2012). Many of these studies have focused on an intertidal hydrid zone in *Littorina saxatilis*, and illustrate the role of mate choice in the speciation process (Johannesson *et al.*, 1993; Pickles and Grahame, 1999).

While the Caenogastropoda is almost exclusively gonochoric, a few hermaphroditic species have been reported (Webber, 1977; Fretter, 1984; Heller, 1993; Ponder *et al.*, 2008; Hodgson, 2010). The eulimids, a group of echinoderm parasites, exhibit both hermaphroditism and gonochorism with dwarf males (Elder, 1979; Heller, 1993; Takano and Kano, 2014). Here, males are much smaller (e.g., one-tenth the size or smaller) than females and live attached (externally or internally) to the female. Heller (1993) also brings up the possibility of environmental sex determination in this group, where a female may recruit a larval individual and induce masculinity. This sort of environmentally induced sex determination is known to exist in the sequentially hermaphroditic genus *Crepidula*, the slipper limpets (Yonge and Thompson, 1976; Heller, 1993; Collin, 1995; Mérot and Collin, 2012). These organisms form stacks on top of one another and change sex so that the individuals on the bottom function as females but newly arriving individuals (on top) function as males. This illustrates an interesting overlap between sequential hermaphroditism, environmental sex determination, and phenotypic plasticity. Often, it is not clear what the exact stimulus is that induces a change in sex, but the availability (and position) of potential mates is certainly important. In her review, Collin (2013) highlighted that protandry has evolved in a few different Caenogastropod groups (Calyptraeids and Coralliophilids; see also Calvo and Templado, 2005); she proposes that aspects of protandry itself (growth repression of males by females) may facilitate the evolution of dwarf males in these groups.

Caenogastropods have also attracted some attention because of the occurrence of asexual reproduction in at least three families (i.e., Hydrobiidae, Viviparidae, and Thiaridae;

Heller, 1993). All of these asexual species dwell in freshwater. This suggests an association between freshwater and asexuality since the vast majority of Caenogastropods live in marine environments (Johnson *et al.*, 1995). One particularly well-studied species with regard to the evolution of sex, for example, its stability and loss, is the New Zealand mud snail (*Potamopyrgus antipodarum*). In this species, diploid, sexual males and females coexist with triploid, apomictic, asexual females, sometimes in the same populations, especially in the native area (Lively, 1987). All else being equal, asexual individuals enjoy the benefit of not needing to produce sons: all offspring are daughters, which doubles the reproductive rate (see, e.g., Maynard Smith, 1978). Nonetheless, sexual individuals are maintained in the population. Research has demonstrated that sexual reproduction is more common when the prevalence of a digenetic trematode is high (Lively, 1987, 1992; Jokela and Lively, 1995a,b; King *et al.*, 2009). When infected by this trematode, the snails are sterilized (castrated). Importantly, long-term studies have revealed oscillations in snail genotype frequencies over time (Dybdahl and Lively, 1998); these results have been viewed as supporting the Red Queen hypothesis for the evolution of sex (Bell, 1982; King *et al.*, 2009; Brockhurst *et al.*, 2014).

Two other Caenogastropod genera that have been studied are *Campeloma* and *Melanoides*. Both of these snails, like *Potamopyrgus*, have sexual and asexual morphs, often coexisting within the same 'population.' That is, they exist as three different reproductive 'types' (asexual females, sexual females, and sexual males), where asexual clones arise from sexual individuals. *Campeloma* is an ovoviviparous snail that is a widespread inhabitant of the southeastern USA. The asexual morphs appear to have arisen by hybridization (Johnson and Leefe, 1999). Some research has shown that asexual morphs of this snail occupy a narrower array of habitats than the sexual morphs (Crummett *et al.*, 2013). Studies of *Melanoides tuberculata* (**Figure 2**), which is a widespread invasive species throughout the tropics, have explored the distribution of asexual reproduction in particular environmental conditions (Ben-Ami and Heller, 2007). Interestingly, we do not know how asexual reproduction arises in *Melanoides*, but we do know that it is associated with an increase in ploidy level and that clones include a variable fraction of males and can hybridize to generate new clones (Samadi *et al.*, 1999). In this case, hybrid clones inherited the full maternal chromosome set (hexaploid) and half that of their father, such that hybrids were nonaploid. As such events have been observed at least twice at a small geographic scale (Martinique island, Lesser Antilles), it can be suggested that clones recurrently exchange genetic material leading to an increase in genetic variance and therefore maintaining some evolutionary potential (Facon *et al.*, 2008). The same long-term studies have shown that clones vary in their competitive ability, which might explain their succession in invasive series in the Lesser Antilles (Facon *et al.*, 2008).

Heterobranchia

The Heterobranchia is a diverse group, also containing marine, terrestrial, and freshwater species. There are three 'informal' groups within the Heterobranchia: the lower Heterobranchia, the Opisthobranchs, and the Pulmonata, the latter group has been studied to a much greater extent than the others (e.g., Dayrat *et al.*, 2011). The lower Heterobranchia have not received a great deal of attention.

Opisthobranchia

The Opisthobranchs are a marine group of ~6000 species that are now recognized to be paraphyletic. They are essentially all simultaneous hermaphrodites (Beeman, 1977; Hadfield and Switzer-Dunlap, 1984; Heller, 1993; Wägele *et al.*, 2008; Valdes *et al.*, 2010), where cross-fertilization with elaborate courtship behaviors appears to be the predominant mode of reproduction (e.g., Anthes and Michiels, 2005; Hamel and Mercier, 2006). Opisthobranchs can have very specific courtship behaviors that coordinate reciprocal sperm transfer (i.e., sperm trading; Anthes *et al.*, 2006; Sprenger *et al.*, 2008, 2009). In some species sperm are injected hypodermically (Anthes and Michiels, 2007; Schmitt *et al.*, 2007), an observation that has prompted research into the role of sexual conflict in the correlated evolution of male and female reproductive morphologies and behavior (Anthes *et al.*, 2008). Work on the sea hare *Aplysia californica* (a popular model system in neurobiology), and other species in this genus, has contributed to our understanding of gender-role preferences and size-assortative mating (Pennings, 1991; Yusa, 1996, 2008; Angeloni and Bradbury, 1999; Angeloni *et al.*, 2003; Ludwig and Walsh, 2008). The prospect of future research of the neurobiology of copulatory interactions in this group seems particularly exciting.

Despite the fact that Opisthobranchs are simultaneously hermaphroditic, self-fertilization is rare. Only a few examples are known, for example, in *Alderia willowi* individuals are capable of selfing following hypodermic insemination (Smolensky *et al.*, 2009). Valdes *et al.* (2010) recently reviewed the reproductive anatomy of this group; they have separate reproductive tracts for incoming and outgoing sperm, which is perhaps a mechanism to ensure outcrossing. They also display elaborate courtships and complex reproductive anatomy, which have been understudied.

Pulmonata

The Pulmonates are largely a group of hermaphroditic terrestrial or freshwater snails; the vast majority are simultaneously hermaphroditic (Tompa, 1984; Geraerts and Joosse, 1984; Heller, 1993; Jarne and Stadler, 1995; Mordan and Wade, 2008). There are about 25 000–30 000 species of Pulmonates (Mordan and Wade, 2008), most belonging to the Stylommatophorans (i.e., land snails). Pulmonates in particular have been extensively studied in terms of their mating system (Berry, 1977; Jarne *et al.*, 1993; Jarne and Auld, 2006; Baur, 2007, 2010; Jordaens *et al.*, 2007; Jarne *et al.*, 2010; Escobar *et al.*, 2011) with some species reproducing primarily by self-fertilization and others primarily by outcrossing. Apparently, asexual reproduction has evolved in at least one Pulmonate, the slug *Deroceras laeve* (Nicklas and Hoffmann, 1981; Hoffmann, 1983; Reise, 2007; but see Lebovitz, 1998). Escobar *et al.* (2011) reviewed the available data on inbreeding depression and the rate of self-fertilization in animals; the majority of these data come from Pulmonates (and specifically, the Hygrophila (freshwater snails – formerly the Basommatophorans)). Interestingly, there was approximately as much variation in the selfing rate within Hygrophila as among hermaphroditic animals in general. In general, inbreeding depression is thought to be a major factor operating on the evolution of the selfing rate (Charlesworth and Charlesworth, 1987; Ronfort, 1999; Husband *et al.*, 2008; Charlesworth and Willis, 2009). Numerous studies on Pulmonates have increased our understanding of mating system evolution and how it is affected by inbreeding depression (e.g., Wethington and Dillon, 1997; Jarne *et al.*, 1991, 2000). Polyploidy, which is generally rare in animals compared to plants, has evolved in a few Pulmonate genera (e.g., *Bulinus*, *Succinea*, *Gyraulus*; Wu, 1972; Burch and Jung, 1993; Anisimov *et al.*, 1995; Jarne and Stadler, 1995; Doums *et al.*, 1998b; Jorgensen *et al.*, 2011). The relationship between polyploidy and inbreeding depression is a complicated topic that requires further study.

Pulmonates have a single gonad (the ovotestis) that produces both eggs and sperm. These gametes are produced in different 'islets' (acini) throughout the organ, but stored in distinct places (Jarne *et al.*, 1993, 2010; Baur, 2010). In the Hygrophila, there are separate openings for the male and female reproductive systems, while in the Stylommatophora the male and female reproductive systems share a common opening. Copulation in the Hygrophila is usually unilateral meaning that when individuals copulate, one individual plays the male role (i.e., sperm donor), while the other plays the female role (i.e., sperm recipient; **Figures 3** and **4**). Sex role alternation (i.e., reciprocal gender-role switching) may follow in this situation. Some species are capable of bilateral copulation (i.e., mating partners play both roles at once; Soldatenko and Petrov, 2012; see also Lamy *et al.*, 2012). In some circumstances, female-role *Lymnaea* and *Physa* have been observed to attach themselves to their partner's shell before copulation has finished – thereby they ensure an opportunity to assume the male role and donate sperm once copulation as a female has ended. In the Stylommatophora, for example, in the garden snail *Cornu aspersum* (*Helix*; Adamo and Chase, 1988), bilateral copulation is more common than in the Hygrophila, but unilateral copulation also occurs, depending in part on shell shape (Davison *et al.*, 2005). Sperm are deposited into the reproductive tract of the recipient via a phallus, and may be used to fertilize eggs, stored for later fertilization (Wethington and Dillon, 1991; Beese *et al.*, 2009; Nakadera *et al.*, 2014a), or diverted to the bursa copulatrix for digestion. Sperm received from a partner (i.e., allosperm) are stored in a different location than sperm made by the focal

Figure 3 Copulation in *Physa acuta* (Heterobranchia: Hygrophila). There are four individuals in this picture; the individual on the left is copulating as a female with the individual that is mounted on its shell (the phallus is visible). Individuals can only copulate in a single gender-role with a given partner at the same time, but a single individual can simultaneously be involved in two separate copulations (i.e., with two separate partners) where it can act as both sperm donor and sperm recipient. Photo by Josh Auld.

Figure 4 Copulation in *Lymnaea stagnalis* (Heterobranchia: Hygrophila). The individual on the left is playing the male role (with phallus clearly visible), the individual on the right is playing the female role. Picture provided by Joris M. Koene based on Koene *et al.* (2010).

individual (i.e., autosperm). This provides the opportunity to preferentially use allosperm for cross-fertilization, and still transfer autosperm during copulation. The location of self-fertilization may also differ between the Hygrophila and Stylommatophora: Selfing appears to occur in the ovotestis in Hygrophila, but in a pouch down in the seminal vesicles in Stylommatophorans; more work on this topic is needed. In some Pulmonates, a polymorphism has been observed where some individuals completely lack a phallus (i.e., aphally, **Figure 5**; Jarne *et al.*, 1992; Schrag *et al.*, 1994; Jordaens *et al.*, 2006a). Aphally has evolved once in Hygrophila, and at least 12 times in Stylommatophorans (Schrag and Read, 1996). Aphallic individuals are capable of reproducing through selfing and outcrossing via the female role, but they cannot function as outcrossing males because they cannot transfer sperm to a partner during copulation (Doums *et al.*, 1996a, 1998a, b). Interestingly, the production of a phallus can be affected by environmental stimuli including temperature, linking this phenomenon with environmental sex determination (Schrag and Read, 1992, 1994; Doums *et al.*, 1996b; Ostrowski *et al.*, 2000, 2003). Some Stylommatophorans (e.g., *Cornu aspersum*) possess a calcareous 'love dart' (**Figure 6**) that is used to stab the partner during courtship and copulation (Davison *et al.*, 2005; Baur, 2010), sometimes thousands of times during a single copulation bout (Koene and Chiba, 2006). While it was initially thought that this dart (which is dislodged in some species, but retained in others) was a form of nuptial gift, recent research has suggested that it may be a tool for partner manipulation stemming from sexual conflict (Koene and Schulenburg, 2005). Here it appears that the dart may introduce accessory gland proteins into the sperm recipient that increase paternity of the sperm donor (i.e., the stabbing snail). This apparently has led to counter-adaptations on the female side of the hermaphrodite (e.g., elaborate reproductive tracts, sperm digestion), an example of antagonistic coevolution and sexual conflict (Beese *et al.*, 2009; Nakadera and Koene, 2013). Such dynamics are not limited to Stylommatophorans; in the freshwater snail *Lymnaea stagnalis* accessory gland proteins that manipulate the sperm recipient are transferred in the ejaculate along with the sperm (Nakadera *et al.*, 2014b; van Iersel *et al.*, 2014). Another oddity in Stylommatophorans is the occurrence of giant phallus in some slug species from the *Limax* genus (**Figure 7**). Why an almost one-meter phallus and external copulation based on twisted (double helix) phallus has evolved in species no longer than 15 cm remains mysterious, but certainly has to do with sexual selection.

Because of their elaborate copulatory behaviors, Pulmonates have served as models for studying sex allocation and sexual selection (Schärer, 2009; Anthes *et al.*, 2010). This includes analyses of gender-role preferences, and, for example, how size, age, and previous mating history affect the social interactions leading to copulation (DeWitt, 1996; Wethington and Dillon, 1996; Koene, 2006; Baur, 2007; Minoretti *et al.*, 2011; Nakadera *et al.*, 2015). In some species, the phallus can become lodged within the sperm recipient and it may be

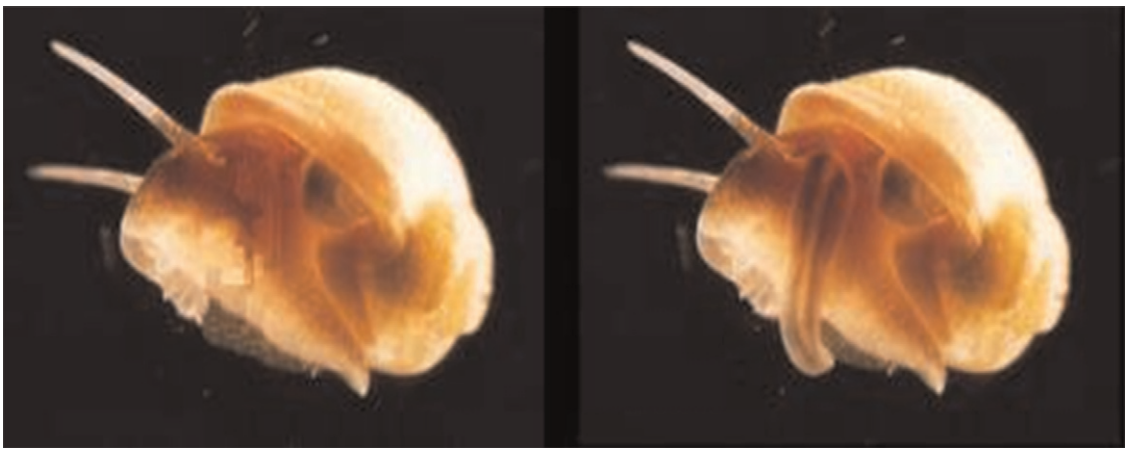

Figure 5 Phally polymorphism in *Bulinus truncatus* (Heterobranchia: Hygrophila). Some individuals have the same reproductive tracts as regular hermaphrodites in Hygrophila (e.g., the individual on the right with an everted phallus). Others are deprived of the male tracts, including the phallus (e.g., the individual on the left). Photo by Philippe Jarne.

chewed off (i.e., apophallation; Leonard *et al.*, 2002; **Figure 8**). Pulmonates have also been recently used as models for understanding sex-specific inbreeding depression and reproductive senescence (Janicke *et al.*, 2013; Auld *et al.*, 2014). Further, despite the fact that the sexes are united in the same body, sexual selection has been shown to operate differently on male and female functions (Charnov, 1979; Pélissié *et al.*, 2012). Evidence that resources may be differentially allocated to one sex function over the other (e.g., De Visser *et al.*, 1994; Koene *et al.*, 2006; Jordaens *et al.*, 2006a,b; Minoretti *et al.*, 2011) has revealed the potential for adaptive plasticity in sex allocation (Charnov, 1996; Schärer, 2009). Collectively this work has shown that while these snails are simultaneously male and female, and the gametes are made within the same organ, expression, and evolution of the two sex functions can occur semiautonomously (Charnov, 1982). This work has significantly advanced research on sexual selection and sexual conflict by clearly illustrating that these phenomena are not restricted to diecious species; male and female reproductive systems can evolve semi-independently within the same body and potentially have reciprocal effects on each other (Anthes *et al.*, 2010; Pélissié *et al.*, 2012).

Conclusions

Due to their plethora of reproductive strategies, snails provide a microcosm within which we can observe a great variety of reproductive strategies at play. They have been and will continue to be an excellent model system to study the evolution of reproductive systems and strategies, including topics such as the evolution of sex-determination mechanisms (Thiriot-Quiévreux, 2003), the evolution of hermaphroditism (Charnov, 1982; Avise, 2011), the evolution of the mating system (Jarne and Charlesworth, 1993; Jarne and Auld, 2006; Jordaens *et al.*, 2007), and the interaction between these factors and other aspects of the life history (Cheptou, 2012; Auld and Rubio de Casas, 2013; McClain *et al.*, 2014). However, we still only know a fraction of what we would like to know. One serious limitation to knowing more about gastropod reproductive systems is that a large fraction of the species, especially marine ones, are very difficult to maintain under laboratory conditions. However, gastropods offer some relevant models, especially among freshwater hermaphrodites, such as *Physa acuta* or *Biomphalaria glabrata*, easy to breed, with decent generation times (6–8 weeks) and improving genomic resources. Note though that, in many cases, a more detailed investigation of the situation in the field is also relevant, especially for model species that are mainly studied in the laboratory.

One very interesting observation to emerge from this review is the apparently independent, repeated evolution of uniparental reproduction in freshwater systems. We have highlighted a variety of instances where asexual parthenogenesis or self-fertilization have evolved in these systems; comparably these mechanisms of uniparental reproduction are not known to occur in the sea. Selfing also occurs widely in terrestrial gastropods. Currently, we do not know the extent to which uniparental reproduction facilitated an invasion into freshwater systems or evolved *de novo* after colonization. If uniparental reproduction in any way enabled the colonization of new habitats (e.g., freshwater systems), it would provide an interesting comparison/example of Baker's law (Pannell *et al.*, 2015). Likewise, the evolutionary persistence of both mechanisms of uniparental reproduction varies within snails. In some species of *Lymnaea* (*Galba*; Correa *et al.*, 2010) selfing has persisted for a very long time (~20 million years) while in others (e.g., *Biomphalaria pfeifferi*), the transition to selfing appears to be rather recent (DeJong *et al.*, 2003). The persistence of selfing in snails appears to be much longer than has

been observed in plants. Similarly, the persistence of parthenogenesis in Thiarids and *Potamopyrgus* appears to vary substantially. Future work that explores the origin and maintenance of these different mechanisms of uniparental reproduction will be very important.

With the advent of better molecular and genomic tools, further analysis of loci affecting sex determination and expression will be extremely useful. Future work that clarifies the phylogenetic relationships among the major gastropod clades will facilitate our understanding of where (and how often) shifts in sexual systems, sex-determination mechanisms (including sex chromosomes), mating systems (e.g., sex ratios, self-fertilization), and other traits have occurred. While molecular phylogenies are available for particular groups (e.g., Cerithioidea within the Caenogastropoda (Strong *et al.*, 2011) and Pulmonata within the Heterobranchia (Dayrat *et al.*, 2011), they are generally lacking – a situation that seriously hinders our ability to understand transitions in reproductive systems (and other traits). Furthermore, continued population genetic data will reveal information on levels of inbreeding including the potential for biparental inbreeding. Lastly, future work that explores the evolution of sex and recombination within a spatially explicit framework, for example, in metapopulation models (Pannell, 2015), will be particularly useful, especially for understating the dynamics of mating-system and life-history evolution.

Acknowledgments

We thank R. Kliman, N. Wedell, W. Bowden-Green, and the Elsevier staff not only for the invitation to write this article, but also for their patience during the process. We also thank R. Collin, P. David, R. Dillon, J. M. Koene, J. Leonard, and N. Wedell for comments that improved the manuscript.

Sex and Selfish Genetic Elements

RL Verspoor and TAR Price, University of Liverpool, Liverpool, UK

Glossary

Androdioecy A situation where individuals are either male or hermaphrodite.
Chromosome A large DNA molecule found within a cell, often carrying large numbers of genes. An organism may contain many different chromosomes.
Dioecy A situation where there are two sexes, and individuals are either male or female.
Diploid When a cell contains two copies of each chromosome. In clonal species, all cells may be diploid, whereas in other organisms there may be a haploid gamete phase, one sex may be haploid, or there may be alternation between haploid and diploid generations.
Endosymbiont An organism that lives within the cells or body of other organisms. These can be obligate endosymbionts, whereby they can only complete their life cycle with the use of their host organism.
Gametes These are reproductive cells which fuse (fertilization) to form a zygote during sexual reproduction. For example, sperm, pollen, and ova are gametes.
Gene A unit of genomic sequence that contains regulatory regions, sequences that are transcribed, and other functional regions.
Gynodioecy A situation where individuals are either female or hermaphrodite.
Haplodiploidy A genetic system whereby diploid individuals develop as females, whereas haploid individuals develop as males.
Haploid When a cell contains only one copy of each chromosome. This can apply to gametes of a diploid species, to a haploid sex, or to species where every individual is haploid.
Hermaphrodite An individual capable of producing both male and female gametes. Hermaphrodites are not necessarily able to self-fertilize.
Intragenomic conflict Conflict which arises within the genome of an organism due to different genetic elements having opposing interests, and being selected to increase their own success despite the costs this causes to other genes in the genome.
Parthenogenesis A form of asexual reproduction. Embryos can develop in the absence of sexual fertilization, with offspring only inheriting DNA from their mother.
Spermatogenesis The process by which functional spermatozoa are generated from reproductive germ cells in males.

Introduction

Sexual reproduction is extremely widespread across eukaryotes. This process, by which genetic material is inherited from generation to generation, involves the production of haploid gametes that subsequently fuse into (predominantly) diploid offspring (Figure 1). This fusion of genes from two parents, alongside recombination that allows genetic exchange between chromosomes, provides the offspring with a novel and diverse genetic assemblage. Within this broad definition of sex, a huge degree of complexity and variety exists, with important implications for biology. For example, many organisms are split into male and female sexes that invest in either many low-cost gametes or fewer expensive gametes respectively (anisogamy), as is the case with sperm and eggs in mammals. Mating systems, which describe how individuals interact with one another sexually, also show a remarkable variety in nature (Emlen and Oring, 1977; Goodwillie *et al.*, 2005). For example, two closely related plant species can have completely different mating systems, where one can self-fertilize while the other requires gametes from two different parents. Mating system diversity ranges far beyond this, including individuals that change sex depending on age or the presence of rivals, parthenogenetic species that require sperm from males of other species to reproduce, and unusual genetic systems such as haplodiploidy (Figure 2). How this diversity has come about, and the impacts it has, is a major focus of biological research. Increasingly, the causes and consequences of mating systems are being found to be intimately related to the existence and proliferation of selfish genetic elements (SGEs) – rogue genes that disobey Mendel's laws of inheritance.

From the process of sex, Mendel established our early understanding of genetic inheritance. He suggested that gametes are generated and recombined in a random manner, resulting in an equal chance for any part of the parental genome to reach the next generation. This 'fair' Mendelian ratio of segregation during the production of gametes ensures that the interests of genes are aligned and all will benefit when the collective (diploid organism) is more successful. However, there has been a growing realization that this cooperative view of the genome is not the whole story. Increasing numbers of cases have been found where genes act selfishly within the genome and it is now recognized that the living world contains a wide range of SGEs, ubiquitous across the tree of life (Burt and Trivers, 2006). The character that unifies these diverse elements is that they all increase their own frequency in subsequent generations to a degree greater than that expected by Mendelian inheritance, without increasing the fitness of the organism that carries them. The methods for achieving this, however, vary widely between different SGEs: from transposable elements (TEs) that can replicate and proliferate within the genome of a cell to killer chromosomes that sabotage the production of gametes that do not carry a copy of themselves

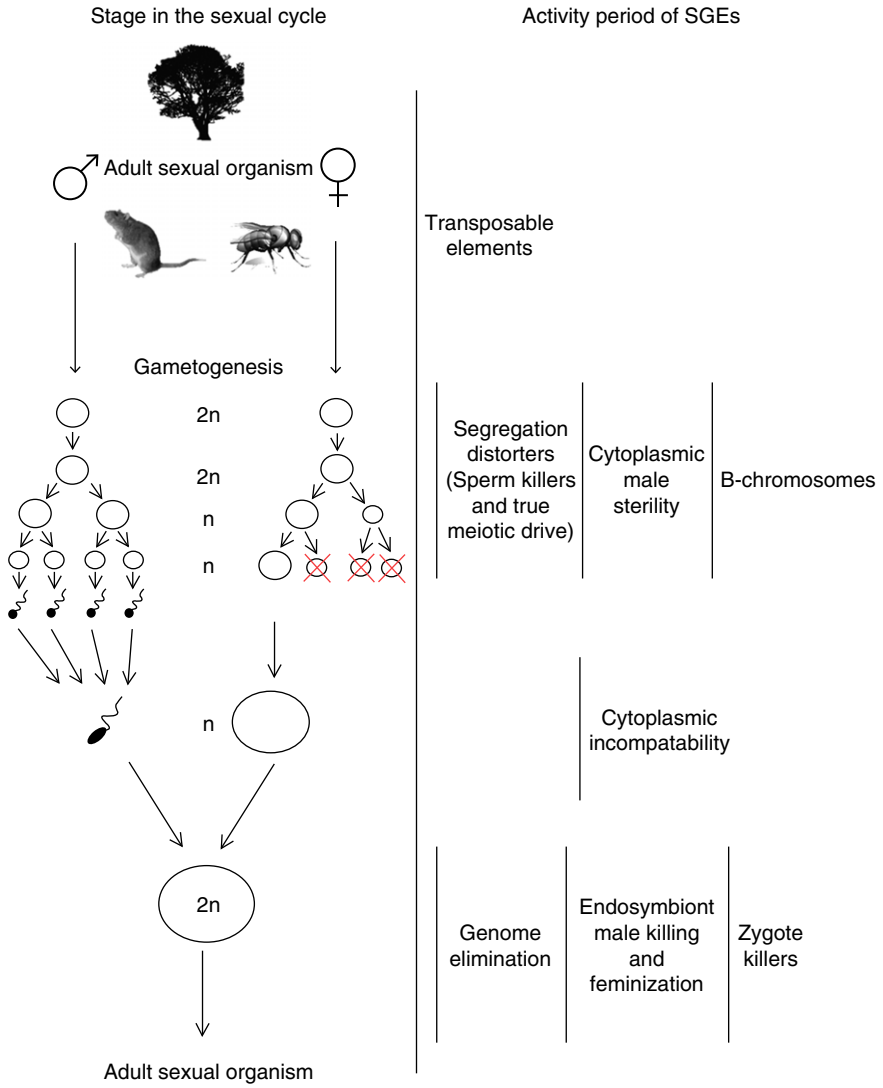

Figure 1 A schematic of the stages of sexual reproduction and the different points at which selfish genetics elements can be active.

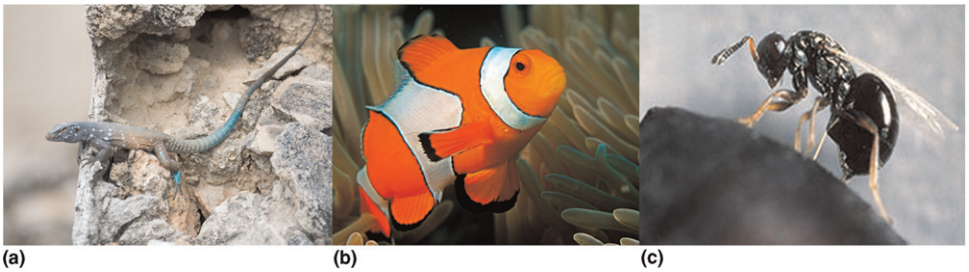

Figure 2 Example of different mechanisms of having sex. (a) Whiptail lizards can have species with two sexes that reproduce sexually, or have a single sex and reproduce parthenogenetically. (b) Clown fish have males that can turn female when the dominant female dies. (c) *Nasonia,* an example of a wasp species that has haplodiploid sex determination. It is this wasp genus that harbors the paternal sex ratio (PSR) system where the paternal genome is eliminated.

(Burt and Trivers, 2006; **Table 1**). In their most extreme form SGEs can result in 50% of the genome being lost. One of the best examples of this is the paternal sex ratio (PSR) system in the wasp genus *Nasonia*. PSR is an extremely small extra chromosome that is not essential for the survival of males and does not appear to increase the fitness of males in any way. Such supernumerary chromosomes are widespread in nature, and referred to as 'B-chromosomes.' However, what is (so far)

Table 1 Some classes of selfish genetic elements and some of their potential interactions with sex. Note that selfish genetic elements (SGEs) are highly variable, and cannot easily be separated into distinct classes. Transposable elements, B-chromosomes, and segregation distorters are all defined here by their genetic basis. In contrast, zygote killers, paternal genome elimination, cytoplasmic incompatibility, and cytoplasmic male sterility are all defined by the impacts they have on their host. This list of SGEs is not exhaustive, and we expect many new kinds of SGE to be discovered in the future

Type	*Description*	*Interaction with sex*
Transposable elements	DNA sequences that are capable of moving their location within an organism's genome. This frequently results in an increase in the copy number within the genome	• Whether an organism is sexual or asexual is expected to alter the evolutionary pressures on TEs • The degree to which organisms self-fertilize is also expected to impact the frequency of transposable elements
Segregation distorters	Elements that are active in increasing their frequency during gametogenesis. These elements distort inheritance at the level of the chromosome. These elements can be active in males or in females, either by killing non-self sperm or biasing the likelihood of their own type being present in mature female gametes	• Sperm-killing segregation distorters could be negatively affected by polyandry and sperm competition. This could select for increased polyandry to avoid the costs of mating to meiotic drive males • The spread of sex-linked drivers can rapidly alter the sex ratio of populations, thereby altering the behavior of each sex • Mating systems that allow segregation distorters to spread may be eliminated by sex chromosome drivers
Cytoplasmic male sterility (CMS)	When male sterility is driven by non-nuclear genes, for example, those contained within mitochondria. These genes are inherited solely through the maternal lineage. These genes gain a transmission advantage despite causing male sterility	• CMS results in shifts between hermaphrodite populations and gynodioecious ones. This may be a stepping stone toward evolving dioecy • Cyclical evolution between organelle CMS genes and nuclear suppressor genes can generate incompatibilities between populations
B-chromosomes	These are extra units of DNA within a cell that are not necessary to survival and replication. These supernumerary chromosomes can build up in cells during meiosis, increasing their own frequency in that lineage, despite often being deleterious to fitness	• High numbers of B-chromosomes can reduce male fertility, potentially creating sperm or pollen limitation in a population. This might also drive the evolution of increased investment in female gametes in hermaphrodites
Paternal genome elimination	This occurs when genetic material inherited from the father is either inactivated or lost after the formation of the zygote. This can result in the males being effectively haploid (parahaplodiploidy) and occurs in species of mites, mealybugs, and beetles. Maternal genome elimination is also possible	• High costs to the eliminated genome are expected to drive the rapid evolution of resistance. This coevolution may alter the genetic sex determination systems of species
Zygote killers	These systems result in a failure of the zygote to develop after fertilization. This is thought to be caused by a toxin–antidote system. The best known example of this is the medea system in flour beetles	• In a brood where many offspring die due to zygote killer incompatibility, the surviving offspring carrying the zygote killer may gain a slight advantage, due to decreased competition with their siblings. This might drive the evolution of increased polyandry
Cytoplasmic incompatibility	These incompatibilities occur when gametes are unable to form a zygote and is driven by intracellular endosymbionts. Sperm of carrier males are only compatible with eggs of infected females, meaning the infection has a transmission advantage	• Some evidence that endosymbiont carrying males have poor sperm competitive ability. Hence females might evolve to remate more often, thereby reducing their exposure to cytoplasmic incompatibility

unique about PSR is that it is transmitted only through males, making daughters a dead end for PSR. It has therefore evolved an extraordinarily damaging method of ensuring it is passed on only to sons. In *Nasonia*, males are haploid, carrying a single copy of each chromosome, while females are diploid, inheriting one copy of each chromosome from each parent. PSR eliminates all paternally derived chromosomes following the fusion of gametes, which means that individuals carrying the B-chromosome always develop into males. This ensures the continued transmission of the PSR B-chromosome, but reduces the fitness of all the other genes carried by the male to zero.

Across these diverse examples, it is the transmission advantage gained to the next generation that is central in defining SGEs. Sex, and all the diversity and variation associated with it, is responsible for how genetic material reaches the next generation. Therefore it follows that SGEs and sex are inextricably linked. This article explores four case studies of how sex and SGEs interact. Using these, we hope to highlight the diversity of interactions that occur across a range of organisms. The time frame in which these processes occur can be extremely wide and the interactions between SGEs and sex can be bidirectional (Figure 3). These emerging fields of research offer many unresolved questions and there remains exciting scope for future discoveries. More broadly, the interactions of SGEs and sex have the potential to inform a wide range of subject areas in evolution and ecology: from behavior and population ecology to genome architecture, speciation, and extinction.

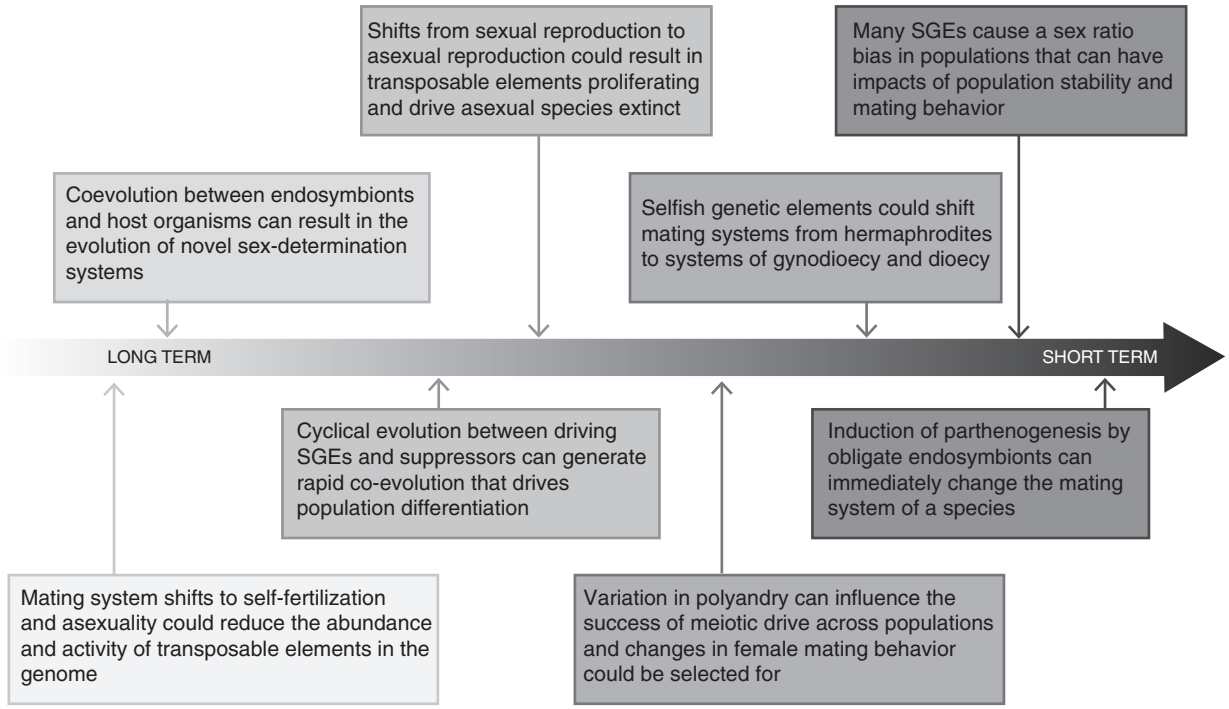

Figure 3 A timeline showing examples of the different interactions and impacts that selfish genetic elements and aspects of sex can have on each other.

Short-Term Impacts of Mating Behavior on SGEs: Sperm-Killing Meiotic Drive and Polyandry

The interaction between female remating behavior (known as 'polyandry') and sperm-killing meiotic drive provides a compelling example of how mating system can impact on an SGE. Sperm-killing meiotic drive occurs when one chromosome selfishly increases its own transmission by eliminating sperm that carry the rival chromosome during spermatogenesis. These drivers can be located on sex chromosomes, which has the added consequence of producing sex-ratio biases in broods (Jaenike, 2001). These systems have evolved repeatedly in a broad range of organisms, with classic examples in mice, mosquitos, *Drosophila*, and stalk-eyed flies (Burt and Trivers, 2006; Jaenike, 2001), with pollen drive being a parallel system in plants (Taylor and Ingvarsson, 2003). Sperm-killing meiotic drive typically results in the carrier producing only half as many sperm as a standard male. Males, however, typically produce vastly more sperm than females produce eggs. As males generally produce such huge numbers of sperm, losing half to the action of a selfish meiotic-drive element may not result in a significant fertility cost when females mate once. This is because a male will typically still be able to transfer sufficient sperm to fertilize all the females' eggs. However, in an estimated 90% of internally fertilizing animal species, females mate with more than one male, allowing sperm from multiple males to compete within females to fertilize her ova (Taylor *et al.*, 2014). In general, males that transfer more sperm to females are more successful in this competition between sperm, and father more offspring (Simmons, 2001). Therefore, if a male loses half of his sperm due to carrying a meiotic drive element, his fitness could be severely impaired if females remate frequently (Haig and Bergstrom, 1995).

Wu (1983a,b) was the first to examine sperm competition in the 'sex-ratio' ('SR') drive system in the fruit fly *Drosophila pseudoobscura*. It was shown that males carrying SR transfer half the number of sperm to female than standard males (Price *et al.*, 2014), and as a result father far fewer offspring than standard males when females mate with multiple males (Wu, 1983a,b). Subsequently, this pattern of meiotic drive males being poor sperm competitors has been found in other *Drosophila* (Angelard *et al.*, 2008; Unckless and Clark, 2014), other fly genera (Wilkinson and Fry, 2001), and mice (Sutter and Lindholm, 2015). Experimental work has also shown that when female remating is artificially suppressed then meiotic drive elements can spread rapidly through laboratory populations (Price *et al.*, 2010). A meiotic drive element at high frequency can also result in biased population sex ratios in nature (Bryant *et al.*, 1982). These changes in population sex ratio could alter per capita birth rate, affecting a population's ability to compete with neighboring populations or other species within the community (Unckless and Clark, 2014). Alternately, extreme sex-ratio biases could destabilize populations, potentially causing population extinctions (Price *et al.*, 2010).

Polyandry is extremely variable in nature, with differences in the level of polyandry between species (Taylor *et al.*, 2014), populations (Pinzone and Dyer, 2013; Price *et al.*, 2014), seasons (Torres-Vila *et al.*, 2005), and even individual females within a population (Price *et al.*, 2011). Recently, studies in two distantly related species of *Drosophila* have shown that patterns of polyandry and the frequency of meiotic drive are

Figure 4 The distribution of X-chromosome meiotic drive (outer circles) and polyandry (inner circles) in populations of two species of fruit fly, *Drosophila neotestacea* (gray circles) and *Drosophila pseudoobscura* (black circles), across North America. In both species, the frequency of meiotic drive decreases to the north, and the frequency of polyandry increases in parallel, suggesting that higher polyandry may reduce the success of the driving X (Pinzone and Dyer, 2013; Price *et al.*, 2014).

linked in populations across North America. Populations of *D. pseudoobscura* and *Drosophila neotestacea* across North America carry sperm-killing X-chromosome drivers, but the driver in each species has evolved independently. Recent work has shown that in both species the frequency of meiotic drive in a population could be predicted by the prevalence of polyandry in that population (Pinzone and Dyer, 2013; Price *et al.*, 2014; **Figure 4**). This strongly suggests that high levels of polyandry results in sperm competition that eliminates the meiotic drive from natural populations. A study of a semi-natural population of house mice in a barn in Switzerland also suggested that polyandry could explain the observed population extinction of the t-haplotype meiotic drive element (Manser *et al.*, 2011). Overall, there is compelling evidence that sperm competition plays a major role in determining the frequency of meiotic drive in males in wild populations.

The influence of mating systems on meiotic drive, however, does not necessarily have to be in a single direction. Currently, the reasons why polyandry varies within and between species are poorly understood (Taylor *et al.*, 2014). Are drivers playing a role in the evolution of mating behavior? A number of SGEs which are costly to females (including meiotic drive), also reduce the sperm competitive ability of males (Price and Wedell, 2008). As a result, increased polyandry may allow females to reduce the costs of mating with SGE-carrying males. In populations of *D. pseudoobscura* kept in the laboratory, females rapidly evolved increased polyandry in populations where they were at risk of mating with meiotic drive-bearing males (Price *et al.*, 2008). The question remains, however: can polyandry evolve as a response to the presence of an SGE in nature?

More broadly, the interaction between polyandry and meiotic drive could play a role in population stability and extinction. In the laboratory, sex-linked meiotic drive is observed to rapidly drive populations extinct through the extreme sex-ratio bias it creates (Price *et al.*, 2010), if females are forced to mate only once. The likelihood of observing localized population extinction events caused by sex-linked meiotic drive in the wild is probably low. Despite this, there is some evidence of a sex-linked meiotic driver causing a population collapse in *D. neotestacea*, in a population with little polyandry (Pinzone and Dyer, 2013). If novel sex chromosome meiotic drivers regularly evolve, then there is a risk that these could spread to a high enough frequency to drive the species extinct (Carvahlo and Vas, 1999). Recently, an X-chromosome drive system in *Drosophila simulans* originating in Southeast Africa has spread across the continent and into Europe and Asia, rapidly creating female-biased population sex ratios (Bastide *et al.*, 2011). In this case, within a few years a genetic resistance allele that prevents the killing of Y-bearing sperm also spread from the same origin, returning sex ratios to approximately equal numbers of males and females throughout Africa (Bastide *et al.*, 2013). In polyandrous species, pre-existing genetic variation in predisposition to polyandry (Price *et al.*, 2011) might allow species to rapidly evolve higher levels of polyandry in the presence of costly sex ratio distorting drive. However, in species where females remate extremely rarely or not at all (monandry), there may be little or no ability to evolve increased polyandry, potentially increasing their vulnerability to extinction by sex-ratio drive. Hence the prevalence of polyandry as a mating system might not simply be due to increased fitness of polyandrous females, but might also be influenced by selection at the population or species level (Price *et al.*, 2010). Are monandrous species more likely to go extinct than polyandrous ones, if novel sex chromosome drivers regularly evolve and spread through the species unchecked by polyandry?

Summary

Males carrying sperm-killing meiotic drivers typically have low success when females remate, because they produce fewer sperm than standard males. As a result, in populations where

Figure 5 (a) A bdelloid rotifer feeding through algae. These anciently asexual organisms harbor extremely low numbers of retrotransposons in their genome. (b) The maize genome is composed of 85% transposable element (TE)-derived genetic material. Maize is also the organism where TEs were first characterized by Prof. Barbara McClintock in the 1950s.

females mate with many males, meiotic drive is rare or absent, showing that mating system can determine the prevalence of an SGE. Monandrous species might be particularly vulnerable to extinction caused by the spread of a sex chromosome meiotic driver, potentially creating species-level selection for polyandry. However, the SGE can also impact on the evolution of mating systems – meiotic drive can cause the evolution of increased polyandry, because polyandrous females avoid many of the costs of mating with drive-bearing males.

Long-Term Impacts of Mating Systems on SGEs: Transposable Elements, Sex, and Mating Systems

TEs have been described as the most abundant genes in nature (Aziz *et al.*, 2010). They are self-replicating units that can copy themselves into other locations in the genome. As a result, they can proliferate within the genome of an individual, with TE-derived material comprising 10–90% of the genome in various species. The maize genome, for example, contains approximately 85% TE-derived material (Schnable *et al.*, 2009; **Figure 5**), while our own genome is around 50% TEs (Human Genome Consortium 2001). Meanwhile, in bdelloid rotifers many retrotransposon TEs appear to be completely absent from their genomes (Arkhipova and Meselson, 2000; **Figure 5**). Despite this abundance, harboring TEs is usually harmful (Pasyukova *et al.*, 2004), and they are implicated in human diseases, including cancer and hemophilia (Burt and Trivers, 2006; Callinan and Batzer, 2006; Hancks and Kazazian, 2012). Nevertheless, variation generated by TEs can sometimes be adaptive (Kidwell and Lisch, 1997). For example, some TEs have been implicated in telomere repair in *Drosophila* (Biessmann *et al.*, 1992). Given the huge range of TEs that exist, and the importance of their activity, understanding the general forces that influence their abundance and distributions remains a central goal in evolutionary genetics. One factor that can have a large impact on the TE dynamics in a population is the mating system of an organism (Arkhipova and Meselson, 2005; Charlesworth and Wright, 2001; Wright and Finnegan, 2001).

Both the presence of sexual versus asexual reproduction, as well as the mating systems of sexual organisms, vary enormously across eukaryotes. A species may be an obligate sexual (e.g., Humans and *Drosophila*), cyclically sexual and asexual (e.g., yeast and daphnia), or purely asexual (e.g., bdelloid rotifers). These differences in the presence and frequency of sex will impact on TE dynamics (Arkhipova and Meselson, 2005; Dolgin and Charlesworth, 2006; Wright and Finnegan, 2001). In one respect, sex allows the movement of TEs between genetic lineages. In disease, increased transmission rates tend to select for higher virulence, whereas diseases that tend to persist long term in a single host are selected for lower harm and lower virulence. Similarly, higher transmission between lineages via sex is likely to select for higher rates of transposition by TEs (Charlesworth and Langley, 1986). This suggests that asexual lineages might harbor lower numbers of TEs with lower transposition rates (Charlesworth and Langley, 1986). However, sexual lineages are also predicted to have a greater capacity for removing harmful TEs from the population via purifying selection, while the absence of sex in obligate asexual species could allow the rapid proliferation of TEs (Arkhipova and Meselson, 2005; Dolgin and Charlesworth, 2006). This potential proliferation of harmful TEs in asexual lineages, and inability to remove them via recombination, could lead to such high costs that it results in population extinction (Arkhipova and Meselson, 2005; Dolgin and Charlesworth, 2006).

In sexual species, how sex occurs is also likely to impact on the success of TEs in the genome. Sexual mating systems vary in how gametes are mixed, with some species requiring gametes of two different parents (obligate outcrossing), while others can combine gametes from the same parent (self-fertilization) (Charlesworth, 2006). Shifts between these systems have evolved repeatedly, and are expected to have important effects on the dynamics of TEs within a species (Charlesworth and Wright, 2001). For example, recessive costs of TE insertions might be more frequently exposed in self-fertilizing species due to increased homozygosity. Hence, these TEs may be purged by selection more effectively from a self-fertilizing population (Byers and Waller, 1999). The spread of TEs may also be inhibited by a lack of outcrossing, and may rapidly be lost in species with high levels of self-fertilization (Morgan, 2001; Le Rouzic and Capy, 2005; Boutin *et al.*, 2012). On the other hand, increased self-fertilization will have the effect of reducing the effective population size of a group, thereby increasing the effect of genetic drift (the stochastic fluctuation in allelic frequency due to random sampling across generations) (Charlesworth, 2006; Wright *et al.*, 2008). This reduced effective population size of self-fertilizing populations could also result in selection being less effective at removing TEs (Charlesworth and Wright, 2001; Tenaillon *et al.*, 2010). Following this argument, TE numbers might be more stochastic

immediately following the evolution of self-fertilization, while over longer time periods outbreeding populations will harbor lower numbers of TEs. Therefore, although differences between sexual and asexual species and variation in mating systems within sexual species will influence TE dynamics, there are competing theories about the direction of these effects.

The effects of asexuality on the dynamics of transposable elements have been examined in a number of model organisms. A study that introduced a TE into sexual and asexual lineages of yeast found the spread was faster and more consistent in sexual lineages, supporting the theory that sex facilitates the spread of TEs (Zeyl *et al.*, 1996). Asexual strains of the water flea, *Daphnia pulex* also carried lower numbers of TEs than cyclically sexual types (Schaack *et al.*, 2010). In contrast, an exciting study in the wasp *Leptopilina clavipes*, where infection by an endosymbiont *Wolbachia* induces parthenogenesis, found evidence of TE proliferation in the asexual types consistent with the initial spread of TEs following a shift to asexuality (Kraaijeveld *et al.*, 2012). Interestingly, this proliferation was specific to certain families of TEs. Meanwhile, a recent comparative study of the evening primrose *Oenothera* failed to find evidence for a reduction in TE abundance linked to functional asexuality (Agren *et al.*, 2014a,b). Studies focussing on how differences in outbreeding or self-fertilizing affect TE dynamics have also shown mixed results. While some studies show increased TE copy number in outbreeding species (Hu *et al.*, 2011; Morgan, 2001), others have shown either little effect or the opposite results (Dolgin *et al.*, 2008; Tam *et al.*, 2007). Across three genomes in the genus *Capsella*, the older self-fertilizing species *Capsella orientalis* (self-compatible) did show lower numbers of TEs, while the two more recent sister species *Capsella rubella* (self-compatible) and *Capsella grandiflora* (outcrossing) showed little difference in TE abundance, possibly indicating that the age of mating systems shifts is important (Agren *et al.*, 2014a,b). Overall, the relative importance of outcrossing facilitating the spread of TEs and reduced efficacy of selection allowing them to accumulate in self-fertilizing lineages remains unclear.

Sex and mating systems clearly play a role in facilitating the spread of TEs in a number of instances, but there remain exceptions. Some of these differences may be explained by the fact that these studies observe only a snapshot of the genome in time, which may be at different stages following a mating system shift. Short-term dynamics of TEs may be more stochastic, and the forces governing TE dynamics could change over time (Dolgin and Charlesworth, 2006; Boutin *et al.*, 2012; Agren *et al.*, 2014a,b). Refining the phylogenies, and better determining the evolutionary timings of mating system shifts, as well as increasing the number of study systems, will be vital to gain a broader understanding. Population parameters are also likely to be important in influencing the level of variation and the importance of genetic drift (Dolgin and Charlesworth, 2006; Tenaillon *et al.*, 2010). A number of studies reported differences between classes of transposable elements, making it likely the genomic ecology and behavior of different TEs a crucial factor. Nonetheless, how TE dynamics interact with mating systems is important to consider when approaching broader questions. What role does TE proliferation and the distribution of mating systems across species play in explaining variation in genome size (Whitney *et al.*, 2010; Agren *et al.*, 2014,a,b)? How do TE dynamics and mating system shifts contribute to differences in gene expression between related species (Hollister *et al.*, 2011)? If mating system shifts consistently change the short- or long-term genomic burden of TEs in a species, how could this impact on speciation and extinction rates (Ågren, 2013; Arkhipova and Meselson, 2005; Oliver and Greene, 2009)?

Summary

Despite their deleterious fitness effects, TEs constitute a huge proportion of the genome for many species and their numbers are highly variable between species. Models suggest that mating systems shifts have major impacts on TE dynamics, with a number of models supporting the loss of TEs in asexual or highly selfing species. A number of empirical studies have found that self-fertilizing or asexual species harbor lower number of TEs. This interaction between mating system and TE dynamics may have an impact on genome size, gene expression, mutation rate, and speciation.

Long-Term Impacts of SGEs on Mating Systems: The Case of Cytoplasmic Male Sterility

Conflict within the genome fundamentally arises when a genetic element can increase its own transmission without benefitting the rest of the genome. When genes carried by an individual have different patterns of inheritance, this can create conflicts of interest, potentially resulting in selfish behavior. A classic example of this is uniparental inheritance of organelles. Eukaryote genomes include nuclear genes, arranged on one or more chromosomes contained within the nucleus, and genes contained within other organelles (additional membrane bound cell structures other than the nucleus). Although not all organelles contain DNA, some vitally important ones such as mitochondria and plastids do. These DNA carrying organelles are typically inherited through the maternal line, and almost never from the father, which means the DNA in these organelles are not passed on through male gametes such as sperm or pollen. These organelles therefore gain no fitness by being carried by a male. Instead, these organelles increase their representation in the next generation by maximizing the number of daughters they produce. As nuclear genes are passed on through both male and female gametes, nuclear genes have a clear evolutionary interest in producing sons. This imbalance, with sons having high value for nuclear genes, but no value for organelle genes, creates a perfect scenario for intragenomic conflict and the evolution of selfish genes.

Mitochondria are found in all eukaryotes, and are essential for a range of key metabolic processes. In particular, the synthesis of adenosine triphosphate (ATP), the main molecule responsible for intracellular energy transport, is dependent on genes found only in the mitochondria. By interfering with these vital pathways, mitochondrial genes might be able to increase the proportion of offspring produced that are female, or increase the success of daughters, at a cost to the individual's ability to produce sons. In cytoplasmic male sterility

(CMS), this is exactly what happens. CMS occurs when a normally hermaphroditic plant has its ability to produce pollen drastically curtailed by the selfish action of the mitochondria it carries. In many cases, CMS eliminates all pollen production in individuals carrying CMS causing mitochondria. In these species, populations consist of hermaphrodites with non-selfish mitochondria, and females carrying CMS mitochondria, fundamentally altering the mating system in that population.

CMS is found in a very wide variety of plant species. However, the molecular mechanisms by which CMS occurs is poorly understood for most species, with only a few model systems having been well characterized (McCauley and Olson, 2008). The elimination of pollen production occurs in very distinct ways in different species, including CMS strains that convert pollen producing stamens directly into seed producing carpels, thereby clearly increasing seed production and increasing the transmission of the CMS mitochondria (Chase, 2007). However, in some CMS strains stamens are converted to petals, or pollen is produced but degrades as it matures. In these cases it is not really clear how this damage to pollen actually increases seed production or benefits the CMS mitochondria.

The costs of CMS to nuclear genes often drives the evolution of suppressors of CMS in the nuclear genome. As a result, CMS is often cryptic, and only revealed when distantly related individuals crossbreed (Budar *et al.*, 2003). This coevolution of CMS and suppressors can occur rapidly and independently, even in nearby subpopulations. Hence, CMS and suppressors can create enormous variation in mating system in different populations and over time (Bailey and Delph, 2007). There is substantial evidence that this conflict may also help produce reproductive incompatibilities between populations, and hence drive speciation (Ågren, 2013). Moreover, as suppressors seem to be effective only against one CMS type and populations can harbor several different strains of CMS, there is the potential for cycles of different CMS strains to become locally abundant, and then be suppressed by the increase in frequency of a specific nuclear suppression allele (Taylor *et al.*, 2001). Hence, it is possible that mating systems in many species may be determined by stochastic factors involving which CMS strains and suppressors happen to have been present in the founders of the population (Nilsson and Ågren, 2006).

However, CMS is also implicated in longer term changes in mating system. Gynodioecy, a mating system in which females and hermaphrodites coexist, is found in 5–10% of angiosperm plants (Renner and Ricklefs, 1995). In some cases this is likely to be driven by a balance between CMS and suppressors. However, in other cases, gynodioecy appears to be controlled by nuclear genes, with no mitochondrial involvement (Dufay and Billard, 2012). It is likely that CMS drives the initial evolution of gynodioecy in most cases, but then details of the ecology of the population can either select strongly for suppressors and a return to pure hermaphroditism, or can stabilize gynodioecy. The benefits of gynodioecy, accrued by nuclear genes as well as mitochondria, are likely to involve removing the risk of self-fertilization. CMS has not only driven a change in mating system in many species from all hermaphroditic to gynodioecy, it is also thought to be a major step in the evolutionary transition from hermaphroditic to dioecious (Touzet, 2012). However, it is still not clear how a gynodioecious species would then transition to full dioecy (Spigler and Ashman, 2012). Nevertheless, transitions from hermaphroditism to gynodioecy, and then to dioecy, are tentatively supported by the available phylogenetic data (Spigler and Ashman, 2012).

An enduring mystery of CMS is why mitochondrial elimination of male gametes in hermaphrodites seems so rare in animals. A reduction in sperm should benefit mitochondria in hermaphroditic animals if this results in a reallocation of resources and the production of increased numbers of eggs. Around 5% of animal species are hermaphroditic, so there is ample opportunity for CMS to have evolved in animals (Jarne and Auld, 2006). In contrast to this expectation, hermaphroditic animals are actually far more likely to evolve androdioecy, a mating system in which individuals are either hermaphrodite or male. The transition from hermaphroditism to androdioecy is ten times as common as the transition to gynodioecy (Weeks, 2012), with only nine gynodioecious animal species recorded, including corals, sponges, two worms, and a hagfish. The reasons why animal mitochondria seem to be unable to create gynodioecy are unclear. Most reviews suggest that the genomes of animal mitochondria are too small to evolve CMS. However, although plant mitochondrial genomes can be several megabases, compared to 16 kilobases in most animals (Touzet and Delph, 2009), and have more complex genomes with potential for recombination (McCauley and Olson, 2008), the number of proteins, rRNAs, and RNAs produced by the mitochondria are similar between plants and animals (Chase, 2007). Moreover, transmission manipulation by selfish mitochondria has been found to

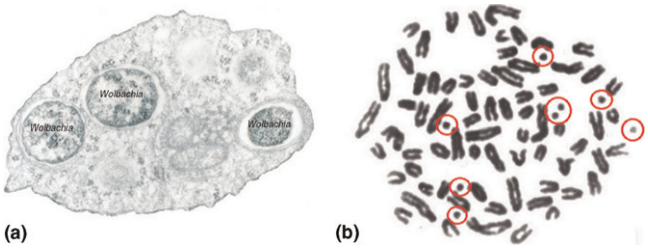

Figure 6 (a) An example of a moth cell that contains a number of bacterial cells within it from the obligate endosymbiont *Wolbachia*. (b) An image showing the karyotype (chromosome compliment) of a Siberian roe deer. Multiple supernumerary B-chromosomes carried by this individual are circled in red.

be widespread in natural populations of a roundworm (Clark *et al.*, 2012). The reasons why gynodioecy is so uncommon in animals therefore remain mysterious.

Summary

The transmission of organelle DNA only through females creates a conflict of interest between organelle and nuclear DNA, resulting in mitochondria that eliminate male gametes. These are very common in plants, and can create a mating system where individuals are either female or hermaphroditic. Rapid evolution, chance, and local ecology can cause this conflict to create differences in mating systems between subpopulations, and changes in the mating system of a single population over time. In the long term, this conflict can play a major role in shifting a species mating system from one where all individuals are hermaphrodites, to one where there are males and females.

Short-Term Impacts of SGEs on Mating Systems: Endosymbiont Manipulation

Many organisms carry intracellular endosymbionts, such as *Wolbachia*, *Cardinium*, *Rickettsia*, and *Spiroplasma* (**Figure 6**). These are microorganisms that infest cells of the host organism, and are extremely widespread and in some clades can be extremely common. They are typically inherited in the same manner as mitochondria, and have the same conflict of interest with nuclear genes, benefiting from transmission through female gametes, but gaining nothing from sons. As a result, they have evolved a wide variety of mechanisms for increasing their transmission through female gametes (Werren *et al.*, 2008). However, endosymbionts can also be beneficial to the host, with some endosymbionts providing protection for their hosts from attack by parasitoids (Jaenike *et al.*, 2010) or viruses (Hedges *et al.*, 2008). Despite the benefits of endosymbiont infection in some cases, in many or most species endosymbionts reduce the fitness of the rest of the genome. In many cases, this occurs because the endosymbiont manipulates the host to ensure it is transmitted through more female gametes. The form of this reproductive manipulation is heavily dependent on the details of the mating system of the species. However, endosymbiont infection can also transform the mating system of the host.

In many organisms, infection by endosymbionts can feminize the host individual, converting genetic males into functional females. As a result, the endosymbiont is passed on through female gametes in an individual that would usually produce endosymbiont-free sperm. However, similar to the X-chromosome meiotic drive case, feminization is likely to cause a heavily female-biased population sex ratio, and nuclear genes will lose fitness by not being expressed in males. Endosymbionts may also kill males in which they occur, if this results in the concentration of resources on their sisters and improves their fitness. In the butterfly *Hypolimnas bolina* in Polynesia, male killing endosymbionts created populations where females outnumbered males (100:1) for decades. Recently a nuclear suppressor of the male killing mechanism spread through Polynesia, rapidly returning sex ratios to a 1:1 ratio (Charlat *et al.*, 2007a; Hornett *et al.*, 2014). Although in continental Asia, males of this species compete with one another for access to females, and females mate with only their preferred males, the male killer completely altered the mating system in Polynesia, with males unable to mate with all the females they encountered and evolving to be extremely choosy, while females evolved to compete with one another for access to males (Charlat *et al.*, 2007b). Hence endosymbionts can rapidly distort sex ratios and modify mating systems, but the rapid evolution of suppression or removal of the endosymbionts may make this transitory, at least in some species.

Summary

Endosymbionts, parasitic bacteria living in the cells of their hosts, are typically passed on only through female gametes, creating a potential conflict of interest with the nuclear genome. As a result, endosymbionts have evolved a wide range of mechanisms for manipulating reproduction that reduce investment in sons and male gametes, and increase it in daughters and female gametes, an evidence that this can rapidly drive changes in sex ratio and mating system.

Final Thoughts

These four case studies demonstrate that the mating system of the host organism plays a key role in determining the arena in which SGEs operate, and so greatly influences their evolution. Moreover, SGEs can themselves alter the mating system of their host, through mechanisms such as changing sex ratios and sex determinations systems, altering the costs and benefits of multiple mating, and eliminating populations, species, or lineages that display mating systems that make them vulnerable to the spread of SGEs.

Beyond those already mentioned in this article, there exists an enormous range of known SGEs that manipulate reproduction (Burt and Trivers, 2006). SGEs have the potential to evolve whenever there is a conflict of interest over transmission of the DNA carried by an organism, making it likely that SGEs occur in all sexual organisms, and potentially all life. The vast majority of organisms have never been examined for the presence of SGEs, and many types of SGE are hard to detect, requiring multigenerational examinations of transmission and fitness. Hence it is likely that an enormous array of novel SGEs await discovery. Recent discoveries of selfish mitochondria (Clark *et al.*, 2012), sperm-based zygote killers (Seidel *et al.*, 2008) in model nematodes, and a novel form of meiotic drive in human oogenesis (Ottolini *et al.*, 2015) also support the idea that many novel types of SGE have not even been thought of, let alone searched for. As a result, it is likely that the interrelationship of mating system and SGE evolution, action, and prevalence, may be even more closely linked than currently known.

Acknowledgments

We would like to thank Arvid Agren for discussion on transposable elements and the evolution of mating systems.

Sex Chromosome Evolution: Birth, Maturation, Decay, and Rebirth

MA Schenkel and LW Beukeboom, University of Groningen, Groningen, The Netherlands

Glossary

Androdioecy Reproductive system in which individuals are either male or hermaphroditic.
Dioecy Reproductive system in which individuals are either male or female.
Gynodioecy Reproductive system in which individuals are either female or hermaphroditic.
Heterogamety Production of gametes with different sex chromosomes (e.g., X- and Y-carrying sperm in humans).
Homogamety Production of gametes with similar sex chromosomes (e.g., X-carrying egg cells in humans).
Recombination Exchange of genetic content between chromosomes during mitosis or meiosis.
Sex chromosomes The chromosome pair on which the master sex determination gene is located, leading to these chromosomes being transmitted differently through both sexes.
Sex determination Process directing development into a sexually functional individual.
Sexual conflict Differences between sexes in optimal fitness strategies.
Sexually antagonistic genes Genes that are under different selective forces between males and females.

Introduction

Eukaryotic genomes typically consist of several chromosomes that contain an individual's genetic information. Sex chromosomes carry the master sex-determining genes, causing them to be transmitted differently through the sexes. Consequently, they are subject to different selection forces compared to their autosomal counterparts (see **Table 1**) and follow an evolutionary trajectory that deviates from the rest of the genome (Rice, 1988). It is generally accepted that sex chromosomes originate from autosomes by acquiring a sex determination function.

In diploid heterogametic systems, which are found in most animals and some plants, one sex chromosome, referred to as the major sex chromosome, is transmitted through both sexes. The other sex chromosome, referred to as the minor sex chromosome in the heterogametic sex, is sex-limited in its inheritance. For example, in humans the X chromosome is transmitted through both sexes, whereas the Y chromosome is limited to males. Over time, the minor sex chromosome reverses to a mostly haploid and clonal lifestyle and adapts to its sex-limited role (Rice, 1988; Bachtrog, 2013). However, the lack of recombination leads to the degeneration of the chromosome, as mutations accumulate and genes are lost. In humans, the Y chromosome is much smaller than the X chromosome, and carries only few functional genes. Due to their specific genomic niche and inheritance pattern, sex chromosomes can play important roles in processes such as speciation, sexual selection, and genomic conflict (e.g., Werren and Beukeboom, 1998; Kirkpatrick and Hall, 2004; Presgraves, 2008; Demuth *et al.*, 2014).

Sex chromosomes are found in a wide variety of organisms, ranging from fungi to plants and animals. They are associated with diverse sex determination mechanisms, though several sex determination mechanisms without sex chromosomes also exist (reviewed in Beukeboom and Perrin, 2014; Bachtrog *et al.*, 2014). Systems with sex chromosomes can be classified in three distinct groups. First, in XY systems, which are found

Table 1 Features of sex chromosomes in comparison to autosomes. Sex chromosomes are responsible for sex determination in the haploid (U and V) or diploid (W, X, Y, and Z) phase of the life cycle and are transmitted through one or both the sexes. Recombination between different types of sex chromosomes is suppressed. Sex chromosomes have different effective population sizes compared to autosomes

	Y/W	*Z/X*	*U*	*V*	*Autosome*
Phase in life cycle in which sex is determined	diploid	diploid	haploid	haploid	not applicable
Sex-specific inheritance	yes, Y through males, W through females	no, but X twice as often through females, Z twice as often through males	yes, through female gametophyte	yes, through male gametophyte	No
Recombination	suppressed	unsuppressed in the homogametic sex, suppressed in the heterogametic sex	suppressed	suppressed	yes
Effective population size	1/4	3/4	1/2	1/2	1

 doi:10.1016/B978-0-12-800049-6.00147-5

in most mammals and insects, sex is determined in the diploid phase of the life cycle. In these systems, males are the heterogametic sex. Second, ZW systems are similar to XY systems, but instead the female is the heterogametic sex. Organismal groups in which ZW systems are found include birds, butterflies, and moths. Third, in UV systems sex is determined in the haploid phase of the life cycle, with the U chromosome in females and the V chromosome in males. UV systems are found in, for example, fungi, algae, and mosses. Some organismal groups, such as fish and amphibians, are rather diverse when it comes to sex chromosome systems. In such groups, some species have XY systems, whereas others have a ZW system. In some cases, the Y or W chromosome is absent. Such systems are referred to as XO and ZO, meaning that the heterogametic sex produces one type of gamete with and one type of gamete without the major sex chromosome. XO systems are frequently found in insects such as beetles and grasshoppers; ZO systems are less common. Finally, systems with multiple sex chromosomes are also known, but these are rare.

The division in homo- and heterogametic sexes stems from the fact that one sex carries two identical (homomorphic) sex chromosomes that are inherited equally to sons and daughters, whereas the other sex carries one sex chromosome that inherits to sons and one that inherits to daughters only. In male heterogametic systems, the male has one X and one Y chromosome, and the female two X chromosomes; the Y chromosome is male-determining. In female heterogametic systems, the female carries one Z and one W chromosome, and the male two Z chromosomes; the W chromosome is female-determining. As the sex-limited chromosomes are often different in size and genetic composition (heteromorphic), this is called the heterogametic sex.

Acquisition of a Sex-Determining Function

Several phases can be distinguished in the evolution of sex chromosomes. Sex chromosomes are formed when an autosome gains a sex-determining function (Charlesworth *et al.*, 2005; Pease and Hahn, 2012, but see Carvalho *et al.*, 2009), typically by acquiring genes causing carriers to develop into a specific sex. This can happen through translocation of existing sex determination (SD) genes from other chromosomes, fusion of an autosome with an existing sex chromosome, or through de novo origin of an SD gene, such as the mammalian *SRY* (*sex-determining region Y*) gene which came into being by mutation of the *Sox3* gene in the ancestor of therians some 150 million years ago. Chromosomes that have recently gained a sex-determining function are referred to as proto-sex chromosomes or neo-sex chromosomes.

Hermaphrodites may give rise to separate sexes, thereby producing proto-sex chromosomes (Charlesworth and Charlesworth, 1978; Charlesworth, 2013). In this scenario, a loss-of-function or sterility mutation may cause hermaphroditic individuals to develop into one sex; a subsequent mutation in the remaining hermaphrodites may then cause offspring to develop into the other sex. Such mutation may first lead to development of females (gynodioecy) or males (androdioecy) depending on which sexual traits are affected by these loss-of-function mutations, before complete dioecy is established (see Charlesworth and Charlesworth, 1978; Charlesworth, 2013 for further details).

Sex chromosomes may support different forms of sex determination. One possibility is that they carry a dominant gene for maleness (Y) or femaleness (W), such as the mammalian *SRY* (Berta *et al.*, 1990), *DMY* in fish (Matsuda *et al.*, 2002), or M-factors in houseflies (reviewed in Dübendorfer *et al.*, 2002). Another possibility is that sex chromosomes are being counted, one sex having two copies and the other only one (X or Z). This is, for example, the case in *Drosophila* (reviewed in Cline, 1993; see also Ericksson and Quintero, 2007), and may be rather common given the frequency of XO and ZO systems in nature.

Though the associated genetic mechanisms of sex determination and the selective forces driving their evolution may differ substantially between species, clear similarities can be distinguished in the evolution of proto-sex chromosomes (reviewed in Bachtrog *et al.*, 2014). After they have been formed, proto-sex chromosomes may undergo rapid evolution as a result of their different transmission through the sexes (Rice and Holland, 1997; Charlesworth, 2013), with the minor sex chromosome becoming haploid and restricted to one sex.

Sexual Conflict and Sex Chromosomes

Males and females often experience different selective pressures. Because sex chromosomes are transmitted differently through the sexes, they are a potential hotspot for genes that are under different selective forces in males and females (Rice, 1984). A locus that is selected differently depending on its genetic background experiences genetic conflict (Rice, 1987a; Werren and Beukeboom, 1998; Stewart *et al.*, 2010). Selection on autosomes will be toward optima intermediate to those experienced by both sexes, whereas for sex-linked genes selection will lead to the optimum experienced by the sex to which these genes are linked. Rice (1984, 1994, 1998) showed that exclusive transmission of a chromosome through one sex can lead to accumulation of alleles on that chromosome that are beneficial for that sex but detrimental for the other sex. Such genes that experience differences in selection sign or strength between sexes are referred to as sexually antagonistic (SA) genes. When linked to an SD gene, SA allele frequencies may shift between the sexes, allowing for the resolution of genetic conflict (Rice, 1987a). However, resolving genetic conflict between the sexes may not necessarily require translocation to the sex chromosomes. Gene expression may already be dependent on sex (Stewart *et al.*, 2010), allowing for divergence of gene expression and conflict resolution. The association between SD and SA genes may be explained by an SD gene evolving near SA genes, which may be favorable to the spread of the new proto-sex chromosome (Van Doorn and Kirkpatrick, 2010). However, enrichment in SA genes on sex chromosomes relative to autosomes suggests that these genes were translocated from other genomic regions to the sex chromosome (Mank, 2012).

Though genetic conflict theory predicts that the X and Y chromosomes become enriched for female- and male-beneficial genes respectively, this need not necessarily be true. A male-beneficial gene may spread when X-linked provided that it is at least partially recessive (Rice, 1988; Graves, 2006). In males, such a gene may easily have its beneficial effect as it is

hemizygous, whereas in females the deleterious effects may be sheltered by dominant alleles. Similarly, the X chromosome may be enriched for female-beneficial genes, though these are only expected to spread easily when sufficiently dominant (reviewed in Ellegren and Parsch, 2007).

Suppression of Recombination

Why Does Suppression of Recombination Occur?

The suppression of recombination along the minor sex chromosome is a key step in sex chromosome evolution. It prevents gene flow between the sex chromosomes and leads to the non-recombining region becoming sex-limited and thus effectively haploid (Charlesworth, 1978). This causes progressive divergence between the sex chromosomes and leads to the degeneration of the minor sex chromosome (see also below).

Late-stage minor sex chromosomes typically no longer recombine along the majority of its length, except for in a small terminal region known as the pseudoautosomal region (PAR, reviewed in Otto *et al.*, 2011). The PAR may be involved in obligate recombination during meiosis; however, its absence in some species shows this is not a universal requirement. The discovery of several evolutionary strata on therian X chromosomes (Lahn and Page, 1999; Nicolas *et al.*, 2005; Roesti *et al.*, 2013), as well as differing degrees of divergence between X- and Y-linked genes (Chibalina and Filatov, 2011; Zhou and Bachtrog, 2012b; Natri *et al.*, 2013) suggest that recombination does not halt abruptly, but rather spreads along the chromosome in a stepwise or gradual fashion. Suppression of recombination will start at the sex-determining region (SDR) for two possible reasons. First, crossovers in the SDR may be selected against because it results in improper sex determination. Second, breaking up the association between SD and SA genes (Rice, 1987a) leads to SA genes being passed on to offspring that will develop into the sex in which they have a deleterious effect, which will be selected against. Tight linkage between SD and SA genes allows for stronger sex-specific adaptation and thus suppressed recombination may be favorable (Muller, 1964; Nei, 1969). As more and more SA genes accumulate on the sex chromosomes, this suppression of recombination is believed to spread outward, until the full chromosome experiences suppressed recombination. It should be noted that this theoretical model of SD and SA gene interaction is broadly accepted but that the experimental support is still weak.

How Is Recombination Suppressed?

The proximate causes of recombination suppression are not well understood, though several mechanisms have been proposed that may explain how it evolves. First, recombination rates often differ between sexes (Burt *et al.*, 1991), which may suggest the presence of recombination-suppressor genes as postulated by Nei (1969). Such a (local) suppressor gene may spread provided that it is linked to a beneficial combination of genes (e.g., SD and SA genes). A sex-linked global recombination suppressor would explain the marked differences in recombination rates between sexes, as this would lead to reduced recombination in one sex.

Second, extensive methylation is known to inhibit recombination (Maloisel and Rossignol, 1998; Melamed-Bessudo and Levy, 2012). Increased methylation in the SDR of the proto-sex chromosome may lead to reduced recombination levels between SD and SA loci (Maloisel and Rossignol, 1998; Gorelick, 2003; Melamed-Bessudo and Levy, 2012). This is in accordance with findings that in some species, for example sticklebacks, recombination between the sex chromosomes stopped in a very gradual fashion (Chibalina and Filatov, 2011; Natri *et al.*, 2013; Roesti *et al.*, 2013).

Third, sufficient levels of sequence divergence between homologues reduce recombination rates. Though sequence divergence appears unlikely to evolve between recombining chromosomes, such divergence can be accelerated by chromosomal inversions (Andolfatto *et al.*, 2001). Inversions have been proposed as an explanation for evolutionary strata on sex chromosomes in various species (e.g., Lahn and Page, 1999; Wright *et al.*, 2014).

Extensive methylation and inversions can cause local suppression of recombination and can be regarded as specialized forms of the suppressor-gene model (Nei, 1969). These mutations may spread provided they are linked to a beneficial combination of genes. Theoretical studies have shown that this is indeed true for inversions (Kirkpatrick, 2010), but similar results are expected in case of extensive methylation.

Sex Chromosome Degeneration

Recombination and Selection

Though suppressed recombination may allow for faithful transmission of co-adapted gene complexes, it also induces the degeneration of the minor sex chromosome. Various models describe how suppressed recombination induces degeneration (**Figure 1**). These can be classified according to two effects of recombination: (1) the creation of novel genotypic combinations and (2) the ability to select on loci separately. Genome-wide effects include Muller's ratchet, a process that leads to the random loss of mutation-free chromosomes, and Hill–Robertson interference, the inability to combine beneficial mutations if these arise on separate chromosomes. Locus-specific processes refer to the interdependence between fitness effects of loci and their genetic background.

Muller's ratchet is considered to be the main cause of mutation accumulation (Muller, 1918; Muller, 1964). It assumes that mutations occur readily, that these mutations are typically near-neutral and thus do not suffer from selection until the mutational load transgresses a certain threshold (see also Rice, 1996). Recombination may lead to the formation of chromosomes with a lower mutational load compared to the ancestral chromosomes. Without recombination, each chromosome will accumulate mutations over time, mutation-free chromosomes will become increasingly rare, and may eventually be lost due to genetic drift. When such mutation-free chromosomes have been lost, the ratchet has turned a single click; compared to the ancestral chromosome, the least-loaded chromosome now carries at least one mutation. Subsequent clicks of the ratchet then lead to loss of all chromosomes carrying one mutation, etc.

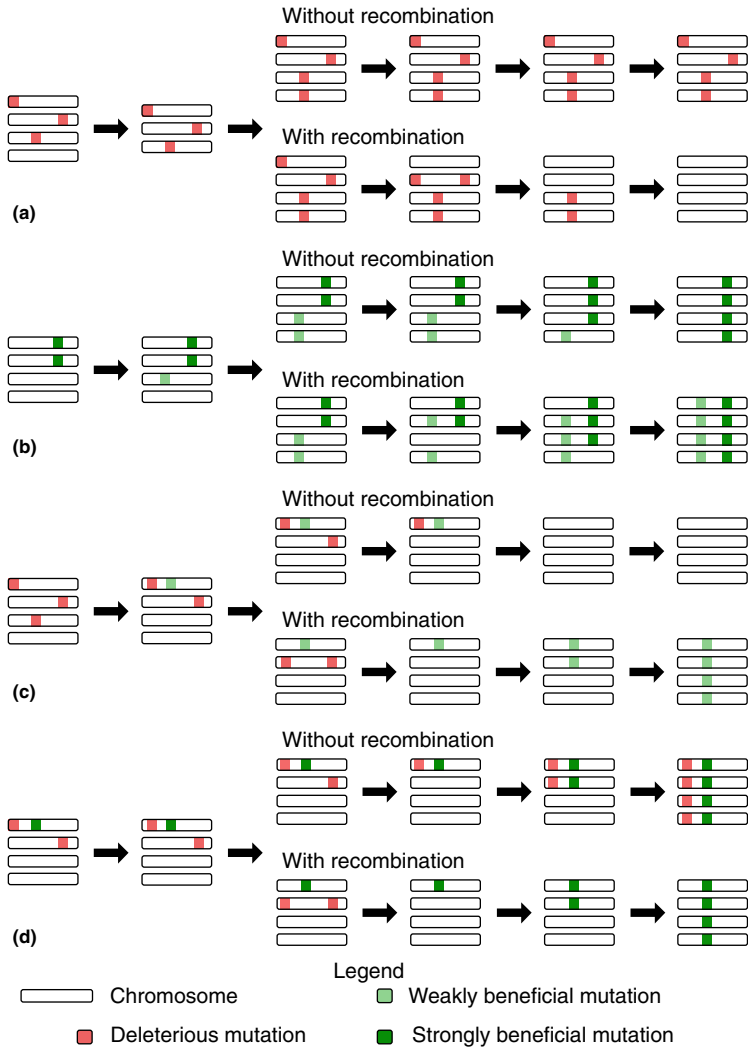

Figure 1 Recombination and chromosomal degeneration. Different models may contribute to degeneration of non-recombining chromosomes. (a) Muller's ratchet. Mutation-free chromosomes cannot be restored when lost stochastically. (b) Hill–Robertson interference. Beneficial mutations cannot be combined if they arose on different chromosomes. (c) Background selection. Beneficial mutations may not spread if they are linked to deleterious mutations. (d) Genetic hitchhiking. Deleterious mutations may spread when linked to beneficial mutations. See text for further details. Adapted from Bachtrog, D., 2013. Y-chromosome evolution: Emerging insights into processes of Y-chromosome degeneration. Nature Reviews Genetics 14, 113–124, with permission from Macmillan Publishers Ltd, © 2013.

Hill–Robertson interference refers to the inability to combine beneficial mutations in the absence of recombination (Hill and Robertson, 1966). In natural populations, beneficial mutations spread as a result of selection. In case such mutations have not yet become fixed, a novel beneficial mutation may occur on a chromosome which does not yet carry a beneficial mutation. Recombination in double heterozygotes may then create a chromosome harboring both beneficial mutations, whereas without recombination, these mutations will compete with one another (Hill and Robertson, 1966; Charlesworth and Charlesworth, 2000). Natural selection will then lead to fixation of the more beneficial mutation, effectively purging the other mutation.

The second effect of recombination, the ability to select on loci separately, is akin to Hill–Robertson interference. Without recombination, ancestral combinations cannot give rise to novel combinations and thus each mutation is restricted to the genetic background it arose in. Consequently, selection can only act on the combined effects of mutations and their respective backgrounds (Rice and Chippindale, 2001); beneficial mutations may be lost due to linkage to deleterious mutations (background selection, Charlesworth *et al.*, 1993), whereas deleterious mutations may spread when linked to strongly beneficial mutations (genetic hitchhiking, Rice, 1987b).

Background selection occurs when a weakly beneficial mutation is lost because it is unable to overcome the negative selection it faces from linked deleterious mutations (Charlesworth *et al.*, 1993; Rice, 1996). An example would be when a weakly beneficial mutation arises on a chromosome already experiencing a relatively high mutational load due to Muller's ratchet. Initially, this may spread, but as time progresses, each copy will only become associated with higher mutational loads as Muller's ratchet turns. As a result, it will eventually transgress the selection threshold and thus, the beneficial

mutation will be lost. With recombination, such a weakly beneficial mutation may end up on a chromosome with a smaller load, where it is able to spread due to natural selection.

Inversely, genetic hitchhiking describes how strongly beneficial mutations may spread and drag along deleterious mutations (Rice, 1987b). Similar to the scenario for background selection, it assumes that several weakly deleterious mutations may already be present on a chromosome due to Muller's ratchet. A strongly beneficial mutation on this chromosome may still become fixed, provided that its net fitness transcends the fitness of chromosomes lacking this mutation, even when having a lower deleterious mutation load. This in turn may help to accelerate Muller's ratchet (Bachtrog, 2008); the mutational load of a chromosome may increase, but a strongly beneficial mutation reduces the selection pressure on this chromosome. As a result, it spreads through the population, eventually outcompeting the ancestral mutation-free chromosome.

The effects of these population genetic processes are amplified by the reduced effective population size of the sex chromosomes (**Table 1**). The ratio between autosomes and X chromosomes is 4 to 3 per mating pair, whereas this is only 4 to 1 for Y chromosomes (and 2 to 1 for both U and V chromosomes; Rice, 1988). This strongly increases the effect of genetic drift and may further accelerate Muller's ratchet.

Males typically experience stronger sexual selection than females. These effects may be further intensified for the male-limited Y and V chromosomes (reviewed in Bachtrog *et al.*, 2011), whereas they may be relatively relaxed on female-limited U and W chromosomes. However, in UV systems and plants, the degeneration of sex chromosomes is often slower compared to diploid animals. This is likely due to purifying selection in the haploid phase (Bergero and Charlesworth, 2011; Chibalina and Filatov, 2011). In plants, gene expression during meiosis of sex-linked genes is much higher than in animals, whereas species with UV systems are haploid during most of their life cycle (e.g., Ahmed *et al.*, 2014). This would prevent sheltering of deleterious mutations as seen in diploids, resulting in higher selection pressure against deleterious mutations, thereby slowing down degeneration (Bergero and Charlesworth, 2011; Chibalina and Filatov, 2011; Charlesworth, 2013).

Intralocus Competition and Selective Gene Silencing

The overall genetic inertness of the Y chromosome (and likely also the W chromosome, though much less data are available) suggests that its degeneration is associated with gene inactivation. Gene silencing may readily occur through transpositional inactivation (Steinemann and Steinemann, 1992, 1998). Though typically deleterious, high mutation rates induced by transposons may allow for rapid inactivation of genes involved in intralocus competition (Rice, 1987b). However, silencing of Y-linked alleles may only be favored if there are no negative dosage effects, or if dosage compensation has readily evolved (Kaiser *et al.*, 2011; see also Mank, 2013). Some genes may be dosage-sensitive and silencing Y-linked alleles without upregulation of X-linked alleles may cause deleterious effects, preventing gene silencing. The link between the evolution of dosage compensation and mutational silencing of Y-linked genes requires further theoretical and empirical study.

Gene Content of Late-Stage Sex Chromosomes

Sex chromosome maturation is associated with major changes in their gene content. Depending on the genetic mechanism of sex determination, variable numbers of sex determination genes may be present on the sex chromosomes. Sex determination genes may be single dominant loci such as *SRY* in mammals (Berta *et al.*, 1990), or they may represent quantitative loci that direct sex determination depending on their dose (e.g., X-linked signal elements as found in *Drosophila melanogaster*, Cline, 1993).

Though predicted to play a major role in sex chromosome evolution, SA genes have proven difficult to be identified. An excessive number of genes involved in male reproductive functioning are sexually antagonistic in *D. melanogaster* (Innocenti and Morrow, 2010) and *Drosophila miranda* (Zhou and Bachtrog, 2012a). Late-stage sex chromosomes are often enriched for genes involved in reproductive processes, such as fertility genes or genes expressed specifically in the gonads (e.g., Skaletsky *et al.*, 2003; Bellott *et al.*, 2010). However, whether such genes are commonly under sexually antagonistic selection is unknown and requires further investigation in other species. In addition, some sex chromosomes show enrichment for genes that are under sexual selection, such as color genes in poeciliids (Kallman, 1970), cichlids (Streelman *et al.*, 2003), and medaka fish (Wada *et al.*, 1998). Possibly, such genes represent additional types of SA genes, as they may be harmful in females for their increasing conspicuousness.

SD genes or genes that confer large fitness benefits are less prone to degeneration. Due to strong selection on these genes, mutations are more likely to have large deleterious effects and thus Muller's ratchet may not operate efficiently, as natural selection will purge such mutations quickly. However, other genes may degenerate, leading to increased sex-specific bias in the remaining gene content on the minor sex chromosome that is typical of late-stage minor sex chromosomes (Y chromosome masculinization or W chromosome feminization).

Though sex chromosomes may acquire genes through translocation, they may also lose genes. Typically, this concerns genes that are located on the major sex chromosome, but are beneficial to or only functional in the heterogametic sex (Wu and Xu, 2003). Genes expressed specifically in the gonads of the heterogametic sex or genes involved in their gamete production were shown to move away from the major sex chromosome in several species (e.g., Emerson *et al.*, 2004; Vibranovski *et al.*, 2009). Coupled with the accumulation of SA genes that confer fitness benefits to the homogametic sex, this leads to feminization, respectively masculinization, of the X and Z chromosomes.

Degeneration-Driven Loss and Turnover of Sex Chromosomes

Does Degeneration Lead to Loss of the Minor Sex Chromosome?

With the plethora of degenerative forces acting upon the minor sex chromosome, it has been predicted that the Y

chromosome will fade away and eventually be lost (Graves, 2006). As a result, males would be lost from the population and extinction would be imminent. These predictions are however based on several incorrect assumptions.

First, degeneration is not constant. It may be rapid on young proto-sex chromosomes, but slows down over time as gene numbers dwindle (Rice, 1988; Bachtrog, 2008; Hughes *et al.*, 2012). Consequently, the probability that a deleterious mutation occurs becomes increasingly small, asymptotically approaching zero. Though degeneration may lead to a highly reduced gene content on the Y chromosome, those genes that remain are usually crucial for male reproduction (e.g., Lahn and Page, 1997). These genes are under strong purifying selection and thus, mutations in such genes may be purged very rapidly, preventing the loss of such genes. Second, gene content of the Y chromosome need not only decrease (see also Graves, 2006); translocation of genes may increase gene content, though the effect on halting degeneration may be limited. The degeneration cycle may be reset by formation of neo-sex chromosomes by fusion between a sex chromosome and an autosome. This increases gene content and allows for partial rejuvenation of the minor sex chromosome (Kitano and Peichel, 2012). Alternatively, sex chromosome turnover leads to creation of novel sex chromosomes, effectively resetting the cycle (see also below). Finally, degeneration may not be as inevitable or irreversible as implied. Novel insights reveal that in many species, sex chromosomes remain homomorphic for extended periods of time, suggesting the existence of mechanisms which counteract degeneration.

Barring all else, loss of the Y chromosome need not initiate population extinction. The widespread occurrence of X0 systems in nature suggests that not all Y chromosomes are essential for male development. Such Y chromosomes may be readily lost, provided that any essential genes originally contained on the Y chromosome have translocated.

Escape from Degeneration and Neo-Sex Chromosomes

Several mechanism may allow for sex chromosomes to escape the degenerative forces acting upon them. Recombination rates often depend on phenotypic rather than genotypic sex, and in some organismal groups, such as amphibians and fish, sex reversal may occur occasionally (reviewed in Mank, 2012). In sex-reversed individuals, recombination may occur between the sex chromosomes provided that divergence between the sex chromosomes is still relatively minor. Occasional rounds of recombination may effectively reverse Muller's ratchet and stop other degenerative processes. Sex reversal may thus function as 'foundation of youth' (Perrin, 2009), effectively allowing the sex chromosomes to circumvent degeneration and decrease their mutational load.

Intra-chromosomal recombination is another mechanism that could prevent degeneration of vital genes. The human Y chromosome contains eight palindromic regions with duplicated genes (Skaletsky *et al.*, 2003). Gene conversion by non-homologous crossover between these duplicated copies allows for removal of mutations (Rozen *et al.*, 2003), conserving duplicated Y-linked genes and reducing degeneration.

Sex Chromosome Turnover and SD System Transitions

As degeneration continues, the mutational load of the Y chromosome increases. At some point, sex chromosome turnover may become selectively favorable compared to retention of ancestral sex chromosomes. Such turnovers can come about in a variety of ways, such as translocation of the SD gene to an autosome resulting in a novel proto-sex chromosome or fusion of a sex chromosome with an autosome resulting in neo-sex chromosomes. High rates of sex chromosome turnover have been described in fish, reptiles, and amphibians (reviewed in Kikuchi and Hamaguchi, 2013) and translocation of the SD gene occurs spontaneously in some species (e.g., Traut, 2010).

Turnovers in sex chromosomes are hindered by the fact that the ancestral Y chromosome often contains many male-essential genes (see also above). Turnover may therefore only occur if the novel Y chromosome confers an especially large fitness benefit, for example when the SD gene maintains an association with one or more SA genes (van Doorn and Kirkpatrick, 2007). As such, it is still unknown whether the spread of novel proto-sex chromosomes occurs when a sex determination gene lands next to an SA gene or whether SA genes land next to SD genes.

Additionally, sex chromosome turnover may be caused by changes in sex determination mechanisms induced by meiotic drive (Kozielska *et al.*, 2010). If sex chromosomes exhibit meiotic drive, sex ratios will become distorted. Balancing sex ratio selection will then favor drive-suppressing mutations or mutations which cause individuals to develop into the rarer sex. In the latter case, this may lead to transitions in sex determination systems and sex chromosome turnover if a different chromosome acquires the master sex-determining gene.

Conclusions and Open Questions

Sex chromosomes have their own genomic niche and evolve in peculiar ways (**Figure 2**). Starting as autosomes, they become proto-sex chromosomes when they acquire a sex-determining function. They mature as sex chromosomes through a complex interplay between SD and SA genes and recombination suppression, ultimately resulting in their degeneration. Much of what we know about sex chromosome evolution is inferred from theory. Experimental investigation of sex chromosome evolution has been hampered by lack of tractable systems and variation within or between closely related species. However, some promising systems that have recently yielded important new insights are several fish species, such as medaka (Wada *et al.*, 1998) and sticklebacks (Natri *et al.*, 2013) as well as insect species such as houseflies (Hamm *et al.*, 2009; Feldmeyer *et al.*, 2008) and *Drosophila* species (Zhou and Bachtrog, 2012a, 2012b).

The role of SA genes in sex chromosome evolution has been firmly established by theoretical models, but the empirical evidence is still meager. It is still disputable how widespread SA genes are, as they have to date been identified in only a limited number of species, despite the fact that many genes are under different selection pressures between the sexes (reviewed in Cox and Calsbeek, 2009).

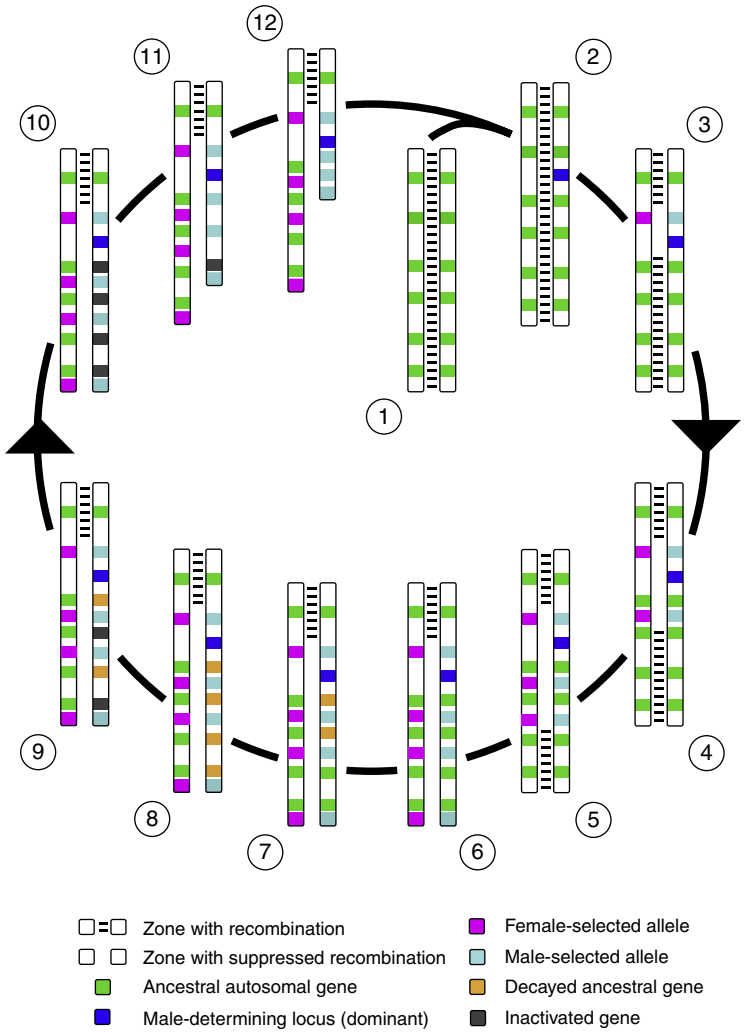

Figure 2 Steps in sex chromosome evolution. Sex chromosomes are derived from autosomes (1), and become proto-sex chromosomes when they acquire a sex-determining function (2). They mature as sex chromosomes as SA genes accumulate and recombination becomes suppressed (3–6). Non-essential genes may decay as they accumulate mutations, leading to reduced functionality (7–8). Decayed genes will be selectively silenced (9–10) and large deletions may lead to chromosome shrinkage (11–12). A novel sex chromosome may be formed when another autosome becomes a proto-sex chromosome, thereby resetting the cycle. Adapted from Bachtrog, D., 2013. Y-chromosome evolution: Emerging insights into processes of Y-chromosome degeneration. Nature Reviews Genetics 14, 113–124, with permission from Macmillan Publishers Ltd, © 2013.

Comparative genomics may help to discover SA genes and to determine whether they have been preferentially translocated to the sex chromosomes. Alternatively, they may act as landing sites for new SD genes in the origin of proto-sex chromosomes. Additionally, transcriptomic analyses may reveal differences in gene expression between the sexes, thereby increasing the power to identify SA genes. More empirical testing of SA effects, for example by manipulating inheritance of sex chromosomes through one sex, will be required to validate the role of SA in sex chromosome evolution.

The advent of the omics era has led to the development of a wide array of tools that may help to further disentangle evolutionary processes of sex chromosomes. Neo-sex chromosomes have proven useful in discerning which processes contribute to sex chromosome degeneration (e.g., Zhou and Bachtrog, 2012b; Zhou *et al.*, 2012). Comparisons between neo-sex chromosomes of various ages will reveal the extent to which the various processes outlined above contribute to the degeneration of sex chromosomes and may elucidate the interplay between degeneration and dosage compensation (Zhou and Bachtrog, 2012a).

The mechanisms of progressive suppression of recombination are not yet well understood. The discovery of novel proto-sex chromosomes and neo-sex chromosomes that still display recombination may allow for more in-depth analysis of how recombination becomes suppressed. Multi-factorial systems such as that of the housefly may be very promising in this respect (Feldmeyer *et al.*, 2008; Scott *et al.*, 2014).

In conclusion, insights in sex chromosome evolution have been much progressed over recent years. However, there still is an emphasis on theoretical approaches, while testing these theories has proven difficult. With the omics era in full bloom,

the field of sex chromosome evolution promises to be an exciting field of research in which novel insights can readily be gained.

Sex Determination

L Ross, University of Edinburgh, Edinburgh, UK
H Blackmon, University of Minnesota, Saint Paul, MN, USA

Glossary

Anisogamy Form of sexual reproduction where the gametes differ in size or structure. The most familiar type of anisogamy is oogamy where females produce a large non-motile egg and males produce small motile sperm.

Dosage-dependent sex determination Sex determination system where the transcription level of certain genes determines whether an individual develops as female or male.

Gonochoristic Having only one of the two possible sexes in any individual organism. In contrast to hermaphroditic where any single individual can function as both male and female.

Hermaphrodites Individuals capable of producing both oocytes and spermatocytes, either as (1) 'simultaneous hermaphrodites' producing both types of gametes at the same time, or as (2) 'sequential hermaphrodites' which can only produce one type of gamete at a given time, but switch sex at some point during their lifetime.

Heterogametic Individual that produces gametes with different sex chromosome complements.

Master switch Gene that acts as the initial trigger of female or male development. Sometimes also referred to as feminizers (causing female development) or masculinizers (causing male development).

Mating types A mechanism that determines the compatibility of individuals in a population to reproduce with one another. Mating types are common in fungi, and the number of different mating types in a population may range from two to many hundreds.

Sex chromosome (X and Y, Z and W) In heterogametic sex determination system, the pair of chromosomes that are responsible for sex determination. In male heterogametic species the male will have an XY complement and females an XX complement. In female heterogametic species the male will have a ZZ complement and females a ZW complement.

Sex determination cascade A process where the transcription of a specific allele or the transcription level of a gene regulates a series of genes downstream culminating in the genes that are responsible for the development of an individual as either female or male.

The prevailing view of reproduction is that of a female and male mating to produce offspring. This is indeed the case in most animals, some plants and even some unicellular organisms. But does reproduction always work this way? How did the sexes originate? And how is an individual's sex determined? These simple but fundamental questions are key to our understanding of evolution across the tree of life.

A Brief History of the Sexes

Sexual reproduction is an ancient feature of eukaryote life, yet the sexes as we currently recognize them are relative latecomers in the evolution of sex (Beukeboom and Perrin, 2014). The ability to reproduce through sex (fusion of haploid gametes) evolved in the common ancestor of all eukaryotes, but did not involve separate sexes; each individual was able to exchange genetic material with any other of the same species, as is still the case in many modern-day unicellular eukaryotes (Lahr *et al.*, 2011). However, throughout the course of evolution this changed in certain organisms: some, for example many fungi, evolved tens or even hundreds of 'mating types,' where certain genotypes become incompatible with others (Perrin, 2012). In others 'anisogamy' evolved: here individuals produce not one but two different types of gametes, a large type – 'oocytes' in low frequency and a more prevalent smaller type – 'spermatocytes.' Anisogamy is thought to evolve because an individual with limited resources has two options to maximize their reproductive success: either by maximizing the number of gametes they produce, or by maximizing the survival probability of each of their gametes (Parker *et al.*, 1972). In many cases an individual can produce both these types simultaneously and either self-fertilize or mate with others to exchange gametes ('hermaphroditism'), yet some – for example, most animals and some plants – specialized on producing one or the other, giving rise to the sexes as we currently recognize them (Jarne and Auld, 2006; Bawa, 1980).

How Sex Is Determined?

But how is an individual's sex determined? The answer to this question is far more complex than you might think. Sex-determining mechanisms are surprisingly diverse and evolutionary biologists have only just started to understand what causes this variation (Beukeboom and Perrin, 2014). Here we will start by describing some of this variation and how it is distributed across different organisms. We only focus on sex determination in species with true separate sexes, not those with mating types, and primarily focus on sex determination in multicellular organisms.

Genetic Sex Determination

Perhaps the most familiar sex determination systems are those that employ 'heterogametic' sex determination where a species

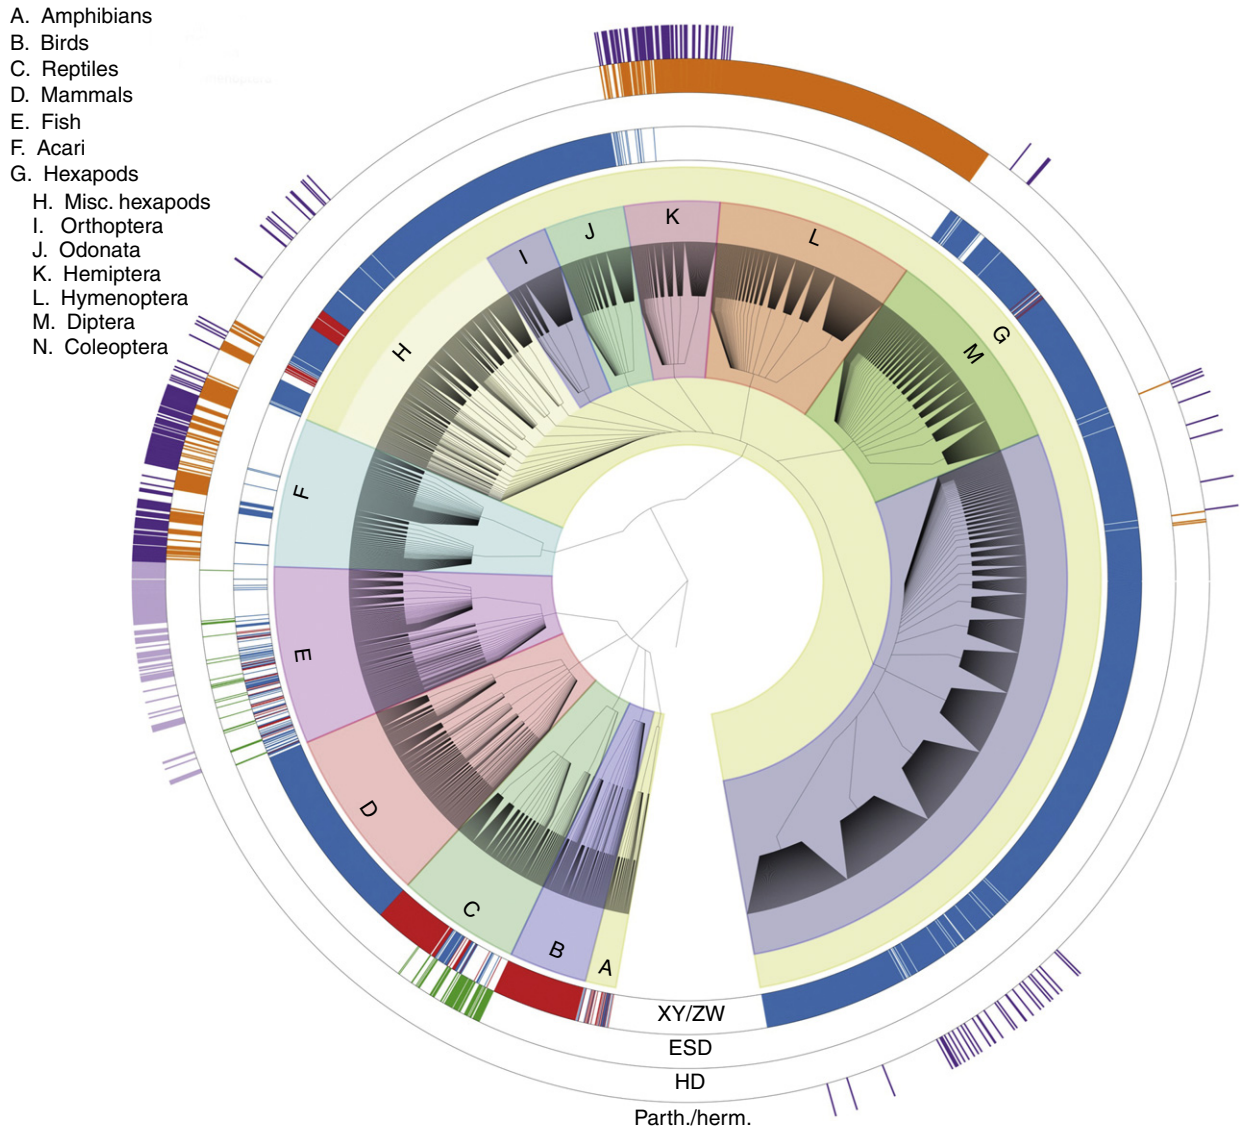

Figure 1 The phylogenetic distribution of sex-determining systems across animals. The tree structure is based on taxonomy and each tip represents all species in genus. The underlying data consist of 13 700 records representing 3886 genera from the tree of sex database. The XY/ZW ring is colored blue for XY and red for ZW taxa. The environmental sex determination (ESD) and haplodiploidy (HD) rings indicate the presence or absence of environmental and haplodiploid sex determination systems, respectively. The Parth./Herm. ring is colored dark purple for parthenogenic taxa and light purple for hermaphroditic taxa. Data reproduced from the Tree of Sex Consortium, 2014. Tree of Sex: A database of sexual systems. *Scientific Data*, 1.

has two alternative versions of a sex-determining region. Whether an individual is homozygous or heterozygous for this region will determine if it develops as a female or male. The sex-determining region can be a single gene, a portion of a chromosome, or even an entire chromosome; regardless, the chromosome that carries the sex-determining region is called the 'sex chromosome.' Heterogametic sex determination systems can be divided by whether the female or male is heterogametic.

In many species, including humans, the male is heterogametic and carries an X and Y sex chromosome while females are homogametic and carry two copies of the X chromosome. XY sex determination is the most common form of heterogametic sex determination and is found in amphibians, non-avian reptiles, mammals, and many invertebrates (Figure 1). In other groups it is the female that is heterogametic and the female possesses a Z and W chromosome while males carry two copies of the Z chromosome. ZW sex determination is found in birds, some amphibians and non-avian reptiles, and several groups of invertebrates most notably the butterflies (Figure 1). In both of these systems, the sex chromosome found in only one sex (Y or W) often degenerates and contains few genes in comparison to the X or Z chromosome. The taxonomically widespread observation of XO and ZO sex determination systems indicates that these sex-limited chromosome can be completely lost creating systems where the

heterogametic sex has one copy of the sex chromosome and the homogametic sex has two copies (The Tree of Sex Consortium, 2014). Finally, in some bryophytes and algae only the gametophytes (haploid life stage) have separate sexes and sex is determined by which version of the sex chromosome they carry. The gametophyte develops as a female if it carries a U sex chromosome and develops as a male if it carries a V sex chromosome. While sporophytes (diploid life stage) carry both sex chromosomes and do not have separate sexes (Bull, 1983).

In some fish, plants, and copepods there are multiple genes that can act as the 'master switch' for sex determination. In these polygenic sex determination systems there are more than two distinct versions of the sex chromosomes. For instance in the platyfish *Xiphophorus maculatus* which was ancestrally XY there are three types of sex chromosomes X, X^*, and Y, where X^* is a version of the X chromosome that carries a dominant feminizing mutation. This creates a system where there are multiple types of females, including the normal XX females, but also X^*X and X^*X^* and even X^*Y females, with the dominant female determining mutation (Volff and Schartl, 2001).

Generally the genotype of the offspring determines their sex. Yet a few species exhibit monogenic sex determination where the mother's genotype determines whether she will produce broods of all female or male offspring. One such example is the sciarid fly *Sciara coprophila*, where the sex of offspring produced by a female depends on the presence or absence of an inversion (X') on one of her X chromosomes (Sánchez, 2010).

Environmental Sex Determination

In many unicellular and some multicellular species, males and females have identical genomes and their sex is determined by environmental factors. Environmental sex determination (ESD) is common among unicellular eukaryotes (Beukeboom and Perrin, 2014). Among multicellular organism ESD is found primarily among non-avian reptiles, amphibians, and some fish (Bachtrog *et al.*, 2014). Temperature appears to be the most common determinant of sex under ESD. However, there are other factors too, like social environment. Many fish are sequential hermaphrodites, where they start their life as one sex, but change sex later in development. In the anemone fish (*Amphiprion akallopisos)*, which live in social groups with one dominant breeding pair as well a several subordinate males, sex change occurs when the dominant female dies and the largest male in the group becomes the dominant female (Fricke and Fricke, 1977). ESD systems are more often evolutionary labile than genetic sex determination (GSD): closely related species differ in their sex-determining mechanism and shifts can include changes in the threshold temperature or transitions between ESD and GSD. In some cases there is even variation within species: the lizard *Bassiana duperreyi* determines sex through GSD (XX-XY) but at low temperatures some of the XX females develop as males (Shine *et al.*, 2002).

Other Sex Determining Mechanisms

Among invertebrates the most common alternative sex determining mechanism is haplodiploidy (HD; Normark, 2003; Bull, 1983). Here, males develop from unfertilized eggs and have only a single copy of each gene ('haploid'), while females develop from fertilized eggs and have two copies of each gene ('diploid'). In haplodiploid organisms sex determination is therefore dependent on the fertilization of eggs, which is often thought to be under the control of mothers (Beukeboom and Perrin, 2014). HD has evolved repeatedly across insects, mites, nematodes, and rotifers and has been estimated to occur in around 12% of all animals (Normark, 2003; Jarne and Auld, 2006; The Tree of Sex Consortium, 2014). Another alternative reproductive system that shows similarity with HD is Paternal Genome Elimination (PGE) (Bull, 1983; Burt and Trivers, 2009). Here, both sexes develop from fertilized eggs, yet in males all genes inherited from the father are lost at some point during development. PGE occurs in thousands of species across insects, springtails, and mites. The loss of paternal genes occurs either early in development such that these males are haploid throughout development, or later such that males retain their father's genes in all cells but their sperm (Normark, 2003; Gardner and Ross, 2014). As both sexes develop from fertilized eggs, fertilization cannot serve as the trigger for sex determination, and it is currently unclear what sex-determining factor does. Both HD and PGE tend to occur in closely related species and are only found in terrestrial invertebrates. They are conspicuously absent from tetrapods, plants, and marine invertebrates (Normark, 2003; Normark and Ross, 2014).

Finally there are cytoplasmic sex determination systems where either an intracellular bacterial parasite (e.g., *Wolbachia*) or the genotype of the mitochondria determines the sex of offspring (Beukeboom and Perrin, 2014). Such cytoplasmic elements are only transmitted to the next generation by females and as such have an interest in manipulating the sex determination of their host.

Evolution of Different Sex Determining Systems

The variability of sex-determining mechanisms among eukaryotes is startling. But what evolutionary forces are responsible for transitions between different sex determination systems? Moreover, why are certain groups of plants and animals exceptionally variable in the way they determine sex?

Some of the difference in sex determination can simply be explained by the fact that they evolved independently. For example, separate sexes evolved independently in plants and in animals, so any similarities in sex-determining mechanisms – for example, differentiated sex chromosomes – are examples of convergent evolution (Beukeboom and Perrin, 2014). However, not all diversity is the result of the independent evolution of separate sexes: for example, insects – one of the most diverse group of animals in terms of their sex determination – ancestrally have separate sexes (Normark, 2003). So which evolutionary forces cause this variation? And what sex-determining systems are favored under different conditions?

Sex Ratio Selection

The first important selective force is sex ratio selection, in other words, what is the optimal offspring sex ratio an individual

can produce? In most sexually reproducing organisms the answer is an equal proportion of sons and daughters. The reason for this is that if one sex is more common than the other, the rarer sex has a higher fitness and will increase in frequency until equality arises (Fisher, 1930). Selection for balanced sex ratios is probably a primary explanation for why GSD is so prevalent across life – it is the only SD mechanism that guarantees an equal proportion of males and females (Beukeboom and Perrin, 2014). If this is the case, how can alternative SD systems evolve? One reason is that the sex ratio of an individual's offspring is selectively neutral as long as the population sex ratio is unbiased. So, mutations that alter offspring sex or local fluctuations in temperature under ESD are not selected against until they become so prevalent that they change population sex ratios. In fact ESD can be favorable if the environmental cue that determines sex differentially affects the fitness of males and females. Under that scenario selection favors sex-determining mechanisms that match each sex to its best environment (Bull, 1983). Finally there are conditions under which balanced sex ratios are selected against: for example, when related males compete for matings with their sisters a female-biased sex ratio is preferred (Hamilton, 1967). This would select for SD systems that allow mothers to bias their sex ratio. Several authors have suggested that HD and PGE might have evolved because of such sex ratio selection (Bull, 1983; Beukeboom and Perrin, 2014; Burt and Trivers, 2009; Gardner and Ross, 2014).

Sexual Conflict

The two sexes are defined by their difference in gamete size, however sexual dimorphism generally extends to other traits including differences in morphology and behavior. Sexual conflict occurs when the sexes have different fitness optima for such traits. One form of sexual conflict that is thought to be especially important in the evolution of sex determination systems is sexual antagonistic selection, which occurs anytime that a gene has multiple alleles that have different fitness in males and females. The presence of sexual antagonistic selection increases the probability of a transitions in the sex-determining gene, sex determination method, or sex chromosome pair (Van Doorn and Kirkpatrick, 2007). For instance, in an XY system, if a masculinizing mutation occurs near an autosomal allele that is associated with higher fitness in males, then this may give rise to a new Y chromosome that may fix in the population.

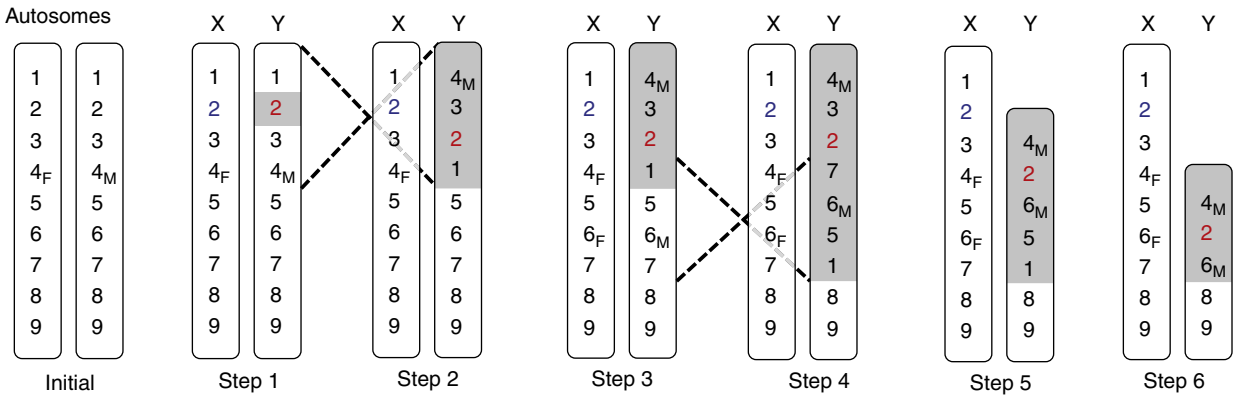
Endosymbiotic Bacteria

A large number invertebrates harbor bacteria that live inside their cells (Buchner, 1965). In some cases these bacteria are mutualists and essential for the survival of their host, often thought they are parasites that evolved ways to increase their frequency without providing any benefits. Many (in particular those in the genera *Wolbachia* and *Cardinium*) do so by manipulating their hosts into producing more female offspring. This benefits the bacteria because only females, not males transmit them to their offspring. By far the best example comes from the woodlice *Armadillidium vulgare*. In those individuals that are uninfected sex is determined genetically by a ZZ/ZW system, but infection with *Wolbachia* lead to the feminization of ZZ males into functional females, or one of two types of intersexes: (1) individuals with female physiology but some external characteristics of males, or (2) individuals that are physiologically male but are sterile (Juchault *et al.*, 1992).

Evolution of Sex Chromosomes

The canonical view of sex chromosome evolution begins with autosomes that gain a sex-determining gene (Westergaard, 1958). Upon the evolution of a sex-determining gene, the Y chromosome is expected to begin a process of degeneration because of its reduced population size (between one male and one female, there is only one copy of a Y chromosome and 3 copies of X chromosomes) and reduced recombination that sometimes evolves between the X and Y chromosomes; both factors reduce the effective population size of the Y chromosome and reduces efficacy of selection, which, in turn, can lead to its degeneration. Selection to reduce recombination may be a byproduct of sexual antagonism (SA), where different SA alleles provide higher fitness in males and females; for example, reduced recombination between the sex-determining region and a SA locus can lead to associations between a male-benefit (female-detriment) allele and the Y chromosome, and thereby restrict the allele's benefits to males and not expose females to its costs. Cessation of recombination often occurs through inversions that isolate increasingly large stretches of the Y chromosome (Charlesworth *et al.*, 2005). In chromosomal regions where recombination is suppressed genes are quickly lost until only a core set of genes essential to the male fertility and viability remain (Bachtrog, 2008) (**Figure 2**). Suppression of recombination between the X and Y chromosome of humans occurred in 5 steps over 200–300 million years (Hughes *et al.*, 2012). This process only affects the sex-limited chromosome; the X is still able to recombine in a normal fashion in females; this process of degeneration is expected to be largely the same in ZW systems, applying to the W chromosome. Sex chromosomes that have gone through this process are described as heteromorphic and the sex-limited chromosome as degenerate. However, not all organisms follow this pattern; for instance the emu as well as some amphibians and fish appear to maintain homomorphic sex chromosomes for long periods. It is likely that different explanations for the retention of homomorphic sex chromosomes apply to these groups. In the case of the emu sex specific gene regulation may allow the resolution of SA (but see Charlesworth *et al.* (2014) for an alternative explanation). In contrast very low levels of intermittent recombination may be responsible for the lack of degeneration seen in amphibians (Perrin, 2009; Vicoso *et al.*, 2013).

While heteromorphic sex chromosomes are usually quite stable, homomorphic sex chromosome often exhibit rapid changes in which chromosomal pair determine sex, and even between XY and ZW systems. The simplest type of turnover involves the translocation of the sex-determining gene onto an autosome creating a new sex chromosome pair. However, masculinizing or feminizing mutations of genes on autosome can create new sex chromosomes or cause transitions between



Initial: No sex chromosomes are present; sex is determined by environmental conditions.

Step 1: A masculinizing mutation occurs at gene 2 creating an XY sex determination system.

Step 2: Sexual antagonistic selection favors an inversion of genes 1 to 4 on the Y chromosome. This keeps the allele of gene 4 that is best for males with the male sex determining region, and expands the portion of the Y chromosome that cannot recombine.

Step 3: A new mutation at gene 6 creates sexual antagonistic selection at this gene.

Step 4: Sexual antagonistic selection favors an inversion of genes 1, 5, 6, and 7 on the Y chromosome further reducing the amount of the Y chromosome that can recombine.

Step 5-6: The region of the Y chromosome that cannot recombine begins to lose genes that are not essential to male fitness.

Figure 2 The process of sex chromosome differentiation. The progression from undifferentiated autosomes to heteromorphic sex chromosomes. The sex-determining locus is gene 2. The female allele is in blue and the male allele is in red. Alleles that have different fitness in males and females are indicated with a subscript where M indicates an allele with high fitness in males and F high fitness in females. The gray shading indicates the region that is non-recombining.

XY and ZW systems. Masculinizing mutations can change the 'master switch' in XY systems or transitions from ZW to XY. Likewise, feminizing mutations can change the master switch in ZW systems or transitions from XY to ZW. Whether these translocation, feminizing mutations, or masculinizing mutations fix in a population is likely determined by presence of SA (Van Doorn and Kirkpatrick, 2007). For instance if a feminizing mutation occurs near a gene with an allele that is associated with higher fitness in females (but lower in males) then the new sex-determining region is more likely to fix in the population.

Sex Ratio Distorters

GSD typically leads to equal sex ratios as a result of meiosis, where each copy of a gene (e.g., the sex-determining locus on a mammalian Y chromosome) has a 50% of being present in a particular gamete. This is not always the case though: we now know of genes that can 'cheat' the fair raffle of meiosis to ensure they are included in the gametes at a higher rate. These 'meiotic drive alleles' can thus rapidly spread through populations and if they are located on autosomes, they have little effect. However if located on a sex chromosome they can have profound effects, often threatening to wipe out populations through the demise of one of the sexes. Such 'sex ratio distorters' can therefore select for the evolution of new sex-determining loci that can override the ancestral locus linked to the driver, thereby restoring an equal sex ratio. The occurrence of autosomal feminizers and masculiners able to override the normal XY sex determination in house flies (*Musca domestica*) have been hypothesized to result through this mechanism, though there is as yet no direct evidence of driving sex chromosomes resulting in novel SD loci.

Molecular Mechanism of Sex Determination

Over the last few decades scientists have unraveled the molecular mechanisms of sex determination for a number of model organisms. This research has lead to some general insights: First of all, the underlying molecular mechanisms can vary dramatically between species that on the surface appear to have very similar sex determination systems (Bachtrog *et al.*, 2014). On the other hand, however, some of the same genes are involved in sex determination across all metazoan and shared among species with very different sex-determining systems (Beukeboom and Perrin, 2014; Smith *et al.*, 1999). Genes involved in sex determination can generally be divided into those that determine the initial switch (the master switch) and those further downstream in the 'sex determination cascade,' which are responsible for organizing and maintaining sexual differentiation. A general pattern that has emerged from genetic studies is that those 'master switch' genes show high turnover between closely related species while those genes further down the cascade tend to be more conserved (Beukeboom and Perrin, 2014). The reason for this pattern is not fully understood, though they might arise from the fact that mutations in the switch genes tend to result in a change in sex ratio, while mutations further down the cascade will lead to more detrimental effects, for example the production of sterile intersex offspring. The sex-determining switch can be a large chromosomal region, a single gene, or even a single nucleotide polymorphism. It can act either by its presence or absence or by the amount of gene product that is present ('dosage' above or below a threshold).

Here we briefly review the molecular sex-determining mechanism of a number of model organisms and how these examples allow us to make inference across the tree of life.

Insects

Most of what we know about the molecular mechanism of sex determination in insects comes from studies on fruitflies in the genus *Drosophila*. *Drosophila* have an XY sex determination system. Sex is determined by a 'dosage-dependent sex determination' factor on the X chromosome (XSEs, see **Figure 3**): those individuals with two copies of the X chromosome develop as females while those with just one copy develop as males. Expression of the X-linked XSEs above the dosage threshold promotes the transcription of another gene called transformer (TRA), which in turn causes the alternative splicing of the gene double sex (DSX) (**Figure 3**; Maine *et al.*, 1985). Double sex is responsible for organizing sexual differentiation across all insects studied to date, while the other genes are more taxonomically restricted. Other flies that seemingly have the same sex determination system as *Drosophila* (XY) do not determine sex through dosage but through a dominant Y-link gene (M) that blocks the transcription of transformer and leads to the male-specific splice form of DSX (**Figure 3**). Unlike most insects butterflies determine sex through a female-heterogametic sex determination system (either ZW or Z0). The molecular mechanisms of sex determination in butterflies has been studied primarily in the silkworm (*Bombyx mori*, **Figure 3**) and like other insects, DSX determines sexual differentiation. However, unlike other insects the master switch is not a protein, instead, a small non-coding RNA molecule located on the W chromosome and acts as a dominant 'feminizer' (Kiuchi *et al.*, 2014). Finally in many insects sex is determined through HD where males develop from unfertilized haploid eggs (Normark, 2003). The mechanisms by which sex determination is accomplished under HD are as yet only known for bees, ants, and wasps (Hymenoptera) (Schmieder *et al.*, 2012). Perhaps surprisingly much of the sex-determining cascade is identical to that found in *Drosophila* (**Figure 3**; Beukeboom and Perrin, 2014). In bees the master switch is the complementary sex determiner gene (CSD). Many different alleles at this locus segregate in a population and those individuals with two different alleles ('heterozygous' individuals) develop as females, while those with just one, either because they are haploid or because they have two copies of the same allele, develop as males (Beukeboom and Perrin, 2014). Although CSD is found across hundreds of hymenoptera, it is absent from some parasitoid wasps and there is no evidence for CSD in any of the other haplodiploid groups of insects or mites.

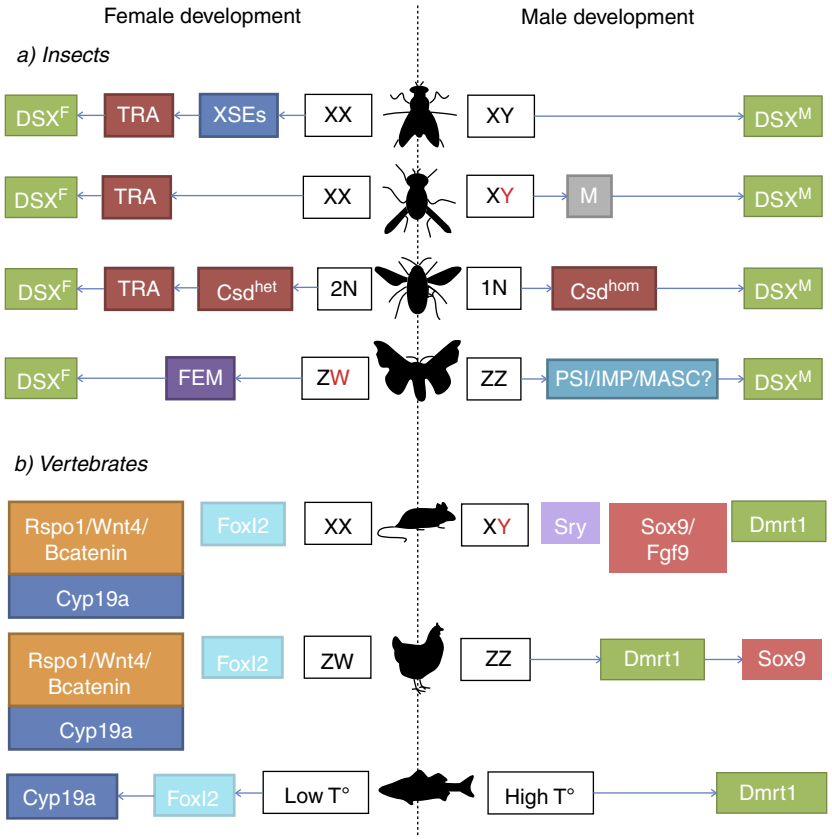


Figure 3 The molecular pathways of sex determination in a range of model organisms. The top half of the panel depicts examples of a number of well-studied insect model with different sex-determining pathways (from top to bottom: the common fruit fly: *Drosophila melanogaster*, the Mediterranean fruit fly: *Ceratitis capitata*, the buff-tailed bumblebee: *Bombus terrestris*, and the silkworm: *Bombyx mori*), while the bottom half shows such examples for vertebrates (from top to bottom: *Mus musculus, Gallus gallus domesticus*, and *Dicentrarchus labrax*). The solid white box indicates the 'master switch,' while the other colored boxes depict sex-determining genes further down in the cascade. Genes with a shared evolutionary history are depicted in the same color. Based on various references (Beukeboom and Perrin, 2014; Schmieder *et al.*, 2012; Kiuchi *et al.*, 2014).

Vertebrates

Across vertebrates sexual differentiation is regulated by Dmrt1 (Smith *et al.*, 1999), which simultaneously turns on male development, while suppressing female development (**Figure 3**). Dmrt1 is a transcription factor that belongs to the same gene family as *doublesex*, but it is its presence or absence, not its alternative splicing, that causes sex differentiation (Beukeboom and Perrin, 2014). While Dmrt1 is pivotal for vertebrate sex determination, it does not usually act as the primary master switch, which – like in insects – is much more variable across species. In mammals the master switch is a dominant masculinizing gene called Sry that is located on the Y chromosome (**Figure 3**; Foster and Graves, 1994). The identity of the master switch in birds remains controversial, though most evidence points to Dmrt1 fulfilling this role (Smith *et al.*, 2009; Beukeboom and Perrin, 2014). Dmrt1 in birds is Z-linked and the dosage of Dmrt1 is thought to directly determine male development. (**Figure 3**) In vertebrates with ESD, like some reptiles and fish, much of the downstream sex determination cascade is similar to that of species with genetic sex determination. Temperature-dependent sex determination is often mediated by the temperature-dependent expression of aromatase (Cyp19a), an enzyme that is involved in the synthesis of estrogens. Finally in some vertebrates, especially telost fish, sex is not controlled by a single master regulator but is instead a quantitative threshold trait with either a male or female outcome, which is determined by multiple regions in the genome (Bachtrog *et al.*, 2014).

Flowering Plants

Among flowering plants, separate sexes (dioecy) are rare (about 6% of species (Renner and Ricklefs, 1995)), and have evolved relatively recently from hermaphroditic ancestors. The transition from hermaphroditism to separate sexes is generally thought to involve two separate mutations: one suppressing male function and one suppressing female function. Indeed sex is determined by two separate genes in papaya, one of the few plants for which the sex-determining cascade has been deciphered. Like most dioecious plants papaya has a male heterogametic (XY) sex determination system and sex is determined by an X-linked feminizer and a Y-linked masculinizer (Beukeboom and Perrin, 2014).

Why Are Some Groups so Variable?

From an evolutionary viewpoint, one of the most intriguing questions is why some groups of plants and animals (e.g., reptiles, fish) are exceptionally variable in the sex-determining systems, while others display hardly any variation (e.g., birds, mammals). One possibility is that certain SD systems are more labile than others. Generally, GSD is thought to be more stable than environmental SD. For example in reptiles transitions from ESD to GSD occur frequently, but there are no clear examples of transitions the other way. And even among GSD systems, those with highly differentiated sex chromosome (XY, ZW), are thought to be more stable than those where the sex chromosomes are monomorphic, or those that have lost one of the sex chromosomes (X0 or Z0). Finally, HD is thought to serve as an 'evolutionary trap'; no haplodiploid lineage has re-evolved an SD system with diploid males (Bull, 1983).

Outstanding Questions

Some aspects of sex determination – such as the evolution of sex chromosomes and the molecular mechanism of sex determination in model organism – are now well understood. However many unresolved questions remain. Many of these involve the large-scale phylogenetic distribution of different sex determination systems. For example, why is male heterogamety more common than female heterogamety? Why does HD only occur in certain groups of invertebrates? Why do sex-limited chromosome degenerate in some groups but not others? Finally an important challenge is to understand how a species' sex determination mechanism can impact other aspects of their biology and evolution, such as rates of speciation (Orr, 1997), and the evolution of male ornaments (Kirkpatrick and Hall, 2004). Solving these challenging questions will require the concerted effort of scientist from a wide range of disciplines as well as a broad taxonomic outlook.

Sex, Evolution and Maintenance of

K Jalvingh, J Bast, and T Schwander, University of Lausanne, Lausanne, Switzerland

Introduction

The ability to reproduce is one of the most fundamental aspects defining life, yet reproduction is achieved through a panoply of mechanisms. Reproduction can involve different levels of recombination and genetic exchange between individuals, ranging from clonal reproduction to meiotic parthenogenesis, self-fertilization or mating between relatives, to sexual reproduction with outcrossing. Definitions of sex therefore often depend on the context. A broad definition is the joining of genetic material from two individuals to form offspring that combine genes from both of them. If defined in this way, sex is almost universal as it includes horizontal gene transfers observed in prokaryotes and some eukaryotes, as well as other types of 'parasexual' genetic exchange between individuals. A second definition of sex, the one adopted here, refers to the formation of haploid gametes through meiosis, followed by the fusion of these gametes (syngamy).

The evolution of sex combines two different topics; the origin and the maintenance of sex. **The origin of sex** is highly speculative as it happened during the early history of life on Earth, when the first self-replicating RNA/DNA molecules appeared. The single evolutionary origin of meiotic sex would have occurred during this time, some 1.5 billion years ago. There are different opinions concerning the mechanisms that would have favored sex at its origin. For example, meiotic sex could have been selected as a mechanism for DNA repair (Bernstein *et al.*, 1985). However, a more broadly accepted view is that sex at its origin was favored through the same mechanism that currently maintains it: it allows selection to work efficiently. How exactly sex could facilitate selection is explained below. Importantly, even small benefits conferred by sex at its origin may have been enough. This is because direct costs associated with sex at this time would have been small since sex occurred between isogametic cells. By contrast, sex has to generate strong benefits to be 'maintained' under anisogamy and biparental reproduction, the typical situation in metazoans.

Sex is indeed associated with significant direct costs in metazoans. In species where males provide little or no resources to their offspring, females pay the full cost of reproduction, yet only provide half of each sexually produced offspring's genes. This generates a transmission disadvantage relative to asexual reproduction, which is two-fold in species that invest equally in both sexes (formalized by Maynard Smith (1978) and Williams (1975)). Even in cases where males do contribute resources to their offspring, sex is typically still costly because it requires attracting mates and eventually mating. These behaviors may be costly and increase risk of predation or of infection with a sexually transmittable disease. Sex can further cause reproductive failure if individuals fail to find a mating partner. **The paradox of sex** – the fact that it is associated with considerable costs but maintained in the vast majority of organisms – thus stems in great part from a metazoan-centered view.

Fitness effects of sex – the costs and benefits it generates – can be expressed within populations (short-term consequences) or at the lineage level (long-term consequences), affecting the rate of adaptation, diversification, or extinction. Within populations, sex can affect fitness directly or indirectly. Direct fitness effects of sex are usually negative, for example, the cost of males or costs related to mating. This means that benefits of sex most likely stem from either indirect effects on fitness or from long-term consequences. Long-term consequences alone are probably insufficient to explain the maintenance of sex, given the considerable direct costs of sex (see Section Lineage-Level Selection For Sex). Indirect effects on fitness arise when sex breaks up associations between alleles under selection (see Section Short-Term Benefits of Sex). The intuitive idea that sex is good for the species was accepted until the 1970s, when it was realized that there has to be a gene-level advantage for sex and that this advantage has to be strong enough to fully outweigh all the costs (Williams, 1975; Maynard Smith, 1978). Therefore, there is an ongoing search for strong short-term or individual-level benefits to explain the maintenance of sex.

Short-Term Benefits of Sex

Sex generates indirect effects on fitness when it breaks up associations between alleles under selection. Much effort has been invested into identifying situations where breaking up such associations generates short-term fitness benefits. Before examining situations where this might be the case, it is useful to consider that for sex to have any indirect effect on fitness (positive or negative), associations between selected alleles at the same or at different loci need to exist in a population. Without **such linkage disequilibrium (LD)**, sex has no effect (**Figure 1**).

Generating indirect benefits from breaking up LD requires two mechanisms: (1) a mechanism that generates continuous directional selection, for example, mutation or unceasing changes in selection pressures. This is necessary to maintain additive variance for fitness – in the absence of such variance, there is no possibility for adaptation (and sex can thus not facilitate it). (2) A mechanism that generates associations between genes with opposite ($-$ and $+$) fitness effects. If associations were between genes of identical fitness effects, recombination would reduce the variance in fitness and thereby slow down adaptation (**Figure 2**).

Identifying the mechanisms that generate continuous directional selection is largely an empirical challenge, and these mechanisms most likely vary among different organisms. A general understanding of the advantage of sex therefore requires understanding why associations between genes with

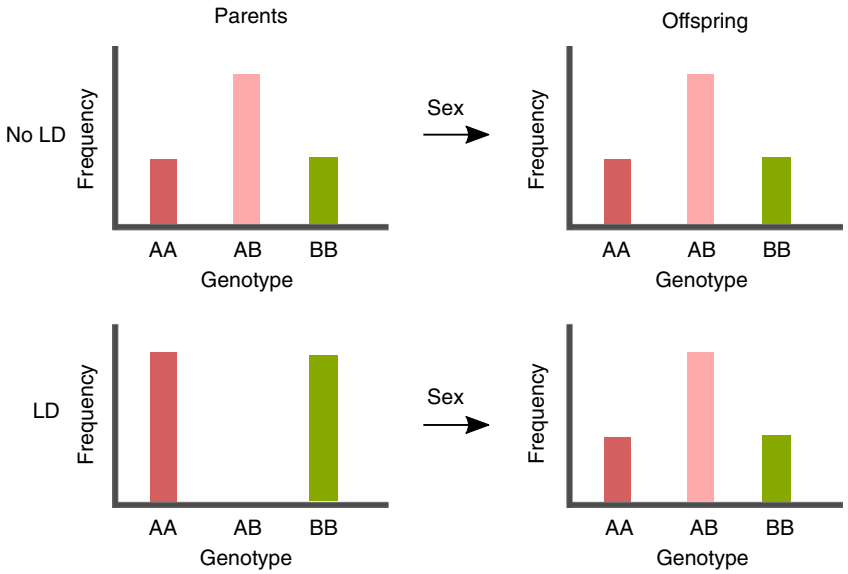

Figure 1 Linkage Disequilibrium (LD). Under LD, there is a nonrandom association of alleles at different loci. If there is no LD in a population, sex will have no effect. If there is LD, sex can generate new genotypes in the offspring that were not present in the parental population. Note that LD concerns the frequency of genotypes in the population, not the frequency of individual alleles.

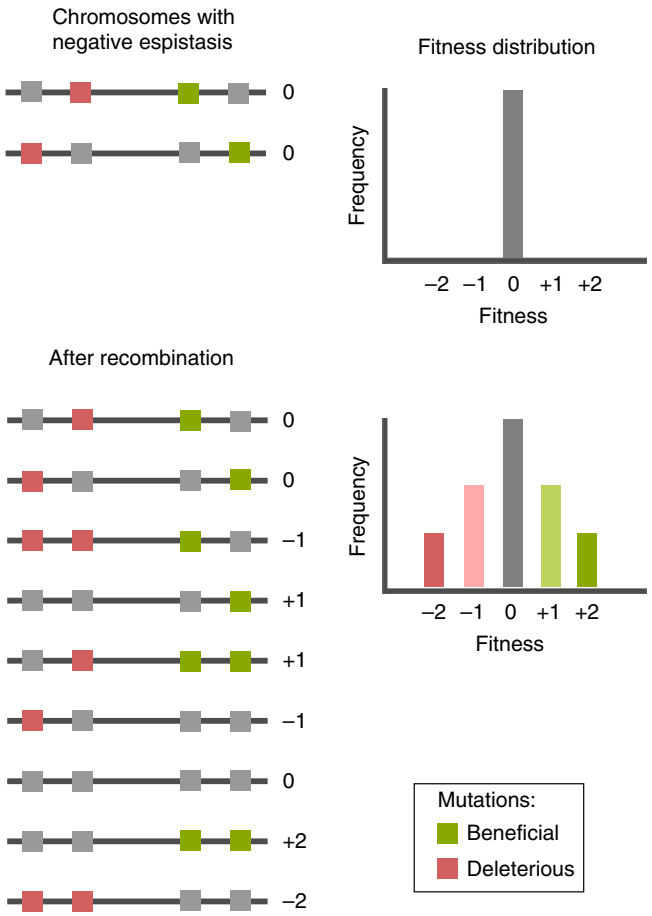

Figure 2 Negative epistasis. In the presence of negative epistasis, interactions between alleles reduce or reinforce fitness effects. Under negative epistasis, sex can generate benefits by breaking up LD and thereby increasing fitness variance, which will improve the response to selection.

opposite fitness effects should be predominant. The four best studied mechanisms that could generate such associations are:

Epistasis

If the effect of a locus on fitness depends on other loci (i.e., if there is epistasis), selection systematically generates LD. If epistasis is generally negative, sex would be favored because it would increase fitness variance in the next generation (Barton, 1995). Because fitness variance increases, recombination provides a benefit by increasing the response to selection. In addition to this benefit, recombination also generates a cost. This cost stems from the fact that LD was generated by selection, meaning that recombination breaks up good gene combinations and generates worse ones. This 'recombination load' causes an immediate reduction of mean fitness, which has to be compensated by the benefit of the increased response to selection. As a consequence, for recombination with negative epistasis to generate a net benefit, epistasis cannot be strongly negative or the costs due to the recombination load would be too high (Otto and Feldman, 1997). The current empirical evidence indicates that epistasis is generally not negative (Elena and Lenski, 1997; De Visser and Elena, 2007). This implies that negative epistasis is unlikely to be a main driver in the evolution and maintenance of sex.

Temporal Changes in Selection

Epistasis can generate a short-term advantage for recombination when it fluctuates over time, with different allele combinations being favored during different time intervals (Maynard Smith, 1971; Charlesworth, 1976; Barton, 1995). The evolution of recombination requires that these time intervals are quite short (a few generations), which is perhaps most likely if fluctuating epistasis is caused by interactions between coevolving species (Peters and Lively, 1999; Gandon and Otto, 2007).

Much research effort has been dedicated to the study of coevolution, especially between hosts and parasites. In the context of Red Queen dynamics, a parasite would adapt to the most common host genotype, because it can then infect many hosts. In this situation, a rare host genotype would be favored, causing its frequency to increase until it becomes common (negative frequency-dependent selection). Parasites should then shift to infect this newly common genotype, reducing its fitness in the current generation. There is accumulating evidence for Red Queen dynamics in natural populations and from experimental evolution (e.g., Lively, 1987; Decaestecker *et al.*, 2007; Morran *et al.*, 2011). However, whether these dynamics contribute to the maintenance of sex in many species remains unknown. For example, negative frequency-dependent selection does not require sex but can also work in asexual species consisting of a genetically diverse assemblage of clones. In that case, negative frequency-dependent fitness of different clones would act to maintain clonal diversity rather than sex. Furthermore, there are several examples where parasites appear to not contribute to the maintenance of sex (e.g., Parker, 1994; Hanley *et al.*, 1995; Elzinga *et al.*, 2012).

Migration and Spatial Changes in Selection

Spatial variation in selection can generate locally adapted allele associations with locally maladapted associations introduced by migration. Sex can then provide a benefit because it breaks such maladaptive allele associations, provided migration rates are high enough to regularly introduce locally maladapted associations, yet low enough to not constrain local adaptation via gene flow (Agrawal, 2009; Lenormand and Otto, 2000; Pylkov *et al.*, 1998). These theoretical predictions were supported by results from an experimental evolution approach in cyclically parthenogenetic rotifers. By controlling migration rates between similar and different rearing environments, Becks and Agrawal (2010) showed that higher rates of sex are maintained under migration between different environments.

However, potential benefits for sex under spatially heterogeneous selection depend on the specific conditions. For example, selected alleles should be dominant under conditions where they are beneficial, and recessive under conditions where they are maladaptive (Agrawal, 2009). Furthermore, depending on the correlation in selection on different loci across populations, migration can generate either positive or negative linkage disequilibria across loci (Lenormand and Otto, 2000).

Drift and the Hill–Robertson Effect

In finite populations, negative LD between loci under selection is generated by the combined effects of drift and selection. Drift generates all possible types of LD between loci under selection: associations between beneficial alleles, associations between deleterious alleles, and associations between alleles with opposite fitness effects. Selection acts efficiently on the first two categories, given the big fitness differences they generate. This means that most cases of LD that persist after selection are due to associations between alleles with opposite fitness effects (Hill and Robertson, 1966). This so called 'Hill–Robertson effect' favors sex because breaking up associations between alleles with opposite fitness effects increases the variance in fitness (Felsenstein, 1974; see also **Figure 2**).

Since natural populations (at least of macroorganisms) are typically within the size range where Hill–Robertson effects can generate benefits for sex, drift generates perhaps the most broadly applicable benefits for sex. However, it remains unknown to what degree such benefits can compensate for the direct costs associated with sex.

In summary, breaking up associations between alleles at different loci can provide an advantage for sexual over asexual reproduction when these associations hamper adaptation, as is often the case within finite populations, or when selection varies over time or space. Whether such indirect benefits of sex may be sufficient to outweigh the direct costs remains unknown. Furthermore, for obtaining benefits from reducing associations between loci, even very rare events of sex are sufficient. The presented models do therefore not explain the prevalence of obligate sex with high recombination rates (Hurst and Peck, 1996). There is currently no LD-based hypothesis that can account for obligate sex, the most widespread form of reproduction among metazoans.

Short-term benefits of sex not related to linkage disequilibria

A specific form of spatial variation in selection is at the root of some of the classical, ecology-based models proposing benefits to sex, which include the '**Tangled Bank**' model (e.g., Ghiselin, 1974; Maynard Smith, 1978; Bell, 1982; Song *et al.*, 2011). These models posit that there is genetically based variation among individuals for exploiting different niches. As a consequence, genetically identical individuals should experience more intense competition than genetically different individuals. Here, sex could provide benefits because sexually produced offspring would display more genetic variation than asexually produced ones. The 'Tangled Bank' concept thus proposes an advantage for sex in environments that are saturated, as sex would reduce sibling competition in this case.

Some recent extensions of the 'Tangled Bank' (Song *et al.*, 2011) work in similar ways to negative frequency-dependent selection under host–parasite coevolution. Here, the availability of resources depends on the frequency at which these resources are exploited and replaced. If different genotypes exploit different resources, rare genotypes will be favored because they use a resource that is temporarily abundant.

Lineage-Level Selection for Sex

As explained above, meiotic sex has evolved once and has been maintained in the vast majority of lineages on the tree of life. This means that current asexual lineages derive secondarily from sexual ancestors. It has been argued that only those sexual lineages that cannot give rise to new asexuals (due to genetic or developmental constraints) persist in the long-term (Williams, 1975; Nunney, 1989). Sexual lineages without constraints would be driven to extinction by the asexuals they generate.

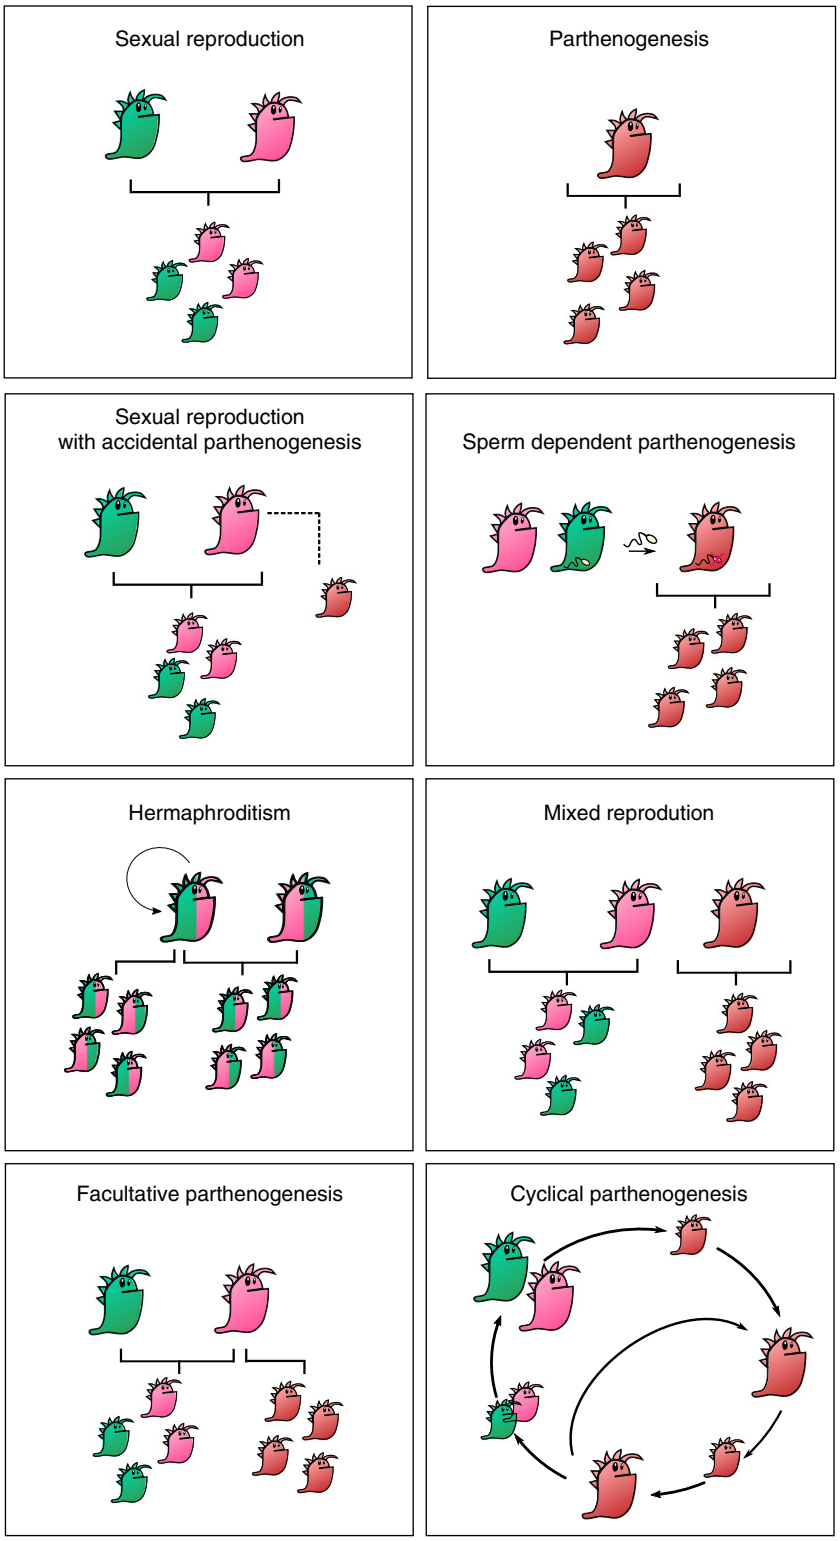
Several hypotheses further propose long-term disadvantages to asexual reproduction. For example, **'Muller's ratchet'** describes the pattern where small populations of asexual lineages tend to accumulate deleterious mutations over time (Muller, 1964). Clones can be lost from small populations as a consequence of drift, including the clones with the fewest deleterious mutations. New deleterious mutations are introduced during replication, such that the average number of deleterious mutations per clone in an asexual population can only increase over time, in a ratchet-like manner (hence the term **Muller's ratchet**). Small sexual populations also lose genotypes as a consequence of drift. However, via recombination and mixis, sex can regenerate mutation-free genotypes and thereby avoid the ratchet.

The **'lottery model'** compares sexual and asexual reproduction to different strategies when buying lottery tickets (Williams, 1975). Asexuality corresponds to buying many tickets with the same number, while sexual reproduction corresponds to buying tickets with different numbers. The expected payoff of the two strategies is similar, but the payoff variance should be greater for asexuals, with the consequence

Figure 3 Overview of the different reproductive modes described in the text. **Sexual reproduction** with or without spontaneous parthenogenesis. In sexually reproducing species, offspring contain the genetic material of the father and mother. Sexual reproduction involves meiosis and recombination, both of which may also be present at some level in alternative modes of reproduction. In some cases, spontaneous parthenogenesis (also called tychoparthenogenesis or accidental parthenogenesis) occurs under sexual reproduction when virgin females are able to produce viable offspring. All known cases of spontaneous parthenogenesis are meiotic. It is widespread among invertebrates and has also been documented in some vertebrate species, especially in species kept in zoos. Spontaneous parthenogenesis is sometimes called 'facultative parthenogenesis' although hatching success under spontaneous parthenogenesis, rarely higher than 1% and often as low as 0.1%, is typically more than an order of magnitude lower than under facultative parthenogenesis, where the majority of unfertilized eggs hatch. **Sperm-dependent parthenogenesis**: it (also called gynogenesis, pseudogamy or sperm parasitism) is a parthenogenesis in which the egg needs to be activated by sperm for embryogenesis to start. Thus as under other types of parthenogenesis, there is no paternal contribution (genetic or cytoplasmic) to the offspring. Sperm-dependent parthenogens derive from sexual ancestors where egg activation is already sperm-dependent, possibly because egg–sperm interactions may function as a control mechanism preventing the unwarranted development of eggs prior to fertilization. Sperm-dependent parthenogenetic lineages must coexist with their 'sperm donors,' usually males (or hermaphroditic individuals) from a related sexual species or population. Although rare, sperm-dependent parthenogenesis has been reported in a wide variety of animal taxa, including vertebrate and invertebrate taxa. Mating systems like these are potentially unstable, since they depend on the sperm from an individual who cannot gain paternity in return. **Cyclical parthenogenesis:** it is the alternation between a generation of sexual reproduction and one or more generations of asexual reproduction in a single population. During the parthenogenetic generations, females only produce daughters, except for the last generation, preceding the sexual generation. Prior to the sexual generation, females produce sons in addition to daughters. These parthenogenetically produced males and females mate, and the female offspring from these crosses are the first parthenogenetic generation of the next cycle. The parthenogenetic generations are generally mitotically produced (i.e., clonal). The parthenogenetic production of males is achieved via different developmental processes in different species, depending on their sex determination mechanism. In species with environmental sex determination (e.g., in water fleas) male differentiation is induced by specific abiotic conditions. In species with haplodiploid sex determination (e.g., in rotifers or cynipids) females start laying haploid eggs, while in species with other genetic sex determination systems, male development involves complex processes of sex chromosome elimination (as Wilson *et al.*, 1997 described for aphids). **Obligate Parthenogenesis:** parthenogenesis in animals often refers to the production of daughters without genetic contributions from males ('female-producing parthenogenesis' or thelytoky). Under obligately parthenogenesis all individuals only reproduce via parthenogenesis: the ability to produce offspring with genetic contributions from males has been lost. Both obligate meiotic and mitotic asexual reproduction falls under this definition. **Mixed reproduction:** in mixed reproduction a population consists of both sexually and asexually reproducing individuals. Crucially, each individual reproduces either sexually or asexually, and is not able to alternate between reproductive modes, making it functionally distinctive from both cyclical and facultative parthenogenesis. **Hermaphroditism:** these are organisms that combine male and female functions within the same individual. In some cases, hermaphrodites are able to fertilize their own eggs, making them functionally asexual, even though the fusion of gametes still occurs. **Facultative parthenogenesis:** in lineages with facultative parthenogenesis, reproduction can be through biparental sex and through female-producing parthenogenesis. Facultatively parthenogenetic females can flexibly shift between the two reproductive modes and parthenogenesis is generally meiotic.

that asexual lineages should face higher extinction rates than sexual ones.

Sexual and asexual lineages are also expected to differ in their long-term rate of adaptation, i.e., the 'classical' explanation for the benefits of sex. According to the **Fisher–Muller hypothesis**, sexual lineages adapt faster, because beneficial mutations occurring in different individuals can be combined in one (Fisher, 1930; Muller, 1932). In an asexual



lineage, the same beneficial mutations must be fixed sequentially. If different beneficial mutations appear simultaneously in different individuals, competition among such mutations ('**clonal interference**,' Muller, 1932; Gerrish and Lenski, 1998) can slow the rate of adaptation (and theoretical fitness optima may never be reached).

Although intuitively appealing, long-term mechanisms are unlikely to explain the maintenance of sex in the bulk of species. For example, they do not apply under very large population sizes, which are characteristic of many microorganisms. This is because all combinations of beneficial and deleterious mutations appear at their expected frequencies in infinite populations, and recombination confers no advantage. Furthermore, such arguments cannot explain the maintenance of sex in lineages characterized by sexual and asexual reproduction (i.e., in lineages with **facultative parthenogenesis**, **cyclical parthenogenesis,** or **mixed reproduction**): here, sex must confer benefits on a sufficiently short timescale so that its direct costs can be outweighed.

The Diversity and Taxonomic Distribution of Reproductive Modes

The level of sex can vary continuously among reproductive modes, from its complete lack in mitotic forms of parthenogenesis to obligate sex between unrelated individuals (Figure 3). **Female-producing parthenogenesis** ('thelytoky') occurs in different forms – it can be cyclical, facultative, accidental, or obligate. **Cyclical parthenogenesis** (also called heterogony) is a type of life cycle in which a sexual generation (bisexual or hermaphroditic) alternates with one or more generations of parthenogenetic reproduction. Six large animal groups are characterized by this life cycle: trematodes (a parasitic class of flatworms), rotifers, cladocerans (water fleas such as *Daphnia*), aphids (including adelgids, and phylloxerids), cecidomyiids (gall midges), and cynipids (gall wasps). Parthenogenesis typically predominates under favorable conditions; deteriorating or stressful conditions (e.g., linked to seasonality, resource depletion and/or crowding) trigger the production of males and sexual females. Cyclical parthenogens frequently generate strains characterized by **obligate parthenogenesis** in which the sexual cycle can no longer be induced. This is well documented for several strains of aphids and water fleas (Dedryver *et al.*, 2013; Tucker and Ackerman, 2013; Neiman *et al.*, 2014).

Similar to cyclical parthenogenesis, **facultative parthenogenesis** characterizes lineages that can use both biparental sex and female-producing parthenogenesis to generate offspring. In contrast to cyclical parthenogens, facultatively parthenogenetic females can flexibly shift between the two reproductive modes and parthenogenesis is generally meiotic while it is mitotic (i.e., clonal) in cyclical parthenogens. The efficiency of parthenogenesis and sexual reproduction (number of offspring produced) is comparable under facultative parthenogenesis, distinguishing it from **spontaneous parthenogenesis** in sexual species. However, survival rates are typically higher for sexually than parthenogenetically produced offspring such that, given the option, females will prefer to produce sexual rather than parthenogenetic offspring. Facultative parthenogenesis occurs and may be widespread in some insect groups such as phasmids, mayflies, or termites, but is most likely rare in other animal groups. More frequent is **mixed reproduction** (species with sexual and parthenogenetic strains) however females in each strain are obligately sexual or obligately parthenogenetic.

In summary, most types of female-producing parthenogenesis would avoid certain indirect and direct costs associated with sexual reproduction, including the breaking up of coadapted gene complexes, the production of sons as well as costs involved in mate finding and copulation. In this context female-producing parthenogenesis is often used interchangeably with asexuality, although parthenogenesis does not necessarily generate clones. Many forms of parthenogenesis involve meiosis whereby ploidy levels (reduced during meiosis) are maintained between generations via specific cell regulatory or developmental mechanisms that act before, during or after the meiotic divisions (Suomalainen *et al.*, 1987).

Among animals, female-producing parthenogenesis has been estimated to occur in approximately 1 in a 1000 species (Vrijenhoek, 1998). However, this estimate is largely based on vertebrates and ignores several species-rich groups with large proportions of parthenogenetic lineages (e.g., hymenopterans and mites). True proportions of lineages capable of parthenogenesis may be up to an order of magnitude higher. The incidence of parthenogenesis varies widely among groups; classic examples of the extremes are mammals and birds without any parthenogenetic species, and cyclical parthenogens where parthenogenetic generations are part of an every species' live cycle.

Evolution of Parthenogenesis from Sexual Ancestors

In species that are not cyclical or facultative parthenogens, the evolution of a transition to parthenogenesis is most likely complex, requiring the acquisition of multiple novel adaptations (such as diploid instead of haploid gametes and spontaneous gamete development without sperm contribution (Neiman *et al.* 2014)). In addition to mutations, at least three different mechanisms can generate new parthenogenetic lineages from bisexual ancestors. First, **hybridization** between two sexual species has generated many described parthenogenetic lineages, and notably all but one known vertebrate parthenogen (Avise, 2008). The overall frequency of hybrid species among invertebrate parthenogens remains to be estimated. The cause of the association between parthenogenesis and hybridization remains largely unknown but may have different origins in different taxa. In some cases hybridization per se induces parthenogenesis. Under the 'balance hypothesis' (Moritz *et al.*, 1989) parthenogenesis via hybridization can only arise when the genomes of parental species are divergent enough to disrupt meiosis in hybrids, yet not so divergent as to compromise hybrid viability or fertility. In other cases, it has been hypothesized that parthenogens of hybrid origin have better competitive abilities relative to sexual sister species than non-hybrid parthenogens (Innes and Hebert, 1988).

Second, in some species, parthenogenesis is induced by **infection with endosymbionts** such as the bacteria *Wolbachia*

and *Cardinium* (reviewed in Duron *et al.*, 2008). Thus far, parthenogenesis induction by endosymbionts has only been experimentally confirmed in species with haplodiploid sex determination (notably in wasps, thrips and mites; reviewed in Neiman *et al.*, 2014). However, there are at least two species with other sex determination systems (the springtail *Folsomia candida* and the hemipteran *Aspidiotus nerii* (Pike and Kingcombe, 2009; Provencher *et al.*, 2005)) with a strong correlation between parthenogenesis and endosymbiont infection.

Finally, in some parthenogenetic lineages, females produce males that, by mating with females of related sexual lineages, generate new parthenogenetic lineages. This process is referred to as '**contagious parthenogenesis**' because gene flow from parthenogenetic into sexual lineages could allow for the spread of parthenogenesis-causing elements in a contagious fashion (Jaenike and Selander, 1979). In some cyclical parthenogens (especially *Daphnia* and aphids), the spread of obligate parthenogenesis is indeed at least partly mediated by such gene flow. However, despite the high potential of this contagious mechanism to generate parthenogenetic lineages, its incidence in natural populations is unknown, and may be limited since the geographic distribution ranges of sexual and parthenogenetic relatives are often distinct.

Sometimes **polyploidy** is hypothesized to cause parthenogenesis because it is more widespread among parthenogenetic as compared to sexual animals (Otto and Whitton, 2000). It is unclear whether polyploidy per se can induce parthenogenesis or whether the evolution of parthenogenesis and polyploidy are generally independent events. Some polyploid parthenogens derive from diploid ones via rare fertilization of parthenogenetic eggs but it is not known how widespread this mechanism is. There is also a lack of broad estimates of polyploidy incidence among parthenogens. Estimates based on small numbers of taxa are unreliable as the incidence of polyploidy varies widely among groups. For example, while the parthenogenetic beetles in the weevil family are generally polyploid, the numerous parthenogenetic hymenopteran and mite lineages are diploid. In cases where parthenogens are polyploid, polyploidy is likely to play a major role in the persistence of sex versus parthenogenesis as it can affect ecology and life-history traits (Otto and Whitton, 2000) and delays the expression of recessive deleterious alleles (Archetti, 2010).

Empirical Evidence for Benefits of Sex

Three different empirical approaches can be used to identify benefits of sex, each with specific advantages and disadvantages. The first set of approaches measures fundamental parameters used in evolutionary models predicting benefits of sex: epistasis (reviewed in De Visser and Elena, 2007) or rates of genomic mutations and the distributions of their fitness effects (e.g., Haag-Liautard *et al.*, 2007; Lynch *et al.*, 2008; Ossowski *et al.*, 2010).

A second set of approaches relies on experimental evolution to test whether mechanisms predicted to favor sex in theoretical studies apply to real organisms. These approaches have shown, for example, that sex speeds up adaptation to new environments in microorganisms (Colegrave, 2002; Poon and Chao, 2004; Goddard *et al.*, 2005; Grimberg and Zeyl, 2005; Cooper, 2007) and that higher rates of sex are maintained during adaptation in cyclical parthenogens and facultatively selfing macroorganisms (Morran *et al.*, 2009; Becks and Agrawal, 2012). These studies thus provide a 'proof-of-principle' that theoretically predicted mechanisms can favor sex given the appropriate conditions. However, these conditions may not be realized in natural populations, such that experimental evolution does not provide insights into the maintenance of sex in natural populations. Indeed, it is impossible to know whether any benefit to sex detected under artificial conditions (that may include controlled migration rates, specific population densities or sizes) would outweigh its immediate costs expressed under natural conditions.

Finally, a third empirical approach involves field studies and comparisons of asexual and related sexual lineages. While such studies provide insights into mechanisms important in natural populations, they generally remain correlational. Furthermore, when benefits of sex are identified in natural populations, it is often difficult to disentangle through which mechanisms such benefits are generated.

One of the best-documented consequences of sexual reproduction in natural populations is that it facilitates the purging of deleterious mutations. Thus, an increase of putatively deleterious (i.e., coding) mutations under asexual reproduction has been shown in a number of studies, both in animals (e.g., molluscs (Johnson and Howard, 2007; Neiman *et al.*, 2010), stick insects (Henry *et al.*, 2012), *Daphnia* (Paland and Lynch, 2006; but see Tucker and Ackerman, 2013)) and plants (e.g., *Oenothera* primroses; Hollister *et al.*, 2014). The extent to which the accumulation of such coding mutations results in negative phenotypic effects remains unknown. Furthermore, deleterious mutation accumulation would generate lineage-level (long-term) selection for sex, which, as explained above is insufficient to maintain sex in most cases.

Host–parasite coevolutionary dynamics can drive the constantly changing conditions required to generate persisting benefits for sex. Accordingly, some of the strongest evidence for benefits of sex in natural populations stems from host–parasite dynamics. In natural populations of New Zealand freshwater snails (*Potamopyrgus antipodarum*), sexually reproducing snails are favored in lakes and microhabitats within lakes with low prevalence of trematode parasites while asexual snails tend to occur in lakes or microhabitats where parasites are rare (Lively, 1987; King *et al.*, 2011). Whether parasites are the main driver to maintain sex in natural populations remains however unclear, as similar evidence lacks for other systems of co-occurring sexual and asexual lineages or even shows benefits for asexuals (e.g., Parker, 1994; Hanley *et al.*, 1995; Elzinga *et al.*, 2012).

Correlational evidence from natural populations is further consistent with Tangled-Bank related mechanisms favoring sex. Relative to asexual mite species, sexual species occupy higher trophic levels and occur in habitats where resource availability is more limited (Fischer *et al.*, 2014). Furthermore, high proportions of sexually reproducing mites are found in locations with low population densities, suggesting that sexual reproduction is favored under resource-limiting conditions (Maraun *et al.*, 2012).

Conclusion

Sophisticated theoretical approaches have generated insights into the mechanisms through which sex could favor adaptation. However, it remains unknown whether any of the identified mechanisms (or all of them combined) is able to generate sufficiently strong selection for sex to be maintained in natural populations, that is, fully compensate the costs expressed under these conditions.

Although many of the predicted benefits of sex have at least some empirical support, the benefits and costs of sex might vary among species. For example, physiological and developmental constraints on asexual reproduction, levels of ecological differentiation within a species and different life-history traits can all affect the relative costs and benefits of sex (Meirmans *et al.*, 2012). Consequently, the maintenance of sex in natural populations has most likely strong lineage-specific components. The implications are that there might be no single universal theory that can explain sexual reproduction in all systems (West *et al.*, 1999).

Sexual Conflict

A Pischedda, University of California, Santa Barbara, CA, USA
AD Stewart, Canisius College, Buffalo, NY, USA

Glossary

Anisogamy Reproduction resulting from the production of differently sized gametes by males and females (i.e., smaller sperm produced by males and larger eggs produced by females).

Interlocus sexual conflict A specific form of sexual conflict that occurs when the optimal outcome of sexual interactions is different for males and females. Interlocus sexual conflict selects for adaptations in each sex that increase their own fitness even if they are harmful to their mates. This conflict can lead to open-ended cycles of sexually antagonistic coevolution.

Intralocus sexual conflict A specific form of sexual conflict that occurs when alleles are beneficial when expressed in one sex but are costly when expressed in the other (i.e., 'sexually antagonistic alleles'). Intralocus sexual conflict can prevent both sexes from maximizing their fitness, as an adaptation in one sex reduces the level of adaptation in the other.

Locus The physical location of a specific gene or DNA sequence in a genome (plural: loci).

Sexual conflict An evolutionary conflict that results from the divergent reproductive interests of males and females (i.e., when males and females maximize their fitness using different strategies).

Sexual dimorphism The existence of phenotypic differences (e.g., physical and/or behavioral) between males and females.

Sexual selection A form of selection that acts on an individual's ability to reproduce. Sexual selection can occur when individuals of one sex (usually males) compete with one another for mating/reproductive opportunities (i.e., intrasexual selection, or 'male competition'), or when members of the other sex (usually females) choose mates based on specific physical or behavioral attributes (i.e., intersexual selection, or 'female choice').

Sexually antagonistic alleles Alleles (i.e., variants of genes at a specific locus) that have opposite effects on fitness when expressed in males and females.

Sexually antagonistic coevolution An evolutionary process that occurs between males and females where an adaptation that benefits one sex harms the other sex, and vice versa. Sexually antagonistic coevolution is caused by interlocus sexual conflict, and it results in each sex evolving and counter-evolving new strategies to maximize their fitness. Sexually antagonistic coevolution is often referred to as a coevolutionary 'arms race' between the sexes.

Speciation The evolutionary process by which new biological species are formed.

Introduction: What Is Sexual Conflict?

Early evolutionary views of reproduction, dating back as far as Darwin (1871), assumed that sexual interactions were mutually beneficial to both males and females. This harmonious view was associated with the assumption that many mating systems were strictly monogamous; under these conditions, the total number of offspring that an individual can produce is inherently linked with their mating partner, and any increase in the reproductive success of one partner will directly benefit the other. However, we now know that strict monogamy is extremely rare; in non-monogamous mating systems, partnerships are more temporary and the numbers of offspring produced by each partner are no longer necessarily equal. This can cause the reproductive strategies of males and females to diverge, creating conflict between the sexes.

Sexual conflict occurs when males and females have conflicting reproductive interests. The underlying cause of this conflict is anisogamy, i.e., the production of differently sized gametes by males and females. While male gametes (sperm) tend to be numerous, small, and relatively inexpensive, female gametes (eggs) tend to be fewer in number, larger, and relatively expensive. This causes a male's reproductive success (i.e., the number of offspring he sires) to be primarily limited by his number of successful fertilizations, whereas a female's reproductive success is limited by her number of eggs. Bateman (1948) demonstrated that this imbalance in gamete investment can lead to conflict over mating frequency. He found that the reproductive success of *Drosophila melanogaster* males increased rapidly with each additional mating, while female reproductive success did not. The optimal mating rate for males is thus higher than that for females. Parker (1979) was the first to show that, under these conditions, a trait increasing male mating success can spread in a population even if it is directly harmful to females. These two observations form the foundation of sexual conflict theory – males and females maximize their reproductive success in different ways, and the strategies that benefit one sex are often harmful to the other.

The field of sexual conflict has exploded since Parker's seminal work, and sexual conflict is now recognized as a ubiquitous and important force shaping the evolution of sexual species. As our understanding of the consequences of divergent sex roles has increased, we now recognize that sexual conflict can manifest in two fundamentally different ways. The first form of sexual conflict recognized by Parker is now referred to as 'interlocus' sexual conflict. This conflict occurs when the optimal outcome of sexual interactions differs for males and females, such that each sex evolves adaptations that increase their own fitness

(i.e., move them closer to their sex-specific optimum), but are harmful to their mates (Rice and Holland, 1997). In contrast, 'intralocus' sexual conflict occurs when a trait that is expressed in both sexes has opposite effects on male and female fitness, such that genetic variation that is beneficial for males is costly when expressed in females, and vice versa (reviewed in Bonduriansky and Chenoweth, 2009; Lande, 1980).

Both inter- and intralocus sexual conflict result from the divergent reproductive roles that males and females have in non-monogamous mating systems, and both are thus inherently linked with sexual selection. Sexual selection on males can lead to the evolution of competitive male traits that increase their reproductive success while harming their mates (interlocus sexual conflict), and it can also cause the sexes to maximize their fitness in different ways, such that alleles or traits that are beneficial when expressed in one sex are costly when expressed in the other (intralocus sexual conflict). Below, we describe both forms of sexual conflict in greater detail, provide examples for each, and discuss the evolutionary consequences of these conflicts.

Interlocus Sexual Conflict

Why Harm Your Mate?

It is somewhat paradoxical that selection could favor traits in either sex that are harmful to their mates, when each sex is directly dependent on the other to reproduce. Indeed, in the situation of strict monogamy, any male behavior or trait that harms his mate would directly lower his own fitness and likely not persist. However, when a male mates with multiple females, each female contributes less to his overall reproductive success, and an adaptation that increases male mating success can still be beneficial to males even if it is somewhat harmful to females. For example, a trait that doubles male mating success is expected to persist in a population as long as it lowers female reproductive success by less than 50%, because these 'harmful' males will still receive a net advantage in terms of offspring number. Thus, selection does not favor male harm itself, but it instead favors traits that increase male reproductive success, with female harm occurring as a pleiotropic by-product. Moreover, it is worth noting that sexual conflict can still occur even in a monogamous mating context. For example, males often invest heavily in strategies to prevent females from engaging in extra-pair matings; while this may be successful at ensuring female fidelity, it may also prevent males from securing additional matings for themselves if this investment is costly (Hosken *et al.*, 2009). Functional monogamy, therefore, does not always equal the absence of sexual conflict.

Interlocus Sexual Conflict: An Evolutionary Battle of the Sexes

As we describe above, interlocus sexual conflict occurs when there is conflict over the outcome of male–female interactions, with different outcomes maximizing reproductive success for each sex. This can occur any time males and females interact, and such conflicts often involve traits like mating frequency and duration, fertilization, reproductive rates, and parental investment/care. At the genetic level, interlocus sexual conflict reflects the fact that this conflict occurs between different genes at different locations in the genome (loci). Consider the example of mating frequency, in which male reproductive success is maximized by a higher mating rate than is optimal for females. Under these conditions, a 'persistence' allele may arise at a gene locus involved in male mating success, enabling males carrying this allele to mate more often. If the overall mating rate in the population increases to the point that it is detrimental to females, a 'resistance' allele may arise in a different gene locus involved in female resistance to male mating attempts. This resistance allele may then be met by another persistence allele, which leads to another resistance allele, and so on. This ongoing conflict between persistence and resistance alleles at different gene loci manifests as overt battles between males and females. An adaptation in males that increases their ability to mate females will shift the mating rate in the population closer toward the male optimum (benefiting males) and further away from the female optimum (harming females). Females may then counter-evolve an adaptation that mitigates this harm by making females resistant to male mating attempts, shifting mating frequency back toward the female optimum (Figure 1).

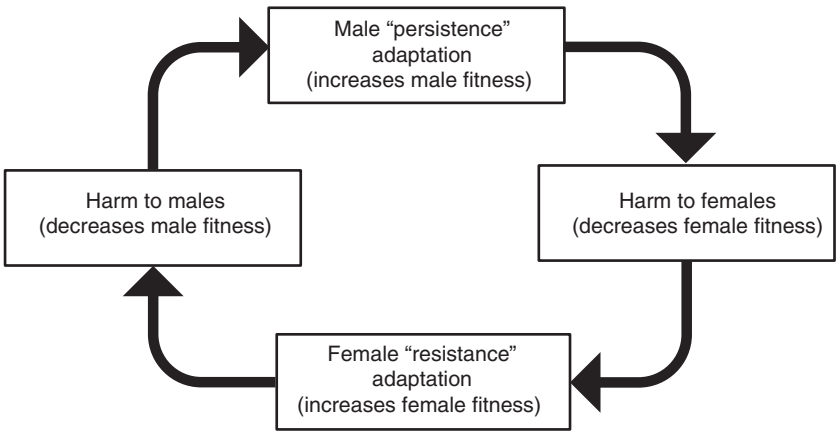

Figure 1 Sexually antagonistic coevolution can lead to an ongoing arms race between males and females as each sex evolves and counter-evolves new adaptations to maximize their respective fitness.

Interlocus Sexual Conflict and Sexually Antagonistic Coevolution

As the previous example suggests, interlocus sexual conflict can lead to ongoing, open-ended cycles of coevolution between the sexes, with each sex evolving and counter-evolving new strategies to maximize their fitness. This sexually antagonistic coevolution is an intraspecific coevolutionary 'arms race' between males and females that can involve any male–female interaction. The sexual arms race models developed by Parker (2006, 1979) assume that the costs of 'armament' (physical or behavioral) and the potential values of winning the arms race differ between the sexes. If females have a low arms level, any male mutation that is sufficient to overcome the female trait will be favored. Females can then counter-evolve by increasing their arms level, and this ongoing escalation of arms will continue until one sex reaches the point where evolving larger armaments is more costly than the value of winning. This 'losing' sex will then be selected to reduce its armaments to zero, because it will have higher total fitness by losing the race, but not paying any arms costs, than if it pays the costs necessary to win. The 'winning' sex can then continue to win the race with smaller armaments (and lower costs), so it will be selected to reduce its arms to just above the level necessary to win. However, in so doing, the 'losing' sex can then increase its armaments at a lower cost, potentially triggering another round of adaptation and counter-adaptation. This cycle can repeat indefinitely.

The ongoing nature of this coevolution makes it difficult to detect empirically, because at any given time, one sex could be 'ahead' of the other in this arms race, or the two sexes could be relatively 'even,' depending where they are in the cycle. However, a number of different approaches have been used to effectively demonstrate sexually antagonistic coevolution. Phylogenetic and experimental comparisons between closely related species of water striders have revealed intraspecific antagonistic coevolution involving mating behaviors and male grasping/female anti-grasping structures (Arnqvist and Rowe, 2002a, 2002b; Rowe and Arnqvist, 2002). Experimental evolution studies in the fruit fly, *D. melanogaster*, have indirectly demonstrated sexually antagonistic coevolution by showing that males evolve to be more harmful when females are unable to coevolve (Rice, 1996), and less harmful when reared under continuous monogamy (Holland and Rice, 1999).

Sexually antagonistic coevolution leads to a diverse array of behavioral, morphological, and physiological adaptations that can potentially influence any interaction between males and females. However, conflicts over the amount of parental investment or parental care may not be as strongly associated with harmful adaptations and sexually antagonistic coevolution as conflicts over mating (Lessells, 2006). These inconsistent outcomes likely result from differences in the benefits, costs, and feasibility of manipulating or resisting manipulation. Theory suggests that the benefits of manipulating parental investment are smaller, and the costs higher, compared to the benefits and costs of manipulating mating. Sexually antagonistic coevolution involving parental investment may consequently occur less frequently than antagonistic coevolution involving other forms of sexual conflict.

Can Interlocus Sexual Conflict Lead to Speciation?

Interlocus sexual conflict is now recognized as a dominant driver of evolutionary change within and between species. At the population level, these open-ended cycles of coevolution between males and females follow independent trajectories, indicating that interlocus sexual conflict may lead to divergence between populations, and can potentially act as an 'engine of speciation' (Gavrilets, 2000; Gavrilets and Waxman, 2002; Parker and Partridge, 1998; Rice, 1998; Rice *et al.*, 2005). Much of the work supporting this hypothesis is theoretical, but empirical support is mixed. A comparative study found that insect groups with strong interlocus sexual conflict speciated at a rate four times higher than groups without sexual conflict (Arnqvist *et al.*, 2000). Similarly, an experimental evolution study in dung flies found that large populations with stronger sexual conflict diverged more than small populations with weaker conflict (Martin and Hosken, 2003), but comparable experimental evolution studies in other species have failed to detect such a relationship (Gay *et al.*, 2009; Wigby and Chapman, 2006). Although interlocus sexual conflict can lead to population divergence and speciation, this may only occur when certain conditions are met and conflict is unconstrained in populations (Gavrilets, 2014).

Intralocus Sexual Conflict

Intralocus Sexual Conflict: A Genetic Tug-of-War Between the Sexes

Intralocus sexual conflict occurs when alleles for a shared trait are beneficial when expressed in one sex, but are detrimental when expressed in the other sex. Unlike interlocus sexual conflict, which occurs between alleles at two different loci, intralocus sexual conflict involves only a single locus, with alleles at this locus having opposite effects when expressed in each sex. Given that males and females are both members of the same species, how can such a genetic conflict exist? Intralocus sexual conflict results from the different selective pressures that males and females experience when their reproductive roles diverge, as is the case in non-monogamous mating systems. Although these different selective pressures create different optimal phenotypes for males and females, both sexes share largely the same genome; broadly speaking, each male and each female possess the same autosomes, and only differ with respect to the number and types of sex chromosomes. Therefore, the majority of gene loci are present in both sexes, and an allele that makes for a 'good' male (one with high fitness, compared to other males) may not make for a 'good' female, and vice versa. In other words, intralocus sexual conflict results in a genetic 'tug-of-war' between males and females over the optimal expression of these sexually antagonistic alleles, and it can ultimately lead to a negative genetic correlation between male and female fitness (**Figure 2**).

Hypothetically speaking, what would such a conflict look like? Imagine a population of early evolving humans, in which both males and females utilize the same skeleton for largely the same tasks (e.g., anchoring and protecting organs, calcium

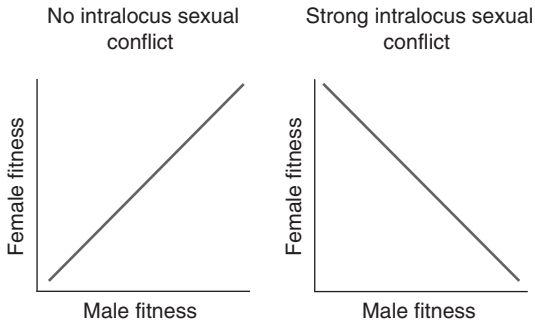

Figure 2 In the absence of intralocus sexual conflict (left), we would expect a positive genetic correlation between male and female fitness, with genetic variation influencing male and female fitness in the same way. In contrast, when there is strong intralocus sexual conflict in a population (right), we would expect a negative genetic correlation between male and female fitness, such that genetic variation that increases male fitness decreases females fitness, and vice versa.

storage, and locomotion). However, females have an additional functional constraint: childbirth. The head of the child must be able to pass through the pubic arch of females during childbirth, otherwise the life of the infant, the mother, or both, may be lost. Now suppose that a new mutation enters this population, one that widens hips to a small degree. The fate of this new mutation will depend on its effect in the individual in which it is expressed. If this mutation is present in a female, she will likely have a slightly easier time during childbirth, and the decreased risk of death (for both mother and infant) will increase her fitness relative to females that do not possess the mutation. This change in hip width might reduce her locomotor ability by decreasing speed and/or endurance, but if the benefit in reduced mortality during childbirth is larger than these costs, the net effect of this mutation in females will be positive, and natural selection will increase its frequency in the population. The daughters of this female will inherit this mutation and will have a similar increase in childbirth survival (and decrease in locomotor ability). Since the skeleton is a shared trait that is expressed in both sexes, the sons of this female will also possess wider hips. Unfortunately, males do not give birth, so they will receive none of the benefits of having wider hips but will suffer all of the locomotor costs. Thus, when expressed in males, the net effect of this mutation will be negative, and natural selection will decrease its frequency in the population. While this example is purely hypothetical, it is exactly the sort of relationship (a selective advantage in one sex, and a selective disadvantage in the other) that drives the genetic tug-of-war seen in intralocus sexual conflict. But, aside from theoretical and hypothetical arguments, what evidence is there that intralocus sexual conflict actually exists?

Empirical Evidence for Intralocus Sexual Conflict

Intralocus sexual conflict has been most extensively studied in laboratory populations of the fruit fly, *D. melanogaster*. Chippindale *et al.* (2001) provided the first direct evidence for intralocus sexual conflict by experimentally cloning multiple haploid genomes (i.e., a single copy of all major chromosomes) and measuring the fitness effects of these genotypes when expressed in males and females (a method referred to as 'hemiclonal analysis'). As predicted by intralocus sexual conflict, there were significant interactions between genotype and the sex that it was expressed in. Specifically, haploid genotypes that created males with high fitness also created females with low fitness, and vice versa. Follow-up work using similar techniques demonstrated that the majority of this intralocus sexual conflict was attributable to the X chromosome (Gibson *et al.*, 2002). Hemiclonal analysis in *D. melanogaster* was later used to demonstrate a fundamental consequence of intralocus sexual conflict: a negative relationship between the fitness of parents and their opposite-sex offspring. In this study, higher fitness mothers produced lower fitness sons, and higher fitness fathers produced lower fitness daughters (Pischedda and Chippindale, 2006). Additional evidence for intralocus sexual conflict in *D. melanogaster* comes from experimental evolution studies in which genomes evolved exclusively in males ('male-limited' genomes), removing any potential counter-selection on alleles when expressed in females (Prasad *et al.*, 2007; Rice, 1996). Males expressing these male-limited genomes exhibited increased fitness, but the same genomes substantially lowered fitness when expressed in females. Finally, a genomic analysis of intralocus sexual conflict estimated that at least 8% of the genes in *D. melanogaster* have sexually antagonistic effects on fitness (Innocenti and Morrow, 2010).

While experimentally tractable, laboratory studies of *D. melanogaster* do not provide sufficient evidence that intralocus sexual conflict is a widespread phenomenon. To that end, many other studies have shown that intralocus sexual conflict is present in a range of different species. For example, negative correlations for fitness between related males and females have been reported in populations of crickets (Fedorka and Mousseau, 2004), side-blotched lizards (Calsbeek and Sinervo, 2004), red deer (Foerster *et al.*, 2007), collared flycatchers (Brommer *et al.*, 2007), brown anole lizards (Calsbeek and Bonneaud, 2008), mountain goats (Mainguy *et al.*, 2009), Indian meal moths (Lewis *et al.*, 2011), bank voles (Mills *et al.*, 2012), and a number of different plant species (reviewed in Prasad and Bedhomme, 2006). It thus appears that intralocus sexual conflict is indeed widespread across sexually reproducing species.

Specific Traits Involved in Intralocus Sexual Conflict

Alongside attempts to demonstrate the action of intralocus sexual conflict, there have been a number of studies devoted to identifying specific traits that are involved in this conflict. For example, the same hemiclonal analysis used to provide evidence for intralocus sexual conflict (Chippindale *et al.*, 2001) was also used to identify locomotor activity as a trait at least partly responsible for the intralocus sexual conflict seen in *D. melanogaster* (Long and Rice, 2007). Specifically, genotypes that coded for relatively high rates of movement increased male fitness (possibly by increasing their contact rate with females), but decreased female fitness (possibly due to unnecessary energy expenditure).

Some of the most common traits involved in intralocus sexual conflict are those relating to overall body size or the size of different morphological structures. Body size is often genetically correlated between the sexes, but in many species

larger body sizes are favored in males and smaller body sizes are favored in females. This sexually antagonistic selection on body size has been reported in species like side-blotched lizards (Calsbeek and Sinervo, 2004), haplorhine primate species (Lindenfors and Tullberg, 1998), and humans (Stulp *et al.*, 2012). There are also several species in which large body size is favored in females and small body size is favored in males, including the mosquito *Aedes aegypti* (Bedhomme *et al.*, 2003) and collared flycatchers (Merilä *et al.*, 1997).

Sexual selection on males often creates a fitness advantage to males expressing large or elaborate structures, while the energetic and mechanical constraints associated with these traits are costly in females. For example, in carrion flies, males with elongated heads are favored by females and receive a fitness advantage, while females with elongated heads have lower fitness due to their reduced coordination, visual acuity, and movement (Bonduriansky and Rowe, 2003; Bonduriansky and Rowe, 2005). In Soay sheep, males with larger horns have a fitness advantage over males with smaller horns, while the opposite is true in females (Robinson *et al.*, 2006). Similar effects of wing length are seen in reed warblers, as wing length is positively associated with male fitness and negatively associated with female fitness (Tarka *et al.*, 2014). Alternatively, females may possess a complex trait that is necessary for reproduction but is not utilized in males (as in the human hip width example we describe above). This appears to be the case in the parasitoid fly *Emblemasoma auditrix*, as females use specialized 'ears' to locate hosts for oviposition, but males do not seem to use these costly structures for either mate location or predator avoidance (Lakes-Harlan *et al.*, 2014).

Although the genetic basis of many of the above traits is unknown, a specific allele has been identified in *D. melanogaster* that experiences intralocus sexual conflict. In this species, resistance to the pesticide DDT is caused by a single allele in the detoxification gene, *Cyp6g1* (Daborn *et al.*, 2002). In the absence of DDT, this allele has opposing fitness effects when expressed in males and females: it increases female fecundity (McCart and Buckling, 2005), but decreases male mating success (Smith *et al.*, 2011). Theory and experimental populations of *D. melanogaster* indicate that this sexually antagonistic selection is sufficient to maintain genetic variation at this locus (Rostant *et al.*, 2015).

Can Intralocus Sexual Conflict Be Resolved?

While there is ample evidence for intralocus sexual conflict across a range of species, this conflict is not expected to operate at every gene locus for two primary reasons. First, many gene loci are likely similarly selected in the sexes, in that alleles beneficial to a male will also be beneficial for a female (with the same being true for deleterious alleles). Secondly, unlike interlocus conflict, there are a number of genetic mechanisms that can potentially ameliorate intralocus sexual conflict (Stewart *et al.*, 2010). For example, if the conflict results from different optimal amounts of gene product, then natural selection could favor sex-specific regulatory elements (like androgen and/or estrogen receptors) that modify the amount of gene product produced in each sex, allowing each to move closer to their optimum. Alternatively, if the optimal amino acid sequence differs between the sexes, then gene duplication followed by sex-limited gene expression could restrict the expression of sexually antagonistic alleles to only the sex that they benefit (Rice, 1984). Day and Bonduriansky (2004) argued that selection should favor the evolution of genomic imprinting for sexually antagonistic alleles, such that maternally inherited alleles are silenced in sons, and paternally inherited alleles are silenced in daughters; this hypothesis is supported by evidence that sexually antagonistic alleles have reduced heritability to opposite-sex progeny (Bonduriansky and Rowe, 2005).

Although it appears that intralocus sexual conflict can be reduced, if not eliminated, the speed at which this resolution occurs remains an open question (Stewart *et al.*, 2010). Sexual dimorphism, in which males and females exhibit different phenotypes, is a likely outcome of resolved intralocus sexual conflict. However, many sexually dimorphic traits still show strong genetic correlations between the sexes (Bedhomme and Chippindale, 2007; Cox and Calsbeek, 2009), indicating that conflict has not been completely resolved. In addition, intralocus sexual conflict can continue to involve sexually dimorphic traits that have become genetically decoupled between the sexes. For example, male broad-horned flour beetles develop enlarged mandibles to use in male–male competition, and males with larger mandibles have higher fighting and mating success (Harano *et al.*, 2010). Female beetles do not have enlarged mandibles, and mandible size is uncorrelated between the sexes. However, males have evolved a modified body form with a larger thorax and smaller abdomen to support these large mandibles, and body size *is* correlated between the sexes. Small abdomens are costly to females, as abdomen size determines the number of eggs a female can carry. Thus, despite sexual dimorphism for mandible size in this species, intralocus sexual conflict over this trait persists because of its pleiotropic effects on body size.

Persistent intralocus sexual conflict should select for traits in males and females that minimize the associated costs. For example, females of several species, including side-blotched lizards (Calsbeek and Sinervo, 2004), anole lizards (Calsbeek and Bonneaud, 2008; Cox and Calsbeek, 2010), and *D. melanogaster* (Fuller and Mousseau, 2007) appear to bias the sex-ratio of their progeny depending on the fitness of their mate, producing more sons when mated to high fitness males and more daughters when mated to low fitness males. This 'cryptic female choice' is a behavioral adaptation by females that minimizes the fitness costs associated with intralocus sexual conflict (Cox and Calsbeek, 2010). Even if intralocus sexual conflict were completely resolved at a given point in time, each new mutation reopens the possibility of conflict, so the elimination of intralocus sexual conflict is unlikely to ever be absolute, and the tug-of-war will persist.

How Does Sexual Conflict Affect Populations?

Sexual conflict occurs between males and females (or, more specially, between alleles expressed in males and females), but it has consequences for fitness at the population level. Because both sexes are prevented from reaching their respective reproductive optima, sexual conflict lowers the overall reproductive output of a population, potentially interfering with adaptation. Interlocus sexual conflict has been shown to reduce the reproductive performance of whole populations

(Holland and Rice, 1999), indicating a strong cost to sex in non-monogamous species. Moreover, a combination of theoretical and experimental work suggests that male harm not only impedes female adaptation, it can also reduce the effectiveness of natural selection within a population (Long *et al.*, 2009). Intralocus sexual conflict can similarly lower the fitness of populations by preventing both males and females from maximizing their fitness. In support of this, both sexes exhibit decreased fitness in populations of *D. melanogaster* with higher levels of intralocus sexual conflict (Morrow *et al.*, 2008). The reduction in population fitness associated with sexual conflict has led to the hypothesis that sexual conflict may lead to an increased risk of extinction, but there is no clear relationship between the strength of sexual selection (and, by extension, sexual conflict) and the risk of species extinction in birds (Morrow and Pitcher, 2003) or mammals (Morrow and Fricke, 2004).

The impacts of sexual conflict on males, females, and the population as a whole demonstrate the substantial costs of divergent sex roles. Sexual conflict is unavoidable in non-monogamous mating systems, and will exist in populations whenever there are deviations from strict, lifelong monogamy. Sexual conflict is thus inherently linked to sexual selection, and both inter- and intralocus sexual conflict increase when sexual selection operates more strongly in populations (Cox and Calsbeek, 2009; Holland and Rice, 1999; Nandy *et al.*, 2013). Sexual conflict is thus a ubiquitous and powerful force driving diversity, and it directly influences the evolution of behavior, morphology, and reproduction in sexual species.

Sexual Dimorphism

DJ Fairbairn, University of California, Riverside, CA, USA

Glossary

Allometry (*adj.* allometric) Departure from geometric similarity; disproportionate change in a given variable (often size of a body part) with some measure of body size. A relationship is allometric if the ratio of trait value to body size increases or decreases with body size.

Clade A group of species defined by descent from a single common ancestor and including all descendants from that ancestor.

Dioecy (*adj.* dioecious) The allocation of reproductive roles in a population such that all individuals are either male or female and possess only male or female reproductive organs. Individuals with the reproductive organs of only one sex are *gonochoric*, so dioecious species contain only gonochoric individuals.

Disruptive selection Selection against intermediate values and in favor of values both above and below the population mean.

Fecundity The number of eggs or offspring produced by a female.

Fertility When referring to individuals: the quality of being fertile; being able to produce offspring. When referring to populations: the average number of births per female within a given age class.

Fitness In evolutionary biology: an abstract concept that refers to the success of an individual in contributing genes to future generations. Fitness is determined by survivorship (viability), reproductive success (mating success, fertility, and fecundity), and generation time.

Genetic correlation Correlated variation in the breeding values of two or more traits caused by the additive effects of overlapping sets of genes (pleiotropy) or linkage. If traits are genetically correlated, selection on one trait causes a correlated response in the other.

Genomic imprinting An epigenetic mechanism whereby the expression of alleles at a given locus depends upon the parent of origin. For example, if the allele inherited from the father is imprinted (epigenetically silenced), only the allele inherited from the mother is expressed in the offspring.

Haplodiploidy A sex-determining system in which females develop from fertilized eggs and are diploid, whereas males develop from unfertilized eggs and are haploid.

Sex-linked gene A gene located on a sex chromosome.

Somatic Referring to body components (cells, tissues, organs, or traits) other than those that comprise the reproductive system.

What Is Sexual Dimorphism?

The term *dimorphism* denotes a trait that occurs in two distinct forms or morphs within a given species and traits that differ consistently between males and females are *sexual dimorphisms*. Sexually dimorphic traits may differ so radically between sexes that they can be reliably used to differentiate males from females. Color dimorphisms in many species of birds, lizards, and fishes are familiar examples of this (**Figure 1**). Other common examples include the presence of antlers or other weapons in only one sex (usually males), adaptations of one sex (usually females) for parental care (e.g., mammary glands in female mammals and brood pouches in many invertebrates), and externally apparent differences in genitalia (**Figure 2**). However, many sexual dimorphisms are not as extreme as this. Any trait that differs on average between sexes is considered sexually dimorphic, even if the trait distributions overlap considerably between sexes. Height in humans provides a familiar example of this type of sexual dimorphism (**Figure 3**).

Primary and Secondary Sexual Dimorphisms

Sexual dimorphisms have traditionally been categorized as either primary or secondary, depending upon what role they play in reproduction. This distinction goes back to Darwin's initial discussions of sexual differences in which he defined sexually dimorphic traits as primary if they were directly connected to reproduction and as secondary if they were not (Darwin, 1859, p. 150). He later clarified that primary sexual traits are components of the reproductive tract; specifically the organs and tissues that produce and release large, nutrient-rich macrogametes (eggs) in females and more numerous, smaller, and more motile microgametes (sperm) in males (Darwin, 1871). Secondary sexual traits are not essential for reproductive function in this strict sense, although they often increase mating or reproductive success. Familiar examples include sexually dimorphic breeding plumages in many birds (**Figure 1**), antlers in male deer and bright throat and belly patches in male lizards. In humans secondary sexual traits include, but are not limited to, enlargement of female breasts, increased male facial hair, deepening voice in males and differences between the sexes in body size, shape, muscle mass, and fat distribution (Mealey, 2000).

Why Do Sexual Dimorphisms Evolve?

Sexual dimorphisms evolve in response to persistent selection favoring different trait values in the two sexes (Lande, 1980; Slatkin, 1984; Reeve and Fairbairn, 2001; Blanckenhorn,

Figure 1 A pair of mallard ducks illustrate sexual dimorphism in color (*sexual dichromatism*) that clearly distinguishes the breeding male (bottom) from his mate (top). Photo by Derek Roff.

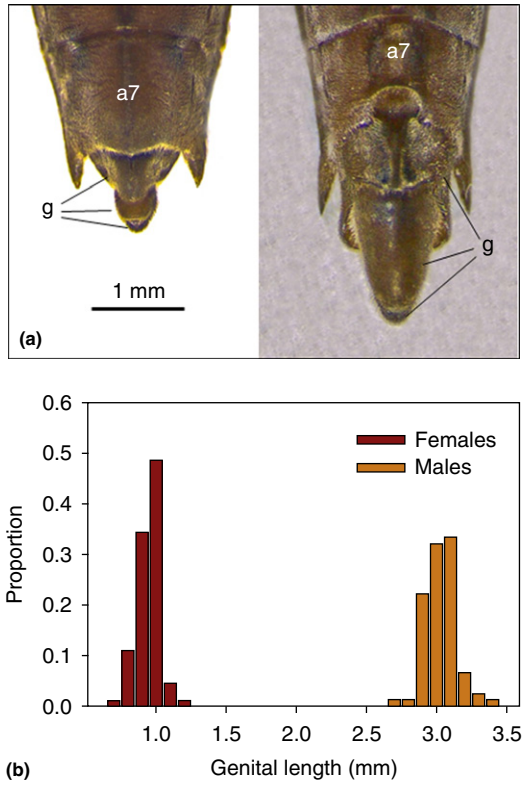

Figure 2 The terminal segments of an insect, the water strider *Aquarius remigis* (Hemiptera, Gerridae) exemplify dimorphisms that clearly distinguish the sexes. (a) Ventral views of a female (left) and a male (right) photographed on the same scale. a7: the seventh and final abdominal segment; g: the three genital segments. (b) Distribution of genital lengths for males and females from a single population. Genital length is measured at midline in ventral view.

2005). For example, in many sexually dichromatic species selection favors bright colors in males but more subdued and often cryptic coloration in females (**Figure 1**). The disparity in selection on the two sexes ultimately arises from the different ways they achieve reproductive success: males through fertilizing eggs and females through producing eggs or live young. Trait values that confer high fitness for male function often differ from those that convey high fitness for female function, resulting in disruptive selection favoring sexual dimorphisms.

Many of the most conspicuous and familiar secondary sexual dimorphisms have evolved in response to sexual selection. Sexual selection on males arising from both direct competition among males for mates (*intrasexual selection*) and female mate choice (*intersexual selection*) has been responsible for the exaggeration and diversification of many traits in males, including body size, weapons, and sexual display traits (Darwin, 1871; Andersson, 1994; Fairbairn *et al.*, 2007; Emlen, 2014). The large size and bulbous noses of male elephant seals (**Figure 4(a)**), the enlarged claw of male fiddler crabs (**Figure 4(b)**), and the colorful plumage of male mallard ducks (**Figure 1**) are classic examples of such traits. Sexual selection also influences secondary sexual traits in females, particularly in species where males invest substantially in mating or paternal care, but its effects are generally more muted than in males (Bonduriansky, 2001; Clutton-Brock, 2009).

Many traits traditionally classified as primary sexual traits are also subject to sexual selection (Eberhard, 1996, 2009; Birkhead and Moller, 1998; Birkhead, 2000; Hosken and Stockley, 2004; Leonard and Cordoba-Aguilar, 2010; Simmons and Fitzpatrick, 2012). For example, if fertilization is internal and females mate with more than one male during a given reproductive bout, competition among males extends to competition for fertilizations within female reproductive tracts. Sexual selection during this internal competition affects many aspects of the male reproductive tract, including the size and sperm-producing capacity of testes, the production and composition of accessory seminal fluids, and the size, shape, and function of the copulatory organ. Females, in turn, evolve adaptations that enable them to resist matings or to preferentially store and use the sperm of different males. The adaptations and counter-adaptations of male and female reproductive tract traits under this scenario provide classic

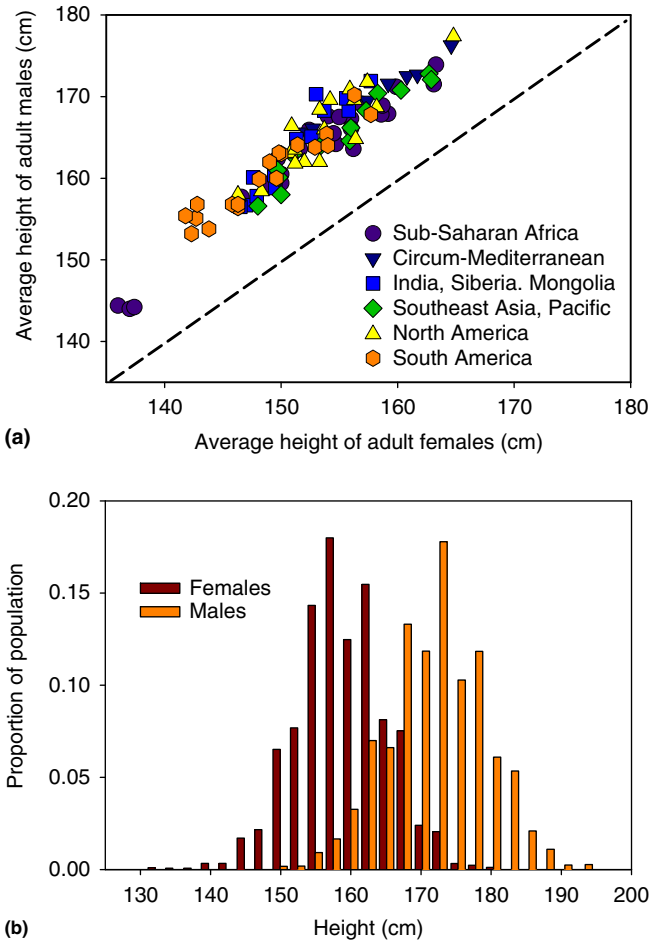

Figure 3 Height in humans is an example of a sexually dimorphic trait that shows extensive overlap between sexes. (a) A plot showing the mean male height versus mean female height for 97 human populations. The dashed diagonal line is the one-to-one line. The average height of males exceeds that of females within every population as well as overall (the overall means are 164 cm for males and 153 cm for females), but the ranges in population means overlap extensively (144–177 cm in males and 136–165 cm in females). Data from Holden, C., Mace, R., 1999. Sexual dimorphism in stature and women's work: A phylogenetic cross-cultural analysis. American Journal of Physical Anthropology 110, 27–45. (b) The distribution of height in adult males and females in the US population, 1960–62. The mean height of males is 172 cm and of females 159 cm, a difference of about 8%, which is typical of human populations. Data from the National Center for Health Statistics, 1966. Public Health Service Bulletin No. 1000, Series 11, No. 14, p.39.

examples of *interlocus sexual conflict* and *coevolutionary arms races* driven ultimately by sexual selection (Rice and Holland, 1997).

Sexual selection contributes to the evolution of many sexual dimorphisms, but it is far from the sole cause. Selection acting through variation in viability, fertility, and fecundity also acts differentially on each sex, tailoring the overall biology of each to maximize fitness through either male or female function (Clutton-Brock, 1988; Blanckenhorn, 2005; Ruckstuhl and Neuhaus, 2005; Fairbairn *et al.*, 2007; Fairbairn, 2013a). For example, adaptations for female reproductive function such as brood pouches, enlarged abdomens, thickened bodies, and modifications of genital openings for spawning eggs or to serve as ovipositors are common distinguishing features of females across the animal kingdom (Fairbairn, 2013a,b). Although these traits may be subject to sexual selection through male mate choice, the primary evolutionary driver is selection favoring female traits that confer high fecundity and parental success (Preziosi and Fairbairn, 1997; Prenter *et al.*, 1999; Blanckenhorn, 2005; Fairbairn, 2013a).

Many sexual dimorphisms in ecological and life-history traits also show little or no influence of sexual selection (Clutton-Brock, 1988; Shine, 1989; Ruckstuhl and Neuhaus, 2005; Barrett and Hough, 2013; Fairbairn, 2013a). For example, males and females often mature and die at different ages, have different diets, occupy different habitats during at least some phases of their lives, and differ in their propensity to disperse or migrate. These differences in ecology and life history are frequently associated with dimorphisms in size and shape and in the appendages or organs used for movement or feeding. Darwin attributed these types of secondary sexual differences to the 'different patterns of life' adopted by each sex as a consequence of their different roles in propagating the species (Darwin, 1871, p. 127). This explanation, now formalized as the 'dimorphic niche hypothesis,' has been well

Figure 4 Examples of secondary sexual dimorphisms that have evolved at least partly in response to sexual selection on males. (a) Male and female northern elephant seals (*Mirounga angustirostris*) show pronounced secondary sexual dimorphisms in body size and shape, and in the size and shape of the nose, which is greatly elongated in males. (b) Male (left) and female (right) fiddler crabs (*Uca pugilator*) differ in body size and color, and males have one greatly enlarged major claw. Photos by Derek Roff.

supported by both theoretical models and empirical studies (Slatkin, 1984; Hedrick and Temeles, 1989; Ruckstuhl and Neuhaus, 2005; Dudley, 2006; Bulte *et al.*, 2008; Fairbairn, 2013a,b). An alternative hypothesis, that ecological differences between the sexes evolve to reduce competition between them, is plausible, but the weight of evidence supports the dimorphic niche hypothesis, with reduction in intersexual competition a beneficial consequence of ecological segregation rather than the initial cause (*op. cit.*).

How Do Sexual Dimorphisms Evolve?

When selection favors different trait values in males and females, the evolutionary response to such selection is constrained by genetic correlations between the sexes that arise because the two sexes share all or almost all of their genome (Lande, 1980; Reeve and Fairbairn, 2001; Mank, 2009). The selection acts antagonistically on genes that influence the trait similarly in the two sexes, producing *intralocus sexual conflict* at those shared loci (Bonduriansky and Chenoweth, 2009). The most pervasive mechanism for mitigating this conflict is the evolution of sex-specific patterns of gene expression such that genes beneficial to females are preferentially expressed in females, whereas the opposite is true for genes beneficial to males (Connallon and Knowles, 2005). Transcriptomic studies have revealed sex-biased gene expression in thousands of genes on both autosomes and sex chromosomes and in both reproductive and somatic tissues (Mank, 2009; Mank *et al.*, 2013; Wright and Mank, 2013; Perry *et al.*, 2014). These sex-specific patterns can evolve through a number of processes including gene duplication, genomic imprinting, sex-specific posttranscriptional regulation (e.g., sex-specific patterns of gene splicing) and co-option of hormones from the sex-determining pathway as regulatory switches (Gallach and Betran, 2011; Wright and Mank, 2013). The latter has the potential to produce very rapid evolution of sexual dimorphisms and may account for rapid evolution of many androgen-dependent traits in response to sexual selection in vertebrates.

Many species lack sex chromosomes and instead use mechanisms such as haplodiploidy or environmental or social cues to determine sex (Beukeboom and Perrin, 2014). In these species sexual dimorphisms must arise solely from sex-specific patterns of autosomal gene expression. However, in species with chromosomal sex determination, genes located on sex chromosomes (*sex-linked* genes) are exclusive to one sex (e.g., genes on Y chromosomes occur only in males in species with XX/XY chromosomal systems) or occur in one sex more often than the other (e.g., genes in X chromosomes spend two-thirds of the time in females). Sex chromosomes thus permit the evolution of sex-limited or sex-biased genes as an additional mechanism for mitigating intralocus sexual conflict. A number of theoretical models have predicted that sex chromosomes should therefore be hotspots for genes subject to antagonistic selection on males and females (e.g., Charlesworth and Charlesworth, 1980; Rice, 1984, 1987; Charlesworth, 2002; Kirkpatrick and Hall, 2004; Connallon and Clark, 2010). In accordance with these predictions, the proportion of genes with sex-biased expression is higher on sex chromosomes than on autosomes and such genes are distributed on the homomorphic (e.g., X in XX/XY systems and Z in ZZ/ZW systems) and heteromorphic (Y or W) sex chromosomes as predicted by theory (Mank, 2009; Stewart *et al.*, 2010; Wright and Mank, 2013; Dean and Mank, 2014). However sex chromosomes typically comprise only 2–18% of the genome and sex-linkage seldom accounts for much more of the variance in sexually dimorphic traits than would be expected based on this proportion (Fairbairn and Roff, 2006; Husby *et al.*, 2013; Dean and Mank, 2014). Thus, although sex-linkage likely facilitates the evolution of sexual dimorphisms, sex-biased expression of autosomal genes accounts for

most of the genetic variation in dimorphic phenotypes even in species that have sex chromosomes.

The Prevalence and Distribution of Sexual Dimorphism in Animals

Variation among Animal Classes

Most animal species are dioecious (ca. 95%; Bachtrog *et al.*, 2014) and exhibit some form of externally apparent sexual dimorphism (Fairbairn, 2013a,b). The following discussion pertains only to dimorphisms in external morphology (hereafter sexual dimorphism in morphological traits (SDM)) because these are the most reliably reported in species descriptions. However, dimorphisms in life history, ecology, and behavior are also common and are often correlated with SDM. Species with SDM occur in at least 73 animal classes (**Figure 5**) and more than 96% of animal species are found in classes where SDM is common to universal.

Among the major animal lineages, SDM is most prevalent in the Ecdysozoa (**Figure 5**; Fairbairn, 2013a). This is the most speciose animal lineage and includes the massive phylum Arthropoda (insects, arachnids, crustaceans, and relatives), roundworms (Nemata), and six minor phyla. Morphological dimorphisms are common to universal in 80% of ecdysozoan classes and these classes contain 99.9% of ecdysozoan species. In the Deuterostomia, the major lineage composed of chordates, echinoderms, and hemichordates, SDM is common to universal in 52% of classes which contain 90% of species. The prevalence of SDM is notably lower in the Lophotrochozoa, the diverse lineage composed of 18 phyla of mainly shelly or vermiform animals, the most speciose of which are the molluscs (Mollusca), flatworms (Platyhelminthes), and segmented worms (Annelida). In this lineage SDM is common to universal in 43% of classes containing 71% of species. By far the lowest prevalence of SDM occurs in the eight phyla not included in these three major lineages, the largest of which are the jellies (Cnidaria), comb jellies (Ctenophora), and sponges (Porifera). In these phyla, SDM is common to universal in only 20% of classes which contain only 19% of species.

Why is SDM more prevalent in some types of animals than in others? Surveys across the animal kingdom suggest several predisposing factors (Ghiselin, 1974; Fairbairn, 2013a). Prevalence is clearly higher in animals that are active and mobile and in which mating requires close behavioral interactions, especially if these include sexual grasping and internal fertilization. If such species occur at high densities or aggregate for reproduction, there is ample opportunity for sexual selection and sexual conflict to drive the evolution of SDM in both primary and secondary sexual traits. Alternatively, if such species occur at low densities, selection for finding mates favors sexually distinct adaptations for sending and receiving sexual signals, as well as adaptations (most commonly in males) for long distance movement in search of mates. Regardless of density, sexual grasping and internal fertilization require sex-specific adaptations in genitalia and somatic traits and are invariably associated with SDM. High female fecundity is another predisposing factor for SDM. Many female animals produce large clutches of eggs or live young and have evolved large body sizes (relative to males), enlarged abdomens, or expanded cavities within their exoskeletons to accommodate these. Similarly, if eggs are brooded after oviposition, the brooding sex (usually females) typically has morphological adaptations for holding and protecting the brood.

Sexual dimorphisms reach their greatest extremes in species with dwarf males (**Figure 6**; Ghiselin, 1974; Vollrath, 1998;

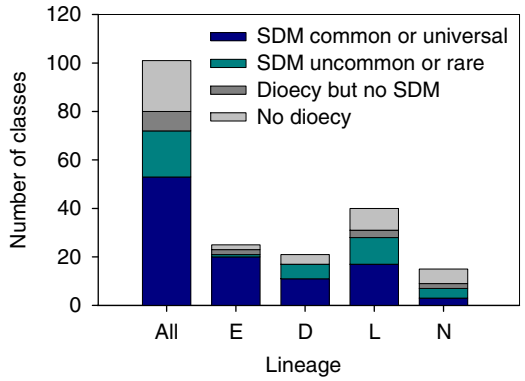

Figure 5 Prevalence of externally apparent sexual dimorphism in morphological traits (SDM) in animals. Each of 101 taxonomic classes has been scored for the presence or absence of dioecious species and for the frequency of SDM among dioecious species (absent, rare, uncommon, common, universal). Small Phyla that lack class designations are treated as single classes. Data are shown for all classes combined (left bar) and separately for the three major evolutionary lineages of bilaterian animals, Ecdysozoa (E), Deuterostomia (D), and Lophotrochozoa (L), and for the phyla not included in these lineages (N). Classification is based upon Roskov *et al.* (2014) and assignment of phyla and their component classes to evolutionary lineages is based upon Hickman *et al.* (2007) and Nielsen (2012). Recent taxonomic revisions cause slight disparities between the frequencies shown and those reported in Fairbairn (2013a,b).

Figure 6 A pair of golden orb spiders, *Nephila clavipes*, illustrate male dwarfism. The large female is in the middle of her mating web and a much smaller male can be seen above and to her right. Photo by Derek Roff.

Fairbairn, 2013a). Males are conventionally defined as dwarfs if they are less than ½ as long or ⅛ the mass of their mates and SDM at least this extreme has evolved independently in 23 animal classes distributed across 12 phyla (Fairbairn, 2013a). Male dwarfism is most common in parasitic and commensal species, an association that occurs in at least 13 classes and 8 phyla, but it also occurs in diverse clades of free-living species. In the latter, females are typically highly fecund but rare and widely dispersed, and males are adapted for long distance mate searching. The tiny males mature early and have short lives relative to their mates. In many species, they die after a single mating or live their reproductive lives attached to or inside the bodies of their mates. In the extreme, mature females outweigh their mates by several orders of magnitude and the sexes are so disparate morphologically that only trained zoologists can discern that they belong to the same species (Fairbairn, 2013a).

Variation among Traits

Some traits are more likely than others to show SDM (**Figure 7**; Fairbairn, 2013a). For example, gonadal dimorphisms are seldom visible externally, whereas dimorphisms in gonopores or external genitalia are common, especially in species that have internal fertilization. The traits most likely to show SDM are body size and shape. Females average larger than males in 42 classes, whereas males average larger in seven and both types of dimorphism occur with nearly equal frequency in two (Fairbairn, 2013a). Females tend to be the larger sex in species in which they are subject to strong fecundity selection favoring large size while sexual selection on male size is absent, weak, or favors smaller males (Roff, 1992; Fairbairn, 1997, 2013a; Blanckenhorn, 2000, 2005; Fairbairn *et al.*, 2007). Conversely, strong sexual selection favoring large males combined with weak fecundity selection on females (as occurs in many large mammals and birds) is the best predictor of male-larger dimorphisms (*op. cit.*).

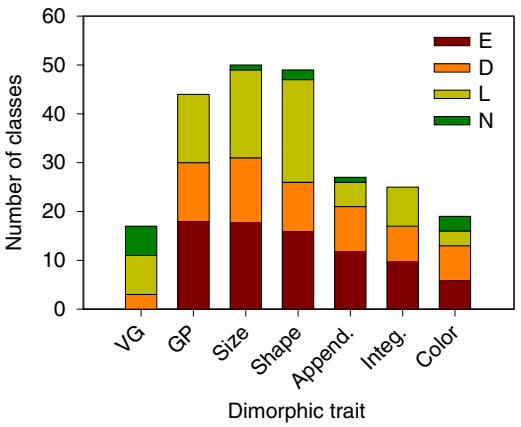

Figure 7 Prevalence of sexual dimorphism in morphological traits (SDM) for different trait types in animals. All animal classes containing dioecious species ($n=80$) have been scored for the presence or absence of SDM in externally visible gonads (VG), gonopores or external genitalia (GP), body size, body shape, appendages (Append.), integumental morphology (Integ.), and color or pigment (color). The few small Phyla that lack class designations are treated as single classes. The stacked bars indicate the number of classes in which each type of SDM has been observed within the three major evolutionary lineages of bilaterian animals, Ecdysozoa (E), Deuterostomia (D), and Lophotrochozoa (L), and in the phyla not included in these lineages (N). See text for further explanation of the trait types. Recent taxonomic revisions cause slight disparities between the frequencies shown and those reported in Fairbairn (2013a,b).

The magnitude of sexual dimorphism in body size often correlates with mean body size when comparisons are made among species within a given clade. Rensch (1959) was the first to describe this trend, noting that size dimorphism increases with mean size in clades where males are the larger sex but decreases as size increases if females are the larger sex. Although seemingly disparate, these two allometric trends (known as *Rensch's rule*) both derive from greater evolutionary divergence in male size than in female size within a given clade. Subsequent analyses have confirmed Rensch's rule in many clades where males average larger than females but in only a minority of clades where females are the larger sex (Abouheif and Fairbairn, 1997; Fairbairn, 1997; Blanckenhorn *et al.*, 2007; Fairbairn *et al.*, 2007; Webb and Freckleton, 2007). The evolutionary mechanisms underlying Rensch's rule have not been fully discerned, but a consistent association with sexual selection on male body size implicates sexual selection as an important driving factor.

Next to size, body shape is the trait most likely to differ between sexes (**Figure 7**). Most commonly females are thicker-bodied than males or have noticeable brood pouches or larger abdomens, all characteristics that adapt female body shape for the production and storage of eggs or live offspring. Conversely, male bodies are most commonly shaped to facilitate grasping and holding females during mating (e.g., the concave plastrons of male turtles and j-shaped tails of nematode males); for success in physical contests with other males (e.g., proportionally larger heads and upper bodies in many mammals; **Figure 4(a)**); or for efficient mate searching (thinner, more streamlined shapes) (Fairbairn, 2013a).

Appendages are much less likely to show SDM than body size and shape (**Figure 7**). This is mainly because many animals do not have appendages, especially among the Lophotrochozoa, where shelly and vermiform body forms predominate. However, where appendages exist, they are frequently modified in sex-specific ways (Fairbairn, 2013a). Some of these differences reflect differences in the dispersal or locomotory strategies of the two sexes (e.g., Roff, 1990), but most relate directly to sexual selection and reproduction. For example, male appendages are often modified for grasping females during mating or to serve as copulatory organs. They may also serve as weapons in contests between males, visual displays to attract females or both (**Figure 4(b)**). Appendages in one or both sexes may also be modified for sending and receiving chemical or acoustical signals (e.g., antennae in many moths, wings in male crickets) or for brooding eggs (e.g., ovigera in male sea spiders (class Pycnogonida)).

Integumental dimorphisms include all visible sexual differences in body covering other than color or pigment, including structures derived from epidermal tissues such as teeth, horns, claws, spines, hair, feathers, and scales. The functions of these dimorphisms often parallel those of appendage dimorphisms (Fairbairn, 2013a). For example,

teeth, spines, horns, and claws often function as weapons in male contests over mates; teeth and claws serve as grasping organs in mating interactions; and many hairs, bristles, feathers, scales, spines, and pits function in sexual displays or long distance sexual signaling. However, not all integumental dimorphisms are so readily interpreted: the functions of many remain obscure, especially in lesser-known species.

Color or pigment patterns are less likely to show SDM than other secondary sexual traits (**Figure 7**) primarily because the majority of animal species lack the ability to distinguish colors or resolve patterns (Kelber *et al.*, 2003; Land and Nilsson, 2012). In such species color and pigmentation cannot function as intraspecific signals, although they may still have ecological functions such as camouflage or thermoregulation. In rare cases SDM in color or pigment *sexual dichromatism*) is unrelated to intraspecific signaling, but most examples are attributed least partly to sexual selection (Badyaev and Hill, 2003; Kelber *et al.*, 2003; Fairbairn, 2013a). Most commonly, sexual selection favors conspicuous colors and patterns in males whereas females are less conspicuous, often to the extent of being cryptic or camouflaged (**Figures 1** and **4(b)**).

Sexual Dimorphisms in Plants

Dioecy is much less prevalent in plants than in animals. Approximately 96% of species within the kingdom Plantae are flowering seed plants (angiosperms; Roskov *et al.*, 2014) and only about 6% of angiosperm species are dioecious (Renner and Ricklefs, 1995; Barrett, 2002; Vamosi *et al.*, 2003). Among the remaining seed plants (gymnosperms) 50% of species are dioecious, including 37% of conifers (Givnish, 1980; Bateman *et al.*, 2011). Among spore-forming plants, dioecy is very rare in ferns (Jesson and Garnock-Jones, 2012) but relatively common in bryophytes (mosses, liverworts, and hornworts) where it occurs in 50–60% of species (Hedenas and Bisang, 2011; Jesson and Garnock-Jones, 2012; McDaniel *et al.*, 2013).

In most dioecious plants, only reproductive structures distinguish the sexes. These consist of primary reproductive organs (e.g., the stamens and pistils of angiosperm flowers) plus surrounding somatic tissues, often formed from modified stems or leaves (e.g., the calyx and corolla of angiosperms). Sexual dimorphisms in these somatic tissues are generally interpreted as adaptations in males for dispersing pollen or sperm and in females for capturing pollen or sperm and for protecting and provisioning embryos (Givnish, 1980; Eckhart, 1999; Geber, 1999; Barrett and Hough, 2013; McDaniel *et al.*, 2013). These are the predominant secondary sexual dimorphisms in plants, and are most pronounced in species that depend on wind or water for pollen dispersal but produce large seeds or fruit that are dispersed by animals (Givnish, 1980; Renner and Ricklefs, 1995; Vamosi *et al.*, 2003; Biernaskie, 2010; Bateman *et al.*, 2011).

The secondary sexual trait most likely to differ between male and female reproductive structures is size. Flower size dimorphisms occur in more than 80% of diecious angiosperm species, with male flowers somewhat more likely to be larger than the reverse (Eckhart, 1999). In contrast, in dioecious gymnosperms the female reproductive organs (strobili) are larger and only the female strobili develop into the large, long-lived cones typical of conifers and cycads. In angiosperms, the number of flowers and the sizes of inflorescences (flower clusters) may also differ between sexes, with males more commonly having more flowers or larger flower clusters than females. In a few families, differences in flower shape and in the position or orientation of the flowers on the plant have also been described (Eckhart, 1999; Barrett and Hough, 2013).

Other than reproductive structures, the most prevalent SDM in plants is overall size. In both angiosperms and gymnosperms, males tend to be larger than females in large, long-lived, woody species (e.g., trees and shrubs), whereas females tend to be larger in small, short-lived, herbaceous species (Obeso, 2002; Barrett and Hough, 2013). Size dimorphism is most extreme in pleurocarpous mosses (class Bryophyta) where, in about a third of species, dwarf males develop from spores that land on the stems or leaves of females and remain attached to the female throughout their lives (Hedenas and Bisang, 2011).

Sexual dimorphisms in other aspects of plant vegetative morphology are much less common but have been noted in at least a few species. Examples include leaf size (females more commonly larger), leaf shape, stem size (females more commonly thicker), and branching architecture (males usually more branched) (Dawson and Geber, 1999; Kavanagh *et al.*, 2011; Barrett and Hough, 2013). As in animals, male and female plants also often differ in ecological and life-history traits (Dudley, 2006; Geber *et al.*, 1999; Barrett and Hough, 2013). The sexes are sometimes partially segregated by habitat, with females more restricted to sites with more water or nutrients, and males often exceed females in their capacity for clonal reproduction, reproduce at an earlier age, and senesce earlier than females. These differences reflect sex-specific trade-offs between growth and reproduction and, as in animals, are interpreted as adaptations for maximizing fitness through male or female reproductive functions.

Sexual Networks

GC McDonald and T Pizzari, University of Oxford, Oxford, UK

Glossary

Assortativity Broadly defined as the correlation between attributes of a focal individual and those of its sexual partner(s).
Bateman gradient The slope of the univariate regression of reproductive success (number of offspring) over mating success (number of sexual partners).
Degree Number of links that an individual node has with other members of the population. Links represent categories of social interactions, such as sexual interactions.
Mating system Spatio-temporal variation of sexual partners across members of one sex within a population.
Node Focal element of a network, usually individuals but can also characterize groups of individuals or gametes.
Operational sex ratio The ratio of males to females in a population that are available for reproduction at a particular point in time.
Polyandry A mating system characterized by females mating with more than one male.

Introduction

In sexually reproducing organisms, a large source of variation in individual fitness and a key determinant of the genetic structure and viability of a population arises through the differential ability to outcompete members of the same sex over reproductive opportunities. Sexual selection is the selective process that promotes those traits which confer an advantage in such competition between members of one sex over access to the gametes of the opposite sex (Darwin, 1871; Andersson, 1994). Resolving the way sexual selection operates and drives adaptive evolution hinges on understanding the mechanisms that govern patterns of variation in individual reproductive success. While the original view of sexual selection was largely restricted to competition over mating opportunities (i.e., premating sexual selection) in males, increasing evidence indicates that sexual selection can also target females and in males often continues after mating (postmating sexual selection), through episodes of sperm competition (Parker, 1970; Parker and Pizzari, 2010) and cryptic female choice (Thornhill, 1983; Eberhard, 1996), whenever females mate with multiple males (polyandry). Intrasexual variation in reproductive success is therefore determined by the outcome of often complex social interactions within and between sexes. Patterns of spatial and temporal variation in the structure of such webs of sexual interactions mean that standard selection approaches based on population-level measures may offer inadequate estimates of sexual selection and a misleading view of the underlying mechanisms and episodes (McDonald *et al.*, 2013). Sexual networks is an emerging quantitative tool designed to enable a more sensitive measure of sexual selection by capturing fine-grained patterns of variation in the structure of the web of sexual interactions within populations.

Sexual Networks

A sexual network is a collection of nodes (male and/or female individuals) connected by edges that may represent any behavior of interest, such as copulations and male–male competitive interactions (**Figure 1**). Originally developed as a tool to characterize social interactions more generally (Scott, 2000; Whitehead, 2008), social network analysis (SNA) as applied to sexual reproduction is an approach that seeks to characterize how interactions between individuals create population-level patterns, and has been used extensively to study the dynamics of infectious disease transfer in sexually reproducing populations (Gupta *et al.*, 1989; Liljeros *et al.*, 2001; Schmid and Kretzschmar, 2012). The more recent use of networks as descriptors in the context of sexual selection, not only represents a conceptual framework to visualize the pattern of interactions between individuals, but also provides a variety of quantitative network analytical tools that can measure patterns of variation in inter- and intrasexual interactions (Croft *et al.*, 2008; Krause *et al.*, 2014, 2007; Whitehead, 2008). By building up the social and competitive structure of populations as an emergent property from individual interactions, sexual networks enable the identification of unique competitive environments for individuals, potentially revealing detail beyond population-level measures of social structure, such as population density and operational sex ratio (Aronsen *et al.*, 2013; De Jong *et al.*, 2009; Kokko *et al.*, 2012; Krupa and Sih, 1993; Wacker *et al.*, 2013). Sexual

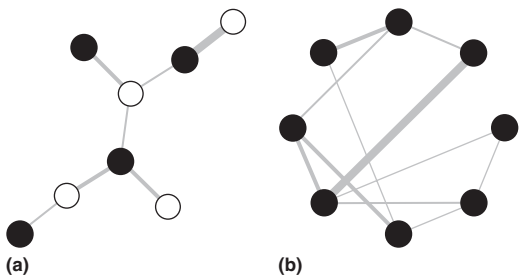

Figure 1 Hypothetical sexual networks (a) nodes represent males (black) and females (white), edges between nodes can represent any sexual interaction including courtship or mating; (b) nodes represent males and edges between nodes can represent any sexual competition, for example, sperm competition or male–male contests. Thickness of edges can represent the frequency or intensity of the interaction.

 doi:10.1016/B978-0-12-800049-6.00162-1

networks can then be used to understand the implications of the pattern of sexual interactions in shaping sexual selection and the evolutionary trajectories of sexual populations. For this reason, an increasing number of studies have begun to study different aspects of mating systems and sexual selection, characterizing sexual networks across a range of organisms. While the concept of 'mating networks' has been used by anthropologists and primatologists for decades (e.g., Wobst, 1976), recent examples include the harvestman (*Serracutisoma proximum*) (Muniz *et al.*, 2015), the Asian red palm weevil (*Rhynchophorus ferrugineus*) (Inghilesi *et al.*, 2015), forked fungus beetles (*Bolitotherus cornutus*) (Formica *et al.*, 2011), the house finch (*Carpodacus mexicanus*) (Oh and Badyaev, 2010), white-throated sparrows (*Zonotrichia albicollis*) (Formica and Tuttle, 2009), and blue tits (*Cyanistes caeruleus*) (Schlicht *et al.*, 2014). We discuss some of these studies below.

Sexual Selection and Competitive Structure

Phenotypic Assortment

A key goal in sexual selection research is to understand how and why sexual selection favors particular traits, disfavors others and why such patterns vary within and across populations. To understand trait evolution at the population level we need to understand the relationship between traits and relative reproductive success. This is because the relationship between a trait and fitness at the level of the population predicts changes in the trait mean value across selective episodes. There are a number of techniques to quantify both the opportunity of sexual selection and the actual strength of sexual selection operating on specific phenotypic characters at the population level. One such population-level approach is based on selection gradients, which are estimated by regressing fitness on trait values (both standardised at the level of the population) as:

$$\omega_i = \beta z_i + \varepsilon \quad [1]$$

where ω_i and z_i are relative fitness and trait value for the ith individual respectively, β is the slope of the regression of relative fitness on the trait (i.e., the selection gradient) and ε represents the residual error. Using this approach we can investigate selection across both pre- and postmating selection episodes. However, this approach assumes that competition within populations occurs at random with respect to individual phenotypes, an assumption that has been undermined by research revealing that populations usually display structure such that interactions are local and nonrandom (Cornwallis and Uller, 2010). For example, when restricted dispersal results in an increased similarity between neighboring individuals, leading to greater similarity/relatedness between locally competing conspecifics (e.g., Duncan *et al.*, 2010; Johannesen and Lubin, 2001). In addition to limited dispersal, structure may arise as a property of a preference of individuals to interact with conspecifics of certain phenotypes (e.g., Formica *et al.*, 2011; Formica and Tuttle, 2009; O'Ha, Blaus 1985; Oh and Badyaev, 2010). The structure resulting from these mechanisms may have strong implications for the patterns of sexual selection at the population level. Imagine a population

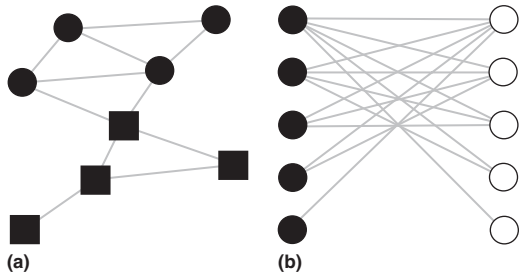

Figure 2 (a) An intrasexual network of competing males displaying positive phenotypic assortment where node shapes represent two distinct phenotypes and edges represent competitive interactions. (b) A sexual network displaying negative degree assortment where nodes represent males (black) and females (white) and edges between nodes can represent copulations.

where individuals are segregated into multiple subgroups and groups are structured such that more similar individuals are found within the same group (i.e., small individuals compete with small competitors and large with large competitors; **Figure 2(a)**). Within each group, individual males compete for mates and those individuals that are larger attain higher reproductive success than their local group competitors (i.e., competition is local and there is positive sexual selection on male size at the local scale). If groups also vary in their mean reproductive success, i.e., groups with on average larger males produce more offspring, then measuring selection at the population level may reveal a positive relationship between body size and relative fitness. However, if groups are equally productive regardless of average group male body size (e.g., because female fecundity is similar across groups), the covariance between trait and fitness may be strong at the local level, but – due to population structure – this covariance may be obscured at the population level. One way to understand how such local structure contributes to population-level selection on traits is to incorporate local variation in competitive environments using multilevel selection techniques. These are extensions of analyses provided in eqn [1] (Heisler and Damuth, 1987; Nunney, 1985; Wolf *et al.*, 1999; Okasha, 2004) and can be used to measure selection in structured populations, providing estimates of selection operating on a focal trait (e.g., tail length) controlling the local competitive environment (e.g., mean tail length of competitors), therefore quantifying the effect of nonrandom competitive structure on the operation of sexual selection. Crucially, these approaches rely on determining functionally competitive groups, i.e., the local competitive environments of individual competitors. Using sexual networks built up by competitive interactions provides a quantitative framework to delineate the local competitive group for each focal individual, which can inform selection analyses across both pre- and postmating episodes of selection (McDonald *et al.*, 2013; McDonald and Pizzari, 2014).

Sperm Competition Intensity

Two key axes in which nonrandom interactions may affect the operation of sexual selection are: (1) assortative phenotypic interactions such as assortative mating (Jiang, 2013) and competition by phenotypes as mentioned above (**Figure 2(a)**),

and (2) patterns of variation in the intensity of competition across individuals. The intensity of competition describes the magnitude of competition, in terms of the number of competitors, with which an individual competes. Individuals are likely to vary in the number of sexual competitors both across and within populations, and such variation may affect the operation of sexual selection, potentially changing its strength and direction on phenotypic traits (Krupa and Sih, 1993). For example, in the myobatrachid frog (*Crinia georgiana*) among-population variation in breeding male density correlates with variation in testes size, suggesting a role for local competitor density to influence between-group patterns of selection on males due to increased risk and/or intensity of sperm competition (Dziminski *et al.*, 2010). When variation in such intensity is spread nonrandomly across phenotypes in the population (e.g., more attractive males must compete with more competitors), this may result in reduced or increased reproductive success for males of a given phenotype, potentially accentuating or abating sexual selection on, and the evolution of, those phenotypes. Such patterns are particularly relevant in the case of postmating sperm competition. In this context, variation in competitor density is determined by the number of males and\or ejaculates with which a male competes across his female mating partners. The polyandry of a male's sexual partners therefore impacts on his chances to fertilize his partners' ova and thus ultimately on his reproductive success. For example, Muniz *et al.* (2015) studied variation in female polyandry in a population of harvestman (*S. proximum*). In this species, males tend to adhere to two alternate mating tactics, larger males that tend to guard territories and females ('territorials'), and smaller males that do not hold territories but furtively mate with females present in other male territories (Muniz *et al.*, 2015). This work suggests that the way females of differing polyandry are distributed nonrandomly across male partners playing such alternative mating tactics, may result in a mating tactics-specific intensity of sperm competition (Muniz *et al.*, 2015), and potentially modulate the reproductive outcomes of different reproductive strategies. More generally, when males that copulate with many females also mate with the most polyandrous females, they may face on average higher sperm competition and this will weaken sexual selection on male mating success (Sih *et al.*, 2009; McDonald *et al.*, 2013). In networks, this would be described as positive assortment by degree between males and females and would be expected to reduce selection on males to increase mating success. Similarly, populations may display negative assortment by degree, which may be expected to increase selection on male mating success (i.e., Bateman gradients) (**Figure 2(b)**). Sexual network analysis provides a variety of metrics to quantify variation in assortment by degree and test hypotheses regarding its effects on the operation of sexual selection, and these methods continue to be refined (McDonald and Pizzari, 2014).

Determinants of Competitive Structure

Ecology

In addition to delineating competitive environments, by providing a mean to quantify population-level patterns of structure of sexual competition, sexual network analysis can also shed light on the forces that generate a given competitive structure.

The mating system of a population describes the pattern of mating behavior across individuals within that population (Klug, 2001; Shuster, 2009; Shuster and Wade, 2003). Research has highlighted an immense variety in animal mating systems between and within species, ranging from strict monogamy to high levels of both male and female promiscuity (Andersson, 1994; Clutton-Brock, 1989; Emlen and Oring, 1977; Shuster, 2009; Shuster and Wade, 2003; Thornhill and Alcock, 1983). Because mating systems describe the distribution of sexual partners across individuals, they also largely determine variation in reproductive success and are therefore expected to be intimately linked to the operation of sexual selection (Emlen and Oring, 1977; Shuster and Wade, 2003). A predominant paradigm is that spatial and temporal variation in ecological factors dictate opportunities for partner monopolization and as such modulate local patterns in sexual interactions (Clark *et al.*, 1997; Crook, 1965; Emlen and Oring, 1977; Endler and Houde, 1995; Kelly *et al.*, 1999; Lack, 1968; Mück *et al.*, 2013; Orians, 1969; Reichard *et al.*, 2009; Reynolds, 1996; Reynolds *et al.*, 1993). Network analytical techniques may provide a useful tool to determine how individual traits and ecological variables interact to shape nonrandom interactions in sexual populations. For example, several studies have assessed whether genetic relatedness, social familiarity or male territoriality determines social network structure (Atton *et al.*, 2014; Hirsch *et al.*, 2013; Wolf *et al.*, 2007; Wolf and Trillmich, 2008). More recently, Schlicht *et al.* (2014) used spatially explicit networks (rather than networks built on interactions per se) to investigate the relative importance of spatial versus nonspatial factors in determining the rate of paternity in blue tits. Such approaches could be used to understand how individual traits and resource ecology together determine population-level interaction patterns such as assortative mating between phenotypes. For example, whether shared dietary preferences result in associations between individuals due to resource distribution. Understanding how such ecological variables determine patterns of assortative mating may also have implications for population differentiation and speciation (McDonald and Pizzari, 2014).

Individual Strategies

Beyond group-level descriptions of interaction structure, network analysis also allows the characterization of an individual's placement within networks (Newman, 2010). The position of individuals within a network may have important implications for their reproductive success. For example, if females within a male–female courtship network are peripheral and interact with few other individuals they may have relatively poor information on the distribution of male quality throughout the population, whereas those females more central to the network may be at liberty to make more informed decisions with regards to mate choice (Sih *et al.*, 2009). Similarly, metrics of individual network positions may represent reproductive strategies and behaviors. For example, using social networks in the house finch, Oh and Badyaev (2010)

showed that males that move between different social groups were able to modify their socio-competitive environment such that they increased their relative attractiveness to prospective mates compared to rivals. Such behaviors would be overlooked without the use of network analysis.

Potential Applications

The potential for sexual networks to help understand eco-evolutionary processes is only beginning to be explored. This potential raises interesting opportunities for the applications of sexual networks in other contexts. For example, in epidemiological research examining the spread of sexually transmitted infections, researchers have understood how sexual networks may provide information for targeted interventions to reduce disease spread (Robinson *et al.*, 2012). One potentially important application of the tools described in this work is in the context of biological control strategies of pest species (Inghilesi *et al.*, 2015). Biological control strategies often involve techniques that interfere with sexual interactions of a pest population, with the aim of significantly reducing the productivity of the population, for example, the introduction of sterile males into the population (Alphey *et al.*, 2010). By providing an important tool to characterize the patterns of sexual interactions, sexual networks may facilitate our understanding of the pattern of male–male competition.

Conclusion

The study of sexual networks in the context of sexual selection is still in its infancy and represents an emerging field in evolutionary ecology. The harnessing of quantitative tools developed by social network theory may provide evolutionary biologists with an additional arsenal to complement more traditional sexual selection research techniques and further refine our understanding of sexual selection. The potential to apply sexual network analysis to the study of sexual selection is expected to increase substantially in the near future, thanks to the increasing availability of large datasets with sufficiently detailed information on mating behavior and reproductive success, that is being catalyzed by rapid advances in animal tracking technology (Krause *et al.*, 2011) and the advent of increasingly more efficient molecular tools to assign parentage, measure genetic relatedness and population structure.

Sexual Selection, Theory of

AG Jones, Texas A&M University, College Station, TX, USA

Glossary

Anisogamy The situation in which one sex produces small, mobile gametes while the other sex produces large, immobile gametes.

Bateman gradient (β_{ss}) The least-squares regression of reproductive success on mating success. The standardized Bateman gradient (β'_{ss}) is the least-squares regression of relative reproductive on relative mating success.

Correlation A covariance standardized to have a minimum value of -1 and a maximum value of 1. The equation for the correlation coefficient is: $r_{x,y} = \frac{\mathrm{cov}(x,y)}{\sqrt{\sigma_x^2 \sigma_y^2}}$, where σ_x^2 and σ_y^2 are the variances in x and y.

Covariance A statistical concept that summarizes the extent to which two variables are non-independent. A positive covariance indicate that high values of one variable are associated with high values of the other variable, whereas a negative covariance indicates that high values of one variable are associated with low values of the other variable. The equation for an unbiased estimate of a covariance from a sample is: $\mathrm{cov}(x,y) = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})$, where n is the number of individuals in the sample.

Environmental potential for polygamy The extent to which the ecological setting permits individuals of one sex to monopolize access to individuals of the other sex in the context of mating.

Fitness (or absolute fitness) The number of offspring produced by an individual or the average number of offspring produced by individuals with a particular genotype or phenotype.

Genetic mating system A summary of the mating interactions among individuals in a population that result in the production of zygotes. Genetic mating systems include monogamy, where each individual mates with only one individual of the opposite sex; polygyny, where successful males mate multiple times but each female mates at most once; polyandry, where females mate with multiple males but each male mates once; and polygynandry, where both sexes have multiple mates.

Intersexual selection Sexual selection arising from mate choice. Members of one sex are predisposed to mate with individuals of the other sex with particular attributes, so the most attractive individuals tend to have more mates than less attractive individuals. The term 'mate choice' is unfortunate in that it implies a conscious decision-making process, which is unnecessary for sexual selection to operate. It is enough for individuals simply to respond more strongly in a mating context to certain stimuli. The organisms needn't 'think' about which choice is the best.

Intrasexual selection Sexual selection arising as a consequence of direct competition among members of the same sex. For instance, males might fight each other in ritualized combat for access to females or males might race each other to the females. In either case, the winner would typically mate with the female, although even in these systems females could still exert some choice.

Mating differential (m) The covariance between trait values and relative mating success. If the trait values are standardized to have a variance of one, then the mating differential is called the standardized mating differential (m').

Mating success The number of other individuals with whom a focal individual produces offspring during a time period of interest.

Operational sex ratio The ratio of males ready to mate to females ready to mate in a local breeding population. The operational sex ratio is often expressed as the fraction of receptive adults that are male, with a value of 0.5 indicating that half the adults ready to mate are male and half are female.

Opportunity for selection (I) The variance in relative fitness.

Opportunity for sexual selection (I_s) The variance in relative mating success.

Relative fitness An individual's absolute fitness divided by the mean absolute fitness in the population.

Relative mating success An individual's actual mating success divided by the mean mating success in the population for individuals of the same sex.

Reproductive success The number of biological offspring produced by an individual during some specified time frame.

Selection differential (s) The covariance between trait values and relative fitness. The selection differential is a major determinant of the response to selection, which is described by the breeder's equation: $R = h^2 s$. The response to selection (R) is the product of the heritability of a trait (h^2) and the selection differential (s). The heritability is the proportion of the variance in trait values that is due to additive genetic effects. If the trait values are standardized to have a variance of one, then the selection differential is in units of phenotypic standard deviations and is called the standardized selection differential (s').

Sexual selection Variation in fitness arising from competition for access to mates or fertilization opportunities.

Social mating system The behavioral interactions among adult individuals in a breeding population. Examples of social mating systems include monogamy, in which individuals form reciprocal pair-bonds involving one male and one female, and promiscuity, in which individuals mate with multiple partners without forming any long-term bonds. Other social mating systems also exist, but they are beyond the scope of our discussion.

Introduction

'Sexual selection' is often defined as variation in 'fitness' that arises from competition for access to mates or fertilization opportunities (Andersson, 1994; Jones and Ratterman, 2009). Fitness here is defined in the Darwinian sense as the total number of offspring produced by an individual during its lifetime, and in the sexual selection literature fitness is often also called 'reproductive success.' In Charles Darwin's original formulation of sexual selection (Darwin, 1859, 1871), he correctly realized that competition for mates could occur as a consequence of either direct contests among rival males, a process now called 'intrasexual selection,' or choice of members of one sex as mates by individuals of the other sex, or 'intersexual selection.'

It is instructive to consider why sexual selection theory is important and what puzzles this theory has been developed to solve. Some historical context will illustrate part of the problem. When Darwin first proposed the idea of sexual selection (Darwin, 1859, 1871), it was not embraced by the scientific community (see Andersson, 1994 for a review). Even Darwin (1871) believed that sexual selection only occurred in species with sufficiently developed intellectual faculties to have a sense of aesthetics. His critics argued that no nonhuman species were intelligent enough to care about something as frivolous as the beauty of a prospective mate's plumage, for example, and sexual selection was consequently pushed aside from mainstream evolutionary biology. Thus, for sexual selection to be a topic worthy of study, the field needed some plausible models for how it could operate even in species incapable of making rational decisions.

Perhaps the two biggest questions facing sexual selection theory were (and still are), first, why some lineages, such as peafowl, display dramatic evidence of sexual selection, while other lineages do not; and second, how mating preferences could originate and be maintained in populations. The first question resulted in the development of theory related to the strength of sexual selection, and the second led to the development of an impressive body of literature on how mating preferences could evolve as a consequence of understandable evolutionary processes. Other smaller issues arose along the way, but these two challenges form the core body of sexual selection theory.

The Intensity of Sexual Selection

Selection and Mating Patterns

An understanding of the intensity of sexual selection starts with the realization that sexual selection is one form of selection acting on natural populations of organisms, so general selection theory can be applied. Selection on a trait arises from the 'covariance' between trait values and fitness (Price, 1970; Lande and Arnold, 1983). This idea makes sense, because if, for instance, large males tend to have more offspring compared to small males, then there will be a positive covariance between male size and male fitness. The larger males will pass more genes to the next generation, and if their size happens to have a genetic basis, then the 'large size' trait will tend to increase in frequency in the population. In fact, one way to quantify the intensity of selection is by using the 'selection differential,' which is simply the covariance between the values of the trait of interest and 'relative fitness' (Falconer and Mackay, 1996).

If selection can be quantified by a selection differential, then an important question is how a selection differential arises in the context of sexual selection. In its simplest form, sexual selection arises from competition for access to mates, which means that the 'winners' of sexual selection have more mates than the 'losers' of the competition. If success in this competition depends on the trait values of the competitors, and it makes sense that it would, then individuals with trait values favored in the competition will have greater numbers of mates (i.e., greater mating success) compared to individuals with poor trait values. In this case, it does not matter whether the competition is due to direct combat among the competing individuals or choice by the opposite sex. Regardless of the exact manifestation, competition for mates can result in a covariance between trait values and mating success, a quantity known as the 'mating differential' (**Figure 1**; Jones, 2009).

A nonzero mating differential indicates that individuals with certain trait values have more mates than individuals with other trait values, but the mating differential by itself does not measure selection on the trait. Selection arises due to a nonzero selection differential, which measures the extent to which particular trait values covary with relative fitness, measured in terms of offspring numbers. Of course, individuals with more mates often have more total offspring, but not always. The last piece of the puzzle, then, is the relationship between number of mates (or mating success) and number of offspring (or reproductive success). This relationship is called the 'Bateman gradient' (**Figure 2**), as it was devised as an outgrowth of a classic experiment on mating patterns in *Drosophila melanogaster* conducted by A. J. Bateman in the 1940s (Bateman, 1948; Arnold and Duvall, 1994; Jones, 2009).

We can put all of this information together with a simple equation that describes the source of the selection differential due to competition for mates: $s' = \beta'_{ss} m'$ (Jones, 2009). In words, the standardized selection differential (s', with the prime sign merely indicating that the selection differential is standardized to be in units of phenotypic standard deviations) equals the product of the standardized Bateman gradient (β'_{ss}) and the standardized mating differential (m'). This way of viewing the selection differential is useful because it identifies the underlying processes giving rise to selection on traits as a consequence of mating competition. On the one hand, we need to understand the sources of the covariance between trait values and mating success, an issue embodied by the mating differential. On the other hand, we also need to understand how a mating differential is converted into a selection differential, a conversion facilitated by the Bateman gradient. Many extrinsic ecological factors and intrinsic biological constraints act together to affect the magnitudes of both mating differentials and the Bateman gradient, and some of the most important of these factors are discussed below.

The Maximum Strength of Precopulatory Sexual Selection

One other topic worth mentioning here is that the definition of the selection differential as a covariance makes it possible to

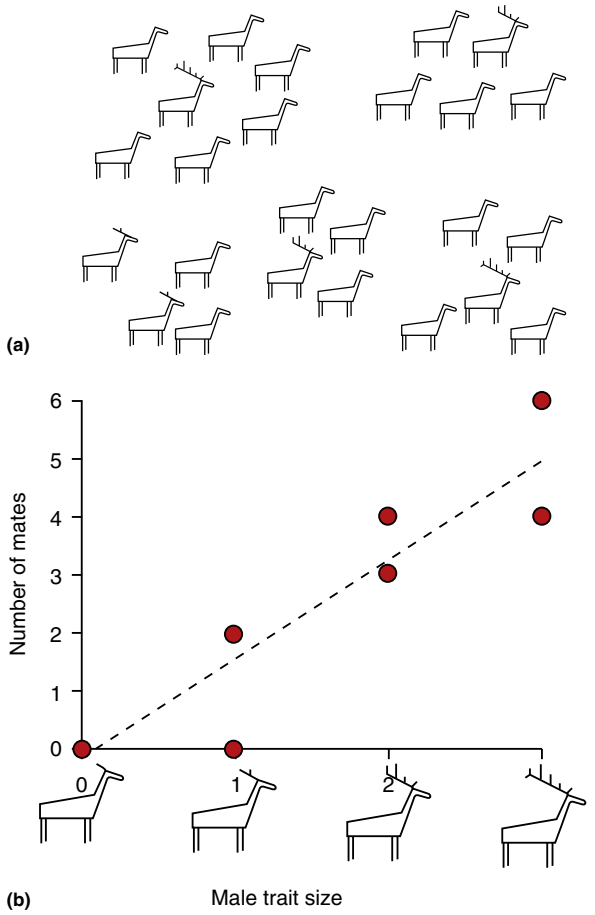

Figure 1 An example of how a mating differential can arise. In this hypothetical species of deer, which is much like the real red deer (*Cervus elaphus*), males with larger antlers can defend larger harems of females. In the top panel (a), males (with antlers) are shown associated with groups of females (without antlers). The males with larger antlers have larger groups of females, and the female mates with the closest male. The bottom panel (b) shows a graph of number of mates as a function of male antler size for the population in (a). A least-squares regression line is shown, and a positive slope means there must be a positive covariance between the two variables. Incidentally, the slope of a regression line is given by the covariance between the *x* and *y* variables (in this case this covariance is the mating differential) divided by the variance in the *x* variable. This graph thus indicates a positive mating differential on male antler size, a sexually selected trait in red deer (Kruuk *et al.*, 2002).

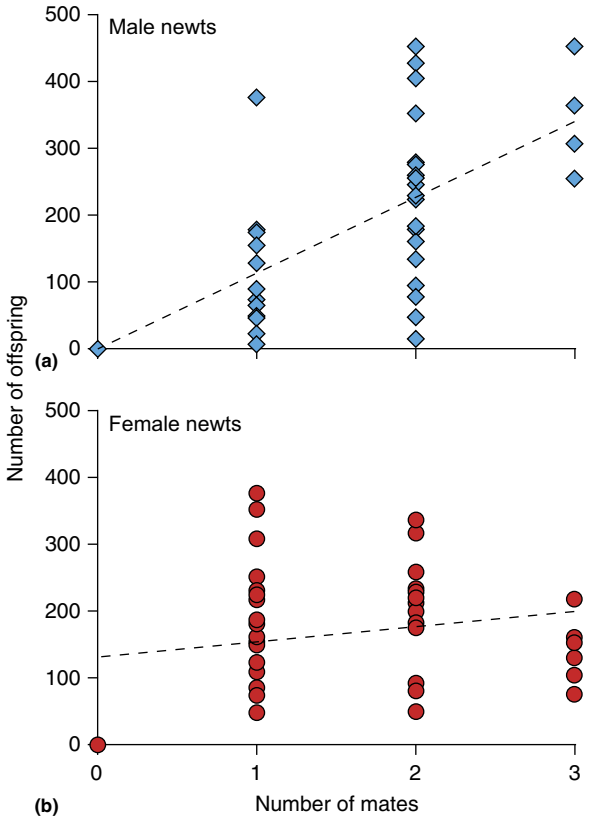

Figure 2 Bateman gradients for male and female rough-skinned newts (Jones *et al.*, 2002). Rough-skinned newts are sexually dimorphic. Males are larger than females, have nuptial pads that are absent on females, and have an enlarged tail crest. Males compete for access to receptive females and sometimes even wrestle females away from rival males. The Bateman gradient for males (a) is significantly positive, with males gaining on average an additional 74.6 offspring per mating event. The female Bateman gradient (b), however, is not significantly different from zero.

derive mathematically some limits on its magnitude. If, for instance, we assume that a phenotypic trait has been standardized to have a variance of one, then we can use the definition of the correlation to see that the selection differential cannot be larger than the square root of the variance in relative fitness (Crow, 1958; Arnold and Wade, 1984). The variance in relative fitness is called the 'opportunity for selection (I),' and a population with a larger opportunity for selection is mathematically capable of experiencing stronger selection than a population with a smaller opportunity for selection (Crow, 1958). A similar argument can be applied to the mating differential, and in this case the maximum value of a mating differential is equal to the square root of the variance in 'relative mating success' (Arnold and Wade, 1984; Jones, 2009). The variance in relative mating success is called the 'opportunity for sexual selection (I_s),' so a larger opportunity for sexual selection indicates a greater potential for a mating differential in a population (Wade, 1979; Arnold and Wade, 1984). If we consider the opportunity for sexual selection in the context of the equation $s' = \beta'_{ss} m'$ from above, then we see that the maximum value of a selection differential on any trait (in units of phenotypic standard deviations) due to mating competition in any population must be: $s'_{max} = \beta'_{ss}\sqrt{I_s}$ (Jones, 2009). This relationship can be useful whenever the mating differential is difficult to estimate directly.

Factors Affecting the Mating Differential and the Bateman Gradient

With the appreciation that sexual selection results in a selection differential on a trait and that this selection differential largely arises through the mating differential and the Bateman gradient, it is worth considering the various factors that can

affect these aspects of the reproductive ecology of a population. Some of these factors arise from intrinsic constraints on the organism, such as how often an individual is capable of mating or how many gametes can be produced, whereas other constraints are products of the ecological setting. Numerous such constraints exist in natural populations, so only the most important ones are considered here.

Anisogamy

We will see why in a moment, but sexual selection usually acts more strongly on males than on females in most taxa. Discussions related to the source of this pattern usually start with the idea of anisogamy, a term that refers to the observation that one sex produces small, relatively mobile gametes (i.e., sperm), whereas the other sex produces larger, relatively immobile gametes (i.e., eggs). Why anisogamy evolves is beyond the scope of our discussion, but anisogamy frequently does evolve and it leads to a situation in which the smaller gametes tend to be more numerous in a population than the larger gametes because smaller gametes are less costly to produce on a per-gamete basis (Parker *et al.*, 1972; Maynard Smith, 1978). The larger gametes, being relatively rare, are thus a limiting resource for reproduction, which means that only a subset of the sperm will find an egg to fertilize. If the individual sperm cells differ with respect to traits that affect fertilization success (such as swimming speed), then only the sperm with the most effective traits will pass their cargo of genes to the next generation. Thus, ignoring for the moment all of the complications that might arise from the attributes of the organisms carrying the gametes, sperm will tend to compete for eggs. Because the male, by definition, is the sex producing the smaller gametes, males also tend to be the sex that experiences a stronger intensity of sexual selection. As we will see, however, anisogamy is important, especially heuristically, but many other factors are involved in determining the intensity of sexual selection, and in some extreme cases sexual selection can act more strongly on females than on males. Thus, we still have a mystery: if, in almost all species with separate sexes, males produce relatively numerous, small sperm and females produce relatively rare, large eggs, then why do species differ from one another in terms of the intensity of sexual selection? Clearly, mitigating factors must be involved, and the next several sections explore these factors.

The environmental potential for polygamy

A breakthrough in sexual selection research came with the realization that many of the ideas related to mating competition could be expressed in economic terms. Even in biological systems, the economics of mating competition can instructively be considered in the context of supply and demand. This thread of logic stretches all the way back to Darwin (1871), who realized that an inequality of the sex ratio could result in strong sexual selection, and was taken up by some of the most important evolutionary thinkers of the twentieth century, such as George Williams (1975) and Robert Trivers (1972). Perhaps the most important paper in this vein, however, was one published by Stephen Emlen and Lewis Oring in 1977, which formalized the notion of the 'environmental potential for polygamy.'

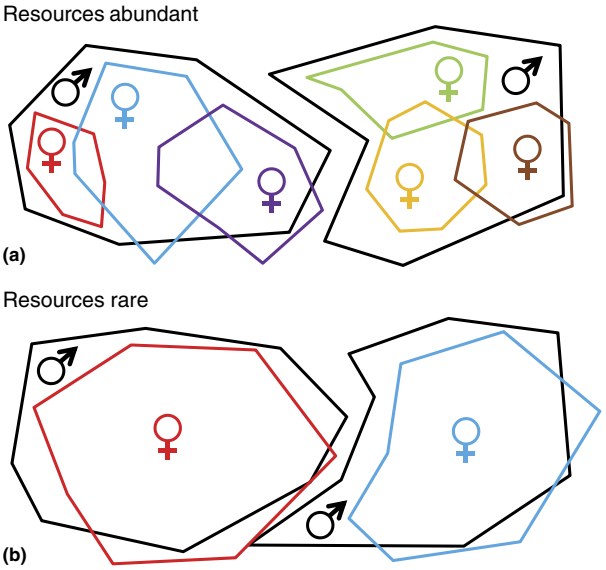

Figure 3 An example of how the environmental potential for polygamy can affect the mating system. In this hypothetical example, males defend territories (black polygons). Females have home ranges indicated by the colored polygons. When resources are abundant (a), female home ranges can be small, and a male's territory may encompass many female home ranges. If females mate on their home range, then each territorial male can expect high mating success. When resources are rare (b), however, female home ranges are larger and each male territory encompasses only one female home range. In this case, territorial males will experience reduced mating success on average, the mating system will tend toward monogamy, and the strength of sexual selection will generally be reduced. This figure provides one example of how the environment can affect mating systems, but any environmental factor that alters access to mates can have an impact on the environmental potential for polygamy (Emlen and Oring, 1977).

The environmental potential for polygamy refers to the ecological factors that make it possible for some individuals to monopolize access to members of the opposite sex for reproduction. For instance, if females are spatially clustered, then one male may be able to defend a territory encompassing many females (**Figure 3**). If the females also prefer to mate on the territory, then the defending male may experience considerably higher reproductive success compared to males without territories. This sort of territorial behavior would be sexually selected in this context. Any ecological factor that affects the temporal or spatial clumping of potential mates or the defensibility of other resources related to reproduction can, in principle, affect the environmental potential for polygamy, which in turn impacts the intensity of sexual selection (**Figure 4**; Emlen and Oring, 1977).

The operational sex ratio and the potential reproductive rates of the sexes

The concept behind the role of the 'operational sex ratio' in sexual selection is simple: if more individuals of one sex are ready to mate than individuals of the other sex, then the sex in abundance will be forced to compete for the sex in short supply. This concept, also formalized by Emlen and Oring

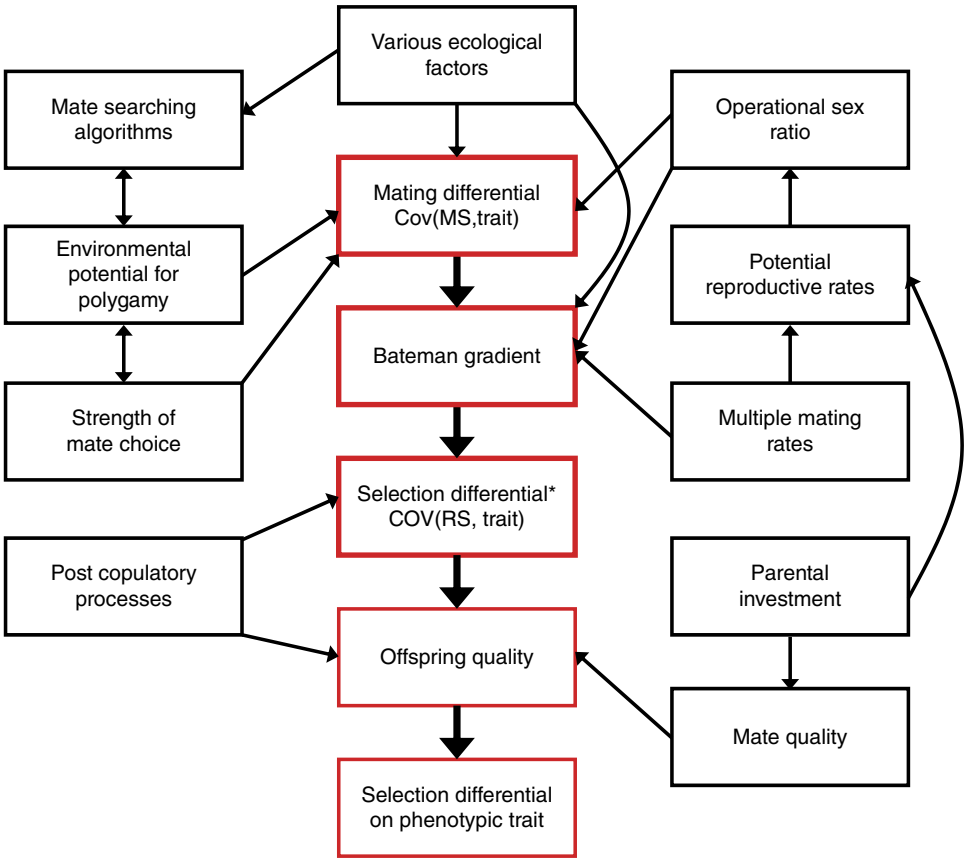

Figure 4 A 'reproductive ecology web' showing interactions among some of the important variables related to the intensity of sexual selection. Some arrows are certainly missing, and other factors probably could be included. At the center of this figure, in red, are the boxes that form the path to fitness from the mating differential, through the Bateman gradient to the selection differential on sexually selected traits. The selection differential with the asterisk represents selection due to mating success and number of offspring. If post-copulatory processes occur or mate quality alters offspring quality, then the true selection differential could be modified by these effects. All of the other behavioral and ecological factors interact in various ways to affect both the mating differential and the Bateman gradient. Reproduced from Jones, A.G., Ratterman, N.L., 2009. Mate choice and sexual selection: What have we learned since Darwin? Proceedings of the National Academy of Sciences USA 106, 10001–10008.

(1977), is a close outgrowth of the economics of mating dynamics. The operational sex ratio is defined as the ratio of receptive males to receptive females in the population, and many ecological factors can affect this ratio. The most obvious factor is the adult sex ratio, but even when the adult sex ratio is even, complications such as parental care, limited periods of receptivity, and the need to obtain a territory can alter the operational sex ratio (Figure 4).

One very important determinant of the operational sex ratio is the 'potential reproductive rate' (Clutton-Brock and Parker, 1992). If the two sexes differ dramatically with respect to their potential reproductive rates, defined as the maximum expected reproductive rate of the members of a sex given unconstrained access to potential mates, then, all else being equal, the sex with the higher potential reproductive rate should compete for members of the sex with the lower potential reproductive rate. Thus, potential reproductive rates, acting in concert with many other ecological factors, are an important part of the pathway leading from the ecology of reproduction to the intensity of sexual selection (Figure 4).

Parental care and parental investment

Armed with the ideas presented in the previous sections, we can see why parental care has an overriding influence on the intensity of sexual selection. Parental care refers to virtually any effort that a parent expends on behalf of its offspring. Parental investment, on the other hand, has a very specific definition, and it is probably best defined by Trivers (1972) as "any investment by a parent in an individual offspring that increases the offspring's chance of surviving (and hence reproductive success) at the cost of the parent's ability to invest in other offspring". Hence, parental investment is a limited resource (Williams, 1966; Trivers, 1972).

From a sexual selection standpoint, parental investment is important because it represents a cost for the parent and this cost reduces the rate at which individuals can produce offspring. Parental investment can take the form of provisioning eggs, for example, and when eggs become sufficiently costly they will be a limiting resource for reproduction. This situation leads to a higher potential reproductive rate for males than for females, a surplus of males in the operational sex ratio, and thus a higher intensity of sexual selection in males than in females.

The importance of parental investment is especially noticeable in the few species in which sexual selection acts more strongly on females than on males (**Figure 5**). Species falling into this category include some birds, such as spotted sandpipers, red-necked phalaropes and wattled jacanas (Oring, 1986); some fishes, such as the pipefishes (Berglund *et al.*, 1986); a number of insects (Gwynne and Simmons, 1990); and a smattering of other taxa (Clutton-Brock, 2007), most of which have not been well studied. All of the species with stronger sexual selection on females than on males thus far studied exhibit substantial male parental investment in offspring, such that male potential reproductive rates are depressed below those of females. This situation tends to result in a female-biased operational sex ratio, steeper Bateman gradients in females than in males, higher variances in mating and reproductive success in females than in males, and thus a situation conducive to strong selection differentials on female sexually selected traits.

Social and genetic mating systems

Another useful concept to organize thought on the intensity of sexual selection is the mating system. In the sexual selection literature, the mating system describes the mating interactions among reproductive individuals in a population (Andersson, 1994; Arnold and Duvall, 1994). The 'social mating system' refers to the behavioral interactions among individuals, such as pair-bonding or promiscuity, whereas the 'genetic mating system' describes whose gametes actually unite to form zygotes (Searcy and Yasukawa, 1995). Both sorts of mating systems are relevant to the sexual selection process, because mating systems are closely tied to the other factors that determine the strength of sexual selection. However, the genetic mating system is more closely tied to fitness, and the social mating system is important because it represents a major source of constraint for the genetic mating system. For instance, in a population characterized by perfect monogamy with an equal sex ratio, sexual selection will usually be quite weak, because every individual should have a mate. If everyone mates exactly once, then there simply is not enough variation in mating success to generate much sexual selection. Other genetic mating systems include polygyny, in which successful males mate multiple times but each female mates with only one male; polyandry, in which successful females mate multiple times but each male mates once; and polygynandry, in which both sexes have multiple mates. Any of these non-monogamous mating systems can generate very strong sexual selection, depending on the particulars of patterns of multiple mating (**Figure 6**).

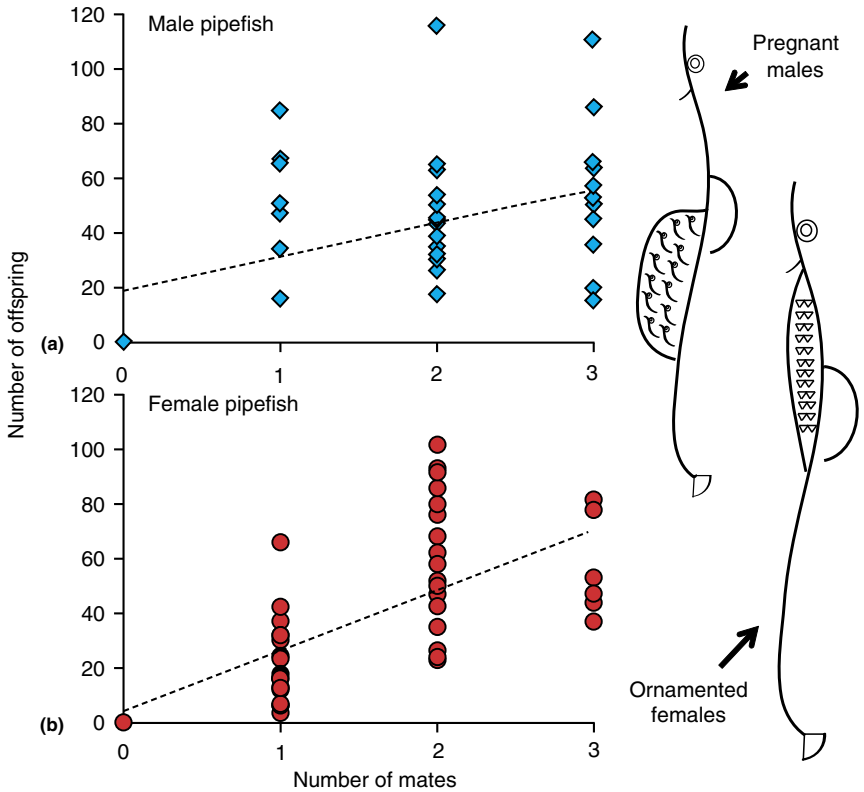

Figure 5 Bateman gradients in a sex-role-reversed pipefish. In this species of pipefish, *Syngnathus typhle*, males become pregnant and carry developing offspring in their pouches (as seen in the diagram of a pregnant male to the right). Male pregnancy depresses male potential reproductive rates and makes males a limiting resource for reproduction (Berglund *et al.*, 1989). Females compete for males, males are choosy, and females consequently evolve ornaments that are not present in males (see 'B'-shaped ornament in female diagram to the right). Bateman gradients for males (a) are less steep than those for females (b), a pattern that is to be expected for a species in which sexual selection acts more strongly on females than on males (Jones *et al.*, 2000).

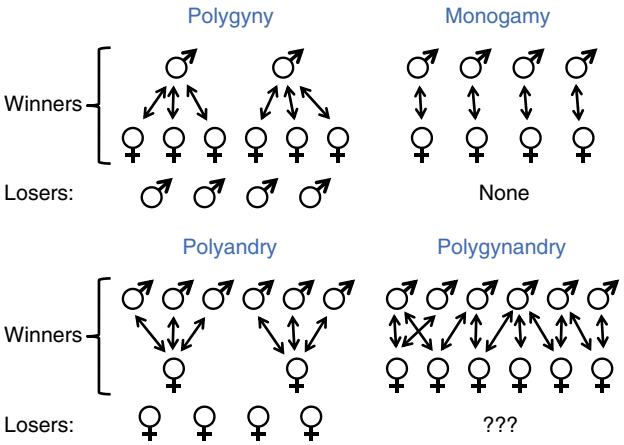

Figure 6 A graphical depiction of the four categories of genetic mating systems. Two-headed arrows indicate mating events among individuals. Assuming an equal sex ratio, polygyny will produce a situation in which successful males mate with multiple females and some males are left out of reproduction. If the males left out have different trait values than the males that succeed, then a nonzero mating differential will result. Conversely, polyandry will result in some females being left out, causing stronger sexual selection on females than on males. In monogamy with an equal sex ratio, selection should be weak because everyone will have a partner. Finally, in polygynandry almost any strength and direction of sexual selection is possible, depending on the relative patterns of multiple mating of the sexes.

The Evolution of Intra- and Intersexual Selection

The previous section dealt mainly with the question of the factors that produce a given intensity of sexual selection in a population. A separate, but related, question is why some organisms experience intrasexual selection, usually in the form of male–male contests, and other species are characterized by intersexual selection, or mate choice by one sex for members of the other sex. In the case of intersexual selection, the evolution of mating preferences has been a particularly challenging area of inquiry.

Intrasexual Selection

Called the Law of Battle by Darwin (1871), intrasexual selection makes a good deal of sense from an evolutionary standpoint, and Darwin's original explanation for it still remains valid (Andersson, 1994). In a population in which males can effectively defend females or resources, those males better at defending these reproductive resources will have more mates compared to the less competitive males. Sexual selection in such cases usually favors the evolution of weaponry or body size. Some excellent examples include the evolution of antlers in male deer (Clutton-Brock *et al.*, 1980) and the evolution of large male body size in elephant seals (Le Boeuf *et al.*, 1972). If all sexual selection were of the intrasexual variety, then the process of sexual selection would make a lot of sense, but even species with apparently strong intrasexual selection often have a large component of mate choice involved in their mating dynamics.

Intersexual Selection

The origin and maintenance of intersexual selection is perhaps the most enduring and baffling question in sexual selection theory, and progress in the field stalled for almost a hundred years waiting for a workable set of hypotheses to explain mating preference evolution (see Andersson, 1994 for a review). An important realization here is that the challenge is to explain the evolution of the preferences, not the traits upon which the preferences act, because once the preference evolves, the evolution of the preferred trait is entirely straightforward. In other words, if a preference exists and the trait upon which the preference acts is variable, then a mating differential on that trait will almost certainly arise due to mate choice. Darwin didn't even address the question of where preferences originate, and this topic did not become an active area of research until the 1970s and beyond when a number of hypotheses originated during a sort of sexual selection theory renaissance. Some of the most important models are discussed here (**Figure 7**). For simplicity in the discussion of these models, I will assume that females are choosy and males are the sexually selected sex, since most species have stronger sexual selection on males than on females. However, these same mechanisms can explain the evolution of male choice in species with strong sexual selection on females.

Sensory bias

The sensory bias hypothesis is based on the premise that organisms evolve to be attuned to certain sensory stimuli in order to thrive in their environments (Ryan, 1990; Endler and Basolo, 1998). For example, a species that eats orange fruit might be especially responsive to stimuli in the orange color range (Endler, 1983). If a male can mimic this sensory stimulus, then he can be more noticeable to females. Because the first step in mating is to be noticed by the members of the opposite sex, these noticeable males could experience heightened mating success relative to less noticeable males. In this way, a male sexually selected trait could be adaptive for the males even though the females derive no real benefit from mating with these males. The female preference, then, should not be seen as a behavior that evolved due to selection but rather as a by-product of the female evolving a sensory system that functions well in the current ecological setting.

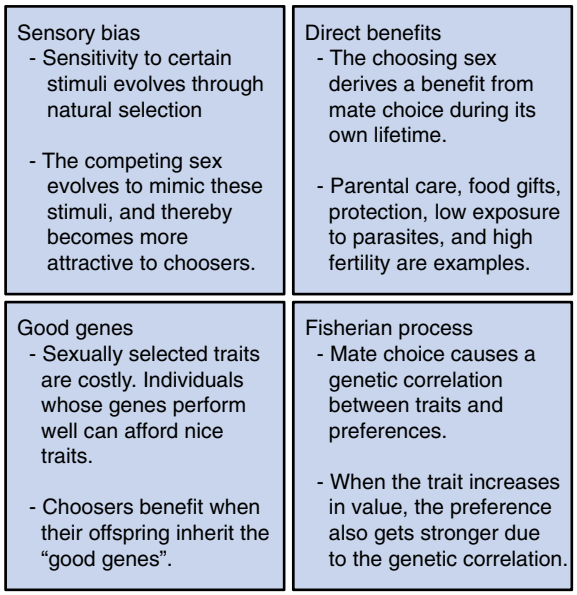

Figure 7 The four main models for the evolution of mating preferences. Some other ideas, such as genetic compatibility (Tregenza and Wedell, 2000) or chase-away sexual selection (Holland and Rice, 1998) are left out, but the four mechanisms shown here form the nucleus of theory on the evolution of mating preferences.

Direct benefits

Direct benefits models posit that mate choice is beneficial to females because choosing females are rewarded for their choice with a beneficial resource or outcome within their own lifetime (Williams, 1975; Kirkpatrick and Ryan, 1991). For instance, females sometimes choose males that provide excellent parental care, freeing the female from some of her caring duties and saving her energy for future reproduction. Other direct benefits include defense of foraging territories, food gifts for the female (i.e., nuptial gifts), and higher fertility. In some cases, the direct benefits may not be entirely obvious. For example, females may prefer males with well-developed ornaments because they have lower parasite loads, reducing the risk that females will become infected. Regardless of the exact nature of the direct benefit, the direct benefits model is accepted as an explanation for the evolution and maintenance of mate choice in a large number of taxa (Kirkpatrick and Ryan, 1991; Andersson, 1994).

Good genes

Good genes models are also known as indicator models, because the attractiveness of a male is a sign that he has genes that perform especially well in the current environment (Williams, 1966; Zahavi, 1975). The most intuitive good genes models assume that the sexually selected traits are condition dependent, such that males of better overall phenotypic quality can produce the most elaborate plumage or most potent pheromones or the most impressive manifestation of whatever the trait happens to be (Rowe and Houle, 1996). Good genes models can be rather involved (Mead and Arnold, 2004), so many of the nuances are beyond the scope of this article. However, the essence of the idea is that a female chooses a male with an elaborate trait because the trait signals that the male has a genetic constitution that will excel in the current environment. The benefit to the choosing female is that her offspring inherit the good genes and thus have higher fitness than if she had mated at random.

Good genes models, while they make sense, are controversial because they lead to several difficulties not present in some other models of preference evolution. The most significant problem is the 'paradox of the lek,' which observes that genetic variation is expected to disappear in the face of strong directional selection (Kirkpatrick and Ryan, 1991), so the good-genes benefit should quickly vanish. Another problem is that production of the trait must result in a substantial cost to its bearer or cheaters will evolve to express the trait even when they don't have good genes.

The Fisherian process

The final model of preference evolution we will discuss here is the 'Fisherian process' (Fisher, 1930), which in its most extreme case can be called 'runaway sexual selection' (Lande, 1981; Pomiankowski and Iwasa, 1993). The Fisherian process occurs as a consequence of the fact that mate choice results in a genetic association between preference genes and trait genes. In other words, when females with strong preferences mate with males with extreme traits, their offspring have both extreme traits and strong preferences. When this sort of genetic coupling of traits and preferences occurs, a change in trait values also results in a correlated change in preference values, even without any direct selection on the preference. Given appropriate starting conditions, this Fisherian process can result in a positive feedback loop in which traits get more extreme, resulting in stronger preferences, which in turn select for even more extreme traits, and so forth. In the most extraordinary cases, mathematical models show that this process can runaway to infinitely large trait values and infinitely strong preferences (Lande, 1981; Mead and Arnold, 2004). Of course, this theoretical outcome is not possible in living systems, because other constraints will eventually place limits on both the magnitude of traits and the strengths of preferences. Nevertheless, the kind of correlated selection described by the Fisherian process likely does play a role in some natural systems.

Summary

In summary, this article has discussed some of the most important aspects of sexual selection theory related to sexual selection based on mating competition. The intensity of sexual selection is determined by the mating differential, which summarizes the extent to which individuals with different trait values differ in mating success, and the genetic mating system, as embodied by the opportunity for sexual selection and the Bateman gradient. Many ecological factors are involved in determining the exact values of mating differentials and Bateman gradients in nature, but the field continues to move toward answers to these questions. In a population with a reasonable potential for sexual selection, then, we have to wonder why sexual selection takes its particular form. For instance, why are some taxa characterized by intrasexual selection and others experience intersexual selection? The answer

again lies in ecological circumstances, and a body of theoretical literature addresses the exciting issue of mating preference evolution, a topic that still has not been fully resolved.

Several additional complications are ignored here. For example, sexual selection can continue after mating in the forms of gamete competition or cryptic choice. Mate choice can also be based on genetic compatibility, a topic that was not covered here. Each topic addressed in this article further has many complications and nuances that were not discussed. Overall, the field of sexual selection has explained many aspects of mating behavior in nature and has generated many testable predictions. However, the field is still young and much work remains to be done.

Shifting Balance Theory, Sewall Wright and

MJ Wade, Indiana University, Bloomington, IN, USA

Glossary

Adaptive landscape This is the surface of mean fitness of a population as a function of its multidimensional genetic composition.

Additive effect Additive effect of a gene on the phenotype is the gene's effect averaged across all multi-locus genotypes and all environments.

Deme It is a local, randomly mating and interacting population of individuals.

Effective number It is a concept developed by Wright in order to relate the properties of individuals in real biological populations with those of the idealized individuals of evolutionary genetic theory. For example, real populations vary from one generation to the next in the numbers of breeding males and females; sometimes there are more breeding males than females or vice versa. Evolutionary genetic theory often tends to assume that the numbers of males and females are equal. Wright's concept of effective number translates the real world variation in male and female numbers into a smaller number, equivalent to an idealized theoretical population where the numbers of breeding males and females are always equal.

Epistasis It refers to the interactions between combinations of genes that affect the phenotype of an individual, such that the effect of a gene on a phenotype depends upon another gene or genes elsewhere in the genome.

Fitness peak It is an optimum on the adaptive landscape, which can have many optima of different absolute heights when there are interactions between genes, between genotypes or between genes and the environment.

Indirect genetic effect It is the effect of a gene in the genome of one individual on the phenotype of another individual. For example, some genes in the maternal genome are transcribed into messenger RNA that initiate and control early development of the offspring; these same genes may be carried in the offspring genome but may not be expressed at that time in development or may never be expressed, particularly if the offspring is a male.

Interdemic selection It is a process of selection that favors some local demes at the expense of others. In Wright's theory, demes of high average fitness send out more migrants than local demes of lower average fitness. In addition to Wright's interdemic selection by differential dispersal, interdemic selection could occur by the differential extinction of existing demes (where some demes persist longer than others) or differential colonization of new demes (where some demes have more successful colonizing propagules than others).

Island model migration It is the random movement or dispersal of individuals among demes.

Pleiotropy It occurs when a single gene affects two or more aspects of the phenotype.

Random genetic drift It is the local change in allele frequencies that occurs in populations with finite numbers of breeding adults owing to the sampling of gametes that occurs in the formation of zygotes for the next generation. Since this sampling is independent of the consequences of the alleles for fitness, alleles with harmful effects on fitness may increase in frequency by chance and conversely alleles with beneficial effects may decrease in frequency by chance.

In his studies of the deep pedigree of shorthorn cattle and his colony of inbred lines of guinea pigs, S. Wright observed a "… net-like relationship between the genome and complex characters" (Wright, 1968, p. 59). Moreover, just as Darwin used artificial selection as a model for his process of natural selection, Wright modeled his Shifting Balance Theory (SBT) of evolution in Nature after the processes used by breeders to transform longhorn cattle. From these empirical observations, he drew several broad generalizations about genes and the evolutionary process that he considered 'obvious.' These evolutionary genetic generalizations included (Wright, 1968, pp. 59–60): (1) the multiple factor hypothesis, namely, that most traits are affected by a large number of loci; (2) the principle of universal pleiotropy, wherein each gene replacement affects several different traits, so that a gene's different effects contribute differently to selective value; (3) the uniqueness of alleles in light of (2); (4) the dependence of dominance on genetic background and environment; (5) the universality of nonadditive gene interactions (epistasis); (6) the dependence of homology on the expression of similar chains of gene interactions under similar developmental conditions; and (7) the existence of multiple fitness peaks as a result of interaction effects of the most extreme sort with regard to overall selective value.

Wright's SBT (Wright, 1931, 1932) was founded on his empirical observations and the inferences he drew from them about the genetic system. Evidence from experiments and from modern genomic studies of gene expression and gene mapping support Wright's inference that nonlinear molecular interactions are the foundation of the relationship between genotype–phenotype (e.g., Lehner *et al.*, 2006; Szappanos *et al.*, 2011; cf. review in Mackay, 2014). These and other studies provide direct support for each of Wright's genetic principles. Nevertheless, the role of gene interactions (epistasis) in evolutionary genetics and the status of Wright's grand theory of evolution (SBT) remain controversial (Coyne *et al.*, 1997; Wade and Goodnight, 1998; Goodnight and Wade, 2000; Coyne *et al.*, 2000). In this article, the author will discuss the

 doi:10.1016/B978-0-12-800049-6.00036-6

elements of Wright's theory, the evidence in support of it, and some of the reasons behind the controversy.

Wright's Shifting Balance Theory

Wright's SBT (Wright, 1931, 1968, 1977; Wade and Goodnight, 1991; Wade, 1992, 1996; Johnson, 2008) has three phases. Phase I is an 'exploratory phase,' where different gene combinations arise by chance in different local populations as a result of random drift. Phase I is necessary for discovering new adaptive gene combinations. In Phase II, favorable gene combinations spread to fixation within local demes by individual selection. In this phase, demes become more genetically differentiated from one another than they were in Phase I as different demes are attracted to different fitness peaks. Because of gene interactions, Wright conceived of the surface of mean fitness as a landscape with multiple possible fitness optima or 'adaptive peaks.' During Phases I and II, each deme in a metapopulation arrived at a local fitness peak that was generally different from the local fitness peaks of neighboring demes. At the end of this phase, the genetic differences among demes are large owing to the combined effects of drift and local or mass selection. And, each deme in a metapopulation resides on a fitness peak separated from other demes by valleys of lower mean fitness.

For Wright (1932, pp. 358–359) this was an intermediate stage in his SBT: "The problem of evolution as I see it is that of a mechanism by which the species may continually find its way from lower to higher peaks.… In order that this may occur, there must be some trial and error mechanism on a grand scale by which the species may explore the regions surrounding the small portion of the field which it occupies. To evolve, the species must not be under strict control of natural selection." In Phases I and II, each deme in a metapopulation is held to a fitness peak by individual selection while random genetic drift permits it to explore neighboring genotypic space. Together, Phases I and II are Wright's 'trial and error mechanism,' where each deme is a small experiment in adaptive evolution (Wade and Goodnight, 1998).

Phase III of the SBT is interdemic selection where migrants leave demes with higher mean fitness and move into demes of lower mean fitness. With local individual selection, the fittest individuals contribute more offspring to the deme in the next generation. Under interdemic selection, the fittest demes contribute more offspring to the metapopulation in the next generation. After a globally favorable gene combination arrives in a low fitness deme by migration, local selection, recombination, and recurrent migration act together to change its genetic background. Thus, the interdemic selection of Phase III favors the higher fitness peaks and is an essential component of Wright's SBT.

Gene Interactions Create a Multiplicity of Fitness Peaks

Wright argued that some gene combinations would have fitnesses equal to one another while, at the same time, other gene combinations would have higher or lower fitness. Wright accepted a relative constancy of genotypic selective values for adaptation to the external environment, but, for genes involved in interactions with other conspecifics, Wright believed that genotypic relative fitnesses would be a function of gene frequencies. The study of genes that affect the evolution of interactions between conspecifics is currently referred to as the study of Indirect Genetic Effects (IGEs; Wolf *et al.*, 1998; Bijma and Wade, 2008). Adapting to other conspecifics is different from adapting to abiotic environments because, when other conspecifics affect the quality of the environment and the fitness of an individual, the environment must be seen as having a genetic component. In this sense, an individual's phenotype or fitness is affected by the indirect action of genes in the genomes of other individuals. Moreover, the phenotype of the individual will change whenever the 'environment evolves.' With respect to Wright's genetic insight, interacting genotypic fitnesses are not only frequency dependent, but they also respond to inter-group or inter-deme selection in ways that genes with direct effects do not. Indeed, with random local mixing and no correlation between direct and indirect effects, IGEs do not respond to individual selection at all (Wade, 2016). The evolutionary consequences of such IGEs are more complicated than the simple genetic models of most evolutionary theory. As Feldman *et al.* (1983, p. 1009) concluded from their review of models of fertility selection with interacting males and females, "…the simplest interactions between individuals in the process of selection can produce evolutionary conclusions not expected from individual fitness models."

Wright (1931, 1932) introduced his concept of the 'adaptive landscape' or 'surface of selective value' to illustrate how the simultaneous action of mutation, migration, random genetic drift, and natural selection resulted in a multiplicity of selective peaks. "Selection, whether in mortality, mating or fecundity, applies to the organism as a whole and thus to the effects of the entire gene system rather than to single genes. A gene which is more favorable than its allelomorph in one combination may be less favorable in another. Even in the case of cumulative effects, there is generally an optimum grade of development of the character and a given plus gene will be favorably selected in combinations below the optimum but selected against in combinations above the optimum. Again the greater the number of unfixed genes in a population, the smaller must be the average effectiveness of selection for each one of them. The more intense the selection in one respect, the less effective it can be in others. The selection coefficient for a gene is thus in general a function of the entire system of gene frequencies" (Wright, 1931, p. 101). Here, Wright is clearly arguing that the selection coefficient of a gene, i.e., the gene's effect on fitness, changes as the genetic background changes, so that a gene favored by individual selection in one genetic background might be selected against in a different genetic background.

Despite the evidence from modern genomic studies (e.g., Lehner *et al.*, 2006; Szappanos *et al.*, 2011; cf. review in Mackay, 2014) that provide direct empirical support for each of Wright's genetic principles, the role of epistasis in evolutionary genetics remains controversial. Because the local genetic variation for most traits appears to be additive and because the additive genetic variance determines the

heritable response to natural and artificial selection, most of evolutionary genetic theory is framed by assigning genes a fixed, additive effect on fitness at their mutational origin. For example, Hill *et al.* (2008) argued on empirical and theoretical grounds that interactions at the level of genes do not generate much interaction at the level of the phenotypic variance. They concluded (Hill *et al.*, 2008, p. 9) that "…maintaining emphasis on utilizing additive variation by straightforward selection remains the best strategy." In a similar vein, Crow (2010) asserted that epistasis "…is unimportant in polygenic directional selection."

This view is sometimes called the 'gene's eye view' of evolution because it allows the adaptive process to be understood as the sequential substitution of single genes. Williams (1966, p. 56) provided one of the earliest and best expressions of the 'gene's eye view' of adaptation by natural selection:

> No matter how functionally dependent a gene may be, and no matter how complicated its interactions with other genes and environmental factors, it must always be true that a given gene substitution will have an arithmetic mean effect on fitness in any population. One allele can always be regarded as having a certain selection coefficient relative to another at the same locus at any given point in time. Such coefficients are numbers that can be treated algebraically, and conclusions inferred from one locus can be iterated over all loci. Adaptation can thus be attributed to the effect of selection acting independently at each locus.

From the 'gene's eye view,' genetically complex adaptations are assembled gradually, one gene at a time by natural selection. Interactions between genes, genes and environments, or between genotypes variations in finite populations are of little consequence because they do not significantly affect the relationship between a gene and its long-term average fitness effect.

Wright disagreed with this view as is evident in his writings on the "…inadequacy of the simple additive concept of gene effect" stating that, "…all genes that approach additivity in their effects on varying characters will be favorable in some combinations and unfavorable in others in terms of natural selective value (fitness) and, thus, exhibit interaction effects of **the most extreme sort** in the latter respect" (Wright, 1969, pp. 419–420; the author's emphasis in bold). In Wright's theory, the fitness of a genotype is not the sum of the properties of its component genes but rather an indivisible property of the entire genetic system. For this reason, Wright's SBT is different from standard Fisherian theory, where average gene effects are often treated as constants (Williams, 1966; Loewe and Hill, 2010) and the variations about the average are unimportant (Williams, 1966; Crow, 2010; Hill *et al.*, 2008).

In a metapopulation consisting of small, isolated demes connected by migration, Wright proposed that the gene combinations best for fitness would become fixed within local demes by drift or selection even if they conferred relatively poor mean fitness from a more global perspective. The joint influences of selection and random genetic drift would result in a metapopulation whose demes achieved a multiplicity of 'local fitness optima' or 'adaptive fitness peaks.' Because of interactions, Wright argued that the number of possible peaks increased geometrically with the number of genes (Wright, 1968). Without interactions between genes, between genes and environments, or between genotypes, there would be only a single peak and no need for a process like the SBT allowing for the evolution of demes from one fitness peak to a higher one.

Gene Interactions Limit Mass Selection

Importantly, gene interactions do more than simply create an opportunity for interdemic selection by creating a multiplicity of fitness peaks. As Wright argued, gene interactions change the sign of a gene's effect on fitness (Wade, 1992). With changes in sign, a gene can be favored by selection in one background but selected against it in another (Wade, 2001, 2002). Thus, interactions ultimately limit the effect of individual selection because the average effect of local selection includes positive and negative changes in gene frequency corresponding to demes in which a gene is favored and those in which it is selected against, respectively.

A multiplicity of fitness peaks and the conservative nature of local individual selection (which Wright called mass selection) prevented evolutionary innovation. In Wright's view, individual or 'mass selection' not only moved a deme toward the nearest fitness peak, it also held the population at that local optimum. If sufficiently small relative to the strength of selection (Wright, 1931), a deme might move by random drift across the valley of mean fitness from one fitness peak to an adjacent peak in gene frequency space. However, the relative mean fitness of the neighboring fitness peak was not guaranteed to be higher than the peak left behind nor was it guaranteed to be the globally highest fitness peak. Lande (1985) showed that the average time between peak shifts by random drift increases exponentially with the effective number of breeding adults in the local deme, so that doubling the local density more than doubles the time to move by chance from one fitness peak to another. The time necessary for a shift between fitness peaks by chance is so long that environmental changes that alter the landscape of mean fitness are likely to be more common (Whitlock, 1997). However, the 'nearest' peak was unlikely to be a higher fitness peak, let alone 'the highest' peak, given the myriad of possible optima afforded by gene interactions. For Wright, the question became: How could a species find the highest peak? He added interdemic selection to his SBT because it was a process that could provide an answer to this question.

Interdemic Selection

USDA breed histories showed that the selective effort of local breeders was not the primary force transforming the phenotypic characteristics of a breed. The transformation of a breed occurred when, by a combination of chance and local selection, a local farm produced an important combination of genes. Subsequently, demand by other breeders on other farms for that improved quality of animal led to the dispersion of the favorable gene combination out from the originating farm and into other farms. Interdemic selection in Wright's SBT was Nature's version of this process of breed transformation. Interdemic selection occurred as particularly good gene combinations arose within local demes, resulting in higher mean fitness and therefore higher local density. Individuals moved

out from demes of high mean fitness and into demes held at lower fitness peaks by local individual selection. Because more migrants left the demes with higher mean fitness, the globally good gene combinations were differentially exported from demes at higher fitness peaks into demes at lower fitness peaks. The mechanism of interdemic selection, also called selection among demes or group selection, was differential migration.

What feature of Nature could play the role of 'breeder demand' so that populations with higher fitness sent out more migrants than other populations? Wright (1931, 1932) proposed that it was the ecological mechanism of density-dependent migration. Individuals moved out from crowded areas of high density, where competition was intense, and into more sparsely populated areas of lower density with less competition for resources. In his classic book, *Animal Ecology* (Elton, 1927), the eminent ecologist, C. S. Elton had included a chapter on dispersal. He stated (Elton, 1927, p. 156): "… many animals migrate on a large scale in order to *get away from* a particular place rather than *go towards* anywhere in particular. That is to say, there are often very cogent reasons why a large section of the population should migrate somewhere else, the most common one being overpopulation." Wright's ecological idea was founded on the theoretical relationship between mean fitness, W, and population size, N. Mean absolute fitness, the net difference between births and deaths, proscribed the relationship between population numbers at time t, N_t, and population numbers at time $(t+1)$: $N_{t+1}=WN_t$. According to Wright's logic, good gene combinations caused high mean fitness, W; high mean fitness caused high population density, N; and, the competition that attended high density caused dispersal or migration. Wright discussed his argument connecting genes to ecology on many occasions with his colleague at the University of Chicago, Thomas Park, the founder of laboratory ecology, who was a close personal friend of C. S. Elton (pers. comm. from TP to MJW).

The addition of interdemic selection to Wright's theory has been as controversial as its foundation on gene interactions. It has been argued that random migration is sufficient to spread a good gene combination from one deme to another and that, once it has arrived in a deme, local individual selection is sufficient to insure its spread (Barton, 1992; Barton and Rouhani, 1993). As a consequence, some have concluded that the reliance on interdemic selection is a weakness of Wright's SBT (for both sides of this controversy, see: Coyne *et al.*, 1997; Wade and Goodnight, 1998; Goodnight and Wade, 2000; Coyne *et al.*, 2000).

Experimental Tests of Wright's Shifting Balance Theory

The most general, albeit qualitative, prediction about the evolutionary process that Wright drew from his SBT was that the rate of evolution would be faster in a metapopulation than in a large, randomly mating population at least for complex traits closely connected to fitness and involving gene interaction effects. Artificial interdemic selection experiments on 'additive' genetic traits without gene interactions (reviewed in López-Fanjul, 1989) have not shown any advantage of selection in metapopulations over selection in large randomly mating populations. As López-Fanjul (1989) concluded, "it is desirable that experiments of this kind [metapopulation selection] be carried out for epistatic traits in order to test Wright's hypothesis." Wade and Goodnight (1991) tested Wright's theory by focusing artificial interdemic selection on fitness itself, a key trait in Wright's SBT, by creating experimental and control metapopulations, each with 50 demes, where each deme was founded with 20 adult flour beetles of *Tribolium castaneum*. Importantly, the differences in mean deme fitness that developed as the offspring of each group of 20 beetles reproduced and developed were created by the beetles themselves and were not imposed by Wade and Goodnight (1991). That is, despite starting each deme with the same number of founders in the same amount of resource and holding them at the same environmental conditions, the beetles created a multiplicity of fitness peaks across the experimental metapopulations as one group of 20 adults was more or less productive than another.

In the experimental metapopulations, Wade and Goodnight (1991) converted the beetle-created variation in W, into interdemic selection by differential dispersion as prescribed by Wright's SBT. Here, each deme was assigned a 'relative demic fitness' value, W/W_{mean}, by dividing each W by the average (W_{mean}) of all 50 W values in the metapopulation so that highly productive demes, where $W>W_{\text{mean}}$, had higher relative demic fitnesses than less productive demes whose $W<W_{\text{mean}}$. Demes with relative fitness >1 contributed migrants to a migrant pool, while demes with relative fitness <1 received migrants from the migrant pool as per Wright's Phase III interdemic selection.

The control metapopulations were treated in the same way as the experimental metapopulations except that migration among demes was random with respect to demic fitness, W. Wade and Goodnight (1991) imposed the same amount of migration in the control as in the experimental metapopulations. The only difference was the pattern of migration, random in the case of the controls but biased toward demes of higher mean fitness in the experiments. The random migration among demes in the control metapopulations allowed a test of the prediction that random migration was sufficient to spread favorable gene combinations and that interdemic selection was not essential as Wright claimed.

In each of the three experimental metapopulations with interdemic selection, Wade and Goodnight (1991) observed a significant increase in mean fitness relative to the corresponding control metapopulation with the same level of random migration. This finding supports Wright's SBT as a process that can change mean deme fitness. Because the mean fitness of the control metapopulations with random migration was lower in all three cases, the results indicate that interdemic selection changed mean fitness where individual selection with random migration did not (for further discussion see Wade, 2016).

Nonrandom Phase III Migration and F_{ST}

Another aspect of the interdemic selection by differential dispersion (Phase III) of Wright's SBT has been controversial and

that is the contrasting rate of migration between Phases I and II. The exploratory period of Phase I is more effective with low migration rates than it is with high migration rates because Wright's own measure of genetic differentiation among demes, F_{ST}, is a declining function of the migration rate. Differently put, demes become much more genetically different from one another by random genetic drift when migration rates are very low than they do when migration rates are high. The opposite obtains in Phase III: exporting an adaptive peak from one deme to another is more effective when migrations rates out of the deme with high mean fitness and into the deme or demes of low mean fitness are high (Moore and Tonsor, 1994; Coyne *et al.*, 1997). As Lenormand (2002, p. 188) stated: "Gene flow plays a crucial role in shifting balance models; it has to be both low enough for a peak shift to occur (so that drift enables alleles to cross the 'valley') and high enough for a high-fitness peak to spread." Similarly, Gavrilets (1996, p. 1034) suggested that the migration conditions necessary for Wright's shifting balance process are restrictive because "… Migration should be neither too strong not [sic] too weak relative to selection."

Recent experimental studies of migration during Phase III have shed some light on this question (Wade, 2013). When migration deviates from the island model of migration the arithmetic mean migration rate is not the appropriate measure of the genetic mixing that attends dispersion between populations (Sved and Latter, 1977). Where the island model assumes random migration, migration in natural populations tends to deviate from random. Phase III migration is a particular case where migration deviates from the island model. Specifically, where migrants disperse at random among metapopulation demes under the island model, in Wright's Phase III, migrants disperse nonrandomly such that the variation among demes in migrants received (and therefore gene flow) exceeds random. This is necessary for the interdemic selection in the SBT because migrants differentially originate in demes of high mean fitness and disperse into demes of lower mean fitness. In fact, the interdemic selection differential in Phase III of Wright's process is a function of the degree to which the variation in migration at Phase III exceeds random expectation (Wade, 2013, eq. 6). This variation in excess of random 'lowers' the effective migration rate among demes so that the arithmetic mean rate of migration overestimates the effective migration rate and overestimates the effect of Phase III migration in reducing F_{ST}.

Wade (2013) used data from the experimental study of the SBT (Wade and Goodnight, 1991) to illustrate the degree to which Phase III migration increased the variance in migration rate and thereby lowered the effective migration rate. The protocol of Wade and Goodnight (1991) resulted in identical arithmetic mean migration rates in their control (island model migration) and their experiment (Phase III migration) metapopulations. However, the greater variance in Phase III migration resulted in a lower effective migration rate, which manifested itself in higher values of F_{ST} for a neutral genetic marker. Most estimates of migration in natural populations confound its random and differential components, providing estimates of Nm, the effective number of migrants, with unknown and unmeasured biases (Whitlock and McCauley, 1999).

Several Open Questions Remaining

The central question of Wright's SBT (Wade, 1992) remains unanswered: Does natural selection assemble adaptive gene combinations one gene at a time acting on the average 'additive' effects of single genes; does it select directly among different gene combinations; or is the adaptive process a combination of selection processes within and among demes as Wright suggested? Unfortunately, this question remains unanswered because the predictions from Wright's theory are not particularly specific.

Wright's SBT predicts that the additive effect of a gene on fitness should change in sign and in magnitude with genetic background, but it does not specify how different two backgrounds have to be in order to detect measurable changes. Recent studies indicate that epistasis dominates the genetic architecture of *Drosophila* quantitative traits (Huang *et al.*, 2012), accounting for the lack of replicability among gene discovery studies. But no studies to date quantify the variation in gene effect, either on a trait or on fitness, in relation to the variation in genetic background. The relationship between the genome-wide average among-deme genetic variance, F_{ST}, and the among-deme variance in gene effects might be linear or curvilinear, and the latter might be compensatory or synergistic. This unknown relationship ought to affect the rate of speciation with synergistic or compensatory relationships accelerating speciation. Moreover, there may be categories of genes whose effect changes greatly with small changes in background and other categories of genes whose effects change little or not at all with large changes in background. In short, there is a tremendous amount of additional genetic and ecological research that is necessary to determine the scope of Wright's SBT in adaptive evolution.

Social Effects

JW McGlothlin, Virginia Tech, Blacksburg, VA, USA

Glossary

Altruism Any behavior that benefits a conspecific at a cost to the actor's own fitness.
Hamilton's rule A rule first derived by William Hamilton predicting that altruism should be favored by selection when fitness costs are outweighed by benefits to related individuals.
Indirect genetic effect The influence of the genes of one individual on the phenotypic expression of another.
Nonsocial selection The influence of an individual's phenotype on its own fitness.
Social selection The influence of the phenotype of one individual on the fitness of another.

Social interactions among conspecifics are ubiquitous in nature (Frank, 2007). Some species, such as the eusocial insects (ants, bees, wasps, and termites), form complex societies with differentiated castes and division of labor (Wilson, 1971). In these species, social interactions are obviously important for fitness. For example, a queen bee would be unable to reproduce without the cooperation of workers who forage and provide parental care for the colony. In other species, the importance of social interactions might be less obvious but no less important. For example, social competition among conspecifics for resources or mates is often both highly important for fitness and reliant on social interactions (West-Eberhard, 1979). Quorum sensing in bacteria, reproductive aggregation in slime molds, and chemical communication in plants serve as reminders that the importance of social interaction is not limited to animals but extends across all of life's kingdoms (West *et al.*, 2006; Frank, 2007; Karban, 2008).

Despite their importance in nature, social interactions were mostly ignored by evolutionary biologists for over 100 years after the publication of the *Origin of Species*. The founders of theoretical population genetics, Haldane, Fisher, and Wright, made occasional references to sociality but were largely concerned with other issues. A major breakthrough came in 1964 with the publication of Hamilton's theory of inclusive fitness, which demonstrated the evolutionary consequences of genes that influence the fitness of related individuals (Hamilton, 1964a,b). Specifically, Hamilton showed that alleles associated with altruistic behavior may evolve by natural selection when the cost to the actor's fitness is outweighed by benefits to relatives. This prediction has become known as Hamilton's rule.

Later in the decade, Griffing began to explore the consequences of what he called 'associate effects,' which occur when the genes of one individual affect the phenotype of another (Griffing, 1967). Griffing's contribution has received much less attention than Hamilton's, but as will be shown below, such associate effects (or indirect genetic effects (IGEs), as they are typically called today) may have major implications for the evolution of social phenotypes. Today, the work of Hamilton and Griffing has been integrated into the standard quantitative genetic model of evolution, allowing specific predictions for social phenotypes should evolve (Queller, 1992a,b; Moore *et al.*, 1997; Wolf *et al.*, 1999; Bijma *et al.*, 2007; Bijma and Wade, 2008; McGlothlin *et al.*, 2010, 2014). What follows is a brief overview of relevant theory and empirical approaches that explore how social interactions affect the evolutionary process.

Theoretical Background

Two necessary conditions must be met for a trait to evolve by natural selection. First, the trait must be predictably associated with fitness; that is, it must be under natural selection. Second, the trait must exhibit genetic variation such that offspring tend to resemble their parents. To show how these two conditions contribute to adaptive evolution, biologists tend to use the quantitative genetic model of phenotypic evolution, which shows that under many conditions, phenotypic evolution can be predicted by the breeder's equation:

$$\Delta\bar{z} = G\beta$$

(Lande, 1979; Lande and Arnold, 1983; Falconer and MacKay, 1996). This simple equation shows that evolutionary change in the population mean of a trait ($\Delta\bar{z}$) can be predicted by the product of additive genetic variance (G), a measure of the similarity between parents and offspring, and the selection gradient (β), which measures the slope of the relationship between a trait and fitness. Both G and β can be estimated empirically, making this model a powerful way to study evolution in natural populations (Endler, 1986; Mousseau and Roff, 1987, 1997; Kingsolver *et al.*, 2001).

Social interactions among individuals can lead to complexities that alter the predictions of the breeder's equation. Specifically, social interactions can lead to violation of two important assumptions: that traits can be neatly decomposed into genetic and environmental components and that an individual's fitness can be attributed primarily to an individual's own traits. Violation of these two assumptions lead to two pathways by which social interactions can affect evolutionary change: by altering the phenotypes of interacting individuals, giving rise to IGEs, and by directly influencing fitness, giving rise to social selection (**Figure 1**).

Indirect Genetic Effects

The simplest quantitative genetic model assumes that the expression of a trait, z, can be attributed to two sources: an additive genetic component, a, which contributes to the

 doi:10.1016/B978-0-12-800049-6.00052-4

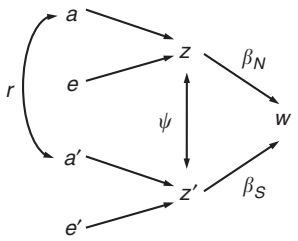

Figure 1 Pathways by which social interactions may influence evolutionary response to selection. In the absence of social interactions, an individual's fitness (w) is influenced only by its own traits (z), which are a function of its genes (a) and environment (e). The strength of this relationship is known as nonsocial selection (β_N). Social interactions may alter this pathway in two ways. First, an individual's phenotype may be influenced by the phenotypes of another individual (z') with strength ψ, leading to indirect genetic effects (IGEs). Because such interactions can involve feedback, this effect is shown as a double-headed arrow. Second, the social partner's phenotype may directly influence fitness, leading to social selection (β_S). Social selection can alter evolutionary response in the presence of IGEs, relatedness (r), or both.

similarity of parent and offspring traits, and an environmental component, e. To obtain an individual's phenotypic value, these components are simply added together:

$$z = a + e$$

Now consider a trait whose expression depends upon a trait in another individual. Animal behavior provides numerous examples of such traits. For example, a territorial holder's aggressive response might depend on the body size of the invader it encounters. These effects can also arise via feedback between the same phenotype expressed in different individuals. For example, a bird might sing more intensely when it hears song from another bird. At the same time, the second bird may be adjusting its song in response to the first. Although these effects on phenotypic expression may seem like just another part of the environment, they may alter evolutionary predictions because now the environment depends upon the traits of others and thus has a genetic component of its own.

The dependence of an individual's phenotype on genes found in another individual is known as an IGE. (Most of the treatment below follows the model of Moore *et al.* (1997), which introduced this term.) Such effects can be modeled by introducing another term into our phenotypic equation:

$$z_i = a_i + e_i + \psi_{ij} z'_j$$

The new term $\psi_{ij} z'_j$ represents the effect of a second individual's trait (z'_j) on the expression of the first individual's trait (z_i). The subscripts i and j allow the consideration of both cases sketched above, and the prime on the latter trait is used to indicate that the trait belongs to a second individual. When i and j are different, this equation represents cases like the adjustment of aggression based on invader body size; when i and j are the same, it represents cases of feedback, like the birdsong example. The coefficient ψ_{ij} represents the strength and direction of the interaction. If ψ_{ij} is positive, z_i increases in response to larger values of z'_j, whereas if ψ_{ij} is negative, the opposite occurs.

IGEs arise when the trait of the interacting individual is heritable. In this case, z'_j can be broken down into an additive genetic effect and an environmental effect of its own:

$$z_i = a_i + e_i + \psi_{ij}(a'_j + e'_j)$$

It is clear from this equation that the expression – and hence the evolution – of trait z_i will depend on both a direct genetic effect or DGE (a_i), which is attributable to an individual's own genes, and an IGE ($\psi_{ij} a'_j$), which is attributable to genes of its social partner. (Again, the primes denote that values belong to a second individual.) Even more complexity can arise when feedback is incorporated into the model. This may occur when one trait influences the same trait in another individual, as in the birdsong example, or when two traits influence each other in a loop. For example, animals might have both aggressive and submissive displays that they may use in an agonistic encounter. The aggressive display from one individual might elicit the submissive display from the other, and in turn, the submissive display might suppress the aggressive display. Such loops can be modeled by adding another term:

$$z_i = a_i + e_i + \psi_{ij}(a'_j + e'_j + \psi_{ji} z_i)$$

After some algebra, this can be written as

$$z_i = \frac{a_i + e_i + \psi_{ij}(a'_j + e'_j)}{1 - \psi_{ij}\psi_{ji}}$$

The denominator of this equation shows that feedback loops will influence the magnitude of both DGEs and IGEs. This effect will depend on the signs of the two ψ coefficients.

These social effects on the expression of phenotypes lead to alterations in the predictions of the breeder's equation. Consider the case of a phenotype that triggers a change in the same phenotype in an unrelated individual, like the birdsong example above. In this case, the predicted change in response to selection is

$$\Delta\bar{z} = \frac{G\beta}{(1-\psi)(1-\psi^2)}$$

The subscripts have been dropped here because this equation considers only a single trait. This equation shows that when a single trait is considered, IGEs affect evolutionary predictions in two ways. First, the term $(1-\psi)$ in the denominator shows that the simple presence of IGEs increases the response to selection when ψ is positive and decreases it when ψ is negative. This effect arises because the genes an individual passes on to its offspring will influence both their own phenotype and the phenotypes of others. When social interactions cause individuals to express more similar phenotypes, effective genetic variance (and thus response to selection) is increased. Social interactions that cause individuals to become more different from each other have the opposite effect.

Second, the term $(1-\psi^2)$ in the denominator arises from feedback in social interactions. Feedback is more important for very strong values of ψ, and cause a rapidly increasing response to selection as ψ becomes more positive. When ψ is negative,

feedback effects can overwhelm the depressive effect of IGEs on genetic variance, leading to a very strong response to selection for values of ψ around -0.9 and smaller. It is unknown whether such values are likely to be realistic, however. As will be discussed later, empirical estimates of ψ are limited, but there is currently no evidence for extreme negative values of ψ.

IGEs may also influence how responses to selection on multiple traits. In the absence of IGEs, a trait may evolve in response to selection on a second trait if the two traits are genetically correlated:

$$\Delta\bar{z}_1 = G_{11}\beta_1 + G_{12}\beta_2$$

In this equation, G_{11} refers to the additive genetic variance in trait z_1 and G_{12} is the additive genetic covariance between the two traits. Clearly, z_1 may evolve even when selection does not act directly on it (i.e., $\beta_1=0$) if z_2 is under selection ($\beta_2 \neq 0$) and the two traits covary genetically ($G_{12} \neq 0$). IGEs may alter this prediction by creating genetic relationships between traits that are otherwise uncorrelated. Consider the case when z_1 is influenced by z_2' in unrelated social partners ($\psi_{12} \neq 0$). If these two traits show no additive genetic correlation ($G_{12} \neq 0$), such IGEs can still cause the evolution of the two traits to be intertwined:

$$\Delta\bar{z}_1 = G_{11}\beta_1 + \psi_{12}G_{22}\beta_2$$

Note that the social effect causes z_1 to evolve in response to selection on z_2 even though the two traits are genetically uncorrelated. The quantity $\psi_{12}G_{22}$, which is the IGE coefficient multiplied by the genetic variance in trait 2, plays the same role as the additive genetic covariance G_{12} above. Interestingly, this equation also shows that z_1 may evolve in response to selection on z_2 even when it shows no additive genetic variance of its own ($G_{11}=0$). This would not be true in the absence of IGEs because genetic covariance is by definition absent when genetic variance is absent.

Social Selection

The second pathway by which social interactions may influence the evolutionary process is via direct effects on fitness. The effect of the phenotype of one individual on the fitness of another is known as social selection (Wolf *et al.*, 1999). Social selection may arise whenever social interactions have fitness consequences that depend on phenotype. For example, if agonistic encounters when larger individuals tend to inflict more harm, social selection would be acting through body size.

Like ordinary natural selection, or 'nonsocial' selection, social selection will only lead to evolutionary change under certain conditions. For nonsocial selection, the relevant variable is genetic variance, but what matters for social selection is the correlation between interacting individuals. Specifically, social selection will only lead to an evolutionary change when there is a nonrandom association between an individual's genes and the phenotype of its social partner (McGlothlin *et al.*, 2010). Using the example above, if large individuals inflicted harm and also sought out smaller individuals to bully, social selection would lead to an evolutionary increase in body size. It is easy to see why this is true: small individuals suffer the most from aggression and thus have the lowest fitness.

To add social selection to an evolutionary model, fitness must be divided into two components: one deriving from an individual's own traits and one deriving from those of social interactants. The simplest version of such a model considers the same trait in two socially interacting individuals. In this model, an equation for relative fitness can be written as

$$w = \alpha + \beta_N z + \beta_S z' + \varepsilon$$

where w is relative fitness, β_N is the nonsocial selection gradient, β_S is the social selection gradient, and α and ε are an intercept and an error term, respectively (Wolf *et al.*, 1999). Although social selection can involve any phenotype, it is easiest to envision acting through behavioral traits: β_S should be positive for behaviors that tend to help another individual (cooperation or altruism) and negative for behaviors that harm another individual (such as physical aggression).

As mentioned above, an evolutionary response to social selection depends on an association between one individual's genes and another's phenotype. This relationship can arise in two different ways: either individuals nonrandomly interact with one another, or IGEs may alter the expression of phenotypes during interactions. As noted above, IGEs are quantified with the parameter ψ. To model nonrandom association, the parameter r is used. This parameter is usually called relatedness, because one of the easiest ways to get a nonrandom phenotypic association is for relatives to interact. However, familial relatedness is not necessary; any nonrandom assortment (such as big individuals seeking out smaller individuals) will do.

Adding these effects to the breeder's equation yields:

$$\Delta\bar{z} = \frac{(1 + r\psi)G\beta_N + (r + \psi)G\beta_S}{(1 - \psi)(1 - \psi^2)}$$

This equation shows that evolutionary response to social selection depends on the quantity $(r+\psi)$, that is, on the presence of relatedness, IGEs, or both (McGlothlin *et al.*, 2010). In addition, the response to nonsocial selection is altered somewhat when both relatedness and IGEs are present $(1+r\psi)$. Social selection can either act in opposition to or in concert with nonsocial selection. The former case is the most interesting, because here the levels of selection are in conflict; in other words, different trait values are favored when we consider an individual's fitness versus the fitness of others. When levels of selection are in conflict, the evolutionary outcome will reflect a balance between nonsocial and social selection. This balance will be determined both by the strength of each selection gradient and the combined effect of relatedness and IGEs.

The most instructive case to examine here is the same one that concerned Hamilton: the evolution of altruism. Altruism occurs when others are helped at the expense of one's own fitness, and hence altruistic behaviors should have positive β_S (Hamilton's 'benefit') and negative β_N (Hamilton's 'cost'). Thus, an altruistic behavior should increase in response to selection ($\Delta\bar{z}>0$) when:

$$-\beta_N < \frac{r + \psi}{1 + r\psi}\beta_S$$

This inequality, which is a slight modification of Hamilton's rule, demonstrates that relatedness and reciprocity can have symmetrical and complementary effects on the evolution of altruism (McGlothlin *et al.*, 2010). In words, this inequality shows that altruism should increase in a population when fitness costs to oneself are outweighed by scaled benefits to others. As Hamilton identified, the effective benefit increases with relatedness; for example, altruistic behavior is more likely to evolve when full-sibs ($r=0.5$) benefit than when half-sibs ($r=0.25$) benefit. Similarly, IGEs enhance the evolution of altruism when ψ is positive, leading interacting individuals to be more similar to each other and slow its evolution when ψ is negative. Positive values of ψ can favor the evolution of reciprocal altruism, a form of cooperation where one individual's actions depend on the actions of its social partner. The modified form of Hamilton's rule indicates that this type of reciprocity can lead to the evolution of cooperation among unrelated individuals ($r=0$) when ψ is strong enough. When both factors are present, they can interact to influence the evolution of altruism.

Empirical Examples

The power of the framework outlined above is that relevant parameters can be estimated in natural populations, allowing evolutionary biologists to assess the importance of social interactions in the evolutionary process. The study of social interactions has traditionally been the domain of behavioral ecology, and its synthesis with evolutionary quantitative genetics is still in its infancy. Empirical work at the nexus of these two fields has begun to bear fruit in recent decades. This section will briefly explore empirical studies of IGEs and social selection and their relevance to understanding evolution interacting phenotypes.

Indirect Genetic Effects

IGEs can be studied empirically taking one of two approaches. Trait-based approaches follow directly from the theory outlined above and attempt to assess the importance of particular phenotypes in generating IGEs (McGlothlin and Brodie, 2009). In contrast, variance-partitioning approaches assess the total strength of IGEs on a particular phenotype without assigning these effects to a particular phenotype in an interacting individual (Wolf, 2003; Muir, 2005; Bijma *et al.*, 2007; Bijma, 2010). Each of these approaches has its advantages and disadvantages, and the choice depends upon the question being asked. Fortunately, the two frameworks are compatible in theory, and results from one framework may often be translated to the other (McGlothlin and Brodie, 2009; McGlothlin *et al.*, 2010).

Studies that measure IGEs use simple modifications of methods used to detect standard quantitative genetic parameters such as heritability. Two ingredients are of prime importance for such studies. First, as for any quantitative study, the investigator must have knowledge of the genetic relatedness among the individuals under study. This is often accomplished using a controlled breeding design, such as mating males to multiple females to generate half-sib families, but may also involve complex natural pedigrees or experimentally generated inbred lines (Falconer and MacKay, 1996). Second, associations among individuals must be known in order to quantify the effects of social interactions (Muir, 2005; Bijma *et al.*, 2007). This may derive from housing individuals together in a laboratory environment or observing natural social groups in the wild.

Most empirical studies of IGEs have used a variance-partitioning approach, and the bulk of this work has been conducted in domestic species such as laying hens or hogs (Bijma *et al.*, 2007; Ellen *et al.*, 2008; Wade *et al.*, 2010). One particularly nice example comes from a study of mortality in domestic fowl (Bijma *et al.*, 2007). Group-housed hens suffer socially induced mortality due to cannibalistic pecking. A large study of 4000 hens with a known pedigree showed that nearly two-thirds of the genetic variation in survival derived from IGEs rather than DGEs. There was no strong correlation between direct and indirect effects, suggesting that avoidance of pecking and pecking others are genetically independent.

Some work has been conducted in nondomestic species as well. In one study that quantified IGEs in aggressive interactions between male deer mice (*Peromyscus maniculatus*) in the laboratory, Wilson *et al.* (2009) detected evidence for IGEs in three of the five traits they measured. Notably, all three traits showed strong correlations between direct and indirect effects. Dominant individuals tend to mount subordinates, and the rate of mounting showed a strong negative correlation between direct and indirect effects. This relationship likely indicates a negative value of ψ: individuals that tend to be submissive induce dominant behavior in their partners and vice versa. This is predicted to lead to a slower response to selection than would occur in the absence of IGEs (cf. Wolf, 2003). Two other traits, rearing (a threat display) and time to initiate a fight, showed strong positive direct–indirect correlations, indicating the presence of positive values of ψ. This result suggests that IGEs should cause certain aggressive behaviors to respond very rapidly to selection.

Although the analyses presented by Wilson *et al.* (2009) suggest certain values of ψ, they cannot directly estimate it because they do not use a multivariate approach to tease apart relationships among correlated traits. Only a few studies have attempted to estimate ψ directly. In one pioneering study, Bleakley and Brodie (2009) used a clever experimental design to estimate ψ for predator inspection behaviors in guppies. This study took advantage of the many available designer guppy strains, which are similar to inbred lines, allowing the experimenters to control the genetic makeup of social groups. Several different strains were placed in groups with a focal individual, and the regression of focal on social group behaviors provided estimates of ψ. Significant estimates of ψ were overwhelmingly positive and tended to involve the same behavior in focal and social individuals. This suggests a pattern of reciprocity: guppies are more likely to approach a predator or school if others do as well. This positive feedback should allow these behaviors to respond rapidly to selection.

In certain systems, direct and IGEs may be assigned to particular regions of the chromosome, sometimes even to particular genes. For example, Mutic and Wolf (2007) used inbred lines of the plant *Arabidopsis thaliana* to map

quantitative-trait loci underlying direct and indirect effects on a number of traits related to plant size and development. Interestingly, direct and indirect effects of given loci tended to be of the same sign, suggesting a pattern of cooperation rather than competition among plants.

Social Selection

Studies that estimate natural selection in wild populations tend to use a regression-based method that teases apart the direct effects of correlated traits on fitness. The partial regression slopes generated by these analyses provide estimates of selection gradients, i.e., a measurement of direct natural selection on each trait (Lande and Arnold, 1983). Social selection can be measured in natural populations using a simple modification such analyses (Heisler and Damuth, 1987; Goodnight *et al.*, 1992; Wolf *et al.*, 1999). In addition to including an individual's own traits as predictors of fitness, a social selection analysis would include phenotypic values from one or more social interactants. The partial regression slopes for an indivdual's own traits would estimate nonsocial selection gradients (β_N), while the slopes for the traits of social interactants would estimate social selection (β_S).

Studies directly applying social selection analysis in wild populations are very rare. One example of social selection comes from a study of forked fungus beetles, which live in groups on bracket fungi (Formica *et al.*, 2011). Social interactions among males are often aggressive and involve competition over access to mates, and larger males typically have the advantage in such contests. Formica *et al.* (2011) found that mating success, which was estimated by observing copulations, was predicted not only by a male's own size but also that of the males with which he interacted. Specifically, males with the highest mating success were larger (positive β_N) and surrounded by smaller competitors (negative β_S). Such social selection is probably common in the context of sexual selection, where a male's trait relative to local competitors is likely to be more important than his absolute trait value. Interestingly, Formica *et al.* found that larger males tended to be surrounded by smaller males. Although they did not measure genetic relationships among individuals, this phenotypic correlation suggests the possibility of a nonrandom genetic association between interacting males, which would predict an evolutionary response to social selection.

Conclusion

Theory shows that when social interactions affect phenotypes, fitness, or both, evolutionary responses to selection may be drastically altered. Depending on the nature of the interaction, evolutionary change may be accelerated or slowed. In addition, traits that are not otherwise genetically correlated may coevolve via their roles in social interactions. The effects of social interactions on evolutionary change may be probed empirically using subtle tweaks of standard quantitative genetic methods. Although early work has provided foundational evidence that IGEs and social selection may be important in nature, the field is still in its infancy and much more work is necessary to establish the evolutionary roles played by these phenomena.

Sociobiology, History of

U Segerstrale, Illinois Institute of Technology, Chicago, IL, USA

Glossary

Adaptation A product of evolution, such as a particular morphological feature or behavior that fulfills a particular function in a particular environment; also the process involved in the production of this feature or behavior.

Adaptationism According to critics of sociobiology, sociobiologists' belief that all traits of an organism are adaptations, or the attempt to study all traits of an organism as if they were adaptations. (The critics, in contrast, point to reasons why individual traits may not be adaptations, for instance, they may be by-products.)

Altruism A behavior that promotes the fitness of another organism at the expense of its own fitness. Note that 'altruism' is used in sociobiology to refer strictly to the outcome of an organism's behavior, it does not involve motives. Altruism was a puzzle for Darwinian theory until Hamilton developed the idea of inclusive fitness in 1964.

Eusociality The 'super sociality' typical of social insects, characterized especially by the existence of a sterile caste of workers who help raise the offspring of the queen.

Evolutionarily stable strategy (ESS) A pattern of behavior ('strategy') is 'evolutionarily stable' when it is the dominant one in the population and will prevail against any invading alternative behavior pattern. Natural selection tends to produce such evolutionarily stable patterns. ESS was coined by Maynard Smith and Price (1973) inspired by Hamilton's 'unbeatable strategy' (1967).

Fitness In biology, 'fitness' refers to the number of offspring produced by an organism, not other types of fitness. Hamilton invented 'inclusive fitness' to take into account also the effects of relatives on each other's reproduction (fitness). His inclusive fitness theory was extended even to formally unrelated individuals, which possessed 'superkinship' traits that enabled individuals with altruistic genes to find each other.

Game theory Game-theoretical reasoning involves considering taking into account what other individuals ('players') in a particular situation ('game') are doing when one considers what behavior ('strategy') to adopt in order to reach the most advantageous outcome for oneself.

Gene's eye view It is useful in Neo-Darwinian reasoning to adopt a 'gene's eye' perspective, since what ultimately counts is not the survival of the individual organism itself but rather the survival of copies of its genes. By adopting this kind of perspective one can easily understand the 'strategy' of a gene (see game theory).

Genetic relatedness The likelihood that two individuals possess copies of the same gene inherited by a common ancestor. The probability of sharing genes is 1/2 for parents and offspring or for full siblings, and 1/8 for first cousins. The principle is to go through the whole chain of related individuals and multiply all the probabilities of sharing genes for the involved individuals. So for two first cousins, starting with one cousin, it is 1/2 for his or her relationhip to his/her parent, times 1/2 for this parent's relationship to his/her sibling, times 1/2 for this siblings' relationship to his/her own offspring (i.e., the other first cousin), this makes the relatedness $1/2 \times 1/2 \times 1/2 = 1/8$.

Genome All the genes of an organism.

Group selection A process of natural selection among groups rather than individuals. An early assumption was that individuals sacrificed themselves 'for the good of the group.' Wynne-Edwards formulated a possible mechanism in 1962. Biologists however, declared group selection a possible but very unlikely phenomenon. The new paradigm of kin selection was accepted as an alternative. Following Maynard Smith and George Williams, many now saw kin selection as an alternative to group selection. However, Hamilton himself (1975) regarded these as alternative ways to describe the same phenomenon.

Haplodiploidy Almost all social and nonsocial Hymenoptera (bees, wasps, ants, etc.) are haplodiploid. The males are haploid, they have only one set of chromosomes from their mother, because they stem from unfertilized eggs. The females are diploid, they have two sets of chromosomes, one each from father and mother, since they stem from fertilized eggs. Haploid males pass on all their genes to their daughters, causing them to be more related to each other than to their own (hypothetical) daughters.

Hamilton's Rule Explains how natural selection can favor altruism between genetic relatives: this can happen if the reduction in fitness (number of offspring) of the donor (cost = c) is more than made up for by the increased fitness (number of offspring) of the recipient (benefit = b). An important consideration therefore is the coefficient of genetic relatedness between donor and recipient (r). One formulation of the rule is $br - c > 0$.

Inclusive fitness This concept, developed by Hamilton in 1964 and again in 1975 (based on the Price Equation), takes into account the fact that related animals affect one another's fitnesses. It explains among other things how it is possible for natural selection to favor altruism. This can happen if the benefits of altruism can be made to fall on individuals who are likely to be altruist rather than random members of the population. A typical case involves relatives but Hamilton intended 'inclusive fitness' to be a broader concept than both 'kin selection' and 'group selection.' It can even involve unrelated individuals. Technically, inclusive fitness of an organism is typically measured as its own fitness plus the effect of its behavior on its relatives' reproduction minus its relatives' effect on its own reproduction, multiplied by its genetic relatedness to each related organism. In practice, the shorthand Hamilton's Rule is used.

Kin selection A process of selection in which individuals are postulated to behave altruistically toward relatives with

 doi:10.1016/B978-0-12-800049-6.00018-4

whom they (probabilistically) have genes in common. Kin selection (a term launched by Maynard Smith in 1964) explains how natural selection works under the assumption of 'inclusive fitness' (Hamilton, 1964) rather than the fitness of an individual organism. Kin selection has often been contrasted with group selection but Hamilton's (1975) reformulation of inclusive fitness presented kin selection and group selection as alternative ways of expressing the evolution of altruism by natural selection.

Pleiotropy The term for one gene influencing many traits at the same time.

Population genetics Population genetics expresses evolution mathematically as a change in gene frequencies in a population. Selection, for instance, is expressed population-genetically as the increase of one genotype at a greater rate than another in the population (Other processes for altering gene frequencies may also be mathematically formulated, such as mutation pressure, meiotic drive, genetic drift, and gene flow). Population genetics typically assumes free competition and recombination, that is, no linkages or interaction between genes. The opponents of sociobiology have typically criticized the lack of realism of these assumptions.

Reciprocal altruism/reciprocity Trivers in 1971 coined this term to refer to the repaying of altruistic acts among unrelated individuals, or at least the promise of repayment in the future. Hamilton wanted him to call this 'reciprocity' instead, since for him altruistic behavior necessarily had a self-sacrificial aspect, having suicide as the imagined outcome when taken to the extreme.

Sociobiology Wilson defined sociobiology in 1975 as "the scientific study of the biological basis of social behavior in all kinds of organisms including man." However, the actual research paradigm in sociobiology applies a few core theories and methods, such as reasoning based on inclusive fitness (or kin selection), reciprocity, game theory, and a gene's eye view. Many biologists prefer the name behavioral ecology or functional ethology. Human sociobiologists often call themselves Darwinian anthropologists or evolutionary psychologists.

The Modern Synthesis After the reconciliation between Darwinism and Mendelism in the early decades of the twentieth century many branches of evolutionary biology were reformulated in the language of population genetics, which expresses evolution mathematically as a change in gene frequencies in a population.

The Emergence of Sociobiology

The Rise of Neo-Darwinism

The development of sociobiology in the second part of the twentieth century was a natural outgrowth of the program of the Modern or Neo-Darwinian Synthesis, taking place between 1920 and 1950. The aim of that evolutionary synthesis was to integrate different areas of biology within a common framework using the language of mathematical population genetics, which formulated evolutionary processes as changes of gene frequencies in a population. The scientists responsible for this important basic translation were Ronald A. Fisher and J.B.S. Haldane in the United Kingdom and Sewall Wright in the United States. Later, in a continuing international effort, Ernst Mayr, Theodosius Dobzhansky, and others worked on integrating a number of biological fields. Julian Huxley (1942) brought the message to the general public with his popularly written *Evolution: The Modern Synthesis*.

The Theoretical Pioneers

The emergence of sociobiology as a research field was a continuation of these earlier efforts. Social behavior, too, was now seen as evolving, just like morphological traits, lending itself to quantitative treatment and hypothesis testing. The insight revolutionizing the field was W.D. (Bill) Hamilton's concept of inclusive fitness (also called 'kin selection') and his models for the four basic types of social behavior (altruism, selfishness, cooperation, and spite) (Hamilton, 1964). Other early core contributions were Robert Trivers's Hamilton-inspired theories of reciprocal altruism (1971), parental investment (1972), and parent–offspring conflict (1974); John Maynard Smith's and George Price's concept of Evolutionarily Stable Strategy (1973); and George Williams' (1966) influential *Adaptation and Natural Selection*.

A novel game-theoretical approach united these theoretical insights. Genes could be seen as strategists 'causing' their carriers to behave in 'selfish' ways, that is, ways that promoted their transmission to the next generation. 'Selfish' genes could 'cause' their carriers to behave altruistically, including sacrificing their lives. Hamilton used this imagery occasionally in early publications; Richard Dawkins took it to new pedagogical heights in *The Selfish Gene* (1976). In contrast, E.O. Wilson (1975) in *Sociobiology: The New Synthesis*, did not use game-theoretical imagery, but instead population genetic reasoning explained in popular form.

Spreading the New Ideas and Establishing the Field

The new ideas were brought to a larger public in the mid-1970s in textbooks (e.g., Alcock, 1975; Brown, 1975) and review articles (e.g., Alexander, 1974). The books that stole the show, however, were Wilson's *Sociobiology* and Dawkins' *The Selfish Gene*. They were written independently and were quite different, but together helped establish the field of sociobiology. Wilson demonstrated that a rich field of social behavior existed and gave it a name, while Dawkins explained how to think about it in Neo-Darwinian terms. And both were later attacked in the sociobiology controversy (see below).

The Name 'Sociobiology'

Before Wilson's book, the term 'sociobiology' itself had already been in use in a division of the Animal Behavior Society led by John Paul Scott and others. Sociobiology is

rooted in ethology, the study of animal behavior in natural environments. Unlike ethology, however, it only asks questions about the function or adaptive value of a behavior. Sociobiology often goes under the name behavioral ecology. Human sociobiologists typically call themselves Darwinian anthropologists or evolutionary psychologists.

Sociobiological Key Concepts

Inclusive Fitness

Inclusive fitness is the key concept in sociobiology, introduced by Hamilton in his path breaking 1964 paper 'The genetical evolution of social behaviour' when he was still a graduate student. The idea of inclusive fitness was able to explain the long-standing mystery how it is possible for altruistic behavior to evolve. Hamilton showed that altruistic behavior toward another individual can in fact be favored by natural selection as soon as the benefit of an altruistic act falls on someone that is likely to share the individual's genes, rather than on random members of the population.

Hamilton intended inclusive fitness to be an universal theoretical principle, applying to all forms of life (he often had plants in mind). Its definition is rather complicated. Assuming we are dealing with relatives (note: it may also apply to other individuals, see his 1964 paper), it is thought about as the organism's own individual fitness, plus the effect of its behavior has on the fitness (reproduction) of its relatives, minus the effect that its relatives have on its fitness, multiplied by the organism's genetic relatedness to each of these relatives (see e.g., Dawkins, 1982, Chapter 10; Grafen, 1984). Researchers, however, use the handy and powerful shorthand, 'Hamilton's Rule' (Hamilton, 1963).

Hamilton's Rule

Hamilton's rule is a simple cost-benefit calculation which can be formulated in many different ways. Basically it says that altruism can evolve if the reduction in fitness of the altruistic donor (the cost c) is more than made up for by the increased fitness for the beneficiary (the benefit b), taking into account their relatedness (r). So br needs to be bigger than c, or $br - c > 0$.

If we are dealing with relatives, the proportion of genes which two relatives are likely to share on average (their 'coefficients of relatedness') can be readily calculated for various relationships; it is 1/2 for parent–offspring and for two siblings, 1/8 for first cousins, and 1/32 for second cousins. Note that relatedness is only one consideration. In principle b and c can include any imaginable factors affecting the situation (typically ecological conditions). This makes Hamilton's Rule very generally applicable.

The Hymenoptera Case and the Haplodiploidy Hypothesis

Hamilton was able to dramatically apply the inclusive fitness concept to solve a long-standing problem in biology, that of sterility in Hymenoptera (social insects such as ants, bees, and wasps). How can it make sense for female workers to help raise their sister's offspring instead of their own? The answer has to do with the unusual genetic relationships (called haplodiploidy) in the Hymenoptera, which make the worker sisters more closely related to their sisters (including the queen) than to their own (hypothetical) daughters. Therefore, helping the queen is in the workers' genetic self-interest. The social insects became an important illustrative example in Hamilton's (1964) paper. He also briefly speculated about a possible relationship between a species' haplodiploid nature and its general ability to evolve eusociality, but later backed away from this idea in the face of empirical counterevidence. Although it was intended just as an example, many somehow got the false impression that inclusive fitness had to do particularly with the social insects. (For the evolution of Hamilton's own views, see Segerstrale, 2013, Chapter 11).

Kin Selection

Inclusive fitness is often understood in practice as the workings of 'kin selection,' natural selection acting on the family or kin group rather than the individual. This term was introduced by John Maynard Smith (1964). But, as Hamilton had noted already in 1964, kinship was only one way of getting the benefits of altruism to fall on individuals likely to be altruist. Moreover, Hamilton never intended kin selection to be an alternative to group selection (as Maynard Smith presented it). Later, however, these terms were used interchangeably. (For a discussion of the troubled relationship between Maynard Smith and Hamilton, see Segerstrale, 2000, 2013).

Kin Selection Explanation as Opposed to Group Selection Explanation

Group selection refers to a process of natural selection among groups rather than individuals. It was often implied in expressions such as 'the good of the species.'

In 1962, the Scottish zoologist Vero Wynne-Edwards (1962) proposed that the gatherings and displays of the Scottish grouse might be a way for the birds to self-regulate their breeding not to outrun their food resources. He postulated (with Darwin) that groups with cooperative individuals would fare better than groups with selfish ones, which would lead to the evolution of behavior that was 'good for the group.' Group extinction was seen as driving evolution. His book stimulated a strong critical response. Even if altruistic traits made a group more fit and this group would have an advantage over other groups, how would altruism initially be able to arise and establish itself in a group of largely selfish group members? Leading biologists declared group selection possible, but unlikely in nature (e.g., Maynard Smith and Williams). Kin selection was soon held up as the alternative. Still, some evolutionists maintained that group selection was a real phenomenon, among them E.O. Wilson.

Kin Selection and Group Selection Explanations as Equivalent

Hamilton, an adherent of individual selection, followed Fisher's population genetics tradition of treating individuals as assemblies of genes. This gave him a dual perspective that

enabled him to understand processes from both an individual selectionist and a 'gene's eye' point of view (see below). As for group selection, Hamilton declared himself 'allergic' to it, both for its seeming woolliness and its perceived association with totalitarianism (Hamilton, 1996). In the 1970s, however, he rederived his inclusive fitness formula as a hierarchical model of multilevel selection with group selection as one level (Hamilton, 1970, 1975). The helpful Price Equation, which makes it possible to assess the total distribution of genetic variance inside and outside groups in a population (Frank, 1995a), allowed him to again derive his original inclusive fitness formula, this time from group selectionist premises (see e.g., Segerstrale, 2013, Chapter 10).

This was also Hamilton's chance to finally clarify the group selection–kin selection relationship. The criterion for spreading of altruism was not relatedness (kinship) per se, but rather 'assortation' of individuals likely to carry the altruistic gene. That could happen in different ways:

> [I]n the assortative-settling model it obviously makes no difference if altruists settle with altruists because they are related (perhaps never having parted from them) or because they recognize fellow altruists as such, or settle together because of some pleiotropic effect on the gene on habitat preference. (Hamilton, 1975, p. 337)

Therefore, he reasoned,

> [i]f we insist that group selection is different than kin selection the term should be restricted to situations of assortation definitely not involving kin. But it seems on the whole preferable to retain a more flexible use of terms; to use group selection where groups are clearly in evidence and to qualify with mention of 'kin' (as in the kin-group selection referred to by Brown), 'relatedness' or 'low migration' (which is often the cause of relatedness in groups), or else 'assortation,' as appropriate. (Hamilton, 1975, p. 337)

This insight, however, hidden away in a book on biosocial anthropology, did not get much noticed. (Dawkins, 1976, however, discussed Hamilton's idea of altruists recognizing each other because of a shared superkinship trait as a 'greenbeard effect').

Reciprocal Altruism (or Reciprocity)

Reciprocal altruism (according to Trivers) is altruism that occurs between unrelated individuals when there will be repayment (or at least the promise of repayment) of the altruistic act in the future (Trivers, 1971). (Hamilton objected to this use of altruism, and suggested 'reciprocity' instead). An example is mutual grooming among many birds and mammals. Mutual assistance between members of different species is called mutualism or symbiosis (e.g., cleaner fish clean the mouths of larger fish, which in turn refrain from eating them).

For reciprocity to work, individuals would need to be able to recognize each other at a future time, and many animals seem capable of that. A problem is cheating, that is, taking advantage of a benefit offered but then not paying back. Trivers (1971) suggested that many of the human psychological characteristics have evolved for us to be able to cheat, to detect cheaters, and to avoid being detected if cheating. Cheater detection is one of the leading concepts of the field of evolutionary psychology.

Selfish Gene Theory

Taking a 'gene's eye' view means seeing the gene as a strategist promoting its own survival and propagation. The ostensibly altruistic behavior of an individual can be seen as actually serving the interest of its selfish genes. The gene's eye view was introduced by Hamilton's (1963, 1964) papers as a pedagogical device, and further developed by Dawkins in *The Selfish Gene* (1976). Dawkins later made an important distinction between 'replicators' and 'vehicles' (Dawkins, 1978). A gene was a replicator; organisms and groups, however, were vehicles, not replicators.

Behavioral Strategies and Game Theory

The gene's eye view can be used for thinking about behavioral 'strategies' adopted by interacting animals. Mating strategies is an example. Depending on the 'investment' its carrier has in its offspring, a gene will 'cause' its vehicle (male or female) to adopt a particular strategy. According to Trivers (1972), because a male typically invests little beyond the act of mating itself, while the female invests a lot, for a male, it is typically advantageous to mate with as many females as possible, while for a female it pays to be choosy. (For an alternative perspective see Hrdy, 1981.)

Reasoning in sociobiology is typically of a game-theoretical nature – an individual's best choice of behavioral strategy often has to do with what others do. An important concept is evolutionarily stable strategy, or ESS, a behavior pattern which, when dominant in a population, will prevail against any invading 'mutant' strategies. Natural selection tends to produce populations of organisms that are evolutionarily stable in this sense, for example, contain a stable ratio of 'hawk' and 'dove' genes (corresponding to two different patterns of behavior). The idea of ESS was developed by Maynard Smith and Price (1973) inspired by Hamilton's 'unbeatable strategy' (1967).

Game theory can be employed to explain a great variety of phenomena. Trivers (1974) used game theory to develop his theory of parent–offspring conflict (where both parties wish to increase their inclusive fitness). Game theory has been used to explain why sex ratios are typically 50:50 (Hamilton, 1967), and to model intragenomic conflicts of various kinds, for instance 'genomic imprinting,' whereby a gene is differently expressed depending on whether it stems from the father or the mother (Hamilton, 1967; Burt and Trivers, 2006). The existence of apparently stable genomes despite possible conflicts, suggests evolutionarily stable strategies (ESS) also at the level of the genome (Haig, 2002).

Also the evolution of cooperation between unrelated individuals (including bacteria) can be explained with the help of game theory (Axelrod and Hamilton, 1981). A famous early winning strategy was known as 'Tit for Tat'; many other strategies have been developed (see e.g., Axelrod, 1984; Nowak, 2006).

The Sociobiology Debate

The last quarter of the twentieth century featured the fierce sociobiology controversy around E.O. Wilson's book *Sociobiology: The New Synthesis* (Wilson, 1975), particularly the book's last chapter, where Wilson suggested that a number of human behaviors, too, including sex roles, aggression, altruism, and even moral and religious beliefs could well have a biological basis. Although he backed his tentative views with primate studies and behavioral genetics research, for a radical group of critics he represented a dangerous biological determinist view of humans. Wilson's own protests were of no avail. After the initial upheaval (including polemics, demonstrations, and Wilson famously getting ice-water poured into his neck at the 1978 AAAS sociobiology symposium in Washington, DC), the critical focus shifted to an attack on 'the adaptationist program' seen as underlying sociobiology. Sociobiologists in general were accused of believing that everything was perfectly adapted in the best of all possible worlds while ignoring other evolutionary forces (e.g., Gould and Lewontin, 1979).

The critics' scientific objection to what they called 'adaptationism' appeared to be based on a moral/political concern. If everything is optimally adapted, there is no point in changing society. But if instead of adaptation the emphasis is placed on such things as discontinuity, contingency, and chance, in a radically new environment new types of individuals will flourish. Everybody gets his chance. In other words, it is not a question of the survival of the fittest (see Gould and Lewontin, 1979). (For a history and analysis of the sociobiology controversy, see Segerstrale, 2000a).

As Wilson later moved on to address environmentalist concerns, the new protagonists became Dawkins and Gould. While Dawkins in *The Blind Watchmaker* (Dawkins, 1987) and other books showed how adaptation over time could give rise to complex design, Gould (especially in *Wonderful Life*; Gould, 1989) emphasized the role of chance and contingency instead. Dawkins' logical explanations of evolutionary mechanisms were treated as erroneous statements about the real world by Gould. This went on for years, producing numerous books.

The sociobiology debate can also be regarded as the next round in an ongoing conflict about the Modern Synthesis and the true meaning of Neo-Darwinism, which started already with the original architects. It was a continuation of the protest against 'beanbag genetics' (Ernst Mayr's term for the British approach) and an attempt to reopen the debate about the relationship between micro- and macro-evolution (Mayr, 1959; Segerstrale, 2000a).

Many have seen the sociobiology controversy as a conflict between the political left and right. But it was rather a conflict between a particular brand of academic activists who believed that dangerous-seeming ideas should be weeded out of science and traditional scientists who believed in the freedom of research and the democratic process (Segerstrale, 2000a).

Bringing in Culture and the Mind

Sociobiology and Anthropology

Some anthropologists had already earlier been thinking along lines similar to Wilson. In 1973, Robin Fox convened an early conference on 'biosocial anthropology' in Oxford, to which he invited Bill Hamilton (Fox, 1975). Together with Lionel Tiger, Fox had produced a number of popular books in a broad biosocial spirit, for example, *The Imperial Animal* (Tiger and Fox, 1971). Wilson acknowledged being influenced by their idea of an innate universal 'biogrammar' (in turn inspired by Chomsky). Later Chagnon and Irons (1979) edited the important *Human Social Behavior: An Anthropological Perspective*. At the University of Michigan and elsewhere Darwinian anthropologists' meanwhile applied kin selection and other theories directly to such things as marriage arrangements, patterns of inheritance, child abuse, and other phenomena (see e.g., Betzig, 1997; Daly and Wilson, 1988).

The Move Toward Coevolution

In the early 1980s Wilson, having been constantly criticized for ignoring human culture, decided to bring it in, his way. In *Genes, Mind, and Culture* (1981) produced with Charles Lumsden, a young theoretical physicist, Wilson demonstrated with the help of mathematical models and empirical evidence, how the human mind, influenced by genes, was in fact geared toward choosing survival-promoting cultural elements. Postulated innate biases, 'epigenetic rules,' guided the development of mind and connected genes with culture by affecting individuals' choices of 'culturgens': behaviors and artifacts seen as isolated units that individuals could either choose or reject (Lumsden and Wilson, 1981).

Wilson saw *Genes, Mind, and Culture* as a new version of sociobiology. Still, the book's particular type of coevolutionary process was clearly aimed at 'keeping culture on a leash.' Many social scientists disagreed with the depiction of culture as a 'sum of mental constructs and behaviors' (e.g., Leach, 1981). Others questioned the mathematics (e.g., Maynard Smith and Warren, 1982). Later, in *Consilience* Wilson (1998) presented a fuller picture of his reasoning, with special focus on the epigenetic rules.

Other coevolutionary modelers allowed culture more independence. It was not necessary to presume genetic predispositions for all adaptive behaviors, argued anthropologist William Durham (1978, 1991). Humans might be maximizing their inclusive fitness for both cultural and biological reasons. Sometimes a type of cultural selection could even replace natural selection. For example, people might maintain a behavior which was no longer biologically adaptive because of its continuing cultural association with high status. Boyd and Richerson (1985) worked with 'dual inheritance' models, which considered biological and cultural evolution at the same time.

The Emergence of Evolutionary Psychology

In the 1980s, Wilson moved away from sociobiology, focusing on environmental activism (Wilson, 1992). This opened an opportunity for the emerging field of evolutionary psychology, energetically promoted by Harvard-trained anthropologist John Tooby and psychologist Leda Cosmides. To many, evolutionary psychology may have seemed as an alternative paradigm to sociobiology. It was not dealing with genes but instead with universal features of the human mind, formed

once and for all in the ancestral Environment of Evolutionary Adaptation. The mind was compared to a Swiss army knife, composed of a set of modules for solving typical problems (shelter, food, mate finding, etc.). Culture was seen as based on a combination and extension of these modules. The 'bible' of evolutionary psychology is *The Adapted Mind* (Barkow *et al.*, 1992). A critical book is Buller (2006). Wilson persistently regarded evolutionary psychology as the same as human sociobiology.

A Change of Climate

In the 'pro-culturist' academic climate of the 1970s and 80s, the sociobiologists could not effectively rebut their critics' political interpretations of sociobiology. Already by the end of the 1980s, however, a social climate change was underway. By 2000 the post-war taboo on biological explanation of human behavior had been broken. With the development of biotechnology and especially the Human Genome Project, genetics was becoming practically a household word.

Instead of emphasizing cultural differences, new studies now documented the existence of human cultural universals (Brown, 1991). New research on language and culture presented animals as more similar to humans, and 'nicer' than earlier depicted (e.g., DeWaal, 1996). Nonverbal communication was reemphasized as a fundamental link between nature and nurture in both animals and humans (e.g., Segerstrale and Molnar, 1997). Finally, and ironically, a new 'cultural left' in academia showed little interest in traditional left-wing concerns such as science and ideology, or 'good' and 'bad' science, being instead preoccupied with postmodern concerns (Segerstrale, 2000b).

Later Developments

Group Selection, an Update

It is important to make a distinction between the 'old' and the 'new' group selection in sociobiology. The 'old' group selection refers to Wynne-Edwards 1960's model of evolution of group-beneficial traits. Wynne-Edwards was strongly criticized and for many kin selections was seen as 'the solution.' A 'new' type of group selection, also called trait group or intrademic selection, was championed especially by David Sloan Wilson in the mid-1970s. This form of selection recognizes a multilevel approach. What is central here are not group level traits but instead the traits of the individual members in the groups. However, in their later book espousing this perspective Sober and Wilson (1998) were criticized for confusing old and new group selection (e.g., Trivers, 1998; Maynard Smith, 1998).

Since group selection or multilevel selection models partition selection into within-group and between-group selection, the general opinion continues to be that group selection models can be readily translated to kin selection models (Hamilton, 1975; Frank, 1998; Lehmann and Keller, 2006). It is also argued that most (all?) examples that purportedly demonstrate the role of group selection – such as the cooperation between cells in a multicellular organism – can equally well be explained by kin selection (e.g., Queller, 2000). Some argue, however, that there are cases of 'pure' group selection. Researchers typically regard it as a matter of choice which approach to use. Working from kin selection is usually more convenient.

Cooperation – A Broader Umbrella for Prosocial Behavior

Hamilton (1964) identified cooperative behavior as behavior that is beneficial to both actor and recipient. However, cooperation can be defined in a number of ways. Some scientists use cooperation in a broader sense to refer to behaviors that are in the first place beneficial for the recipient and additionally either beneficial or costly for the actor. Also, both direct and indirect fitness benefits may be present, for example, in cases of cooperative breeding. (For a broad cross-disciplinary overview of cooperation research, see Hammerstein, 2003.)

When it comes to cooperation between unrelated individuals, reciprocal altruism, or better, 'reciprocity,' is only one of many ways in which this can take place (for other examples, see Clutton-Brock, 2009; Frank, 1995b; Lehmann and Keller, 2006; West *et al.*, 2007a). Interesting new experimental research on cooperation is being conducted with microbes (West *et al.*, 2006; Strassmann and Queller, 2011).

Later theorizing was concerned with the conditions under which the principle of reciprocity could be sustained and free riders and cheaters avoided. A distinction was made between *direct* and *indirect* reciprocity, where indirect reciprocity had to do with reputation (Alexander, 1987; Nowak and Sigmund, 2005). An individual with a reputation for helping is more likely to be helped by members of the same community. *Strong* reciprocity, again, involves not only reciprocation but also punishing 'defectors' or 'cheaters' who do not reciprocate (Bowles and Gintis, 2004). (This can even be taken to a higher level by punishing those who do not punish those who do not reciprocate).

The Role of Culture in Gene–Culture Coevolution

Some researchers give culture a larger role than before as a factor in human evolution. The 'group extinction' required by group selection theory can in fact happen in a number of ways – not necessarily by killing off the defeated group (as believed e.g., by Bowles, 2008; Wilson, 2012). According to Boyd and Richerson (2009), members of the defeated group may get absorbed by the winner and learn their culture by resocialization. They suggest that the human propensity for cooperation may well have arisen through gene-culture coevolution with *culture* as the driver. Culture can speed up evolution by quickly creating a new environment for adaptation and thus put pressure on the genes. The generation of cultural variation does not require inter-group competition or group extinction (Boyd and Richerson, 2005, 2009). Alternatively, a selection pressure for 'cooperative' genotypes may have been created by cultural rules alone (Bell *et al.*, 2009).

The Test of Sociobiology

The Flourishing of Sociobiology

In the first decade of the twenty-first century, the sociobiological paradigm was going strong.

It had been giving rise to burgeoning scientific industries around Hamilton's Rule and kin selection, ESS, and evolutionary game theory (and also different models of parasite-host coevolution, Hamilton's later interest). As new concepts proliferated, serious attempts were made to clarify and streamline the new terminology (for instance in regard to different types of reciprocity and other types of cooperative behaviors) and consistency in the semantics regarding altruism and cooperation as well as group selection (e.g., West *et al.*, 2007b, 2008). There seemed to be no empirical finding that the robust inclusive fitness paradigm could not handle: it could explain conflicts in the life of social insects, the workings of 'green-beard' genes, the social life of microbes, and even behaviors that were thought not to exist, such as spite (Ratnieks *et al.*, 2006; Strassmann and Queller, 2011; Foster *et al.*, 2001; West and Gardner, 2010).

Kin Selection – Attack and Defense

After the deaths of three founders of the sociobiological paradigm in the early 2000s (Hamilton in 2000, Maynard Smith in 2004, and Williams in 2010) an unusual challenge appeared. In an article in *Nature*, Edward O. Wilson, together with two younger mathematically trained Harvard colleagues, Martin Nowak and Corina Tarnita advocated the abandonment of kin selection, the ruling paradigm for 40 years. According to them inclusive fitness was difficult to calculate and had not generated any empirical results, and the theory of kin selection was not empirically supported. Therefore, the authors urged, the unworkable kin selection paradigm needed to be substituted for group – or rather multilevel selection. Contrary to the theory of kin selection, they argued, genetic relatedness was not needed for cooperation to emerge. Under particular ecological conditions (such as the need for common defense) the cooperation of unrelated insects could give rise to eusociality. What was needed was only the emergence of an allele (alternative form of a gene) for cooperation. They had developed a mathematical model to demonstrate this in Hymenoptera (Nowak *et al.*, 2010). (This was related to Wilson's special interest in the development of eusociality in Hymenoptera, just discussed in *The Superorganism* (Wilson and Hölldobler, 2009).

The surprisingly strongly worded attack in the *Nature* article met with a mass response from the sociobiological community, all in all some 150 signatories of five separate letters to the editor of *Nature* (see e.g., Abbot *et al.*, 2011). Together these (well referenced) letters formulated a clear rebuttal to what seemed as a number of persistent misconceptions (e.g., Wilson, 2005; Foster *et al.*, 2006). Kin and group selection were not opposites, they could be translated mathematically into one another (as Hamilton had already shown, based on Price). The kin selection paradigm had in fact generated an abundance of research. And ecological factors were already incorporated as part of the cost and benefit calculation in Hamilton's Rule. Finally, the letter writers noted, the critics had not demonstrated that relatedness was unimportant – they had just left relatedness out of their model. What was the critics' response? The Harvard trio did not budge (Nowak *et al.*, 2011).

The Mathematical Model – From Contention to Agreement?

In 2015, however, the mathematical model was challenged. After painstaking examination a team of researchers (Liao *et al.*, 2015) concluded that it represented a special case of a more general model; its results were obtained because of particular conditions. When – using the modelers' own assumptions – the result for the full range of conditions was calculated, however, it was shown that the outcome obtained by the Harvard critics was in fact the same as that for a model based on a kin selection approach. In other words, the model was not an alternative to kin selection, after all. Rather, it backed it up (Liao *et al.*, 2015; Nowak and Allen, 2015; Queller *et al.*, 2015).

Meanwhile, the persistent attack on kin selection had stimulated serious reviews by leading sociobiologists. How solid was in fact the kin selection (inclusive fitness) theory? The conclusion was that it was solid, both in regard to its general validity and applicability and its empirical support (for comprehensive reviews, see e.g., Bourke, 2011b, 2014). Seldom has a field gone through so much self-scrutiny, and seldom has it come out looking so good. Here, then, an external challenge not only had an integrative function on the field, it also suggested possible new ways of thinking, This would seem like a desirable situation around the 50th year anniversary of sociobiology.

Glossary

Breakpoints Genomic regions delimiting chromosomal rearrangements.
Collinear regions Chromosomal regions with the same gene order (i.e., without rearrangements).
Dobzhansky–Muller incompatibilities (DMI) Epistatic interactions between alleles that manifest in hybrids by lowering their fitness.
Epistatic effect Effect of an allele on a trait (or on fitness) that depends on its interactions with alleles at other loci (genetic background).
Heterokaryotype Individual that is heterozygote for a chromosomal rearrangement.
Meiotic drive Distortion in the expected transmission ratio (50:50) of a particular allele or chromosome at meiosis.
Post-zygotic barrier Contribution to reproductive isolation that operates after zygote formation, for example, hybrid sterility, hybrid inviability or ecologically dependent selection against hybrids.
Pre-zygotic barrier Contribution to reproductive isolation that operates before zygote formation, for example, mate preference, habitat preference, temporal isolation, selection against immigrants, or gametic incompatibility.
Reinforcement The evolution or strengthening of a pre-zygotic barrier between two populations as a consequence of natural selection against hybrids.
Underdominance Case where the fitness of the heterozygote is lower than the fitness of either homozygote.

CRs Within and Between Natural Populations

The history of evolutionary genetics is inextricably linked with the classic work on chromosomal rearrangements (CRs) in *Drosophila* by Alfred Sturtevant, Theodosius Dobzhansky and other early-twentieth century pioneers. In the 1910s and 1920s, a series of genetic factors were discovered in *Drosophila* that prevented recombination as heterozygotes, but did not have the same effect as homozygotes (e.g., Sturtevant, 1917, reviewed in Graubard, 1932). Sturtevant (1926) explained this phenomenon by showing that these recombination suppressors were chromosomal inversions segregating within *Drosophila melanogaster* (Sturtevant, 1921; Sturtevant and Plunkett, 1926; Sturtevant, 1926).

Subsequently, population geneticists spent half a century investigating inversion polymorphisms within, and fixed inversion differences between, *Drosophila* species (Dobzhansky, 1970). Originally using the order of markers inferred from linkage maps, as in Sturtevant's pioneering work, the process was greatly facilitated by the ease with which rearrangements can be characterized in Diptera using giant polytene chromosomes from larval salivary glands (Dobzhansky and Sturtevant, 1938; Dobzhansky, 1970). For some beautiful examples of how abnormal pairing in heterokaryotypes allowed the elucidation of inversion polymorphisms in *Drosophila pseudoobscura* see Dobzhansky and Sturtevant (1938) and **Figure 1**. These studies provided early examples of adaptive polymorphism segregating within species, with evidence that the frequency of chromosomal inversions fluctuated cyclically and geographically in line with seasonal, altitudinal, and latitudinal climatic changes (Dobzhansky, 1943; Dobzhansky *et al.*, 1966; Krimbas and Powell, 1992). They also introduced the ideas of supergenes (Dobzhansky and Pavlovsky, 1958; Prakash and Lewontin, 1968) and of position effects, where inversions might be adaptive by changing the relative positions of genes (reviewed in Dobzhansky, 1970).

With the rise of modern genetics techniques, starting with allozymes in the 1960s, CRs were less frequently used as markers to study genetic variation, and this rich literature was largely forgotten (Kirkpatrick, 2010). In the genomic era, however, it seems that the importance of CRs has become apparent once more (Coghlan *et al.*, 2005). Modern sequencing techniques have afforded even greater insight into the prevalence of CRs, by empowering researchers to detect fine-scale structural changes that could not be resolved cytogenetically (Alkan *et al.*, 2011). It now seems clearer than ever that CRs are an important source of genetic variation and are widespread both within and between taxa, although this finding might not have surprised the classical *Drosophila* geneticists mentioned above. Genomic studies have shown that inversions are common and evolve rapidly in *Drosophila*, at a rate of around one new fixed inversion per million years (Ranz *et al.*, 2001). The rate of chromosomal change may be even faster in nematodes, up to four times the rate in *Drosophila* (Coghlan and Wolfe, 2002). The comparison of genome sequences has revealed around 1500 inversion differences

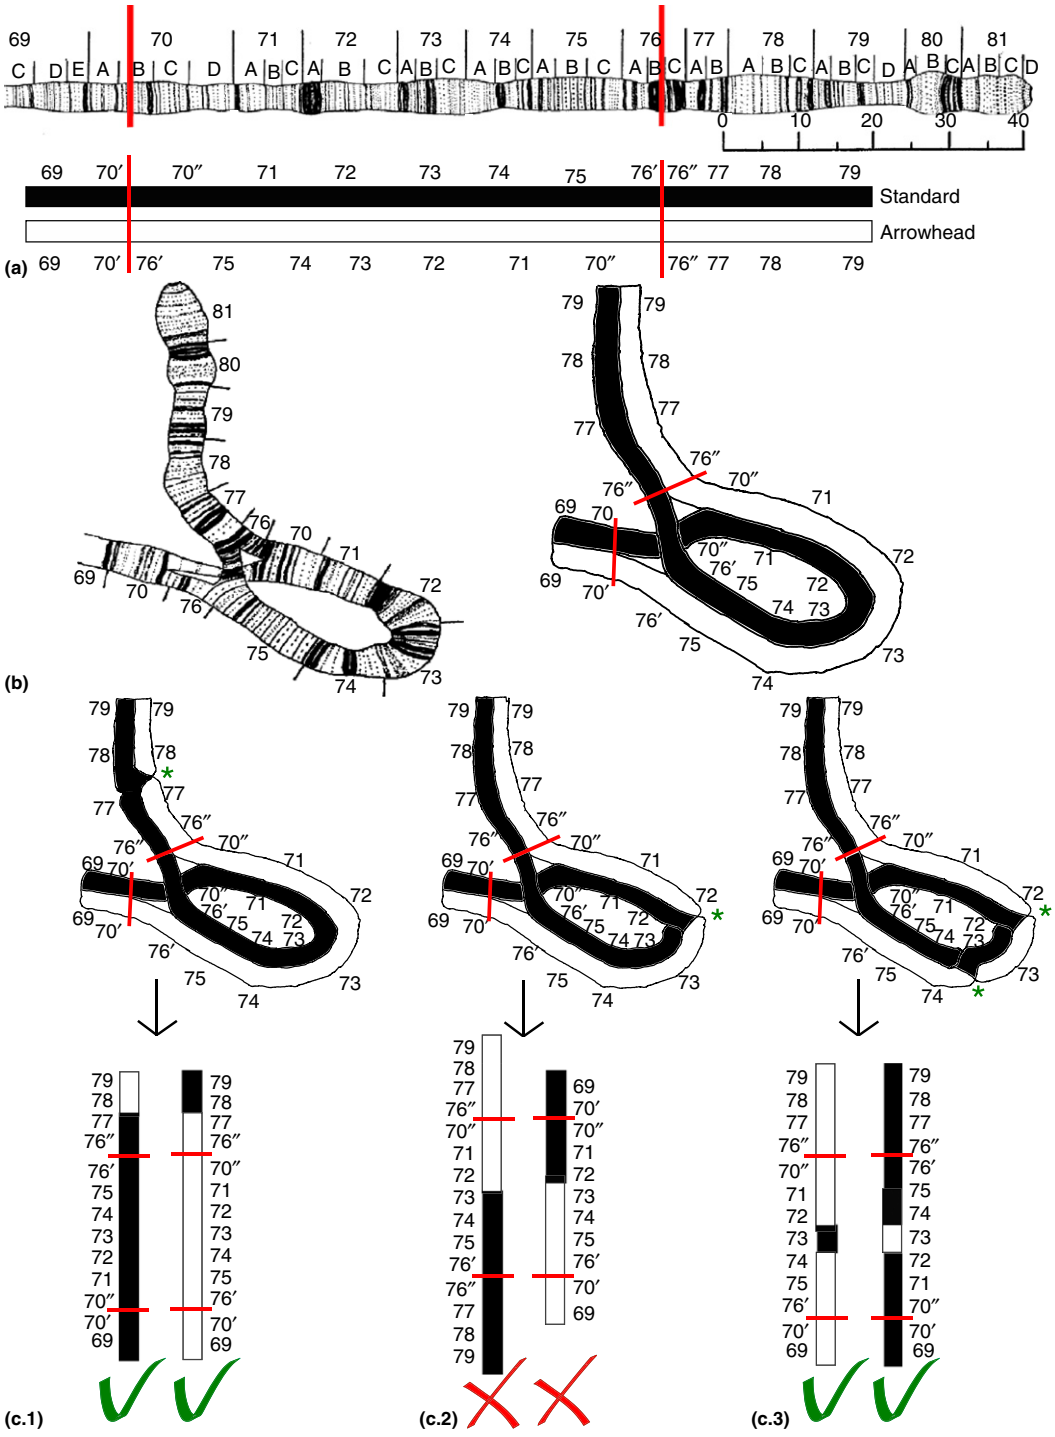

Figure 1 Representation of the pairing between homologous polytene chromosomes differing by a paracentric inversion in *Drosophila pseudoobscura* and possible consequences at meiosis. (a) Partial map of chromosome 3 (standard arrangement) showing several sections (scale in μm) and the location of the breakpoints (in red) of the 'Arrowhead' inversion, adapted from Dobzhansky, T., Sturtevant, A.H., 1938. Inversions in the chromosomes of *Drosophila pseudoobscura*. Genetics 23(1), 28–64 with permission from the Genetics Society of America; and schematic representation of part of the 'Standard' (black) and the 'Arrowhead' (white) chromosomes illustrating the reverse section order within the inversion. (b) Pairing of these homologous chromosomes in heterokaryotypes forming a loop structure (original representation reproduced from Dobzhansky, T., Sturtevant, A.H., 1938. Inversions in the chromosomes of *Drosophila pseudoobscura*. Genetics 23(1), 28–64) (left) and cartoon used in (c) (right). (c) Representation of three possible outcomes at meiosis after crossover(s) (green asterisk): C.1- one crossover in the collinear region resulting in full fertility/viability; C.2- one crossover within the inverted region generating unbalanced gametes (infertility/inviability); and C.3- double crossover (or gene conversion) within the inverted region resulting in viable gametes.

between chimpanzees and humans (Feuk *et al.*, 2005; Kirkpatrick, 2010). Despite many false positives (see also Chaisson *et al.*, 2006), the number of true inversions is much higher than the nine discovered by classical cytogenetics (Yunis and Prakash, 1982). What's more, when investigated further, many of these inversion differences were found to exist as polymorphisms within humans (Feuk *et al.*, 2005). There is also evidence for extensive chromosomal variation within and between plant taxa. Levin (2000) reviewed examples of the prevalence in CRs in the genera *Chaenactis*, *Clarkia*, *Coreopsis*, *Gaura*, *Gilia*, *Helianthus*, and *Lens*, with a focus on their role in reproductive isolation.

The recent access to whole genome sequences not only revealed a larger number of CRs but also a higher diversity of structural variants (including indels, copy-number variation, transposition, centromere repositioning) than previously considered (Rocchi *et al.*, 2012; Rogers and Gibbs, 2014). Here we focus on large-scale rearrangements, fusions/fissions, translocations, and inversions that affect many genes, rather than on small scale or insertion/deletion changes. We do not consider changes in ploidy, which are the focus of another chapter.

The Establishment of CRs in Natural Populations

If CRs are common in nature, how do they become established? Typically, newly arisen CRs show some level of underdominance and therefore should be eliminated from populations (details below, but see Dobzhansky, 1970). Because of this, rearrangements might be more easily established by drift in very small populations (e.g., Walsh, 1982; Lande, 1985; Spirito, 1998). The frequent demographic fluctuations experienced by annual plants together with self-fertilization, may explain why they tend to have a large number of CRs, since both traits reduce effective population size and selfing can generate homozygotes for rare variants, helping to overcome underdominance (Hoffmann and Rieseberg, 2008; Kirkpatrick, 2010).

In species with large effective population sizes, other mechanisms are needed to explain the establishment of underdominant CRs. One possibility is meiotic drive (White, 1978, chap. 6), which may explain the fixation of any type of rearrangement, but particularly those involving Robertsonian fusions/fissions that alter centromere properties and so may cause biased segregation in females (Pardo-Manuel de Villena and Sapienza, 2001a; Pardo-Manuel de Villena and Sapienza, 2001b). Association between CRs and segregation distortion is also expected because suppressed recombination within the region encompassed by the chromosomal rearrangement (**Figure 1**) can benefit a driving system by establishing linkage between drivers and responders (McDermott and Noor, 2010). However, evidence for segregation distortion of rearrangements is mixed (e.g., Gropp and Winking, 1981; Britton-Davidian *et al.*, 1990) and empirical studies of the association between segregation distortion and hybrid sterility have been limited largely to *Drosophila* (McDermott and Noor, 2010).

Other forms of selection may also favor the establishment of CRs. Mayr (1945) first articulated the idea that rearrangements could be adaptive to certain habitats (White, 1978). This might be through direct effects: a rearrangement's breakpoints may cause alterations in the open reading frames of genes or changes in gene expression due to promoter disruption or alteration of the relative positions of genes and regulatory regions (reviewed by Dobzhansky, 1970; Pérez-Ortín *et al.*, 2002; Avelar *et al.*, 2013). Alternatively, Dobzhansky suggested that inversions might hold together 'coadapted complexes of genes' (Dobzhansky, 1950; Wasserman, 1968), which can be interpreted as pairs or groups of loci with epistatic effects on fitness. Charlesworth and Charlesworth (1973) showed that the suppression of recombination by a newly arisen inversion could cause it to spread if it binds together an already-segregating combination of alleles presenting favorable epistatic interactions. A recent model (Kirkpatrick and Barton, 2006) shows how a CR can spread due to geographically divergent selection with gene flow, even in the absence of epistasis and when the CR itself has a small fitness cost. A new CR can become established if it traps advantageous alleles at two or more adaptive loci and if there is gene flow introducing locally maladaptive alleles at those loci. The inversion prevents the formation of suboptimal haplotypes (**Figure 1**), tying the locally adapted alleles together. This model can also explain why some inversions present a clinal distribution across environmental gradients, for example, in mosquitoes of the genus *Anopheles* (Costantini *et al.*, 2009; Ayala *et al.*, 2014) and in *Drosophila* (Krimbas and Powell, 1992; Hoffmann and Rieseberg, 2008).

The Kirkpatrick and Barton process may not be powerful enough to increase the frequency of rearrangements when they first appear as single copy in one heterokaryotypic individual (Feder *et al.*, 2011). Furthermore, the fixation of strongly underdominant CRs implies that several loci involved in adaptation must be captured in the same chromosomal region (Stathos and Fishman, 2014). This may be an unrealistic requirement for many systems. Feder *et al.* (2011) proposed a 'mixed geographic model' that relaxes these conditions: inversions can more easily become fixed during an alternating cycle of geographic isolation and gene flow. In an initial period of allopatry between two locally adapted populations, an inversion slightly increases in frequency due to drift; in a subsequent secondary contact the inversion spreads by the mechanism suggested by Kirkpatrick and Barton's model, because it carries alleles involved in local adaptation, to an equilibrium frequency maintained by selection and migration. In a new phase of allopatry, the inversion may end up being fixed.

Early Models for the Role of CRs in Speciation

The perceived importance of CRs in speciation peaked with the publication of M. J. D. White's book, *Modes of Speciation* (White, 1978) and was still being championed much later than this (King, 1993). Motivated by the frequent observation of chromosomal differences among closely related species and the observation that in some taxa speciation rates are significantly correlated with the rate of chromosomal evolution (Levin and Wilson, 1976; Bush *et al.*, 1977), White concluded that "it appears as if such [chromosomal] rearrangements, of many different types, have played the primary role in the majority of speciation events" (White, 1978, p. 336).

White was a major proponent of a class of 'chromosomal speciation' model whose general mechanism involves negative fitness effects in heterokaryotypes and can be summarized as follows: CRs that differ between populations generate intrinsic post-zygotic barriers to gene flow because heterokaryotes experience mechanical problems with chromosomes (misspairing and nondisjunction) at meiosis and/or their gametes suffer insertions or deletions (i.e., are unbalanced) (**Figure 1**; White, 1978; Davisson and Akeson, 1993). Thus rearrangements are strongly underdominant. White (1978, p. 55) cited the example of *Mus musculus* (house mouse; $2n=40$), which differs from *Mus poschiavinus* (tobacco mouse; $2n=26$) by multiple chromosome fusions: nondisjunction in meiosis occurs at a rate of 6–33%, strongly reducing hybrid fecundity.

Variants of these chromosomal speciation models (also called 'hybrid-dysfunction' models (Ayala and Coluzzi, 2005)) which date from between the 1960s and 1980s, are described by Rieseberg (2001). Most of them suffer from the same problem: in order to be strong barriers to gene flow, CRs must be strongly underdominant. But strongly underdominant rearrangements are unlikely to fix in natural populations because when they first arise they do so as heterokaryotypes, which are selected against (Spirito, 1998). An exception is the case where single rearrangements have very small effects on fitness but interactions between different rearrangements can have large effects: a chromosomal equivalent of the standard Dobzhansky–Muller model for intrinsic incompatibility (i.e., Dobzhansky–Muller incompatibilities – DMIs (Orr, 1995)). For example, the common shrew (*Sorex araneus*), exists as multiple chromosome races over its Palearctic range, each race having a different combination of fusions from an ancestral acrocentric karyotype. A single fusion has little effect on hybrid fertility but a pair of fusions can be highly incompatible (such as a *ko* fusion in one race and a *bk* fusion in another, described as 'monobrachial homology') (Searle, 1993). At the center of a hybrid zone between two races, shrews with acrocentric chromosomes 'reappear,' apparently favored by selection against the mismatched metacentric combinations (Searle, 1993).

The difficulty of fixing underdominant rearrangements means that these historic models for the role of CRs in speciation often rely on some sort of geographic isolation during the speciation process (Rieseberg, 2001). There are also problems with their generality. Because crossovers are suppressed within some CRs, no unbalanced gametes are produced at meiosis, which challenges the idea that CRs always reduce fertility (Coyne *et al.*, 1991, 1993). Hybrid inviability is at least as common as hybrid sterility as a barrier to gene flow, but heterozygosity for CRs is expected to cause the latter much more frequently. These and other patterns (Rieseberg, 2001; Coyne and Orr, 2004, pp. 259–260), suggest that genic factors are at least as important as chromosomal factors in generating incompatibilities. These problems ultimately led to hybrid-dysfunction models falling out of favor amongst most speciation biologists.

A New Role for CRs in Speciation

Interest in the role of CRs in speciation was rekindled by the simultaneous publication, in 2001, of works by Rieseberg (2001) and Noor *et al.* (2001). These authors hit upon the idea that the recombination reducing effect of CRs might facilitate speciation without reducing hybrid fitness (**Figure 2**). In fact, recombination-suppression models predate Rieseberg and Noor *et al.*'s work: see, for example, Dobzhansky (1950) who suggested that balanced inversion polymorphisms within populations maintained coadapted gene complexes, whilst heterokaryotypes for inversions derived from different populations were less fit; Coluzzi (1982) who suggested that inversions might maintain favorable (adapted) gene associations in novel ecological conditions; and Trickett and Butlin (1994) who showed that the recombination-suppression properties of CRs increased the likelihood of speciation in some older models (Felsenstein, 1981; Kirkpatrick, 1982). Rieseberg (2001) was inspired by his work in sunflowers (*Helianthus* spp.) from which he suggested that isolation genes within CRs might prevent gene flow across larger regions of the genome than isolation genes alone. Noor *et al.* (2001) were likewise inspired by their own results, in *Drosophila*, and suggested that CRs might delay the fusion of incipient species following secondary contact, by maintaining DMIs that would be lost from collinear regions due to recombination. Although their ideas are not mutually exclusive, Rieseberg (2001) put the emphasis on the role of CRs in accumulating the fitness effects of different isolation loci, due to suppressed recombination, and thus preventing gene flow across a larger fraction of the genome (Ortíz-Barrientos *et al.*, 2002). In contrast, Noor *et al.* (2001) focused on the asymmetric nature of incompatibilities, which would explain why they would be lost in collinear regions but maintained in CRs (Ortíz-Barrientos *et al.*, 2002). Noor *et al.* (2001) noted that, in their model, CRs increase the opportunity for the evolution of further pre-zygotic barriers between hybridizing taxa, i.e., reinforcement, but this is actually a general feature of chromosomal speciation models (**Figure 2**).

Rieseberg and Noor *et al.*'s models were followed by further theoretical developments. Navarro and Barton (2003a) showed that DMIs are more likely to accumulate if CRs reduce recombination. Under a scenario of divergence with gene flow, their simulations showed that CRs can act as barriers by delaying the fixation of universally advantageous alleles, allowing the establishment and accumulation of incompatibilities. Together, these three models reconciled previously distinct 'genic' and 'chromosomal' views of speciation, by showing that both processes can work together in establishing reproductive isolation. Although none of these models addressed the initial requirement for a CR to become established in a natural population in the presence of gene flow, this problem has been solved in a rather general way by the Kirkpatrick and Barton (2006) model described above (and see Kirkpatrick, 2010, for further generalization). Kirkpatrick and Barton's (2006) mechanism begins with local adaptation, resulting in some reproductive isolation. This is enhanced by the spread of the CR. The resulting chromosomal difference between demes may then facilitate speciation by the accumulation of further incompatibilities, further adaptive divergence, or reinforcement.

Taken together, these recombination-suppression models suggest that multiple classes of reproductive barriers, both pre- and post-zygotic, can be associated with CRs if they are involved in speciation and some of the empirical examples we discuss below support this prediction. The chronology of the

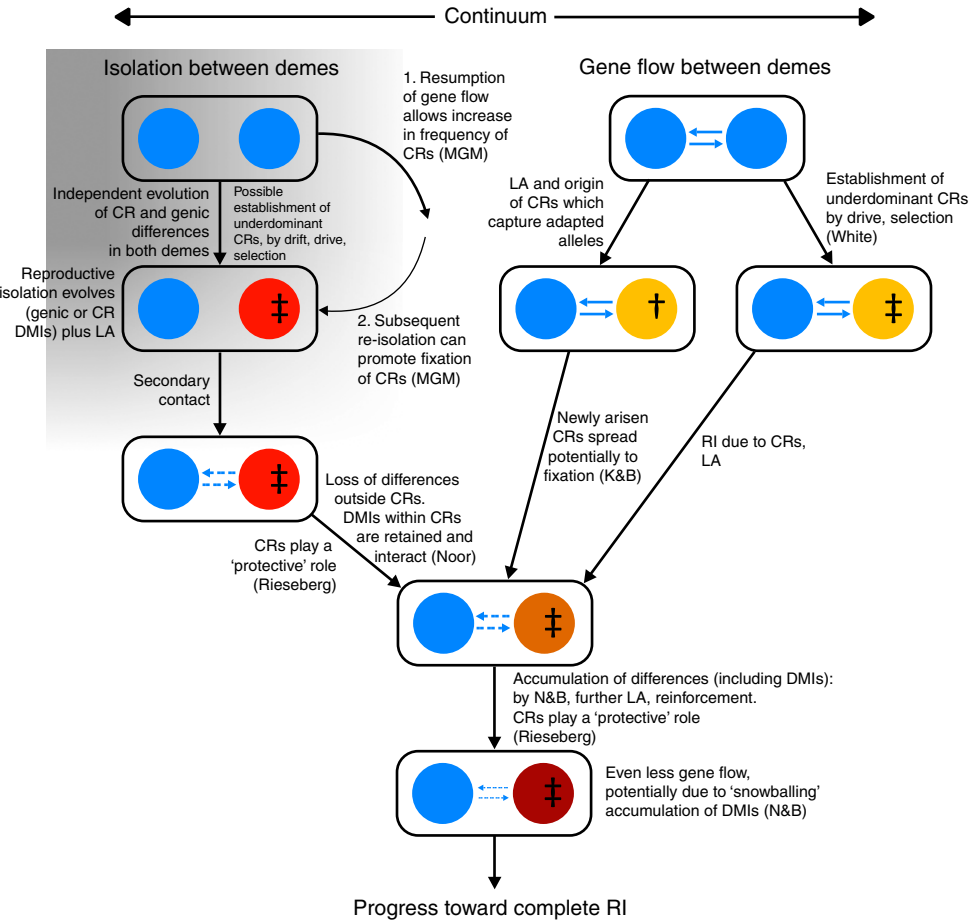

Figure 2 A schematic representation of some different paths toward reproductive isolation (RI) between two demes, invoking different processes that involve chromosomal rearrangements (CRs). We illustrate two starting points: the presence and absence of gene flow (blue arrows) between the demes, representing ends of a continuum. Different deme colors represent the accumulation of (genic or CR) differences from the ancestral (blue) condition: the accumulation of incompatibilities is represented by progress toward darker red in one of the two demes. A double dagger represents the situation where chromosomal rearrangements, including those that are (moderately) underdominant, may fix or have fixed. A single dagger represents the situation where only chromosomal rearrangements with lower direct fitness costs may fix or have fixed. These pathways are illustrative and are a simplification of the real world: other paths are possible in which the various processes occur in different combinations or sequences. Abbreviations and definitions: DMI: Dobzhansky–Muller incompatibility; LA: local adaptation; MGM: mixed geographic model (Feder *et al.*, 2011); K&B: Kirkpatrick and Barton (2006) model; N&B: Navarro and Barton (2003a) model; Noor: Noor *et al.*'s (2001) model; Rieseberg: Rieseberg's (2001) model; White: White's (1978) stasipatric or similar 'hybrid-dysfunction' model.

establishment of different categories of reproductive barrier that different models predict is, however, uncertain. To mention just two examples, one could propose that ecological divergence may contribute to the establishment of CRs (*sensu* Kirkpatrick and Barton, 2006), which in turn, may lead to the accumulation of genetic incompatibilities (*sensu* Navarro and Barton, 2003a) that subsequently promote reinforcement. Alternatively, underdominant rearrangements might themselves contribute to post-zygotic isolation, which paves the way for reinforcement to evolve (Stathos and Fishman, 2014). We present some possibilities in **Figure 2**.

Evidence for the Role of CRs in Speciation

Despite interest in the role of CRs in speciation for nearly a century, their role in reproductive isolation is still unclear. One common finding is an association between karyotypic differences and the opportunity for gene flow between taxa. Such a relationship has been observed at least in *Drosophila* (Noor *et al.*, 2001), butterflies (Kandul *et al.*, 2007), estrildid finches (Hooper and Price, 2015), and mice (Castiglia, 2014). However, this does not distinguish among models and many challenges remain.

The different mechanisms by which CR might contribute to speciation are associated with different geographic scenarios (**Figure 2**). For instance, most hybrid-dysfunction models assume strong underdominance or multiple weakly underdominant rearrangements that accumulate in the absence of gene flow until their combined effect is negative enough to act as a barrier on secondary contact (Rieseberg, 2001). However, there is now convincing evidence that gene flow during speciation is not as rare as previously thought (Pinho and Hey, 2010) and this is the situation in which

suppressed-recombination models are more likely to apply. In fact, the growing interest in understanding how speciation occurs in the face of gene flow may have contributed to a bias in the recent literature on CRs and speciation, which tend to be directed toward testing the predictions of suppressed-recombination models.

Although many closely related species show fixed CR differences (see above), empirical evidence for their role in reducing gene flow between natural populations and in the establishment of reproductive isolation in nature has been collected for only a handful of cases: in *Drosophila* (Noor *et al.*, 2001; Kulathinal *et al.*, 2009) sunflowers (Rieseberg *et al.*, 1999; but see Strasburg *et al.*, 2009), apple maggot flies (Feder *et al.*, 2003; Feder *et al.*, 2005), mosquitoes (Ayala and Coluzzi, 2005; Manoukis *et al.*, 2008; Ayala *et al.*, 2013), mice (Panithanarak *et al.*, 2004; Franchini *et al.*, 2010; Giménez *et al.*, 2013), shrews (Basset *et al.*, 2006; Yannic *et al.*, 2009), and plants of the genus *Mimulus* (Lowry and Willis, 2010; Stathos and Fishman, 2014). In many cases though, we still lack the information needed to form a complete picture of the processes by which CRs have contributed to speciation.

Among the model systems that have contributed the most to our understanding of the role of CRs in speciation, the *D. pseudoobscura* complex is perhaps the best characterized. *Drosophila persimilis* and *D. pseudoobscura* are sister species native to North America that started to diverge around 500 000 years ago and now have overlapping ranges (Noor *et al.*, 2001). They differ by three fixed (or nearly) inversions, two on the X chromosome and another on chromosome 2. Despite showing strong reproductive barriers (pre- and post-zygotic), they still hybridize in nature, although rarely (Noor *et al.*, 2001). Remarkably, all the reproductive barriers identified between these two species map exclusively to a few regions on chromosomes X and 2 in or near the inversions. In comparison, isolation loci identified between allopatric species pairs, such as between *D. persimilis* and *D. pseudoobscura bogotana*, are mostly located in collinear regions (Brown *et al.*, 2004; Chang and Noor, 2007). This suggests that reproductive barriers mapping to collinear regions between *D. persimilis* and *D. pseudoobscura* were eliminated in the face of gene flow, in contrast with those mapping to inversions, which have survived. Consistent with this pattern, divergence between these species is higher within inversions, whereas evidence for introgression is found in collinear regions (Machado *et al.*, 2002; Machado *et al.*, 2007), a trend that is not observed when comparing allopatric populations/species pairs and sympatric pairs where hybridization does not occur, such as between *D. persimilis–D. pseudoobscura* and *Drosophila miranda* (Kulathinal *et al.*, 2009; McGaugh and Noor, 2012).

Higher divergence within CRs compared with collinear regions was also observed between humans and chimpanzees when this prediction was first tested (Navarro and Barton, 2003b). However, this trend was not confirmed by subsequent studies, some based on full genome data (Zhang *et al.*, 2004; Mikkelsen *et al.*, 2005; Marques-Bonet *et al.*, 2007). Contradictory evidence has also been obtained in terms of higher divergence in gene expression patterns within CRs (Karaman *et al.*, 2003; Zhang *et al.*, 2004; Marquès-Bonet *et al.*, 2004). All this contributes to the overall impression of a minor role of chromosomal speciation in primates and, furthermore, it illustrates the complications of using solely divergence measures as evidence for the role of CRs in speciation. The difficulties in the study of speciation in the human lineage are indeed considerable. First, since our species and chimpanzees diverged about 4.5–6 million years ago (Locke *et al.*, 2011), the many other evolutionary processes that occurred since their split (including speciation processes) have shaped the divergence landscape (Ayala and Coluzzi, 2005). Second, the impossibility of mapping studies precludes obtaining the sources of evidence that are so helpful in, for instance, *Drosophila* studies. Finally, inversions could have been segregating before speciation started and thus higher divergence within CRs would not necessarily be associated with speciation (Noor and Bennett, 2009). Thus, despite enormous interest, we are still far from understanding the role that CRs have played in the speciation of humans and chimpanzees, or generally in speciation processes across the primate order. Still, structural variation is known to be high in this taxonomic group (Yunis and Prakash, 1982; Carbone *et al.*, 2014; Rogers and Gibbs, 2014) and is likely to have played a role in primate diversification. Perhaps the best way forward is to focus on recently diverged taxa or those with ongoing gene flow.

A more compelling example of the role of CRs in speciation can be found in the yellow monkeyflower, *Mimulus guttatus*. A perennial ecotype of this species is found in cool, wet coastal conditions, and an annual ecotype is found in inland habitats which experience a summer drought, both in Western North America (Hall and Willis, 2006; Lowry and Willis, 2010). These ecotypes differ in flowering time and morphology, and in other floral, vegetative, and life-history traits (Hall and Willis, 2006). An adaptive shift in flowering time has resulted in temporal pre-zygotic isolation between the two ecotypes. Immigrants are also selected against because of their maladaptive life-history traits (Hall and Willis, 2006). Fascinatingly, Lowry and Willis (2010) found that quantitative trait loci (QTL) for multiple relevant traits map to a chromosomal inversion which is polymorphic within *M. guttatus*, and which is in perfect association with the contrasting life histories of the perennial and annual ecotypes. Crossing experiments demonstrated that the effects of the inversion are independent of the wider genomic background, and reciprocal transplant experiments showed that the inversion contributes to local adaptation, which in turn causes reproductive isolation as described above (Lowry and Willis, 2010). Elsewhere in the genome variation is most strongly related to geography, which suggests that the inversion is maintaining adaptive polymorphism in the face of strong gene flow (Twyford and Friedman, 2015).

Concluding Remarks

Speciation is a process that extends over many generations. During this time, environments and species distributions change, altering population sizes, selection pressures, and opportunities for gene exchange (Abbott *et al.*, 2013). The accumulation of barriers to gene flow is, therefore, likely to occur at an uneven pace, even with existing barriers being lost in some cases, and to be influenced by multiple processes. Where do CRs fit into this picture?

CRs are simply one class of genetic variant. Any new variant with a negative effect on fitness as a heterozygote will be unlikely to spread and so its potential to contribute to isolation between populations fixed for different variants will only be realized under a restrictive set of conditions. These conditions are far more relaxed for variants with small effects in the genetic background on which they arise but with strong epistatic effects when they meet a different background through hybridization, as in the classic Dobzhansky–Muller model (Gavrilets, 2004). In these respects, CRs are no different unless they are particularly likely to fall into the latter class (as with monobrachial homology of chromosomal fusions, perhaps) or have special features, such as meiotic drive. These features are likely to be common only for some rearrangements and in some taxa (as would also be the case for most classes of genetic variants) suggesting that CRs in general do not play a special role in speciation via these routes.

However, CRs are special because of their effects on recombination. These effects vary across classes of rearrangements, with strong reduction in inversion heterokaryotes and new linkage patterns in translocations and fusions. Other classes of genetic variation can also modify recombination (Butlin, 2005; Baudat *et al.*, 2010) but, nevertheless, recombination reduction is a general property of CRs that may impact speciation. Because strong reproductive isolation depends on the build-up and maintenance of associations among traits that contribute barriers to gene flow, suppression of recombination between genes coding for these traits can facilitate speciation (Smadja and Butlin, 2011). The models discussed above show how recombination suppression can make the spread of new CRs more likely (Kirkpatrick and Barton, 2006), how this can result in the more rapid accumulation of both intrinsic and extrinsic reproductive isolation (Rieseberg, 2001; Navarro and Barton, 2003a) and how CRs can protect existing combinations of alleles that contribute to isolation from being disrupted by gene flow (Noor *et al.*, 2001).

Current empirical evidence strongly supports an association between CRs and barriers to gene flow. It would be good to extend the comparative evidence from *Drosophila* (Noor *et al.*, 2001) to more species and other taxa. Case studies show that genic differentiation in the face of gene flow is greater in or near CRs than elsewhere in the genome and that multiple traits associated with barriers to gene flow (intrinsic and extrinsic, pre- and post-zygotic) map to CRs, sometimes exclusively (Noor *et al.*, 2001; Lowry and Willis, 2010). However, it is rare for these studies to go from observing this association to dissecting its origin. We see potential using recently developed approaches to go further in two ways: understanding the relative timing of historical events and identifying loci within CRs that underlie the effect of recombination suppression on reproductive isolation.

Comparative analyses and modeling can address critical questions about the origin of CRs in relation to periods of allopatry and secondary contact, or in relation to the origin of adaptive alleles within CRs. Answers to these questions are critical to distinguishing the contributions of the various possible recombination suppression effects. The example of *D. pseudoobscura* and *D. persimilis* shows how comparisons among geographic regions and with outgroup species can help in unveiling the sequence of events (Kulathinal *et al.*, 2009; McGaugh and Noor, 2012). Recent work on *Drosophila mojavensis* and *Drosophila arizonae* using genome sequence data places the origin of inversions at the time of species divergence as well as demonstrating their impact on subsequent introgression (Lohse *et al.*, 2015). Approaches of this type have great potential for application to other systems.

Finding the genes that matter within CRs has always been a problem. The suppression of recombination usually precludes classical mapping approaches and compromises genome-scan methods. Low levels of double crossovers and gene conversion may actually hold background differentiation within inversions at low enough levels to detect excess divergence at selected loci (Feder and Nosil, 2009; Stevison *et al.*, 2011; Guerrero *et al.*, 2012). More formal models are needed to understand these processes and make predictions for empirical tests. There is also potential to use gene expression, now readily available through deep-sequencing techniques, to identify candidate loci within inversions. This approach has started to produce interesting insights into candidate loci for adaptation in large-scale inversion clines (e.g., Zhao *et al.*, 2015) but, to our knowledge, it has yet to be applied to the role of CRs in reproductive isolation. If candidates can be identified then, at least in principle, their effects on phenotypes and on reproductive isolation can be tested using RNA interference (Mohr *et al.*, 2014) or genome editing (Harrison *et al.*, 2014) methods while coalescent approaches can be used to test the ages of selective sweeps. In these ways, it may finally be possible to say which loci diverged before and which after the origin of the rearrangements, through which traits they contribute to fitness and to barriers to gene flow and whether their effects on fitness are independent or epistatic. We will then have a full picture of the role of CRs in speciation.

Speciation Continuum

DB Lowry and BA Gould, Michigan State University, East Lansing, MI, USA

Glossary

Allopatry It refers to geographically isolated populations.
Allopolyploid A new species resulting from hybridization between two parental species, where the hybrid species has twice the chromosome number of the parental species.
Assortative mating When individuals with similar genotypes mate preferentially with each other at greater frequency than if mating was random.
Autopolyploid A new species resulting from the doubling of the genome of one parental species is called autopolypoid.
Chromosome doubling test A test conducted to determine if chromosome rearrangements are involved in hybrid sterility. Diploid hybrid fertility is compared to artificial allopolyploid hybrid fertility. If the allopolyploid hybrids have increased fertility, then it can be concluded that chromosomal rearrangements are involved in the sterility of hybrids.
Dobzhansky–Muller incompatibility Hybrid sterility, inviability, or lethality that typically results from a negative epistatic interaction between two or more genetic loci. These incompatibilities are thought to evolve in allopatry.
Ecogeographic isolation Reproductive isolation that occurs when two ecotypes or species are geographically isolated as a result of adaptation to local environmental conditions.
Gametic isolation A post-mating prezygotic reproductive isolating barrier caused by the failure of the gametes of two species to generate a fertilized embryo.
Homoploid hybrid speciation A new species resulting from hybridization between two parental species where the hybrid species has the same chromosome number as the parental species.
Parallel speciation Repeated evolution of reproductively isolated populations by the same mechanisms as a result of similar selection pressures in different geographic regions.
Reciprocal monophyly When phylogenetic analysis reveals that two groups form distinct monophyletic clades.
Reinforcement The process by which prezygotic isolation evolves by natural selection to avoid costly mating between species that results from postzygotic isolation.
Sympatry It refers to populations with overlapping geographic ranges.

Introduction

The biological diversity that we observe on earth is the product of a chain of speciation events stretching back to the origin of life. But what do we mean by a speciation event? The formation of a new species is not instantaneous. Rather, each speciation 'event' is a complex continuum that occurs over time as interbreeding populations bifurcate into different species and eventually, distinct phylogenetic lineages. This process generally takes considerable time and thus we can only observe brief snapshots of the continuum in a human lifespan. Over the past century and a half, many evolutionary biologists have attempted to understand the speciation continuum, but many questions still remain (Sobel *et al.*, 2010; Baack *et al.*, 2015).

One of the approaches that evolutionary biologists have adopted is to classify parts of the continuum as stages in the process of speciation. Historically, there were three major points when evolutionary biologists divided the speciation continuum into distinct stages (reviewed in Lowry, 2012). Alfred R. Wallace was the first to clearly articulate the idea of stages in the process of speciation (Wallace, 1865). During the middle part of the twentieth century, multiple plant evolutionary biologists, most notably Gote Turesson and Jens Clausen, developed their own scheme for describing stages in the process of speciation (Turesson, 1922; Clausen, 1951). Recently, a number of zoologists have resurrected the idea of stages in the process of speciation (Wu, 2001; Nosil *et al.*, 2009; Seehausen *et al.*, 2014). By focusing on different stages of the continuum of speciation, it is possible to gain insights into the different evolutionary mechanisms involved along the entire continuum. Recent studies now regularly split the speciation continuum into stages to understand the entire process better (Nosil *et al.*, 2009; Hendry *et al.*, 2009; Powell *et al.*, 2013; Conflitti *et al.*, 2014; Seehausen *et al.*, 2014).

Mathematical modeling can be very useful for clarifying the details of individual stages of the speciation continuum, especially when tailored to particular biological systems (Gavrilets *et al.*, 2014). However, the entire process of speciation is not easily captured in a single model. Instead, the process of speciation is more often constructed as a verbal narrative, whose story arc is revised and edited in response to the positive feedback between modeling and new empirical data. This article explores the reproductive isolating mechanisms that accumulate along the speciation continuum, how the process of speciation is completed, and why disagreements between species concepts could be the result of the continuous nature of speciation.

Reproductive Isolating Barriers along the Continuum

Mechanisms that Initiate the Speciation Process

The process of speciation always begins with the evolution of one or more reproductive isolating barriers. Isolating barriers

are typically categorized as prezygotic or postzygotic, acting before or after the formation of a hybrid zygote. Barriers are also divided between extrinsic (dependent on the external environment) or intrinsic (independent of environment) mechanisms. Prezygotic extrinsic barriers cause *assortative mating* between populations, ecotypes, or species. These barriers typically result from adaptive evolutionary changes in behavior, habitat, and/or pollinators. In contrast, intrinsic postzygotic barriers cause hybrid inviability, sterility, and lethality. Among intrinsic and extrinsic isolating mechanisms, postzygotic barriers tend to be weaker than prezygotic barriers early in speciation (Nosil *et al.*, 2005; Lowry *et al.*, 2008a; Sobel *et al.*, 2010). The initiation of the speciation process occurs most often in groups that are spatially or temporally isolated due to geography and/or ecology. Following this initial isolation, incipient species progress through the speciation continuum by accumulating stronger reproductive isolating mechanisms over time. Much of contemporary speciation research aims to determine the order in which isolating mechanisms evolve throughout the process (Seehausen *et al.*, 2014).

The Genetic Basis of Isolating Barriers

Early theory on the population genetic basis of reproductive isolation recognized that epistatic interactions between two or more loci, which evolved in allopatry, could cause intrinsic postzygotic isolation (Bateson, 1909; Dobzhansky, 1934; Muller, 1942). *Dobzhansky–Muller incompatibilities* constitute mutations that reduce hybrid fitness when populations come into secondary contact with each other following a period of allopatry. Chromosomal rearrangements can cause hybrid sterility through the production of unbalanced gametes in meiosis. While intrinsic barriers can evolve by selection or drift, extrinsic barriers to gene flow result from the evolution of traits in response to selection. Extrinsic barriers can thus result from any gene that has evolved in response to natural or sexual selection.

The genetic basis of several reproductive isolating barriers has been determined in recent years (Presgraves, 2010; Rieseberg and Blackman, 2010; Seehausen *et al.*, 2014). This research has confirmed the Dobzhansky–Muller model of intrinsic postzygotic isolation by identifying the genes that interact epistatically to cause reductions in hybrid fitness. The evolution of incompatibility genes is thought to be driven by an array of mechanisms including genomic conflict, selfish genetic elements, and rapidly evolving immunity genes. Further, ecological adaptations can drive the spread of incompatibilities when the loci under natural selection are genetically linked to incompatibility loci (Wright *et al.*, 2013). Very few studies have identified genes involved in extrinsic barriers to reproductive isolation. Successful gene identification has only occurred in cases where the genetic architecture underlying the barrier was simple (e.g., Hopkins and Rausher, 2011). The dearth of known ecological reproductive isolation genes may reflect the complex genetics underlying the evolution of morphological and physiological traits involved in most extrinsic barriers.

Different Narratives of Speciation

The Selection-Based Narrative of Speciation

Most of the evolutionary biologists who have divided speciation into stages have focused on scenarios in which the initial divergence leading to speciation is driven by selection. We describe the narrative here for speciation driven by selection (**Figure 1**):

The first stage of speciation in this narrative occurs when different populations diverge due to selection. We now have strong evidence that natural and sexual selection can lead to assortative mating, and thus drive reproductive isolation between populations. This is especially true for studies of *parallel speciation*, where reproductive isolation occurs repeatedly between independent pairs of populations due to strong ecological selection. An excellent example of the early stages of parallel speciation is found in the stick insect species *Timema cristinae* (**Figures 2(a)** and **2(b)**). These insects repeatedly form

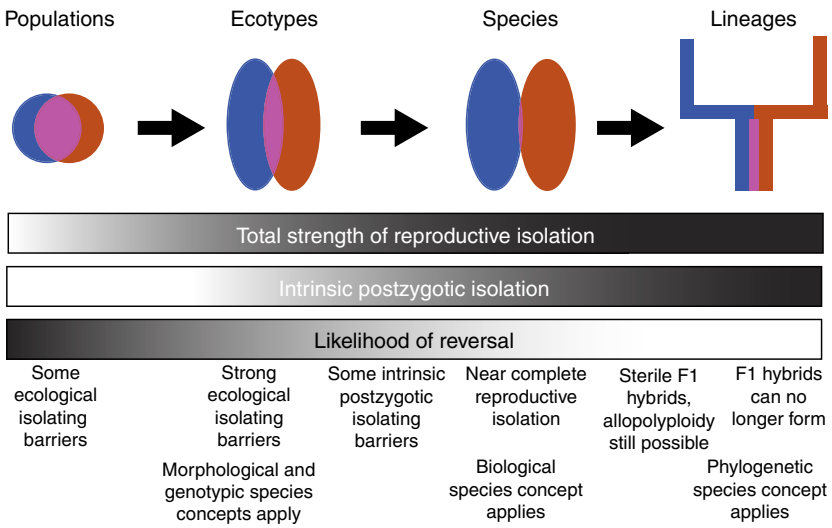

Figure 1 A selection-based narrative of the continuum of speciation. Orange and blue shapes represent diverging groups, with pink indicating potential gene flow between those groups.

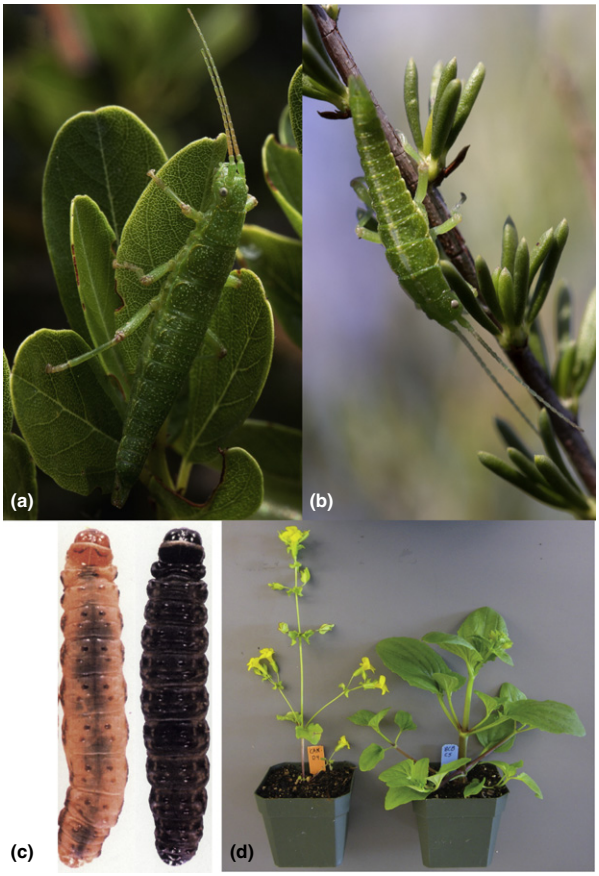

Figure 2 Divergent populations and ecotypes. Parallel patterns of reproductive isolation have occurred between nearby populations of *Timema cristinae* stick insects that are adapted to (a) *Ceanothus* and (b) *Adenostoma* host plants (see Soria-Carrasco *et al.*, 2014; photo credit: A. Comeault). (c) Ecotypes of the larch budmoth *Zeiraphera diniana* adapted to pine (left) and larch (right) trees (see Emelianov *et al.*, 2004; photo credit: W. Baltensweiler and J. Mallet). (d) Inland annual (left) and coastal perennial (right) ecotypes of the yellow monkeyflower *Mimulus guttatus* (see Lowry, 2012; photo credit: D. Lowry).

reproductively isolated pairs of adjacent populations that are adapted to living on different plant host species (Soria-Carrasco *et al.*, 2014).

The next stage of speciation is the formation of ecotypes, which encompass multiple populations that share a set of traits in common (**Figure 2**). Ecotypes have gone by different names, including ecological races, host races, varieties, and subspecies (Clausen, 1951; Mayr, 1982; Dres and Mallet, 2002; Nosil, 2012). The discrepancy in the names of these groups reflects differences in the interests of various biologists and what evolutionary forces are thought to be responsible for the evolution of these groups. Since ecotypes involve multi-trait divergence, they are best characterized by the principal components of the set of traits that define them (Lowry, 2012). Ecotypes are not distinct species. While they have some reproductive isolation that prevents gene flow between them, it is not strong enough to prevent collapse through mating if environmental conditions change or sexual selection shifts. An example of ecotypes can be found in the yellow monkeyflower, *Mimulus guttatus* (Lowry *et al.*, 2008b). Within *M. guttatus*, a geographically widespread perennial ecotype occurs in cool-wet coastal habitats which differs strongly from a closely related annual ecotype adapted to hot and dry inland habitats (**Figure 2(d)**).

Once reproductive isolation reaches a very high level, divergent populations have reached the species stage. Gene flow is rare at this stage, but is still possible. Reversal of speciation is also much less likely at this point. Unlike ecotypes, the species stage is far less controversial and most biologists agree that species exist (Coyne and Orr, 2004). A good example of the species stage is represented by *Helianthus annuus* and *Helianthus petiolaris*, which are two widespread species of sunflowers that have partially overlapping ranges in North America. Reproductive isolation is extremely high between these two species. However, reproductive isolation is not fully complete and recent gene flow has been detected between these sunflower species through molecular methods (Sambatti *et al.*, 2012).

Some biologists assume species is the final stage in the process of speciation, but this view ignores the fact that gene flow often does still occur between many species. Gene flow can also reverse the process of speciation and lead to species collapse if environmental conditions change. Therefore, the final stage of the speciation continuum is two distinct phylogenetic lineages, which will no longer exchange genes in the future through sexual reproduction. To achieve those distinct irreversible lineages requires complete intrinsic postzygotic isolation. While not all evolutionary biologists currently agree, a renewed focus on the continuum of speciation has revived the view that complete intrinsic postzygotic isolation is necessary to complete the process (Seehausen *et al.*, 2014).

Alternatives to the Selection-Based Narrative of Speciation

Speciation that results from natural selection and sexual selection has come to dominate the field of evolutionary biology over the past 20 years. There is now sufficient empirical evidence to suggest that the general selection narrative (**Figure 1**) described above applies to many biological systems (Sobel *et al.*, 2010; Lowry, 2012; Soria-Carrasco *et al.*, 2014; Baack *et al.*, 2015). However, there are many alternative narratives by which speciation can occur.

One major alternative narrative for speciation to occur is through the initial accumulation of strong intrinsic postzygotic reproductive isolation (**Figure 3**). In this scenario, two populations become geographically isolated from each other. Over time, those two populations accumulate genetic changes through drift or selection that contribute to intrinsic postzygotic isolation. When those species come back into secondary contact, the two species can no longer produce fertile offspring. This is the classic allopatric model of speciation and is still a common narrative for the speciation continuum (Grant, 1981; Coyne and Orr, 2004).

While biologists have constructed different verbal narratives of the speciation process, most speciation events likely defy simple classification. It has long been recognized that the entire process of speciation often involves the simultaneous divergences of morphology and physiology with the accumulation of reproductive isolating barriers (Clausen, 1951, p. 90).

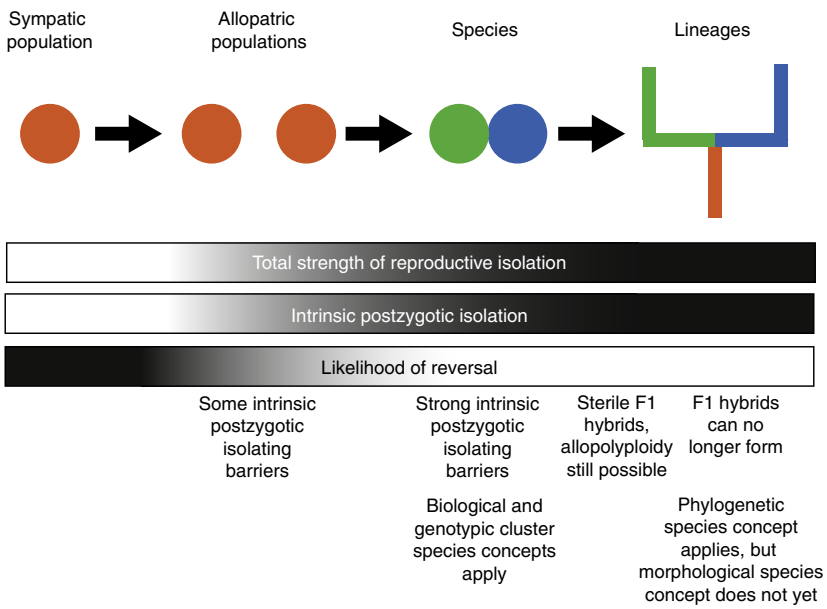

Figure 3 A geographic isolation narrative of the speciation continuum, where most reproductive isolation is the result of intrinsic postzygotic isolation accumulated in allopatry by selection or genetic drift.

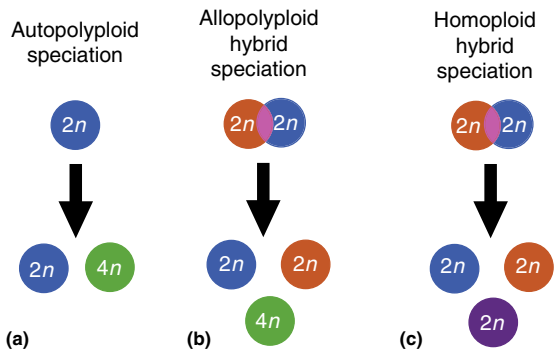

Figure 4 Diagram of three modes of rapid speciation: (a) autopolyploidy, (b) allopolyploid hybrid speciation, and (c) homoploid hybrid speciation. Diploids are represented by 2*n* and tetraploids by 4*n*.

Overall, while there are general patterns of speciation, such as the progressive accumulation of reproductive isolation over time, the process is most commonly the result of a complex combination of multiple selective forces and chance events. The specific details of individual speciation narratives are likely as unique as snowflakes.

The length of time for the speciation process can also be considerably shorter in cases of polyploidy and hybrid speciation (**Figure 4**). Autopolyploid speciation occurs through spontaneous genome doubling, with a tetraploid daughter species instantaneously reproductively isolated from a parental diploid species (Soltis *et al.*, 2007). Hybrid speciation occurs when related species successfully reproduce with the result being the formation of a new species. Allopolyploid hybrid speciation is very frequent in plants and occurs when the hybridization between two diploid species results in a tetraploid (or higher ploidy) daughter species. Reproductive isolation is often immediately strong between diploid parent and polyploid daughter species because hybrids are triploid and can be sterile. Further, both autopolyploids and allopolyploids can have different ecological niches than parents simply as a by-product of changes in genome complement and those differences can lead to immediate habitat isolation (Ramsey, 2011). Homoploid hybrid speciation occurs, for example, when the hybridization between two diploid species results in a new species that is also diploid. There are few good examples of homoploid hybrid speciation and so it is thought to be far less common than allopolyploid hybrid speciation (Schumer *et al.*, 2014).

Geography and the Continuum

The geographic context of speciation is a key component of the speciation. Allopatric separation is thought to occur at least at one point during the process in most of cases of speciation. Allopatry can occur early in speciation and be followed by a secondary contact phase in which speciation is completed. Alternatively, initial ecological divergences among sympatric

or parapatric populations could facilitate a subsequent phase of allopatry in which the accumulation of intrinsic postzygotic isolating barriers completes the process. There are many documented cases where local adaptation to different habitats maintains the allopatric distribution of populations and thus could lead to the further accumulation of reproductive isolating barriers. Allopatry that is maintained by ecological divergence is called *ecogeographic isolation*, and is thought to be very important in speciation (Schemske, 2000; Sobel, 2014).

Alternatively, speciation could occur without an allopatric phase if natural selection was strong enough to restrict gene flow between diverging taxa. Parapatric speciation along environmental gradients likely occurs often and may be the major mode of speciation in the ocean (Bowen *et al.*, 2013). Theoretical models overwhelmingly support the likelihood of parapatric speciation (Coyne and Orr, 2004; Gavrilets, 2014). However, proving that any given speciation event was entirely parapatric, without an allopatric phase, is difficult. Empirical evidence for speciation in *sympatry* is also sparse. There are only a handful of compelling cases of completely sympatric speciation (Barluenga *et al.*, 2006; Savolainen *et al.*, 2006) and those have been brought into question by modeling tailored to those systems (Gavrilets, 2014). Further, classic cases of sympatric speciation, mostly notably *Rhagoletis* fruit flies, now appear to involve genetic variation that first arose in allopatry (Feder *et al.*, 2005).

Mechanisms that Complete the Speciation Process

The Reversibility of the Speciation Continuum

The process of speciation is unstable until new species reach a point at which the process can no longer be reversed (**Figures 1** and **3**). While extrinsic ecological barriers to gene flow can be quite strong, they are contingent on current environmental conditions. If those environmental conditions change, ecological barriers can disappear leading to high levels of gene flow and subsequent species collapse. Reversals along the speciation continuum, linked to environmental changes, have now been documented in multiple fish species. For example, eutrophication has been linked with recurrent declines in differentiation between divergent sympatric lake whitefish subspecies (Vonlanthen *et al.*, 2012) and cichlid fish in Lake Victoria, Africa (Seehausen *et al.*, 2008). Similarly, stickleback fish researchers have documented the collapse of two species into a hybrid swarm following the introduction of an exotic crayfish (Taylor *et al.*, 2006). It should be mentioned that reversals in the speciation process could also occur for intrinsic postzygotic barriers, but those reversals are yet to be documented.

Reinforcement

While intrinsic postzygotic isolating barriers are ultimately responsible for the completion of the speciation process, the accumulation of those postzygotic barriers can actually drive the evolution of strong prezygotic barriers near the end of speciation. Reinforcement is the process by which new prezygotic barriers are selected for in order to avoid costly hybridization between species. Avoidance of hybridization is advantageous because hybrids are less fit than progeny produced by crosses within parental ecotypes or species. While reinforcement was controversial for much of the twentieth century, there are now many examples of reinforcement in both plants and animals (Yukilevich, 2012; Hopkins, 2013). Reinforcement is thought to typically occur when previously allopatric species come into secondary contact. Once in secondary contact, reinforcement is predicted to occur in regions of sympatry but not allopatry. One can assess the occurrence of reinforcement by comparing the strength of prezygotic isolating barriers in allopatric versus sympatric populations.

Hopkins and Rausher's (2012) recent research on *Phlox* identified the first genes to be involved in the process of reinforcement. *Phlox cuspidata* and *Phlox drummondii* come in contact with each other in central Texas, USA. These species produce highly sterile hybrids when they are crossed with each other. In the sympatric zone of these species' range, *P. drummondii* takes on a bright red coloration, which reduces deleterious hybridization with *P. cuspidata*. Two genes in the anthocyanin pigmentation pathway are ultimately responsible for the transition between pink and red flowers (Hopkins and Rausher, 2012). The *Drosophilia* of the island of São Tomé, Africa provide an excellent example of how reinforcement can evolve without changes in mating preference. Both *Drosophilia yakuba* and *Drosophilia santomea* form a hybrid zone on the island and male hybrids between the two species are sterile. Matute (2010) found that these *Drosophilia* species evolved reinforcement through the evolution of *gametic isolation* in sympatric populations. Thus, reproductive isolation that occurs after mating, but before fertilization, can evolve through reinforcement.

Mechanisms Involved in the Completion of Speciation

While recent studies have established that natural selection can initiate the process of speciation through the formation of divergent populations and ecotypes, we have a poor understanding of how diverging groups subsequently acquire intrinsic postzygotic isolation to complete the speciation process. It is largely unknown how often the same environmental factors driving the formation of initial ecological barriers also directly drive the evolution of intrinsic postzygotic barriers. Intrinsic isolating barriers can result from both intrinsic and extrinsic selective forces. Further, intrinsic barriers can spread by genetic drift within populations that are already reproductively isolated by strong ecological barriers. It would be particularly interesting to determine whether ecogeographic isolation could be a major factor facilitating the spread of intrinsic barriers, since this barrier functions by promoting allopatry.

Dobzhansky–Muller incompatibilities have been localized in different types of organisms and are thus thought to be frequently involved in speciation (Presgraves, 2010; Rieseberg and Blackman, 2010). There is also strong evidence that chromosomal rearrangements are commonly involved in plant speciation. This conclusion comes from studies of species that have a high level of sterility in F1 hybrids. When the genomes of those species are artificially doubled to make allopolyploid hybrids, hybrid fertility is often restored. The proposed mechanism for restored fertility is that, rearranged chromosomes no longer pair

at meiosis and unbalanced gametes are in turn no longer produced. Ramsey and Schemske (2002) surveyed multiple highly reproductively isolated plant species and found that diploid hybrids only had on average 17% fertility. When synthetic tetraploid hybrids were made between these same species, fertility was elevated to 71%. A major conclusion of these *chromosome doubling tests* is that rearrangements are largely responsible for hybrid sterility in the later stages of plant speciation. While chromosomal reproductive isolation is common in plants, it does not appear to be as common in animals. There are multiple hypotheses for why chromosomal reproductive isolation is more common in plants than animals (Coyne and Orr, 2004, pp. 266–267), but this question has yet to be resolved.

Another profound implication of the chromosome doubling test is that as long as two species can make F1 hybrids there still may be potential for those species to combine to form a new allopolyploid hybrid species. Therefore, the gradual accumulation of postzygotic isolation barriers will not only lead to the formation of two separate phylogenetic lineages, but will also create the potential to instantaneously form a third hybrid lineage through allopolyploidization. As a result of this observation, Clausen (1951) argued that the continuum of speciation is only finally complete when two species can no longer produce any viable hybrids. For some organisms, it may take a very long time until F1 hybrids can no longer be produced. A recent study identified a natural F1 hybrid fern that had resulted from the hybridization between two species that had been separated for ~60 million years (Rothfels *et al.*, 2015).

Species Concepts and the Continuum of Speciation

Most of the twentieth century was filled with fierce debate over the definition of species. However, much of the differences between species definitions can be attributed to biologists focusing on particular points of the speciation continuum. This controversy is analogous to the Indian parable of the blind men and the elephant. Each of the blind men had very different descriptions of the elephant because they had only touched one particular part of the elephant's body: ears, trunk, tail, tusks, etc. This resulted in a major disagreement between the men about the true nature of the elephant. The disagreement is only settled when a wise man informs the men that they are all correct because the elephant contained all the elements that the men had described.

Viewed as a continuum, it is quite easy to see how the major species concepts have arisen out of a focus on particular points along the continuum. This is clearly illustrated by revisiting the selection narrative of speciation (**Figure 1**). The morphological species concept is often used by taxonomists and primarily relies on a combination of traits quantified from museum specimens to define species. Many taxonomists prefer the morphological species concept because it does not require extensive additional research that other species concepts require. The genotypic cluster species concept defines species as a 'distinguishable groups of individuals which have few or no intermediates when in contact' (Mallet, 1995). A similar definition has recently been proposed for the term ecotype (Lowry, 2012). The reliance of the morphological and genotypic cluster species concepts on distinct traits is likely to bias them toward the earlier points along the speciation continuum. The biological species concept utilizes a strict criterion of reproductive isolation to define species and therefore corresponds well with the species stage of the continuum (**Figure 1**). The phylogenetic species concept defines species by *reciprocal monophyly* between taxa, at least at a large portion of loci across the genome (Baum and Donoghue, 1995; Queiroz, 2007). In other words, species are only recognizable by the phylogenetic species concept when gene flow has ceased long enough that allelic differences become fixed between species. Such a situation will only occur after complete reproductive isolation has occurred between taxa for numerous generations, as shared ancestral polymorphism must be eliminated before gene tree topologies will reflect actual species trees (Cruickshank and Hahn, 2014; Fontaine *et al.*, 2014). Thus, the phylogenetic species concept will, by definition, be biased toward the very end of the speciation continuum.

If speciation only occurred by a single type of narrative, it would be clear that different species concepts simply refer to different points along the continuum of speciation. However, because there are many different narratives of speciation, confusion still persists over different species concepts. For example, imagine a scenario where speciation primarily occurs through the accumulation of intrinsic postzygotic isolation in allopatry without much morphological divergence (**Figure 3**). In this case, different species would be readily identifiable by the biological species concept, and perhaps even the phylogenetic species concept, before those species would be identifiable by the morphological species concept. Essentially, they would be considered as cryptic species. The key take away from this thought exercise is that viewing speciation as a continuum, without assuming any particular narrative, can free us from the need for rigid species concepts.

Going forward, researchers should try to build a more comprehensive understanding of the different stages of speciation. Studies over the past two decades have produced many new insights regarding the role of ecological and sexual selection in the early stages of speciation. A major challenge in the future will be to understand the mechanisms that complete the speciation process and forever maintain distinct non-recombining phylogenetic lineages. A key component of this future research will include the interrogation of the causes of hybrid sterility through combining the chromosome doubling test with modern techniques (e.g., Stathos and Fishman, 2014) as well as the examination of what eventually prevents the formation of F1 hybrids. Overall, we must always keep in mind that there are many routes to producing new species and that no one model will capture the diversity of forms of the speciation continuum.

Speciation Genes

BK Blackman, University of California, Berkeley, CA, USA; and University of Virginia, Charlottesville, VA, USA

Glossary

Bateson–Dobzhansky–Muller incompatibility Combination of alleles at two or more loci that interact epistatically to reduce the fitness of hybrid progeny.

***Cis*-regulatory variation** Polymorphisms affecting the transcription of a gene that are located within noncoding DNA sequences that are proximate to the gene itself.

Coalescence The merging of all descendant gene copies within a lineage at a single ancestral gene copy occurring within that lineage going back in time.

Divergent selection Selection that favors different optima for one or multiple traits in alternate environments or niches.

Ecological speciation The process by which barriers to gene flow evolve between populations as a result of ecologically based divergent selection.

Epistasis Dependency of the effects of an allele at one locus on the genotype at one or more additional loci.

Genome editing Targeted alteration of DNA through expression of factors that bind to specific nucleotide sequences and make double strand breaks proximate to them.

Genomic conflict A phenomenon where the proliferation or non-Mendelian inheritance of selfish genetic elements occurs at the expense of the host genome, which may in turn evolve to suppress the deleterious effects of those elements.

High-throughput genotyping Determination of the allelic composition at thousands of loci for hundreds to thousands of individuals using next-generation sequencing or oligonucleotide array-based technologies.

Hybrid zone Geographic region where two species ranges intersect and interbreeding naturally yields hybrid offspring at some frequency.

Incipient species Populations that share a recent common ancestor and that are partially reproductively isolated.

Knockout mutants Organisms carrying mutations that eliminate the function of a given gene.

Linkage disequilibrium Nonrandom association of alleles.

Meiotic drive Distortion of Mendelian inheritance during meiosis by alleles that are preferentially transmitted to the mature gamete pool (e.g., by inactivating sperm or pollen carrying alternate alleles).

Near isogenic lines Accessions generated by repeated backcrossing that have identical genomes except for differences at one or a few narrow genomic blocks.

Reproductive isolating barriers Biological features of organisms that impede the exchange of genes with members of other populations.

RNAi RNA interference; includes several methods by which dsRNA can be introduced to trigger the degradation or inhibit the translation of specific endogenous transcripts.

Sexual conflict A phenomenon where alleles that confer higher fitness to one sex also confer lower fitness to another sex, which may lead to antagonistic coevolution.

SNP Single nucleotide polymorphism.

***Trans*-acting variants** Polymorphisms affecting the transcription of a gene that are not located within or nearby that gene but are instead located elsewhere in the genome.

As speciation proceeds, genetic changes accumulate that restrict and eventually lead to the cessation of gene flow between populations sharing common ancestry, allowing these lineages to become increasingly evolutionarily independent. Because many questions about the nature of the molecular mechanisms and evolutionary forces that drive speciation can only be addressed with knowledge of the specific genes involved, researchers have long sought to identify the genes contributing to this process. However, these loci, dubbed 'speciation genes,' have been understandably quite difficult to identify. Genetic analysis is a formidable challenge when the organisms of interest are naturally recalcitrant to mating or their offspring cannot produce progeny of their own.

Fortunately, through advances in genetic and genomic resources, creative experimental design, and considerable brute force effort, the field of speciation genetics has made rapid progress over the past two decades (Bomblies, 2010; Moyle *et al.*, 2014; Noor and Feder, 2006; Nosil and Schluter, 2011; Orr, 2005; Presgraves, 2010; Rieseberg and Blackman, 2010; Wu and Ting, 2004). Allelic differences between lineages that cause reproductive isolation (RI) by compromising successful fertilization (pre- or postmating prezygotic RI) or the fitness of hybrid progeny (postzygotic RI) have been identified in diverse systems. Moreover, although their number is still modest, these case studies – whether considered individually or as set – have validated, deepened, and at times challenged longstanding ideas as well as promoted new directions for investigation. The aims of this entry are twofold. First, the conceptual history of the term 'speciation gene' and, following from this, empirical approaches for meeting the criteria implied by that definition will be reviewed. Second, insights into the speciation process that have emerged from the study of known speciation genes will be highlighted. Though the present focus is on genic changes that increase RI, how chromosomal rearrangements and polyploidy may also contribute is reviewed elsewhere in this volume.

 doi:10.1016/B978-0-12-800049-6.00066-4

What are Speciation Genes and How are They Identified?

An Inclusive Definition

As emphasis on particular forms of RI has shifted over time, how authors have defined the term 'speciation gene' has evolved as well. Most early discussions were restricted in scope, focusing solely on genes contributing to intrinsic postzygotic isolation in sexually reproducing organisms (Orr *et al.*, 2004; Orr, 2005; Orr and Presgraves, 2000). This narrow definition was partly motivated by the argument that although prezygotic barriers or extrinsic postzygotic barriers may be important early in speciation, they may also erode due to shifts in the environment or may be insufficient to maintain divergence when allopatric populations come into secondary contact. In contrast, intrinsic hybrid inviability and sterility are generally predicted to be environment-independent and were considered essential to complete speciation (Muller, 1942). Moreover, the genes underlying intrinsic postzygotic barriers have historically been subject to more fervent attention by geneticists and in the literature due to the greater inherent mystery surrounding their identity (Coyne and Orr, 2004). Traits contributing to prezygotic isolation can be studied within species, and it was expected that the proteins that ordinarily function in the genetic networks regulating these phenotypes within species would also contribute to divergence between species. In contrast, intrinsic hybrid inviability and sterility were predominantly studied only in interspecific crosses. Consequently, beyond the prediction that alleles from each parent genome would interact epistatically (Bateson, 1909; Dobzhansky, 1936; Muller, 1942), few *a priori* expectations existed regarding the functions of genes harboring variants affecting intrinsic postzygotic barriers.

The scope of the term 'speciation gene' has since broadened to also include loci contributing to prezygotic barriers and extrinsic postzygotic barriers. As defined by Rieseberg and Blackman (2010), a "speciation gene can be strictly defined as a gene that contributes to the splitting of two lineages by reducing the amount of gene flow between them." Additional authors have advanced similar definitions (Noor and Feder, 2006; Nosil and Schluter, 2011; Wu and Ting, 2004). This more inclusive definition has emerged in part because many have recognized that the speciation process is best understood as continuum proceeding from absent to complete RI. In addition, as the genetics of both prezygotic and postzygotic barriers have received more intense study, it has become clear that postzygotic incompatibilities can diverge contemporaneously with prezygotic barriers, often segregate within species (Cutter, 2012), and may even be genetically related to prezygotic barriers through pleiotropy (Lee *et al.*, 2008).

Genetic Characterization of Speciation Genes

To satisfy the above definition, the contribution of allelic differences to a contemporary barrier phenotype must be characterized with sufficient empirical rigor to make a compelling case for causality. In addition, it has been argued that speciation genes should fulfill several evolutionary criteria that demonstrate these changes contributed to speciation historically, though assessing these requirements can be less than straightforward.

Candidate gene identification

Quests for speciation genes most commonly start with forward genetics approaches in controlled crosses (**Figure 1**). Because winnowing the genomic regions containing causal loci down to segments of tens to several hundred possible candidates requires performing quantitative trait locus (QTL) mapping on panels of related individuals segregating for variation in focal barrier phenotypes, this strategy has often meant working in systems where speciation is incipient and incomplete (**Figures 1(a)** and **1(b)**). That is, existing barriers can be somehow overcome, and F_2 or BC_1 generation progeny descended from partially or fully fertile F_1s are recoverable for at least one of the cross directions between two parental populations. Only classic model organisms, most notably *Drosophila*, where more advanced genetic toolboxes allow for deficiency and introgression mapping in F_1s, have been exceptions to this rule (**Figure 1(d)**; Orr, 2005). When feasible, QTL intervals are further narrowed by fine mapping in advanced-generation crosses (**Figure 1(c)**), by linkage disequilibrium (LD) mapping approaches that exploit historical recombination events in natural populations, or both. Investigators working in systems without sequenced genomes often supplement their mapping efforts with polymorphic markers specifically developed in candidate genes chosen *a priori* for their known functions in the gene networks governing barrier traits (e.g., Kronforst *et al.*, 2006). Even when promising associations between these targeted markers and phenotypic variation are found, fine mapping or LD mapping remain worthwhile pursuits, as they exclude any potential contributions of neighboring genes.

Fueled by advances in array- and sequencing-based methods for high-throughput genotyping, population genomic screens for speciation genes based on patterns of sequence diversity within and among natural populations have become increasingly common alternative strategies to forward genetics approaches (Noor and Feder, 2006; Seehausen *et al.*, 2014). Differentiation studies scour the genomes of incipient species pairs for regions of elevated divergence relative to polymorphism using metrics like Fst (e.g., Chapman *et al.*, 2013). Hybrid zone studies scan for SNPs that do not introgress and thus maintain much steeper allele frequency clines across space relative to genome-wide patterns of introgression (e.g., Teeter *et al.*, 2010). Although powerful, a drawback of these methods is that do not provide any immediate, concrete connection from genotypes back to specific barrier phenotypes, and establishing this link is often challenging. Moreover, positional information alone may be insufficient for assigning highly differentiated SNPs residing in noncoding regions to the genes they functionally affect. In addition, evolutionary causes other than the presence of a speciation gene may produce outliers of high differentiation, leading to false positives (Cruickshank and Hahn, 2014). Consequently, the need to follow up these studies with functional and evolutionary characterization of specific loci is compelling.

Functional characterization of speciation genes

The gold standard for validating candidate speciation genes is experimental manipulation by genetic transformation. Before

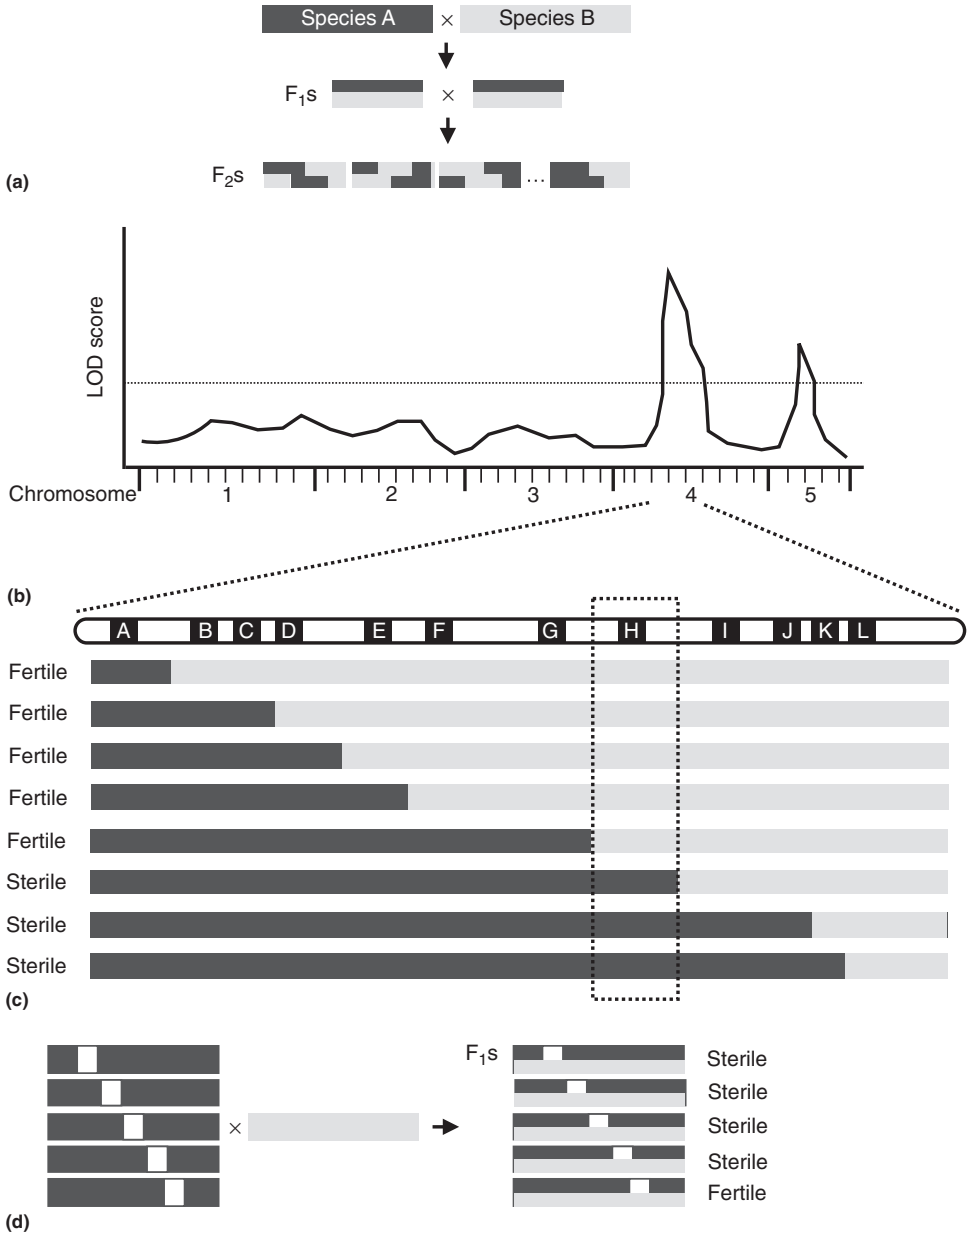

Figure 1 Identifying speciation genes by forward genetics. (a) Genetic mapping requires generating recombinant progeny, a prospect that may be impossible because reproductive isolating barriers in interspecific crosses prevent production of F_1s or leave them infertile. If RI barriers can be overcome, then the phenotypes of recombinants segregating for parental genomic segments can be obtained in the F_2 (shown) or BC_1 generation (not shown). Note that only effects detectable when comparing the heterozygous genotype to the backcross parent homozygote can be studied in a BC_1 generation while effects differentiating the heterozygote and either parental homozygote genotype can be studied in an F_2 generation. (b) Recombinant progeny are genotyped for polymorphic markers throughout the genome, and the effect of the genotype across a coarse genomic interval on segregating variation in a barrier trait is then detected by QTL mapping. The LOD score is the $\log_{10}$ likelihood ratio comparing a model with a QTL present in the interval to a model with no QTL present. (c) Finally, fine mapping may be conducted in the current panel and/or subsequent generations. The QTL interval is narrowed to a region containing one or a handful of genes by genotyping of the subset of progeny recombinant in that interval for additional markers. In the schematic, the region of chromosome 4 contained in the dashed line box is the minimal interval defined by recombination breakpoints affecting hybrid sterility, strongly implicating gene H as the causal locus. (d) In species with libraries of deletions or knockout lines, deficiency mapping can be performed for genes causing F_1 hybrid dysfunction. In the schematic, the genomic interval of Species A spanned by the rightmost deficiency segment contains a hybrid sterility allele.

proceeding with these studies, comparisons of parental coding sequences and gene expression levels in relevant tissues may provide circumstantial evidence useful for reducing the candidate gene set and bolstering support for particular genes in systems where transformation is prohibitively difficult. Allele-specific expression patterns in F_1 hybrids may be evaluated to corroborate that observed expression differences derive wholly or in part from *cis*-regulatory variation affecting the gene itself

rather than *trans*-acting variants located elsewhere in the genome (e.g., Hopkins and Rausher, 2011; Klahre *et al.*, 2011). Network-centered approaches that integrate mapping of barrier traits and gene expression (i.e., QTL and eQTL mapping, respectively) may facilitate description of complex gene interactions often characteristic of postzygotic isolation phenotypes as well (Turner *et al.*, 2014).

Allelic replacement of one species' sequence with that of another, and vice versa, by genetic transformation is the most rigorous experiment for validating a speciation gene. Such tests have historically been possible in only a few model systems, but new genome editing approaches promise to extend the capability for allelic replacement to any transformable system (Turner, 2014). Even when conversion of one species' sequence to that of another is not possible, alternative manipulative experiments may yield solid support. For instance, if crosses involving knockout mutants or individuals carrying RNAi constructs that knockdown expression of candidate gene exhibit reduced RI relative to control crosses, then the candidate gene is necessary for the isolating barrier (e.g., Presgraves *et al.*, 2003). Likewise, if introducing another species' sequence for a candidate gene causes increased RI in an intraspecific cross, then the candidate gene is sufficient for enhancing the isolating barrier (e.g., Phadnis and Orr, 2009). For genes whose protein function can be assessed biochemically, the effects of interspecific substitutions can be determined by *in vitro* assays (e.g., Wessinger and Rausher, 2015). Although not sufficiently rigorous to show causality of a specific gene since contributions of linked variation cannot be excluded, near isogenic lines carrying alternate species alleles in either background can be particularly advantageous for demonstrating a genomic region's effect on RI in field settings (e.g., Bradshaw and Schemske, 2003).

Evolutionary Characterization of Speciation Genes

Recognizing that the evolution of RI is a temporally dynamic process that begins prior to and continues after speciation, the definition advanced above also requires that the gene 'contribute to the splitting of two lineages.' Genetic changes that contribute to contemporary barriers to reproduction between fully isolated species may have accumulated long after speciation was already complete. Likewise, the relative importance of different barriers to gene flow, and consequently the impact of particular alleles on total RI, may change over time. Therefore, it has been argued that speciation genes must meet two additional evolutionary criteria (Nosil and Schluter, 2011). First, divergence at the locus must have occurred before speciation was complete. Second, the gene should have had a measurable effect on RI at the time it diverged. Obtaining empirical data addressing the first criterion can be straightforward, but demonstrating a gene meets the second criterion is potentially far more challenging.

The divergence time criterion is automatically met for genes that contribute to barriers between incipient species. For species pairs that are already completely isolated, divergence time can be assessed with gene trees or genealogies (Nosil and Schluter, 2011). If divergence at a putative speciation gene occurred prior to full cessation of gene flow, then its genealogy should be discordant with genealogies of unlinked neutral loci, which are more likely to show shallower coalescence and greater evidence of gene flow. Such tests can be problematic, however, in that they may yield false negatives depending on the evolutionary process driving divergence (Lessios, 2011). For instance, RI between species often arises as a by-product of accelerated sequence evolution driven by arms races mediated by sexual or genomic conflict within species that continue well after speciation is complete. Thus, a pattern of coalescence within species, rather than a pattern of coalescence prior to the timing of species divergence, may be expected and has been observed for some speciation genes evolving in this manner (Palumbi, 2009).

As for the second criterion, it is unclear whether a speciation gene's effect on RI relative to all other current barriers at the time of its divergence can be rigorously estimated for any species. The absolute effect of allelic divergence at a speciation gene on the strength of a contemporary RI barrier may be readily estimated by the methods discussed above. Moreover, a speciation gene's relative contribution to contemporary RI as a whole may also be estimated to the extent that the full genetic architecture for the barrier trait and the relative strength of that barrier relative to other barrier traits on RI are known. All these parameters are important because isolating barriers, to a large extent, act sequentially to prevent successful fertilization or to impair hybrid fitness, and hence it is possible that loci with major effects on later acting barriers (e.g., hybrid dysfunction) may only have minor contributions to overall RI.

By extension then, estimating a speciation gene's contribution to historical levels of RI would require not only knowledge of the temporal dynamics of evolution at a given locus (and interacting loci if RI is caused by epistatic incompatibilities) in one or both lineages, but also the past history of all other loci contributing to the cessation of gene flow. Thus, meeting this criteria may only be possible in rare systems where speciation in action can be followed over observable time scales. Alternatively, in species pairs isolated by few barriers with tractable genetics, it is conceivable that the historical series of genotypes at speciation loci could be reconstructed if the order of substitutions causing RI were inferable from genes trees or observable in ancient DNA time series. Estimates of absolute and relative contributions to contemporary RI may help determine the bounds to paths historically possible in other systems. However, given the pragmatic hurdles to determining historical dynamics (irrespective of any complexity introduced by gene × environment effects), it seems sufficient to demonstrate a speciation gene affects contemporary isolation and acknowledge the caveat that the specific contribution to total RI at the time of divergence is unknown.

What Have We Learned from Known Speciation Genes?

Beyond important basic knowledge of whether the types of genes or mutations involved follow predictable functional patterns, identifying speciation genes allows many models about the molecular and evolutionary mechanisms that drive speciation to be tested. In addition, while some questions are

addressable without knowing the underlying loci, having causal allelic sequences in hand is often a boon. For instance, patterns of intraspecific polymorphism for RI can be more efficiently assessed by sequencing-based surveys of allelic diversity than through expansive crossing schemes in most systems. Although only a modest set of speciation genes and other strong candidates is known (**Table 1**), the emerging picture supports a plurality of mechanisms while also revealing some broad patterns.

The Identities of Speciation Genes are Predictable for Some Isolating Barriers

As noted above, speciation genes for prezygotic barriers were broadly predicted to be members of networks that govern these phenotypes within species. Although the number of genes known remains insufficient to test this prediction for some barriers (e.g., temporal and mechanical isolation), identification of speciation genes affecting certain forms of RI in multiple systems has proven informative and largely confirms the expectation (**Table 1**). Pollinator isolation stands out in this regard (Yuan *et al.*, 2013a). For floral color and scent, enzymes in pigment and volatile biosynthetic pathways and components of the transcriptional complexes that regulate their expression (often R2R3-MYB transcription factors) are responsible for species differences (Byers *et al.*, 2014; Hoballah *et al.*, 2007; Hopkins and Rausher, 2011; Klahre *et al.*, 2011; Streisfeld *et al.*, 2013; Yuan *et al.*, 2013b). One particularly impressive example of convergence at the genetic level is in the genus *Penstemon*, where function-compromising variants in F3′5′H contribute to flower color shifts in 13 independent transitions from bee to hummingbird pollination (Wessinger and Rausher, 2015). The repeated observation of rapid protein evolution affecting gamete recognition systems in free-spawning marine invertebrates represents a similar case of predictable speciation gene identity (Lessios, 2011).

More surprisingly, the molecular basis of some postzygotic barrier traits in plants also appears predictable. Intra- and interspecific crosses in various groups often yield progeny exhibiting a form of hybrid inviability – hybrid necrosis – in which F_1 or F_2 hybrids show lesioning and compromised growth (Bomblies and Weigel, 2007). Across several systems, the vast majority of loci involved are immune receptors whose faulty epistatic interactions trigger errant autoimmune responses (Bomblies *et al.*, 2007; Chae *et al.*, 2014; Chen *et al.*, 2014; Krüger *et al.*, 2002; Rooney *et al.*, 2005; Todesco *et al.*, 2010). The genetic basis of cytoplasmic male sterility (CMS) barriers appears similarly predictable (Rieseberg and Blackman, 2010). Chimeric mitochondrial transcripts that cause sterility evolve as selfish elements, and the majority of nuclear fertility restorer genes identified to date are members of the pentatricopeptide repeat (PPR) gene family. Although most genetic studies of CMS have been conducted in crosses of cultivated plants to wild species, exciting work in fully wild crosses signals these results will bear out for natural populations as well (Barr and Fishman, 2010; Case and Willis, 2008).

Similar patterns of repeated involvement of common genes or gene families have not emerged for postzygotic isolation barriers in animals or fungi (Presgraves, 2010). An absence of trends here may signal that disruptions to viability or fertility in hybrids are more phenotypically idiosyncratic and taxon-specific in these groups relative to plants, where hybrid necrosis and CMS are widespread isolating barriers. Alternatively, the number of genes identified to date may be too small to reveal trends, but existing examples that implicate particular complexes of proteins regulating recombination, transposable element suppression, and chromosome segregation may prove general (**Table 1**). For instance, allelic differences in the histone methyltransferase PRDM9, a major determinant of recombination hotspots in mammals, have been shown to cause hybrid male sterility in some crosses between subspecies of *Mus musculus* (Flachs *et al.*, 2012; Mihola *et al.*, 2009). Signatures of positive selection altering the number and sequence of zinc finger domains across diverse rodent, primate, and other metazoan species raise the possibility that PRDM9 gene contributes to hybrid sterility in diverse systems (Oliver *et al.*, 2009).

Hybrid Incompatibilities Evolve by Diverse Paths and are Often Polymorphic

The Bateson–Dobzhansky–Muller (BDM) model of reproductive incompatibilities provides a simple and powerful explanatory framework for how alleles that cause hybrid inviability or sterility evolve among lineages that recently shared freely interbreeding ancestors (Bateson, 1909; Dobzhansky, 1936; Muller, 1942). In its most commonly expressed form, Lineage 1 fixes a derived allele at Locus A and Lineage 2 fixes a derived allele at Locus B, but when newly brought onto the same genomic background through hybridization, negative epistatic interactions leading to dysfunction emerge (**Figure 2(a)**). Empirical examples of such BDM incompatibilities have been described (e.g., *Lhr*/*Hmr*; Brideau *et al.*, 2006), as have additional mechanisms. For instance, recent work has described how substitutions of multiple derived alleles in a single lineage can lead to ancestral-derived incompatibilities between lineages involving two unlinked loci (e.g., Krüger *et al.*, 2002; Phadnis and Orr, 2009; Rooney *et al.*, 2005; **Figure 2(b)**) or multiple alleles of a single locus (e.g., Chae *et al.*, 2014; Todesco *et al.*, 2010; **Figure 2(c)**).

In the classic BDM model, the time required for fixation of derived alleles is assumed to be instantaneous, relative to the time spent in allopatry, for mathematical convenience (Orr, 1995; Cutter, 2012). However, numerous empirical studies involving many well-known speciation genes have found that alleles involved in BDM incompatibilities are polymorphic (e.g., Brideau *et al.*, 2006; Mihola *et al.*, 2009; Phadnis and Orr, 2009). In other words, only some strains will produce dysfunctional hybrids in interspecific crosses because the contributing alleles segregate within species. Moreover, intraspecific standing variation in BDM incompatibilities is often found (e.g., Bomblies *et al.*, 2007; Bikard *et al.*, 2009). Describing the evolutionary causes of these polymorphisms and determining whether variable reproductive isolation maintained within an ancestral lineage eventually contributes to postzygotic RI among lineages are major theoretical and empirical challenges in the field of speciation genetics (Cutter, 2012).

Table 1 Representative speciation genes and candidates

Stage	*Isolation type*	*Gene(s)*	*Species*	*Phenotype(s)*	*References*
Prezygotic, Premating	Habitat	Odorant-binding proteins *OBP57d/OBP57e*	*Drosophila sechellia/ Drosophila simulans*	Oviposition preference	Matsuo *et al.*, 2007
		Ectodysplasin (Eda)	Marine and freshwater *Gasterosteus aculeatus*	Lateral plate number and growth rate*	Colosimo *et al.*, 2005; Barrett *et al.*, 2009
	Temporal	*FLOWERING LOCUS C* (*FLC*)	*Arabidopsis suecica/ Arabidopsis arenosa,* and *Arabidopsis thaliana*	Delayed flowering of allopolyploid	Wang *et al.*, 2006
	Pollinator/ behavioral	*R2R3-* and *R3-MYB* transcription factors (e.g., *anthocyanin2* and *ROSE INTENSITY 1*)	Various *Petunia, Antirrhinum, Phlox,* and *Mimulus* species pairs	Flower color differences leading to pollinator shift	Quattrocchio *et al.*, 1999; Hoballah *et al.*, 2007; Schwinn *et al.*, 2006; Hopkins and Rausher 2011, 2012; Streisfeld *et al.*, 2013; Yuan *et al.*, 2013a, 2013b
		Flavonoid 3′,5′-hydroxylase (F3′5′H)	Various *Penstemon* species; *Phlox drummondii/Phlox cuspidata*	Flower color differences leading to pollinator shift	Hopkins and Rausher 2011, 2012; Wessinger and Rausher 2014, 2015
		Methyl-branched CHC-specific fatty acid synthase (*mFAS*)	*Drosophila serrata/ Drosophila birchii*	Cuticular hydrocarbon profile differences affect mate choice	Chung *et al.*, 2014
		ODORANT1	*Petunia axillaris/ Petunia exserta*	Floral scent differences leading to pollinator shift	Klahre *et al.*, 2011
		Stearoyl-acyl carrier protein desaturases 1 and 2 (*SAD1/SAD2)*	Various *Ophyrus* species	Floral scent differences leading to pollinator shift	Xu *et al.*, 2012
		OCIMENE SYNTHASE	*Mimulus lewisii Mimulus cardinalis*	Floral scent differences leading to pollinator shift	Byers *et al.*, 2014
		optix	Various *Heliconius* species	Wing color pattern leading to assortative mating*	Heliconius Genome Consortium, 2012; Reed *et al.*, 2011
Prezygotic, Postmating	Gametic	*ui1.1* (Cullin 1)*; ui6.1* (S-Locus F-box)	Various *Solanum* species	Unilateral incompatibility accompanying mating system shift	Li and Chetelat, 2010, 2015
		Bindin	Various sea urchin genera	Species-specific fertilization	Palumbi 2009; Lessios 2011
		Lysin	*Haliotis rufescens/ Haliotis corrugata*	Species-specific fertilization	Palumbi 2009; Lessios 2011
		Cysteine-rice peptide *LURE1*	*Torenia concolor/ Torenia fournieri; A. thaliana/ Arabidopsis lyrata*	Species-specific chemoattraction of pollen tubes	Kanaoka *et al.*, 2011; Takeuchi and Higashiyama, 2012
Postzygotic, Extrinsic	Ecological	*optix*	Various *Heliconius* species	Wing color pattern intermediates suffer greater predation*	Heliconius Genome Consortium 2012; Reed *et al.*, 2011
	Pollinator/ behavioral	*R2R3-MYB* transcription factor	*Phlox cuspidate/ Phlox drummondii*	Flower color intermediates less attractive to pollinators	Hopkins and Rausher, 2011, 2012

(*Continued*)

Table 1 Continued

Stage	*Isolation type*	*Gene(s)*	*Species*	*Phenotype(s)*	*References*
Postzygotic, Intrinsic	Hybrid Inviability	Various NLR immune receptors (e.g., *DANGEROUS MIX 1*)	*A. thaliana* (intraspecific); *Oryza rufipogon/ Oryza sativa*; *Solanum lycopersicum/ Solanum pimpinellifolium*	Hybrid necrosis	Krüger *et al.*, 2002; Bomblies *et al.*, 2007; Todesco *et al.*, 2010; Chae *et al.*, 2014; Chen *et al.*, 2014
		HISTIDINOL-PHOSPHATE AMINO-TRANSFERASES 1 and 2 (*HPA1/HAP2*)	*A. thaliana* (intraspecific)	Arrest of seed development	Bikard *et al.*, 2009
		Nucleoporins Nup96 and Nup160	*D. melanogaster/ D. simulans*	Hybrid lethality	Presgraves *et al.*, 2003; Tang and Presgraves, 2009
		Lethal hybrid rescue (Lhr)/ Hybrid male rescue (Hmr)	*D. melanogaster/ D. simulans*	Hybrid lethality	Barbash *et al.*, 2003; Brideau *et al.*, 2006; Thomae *et al.*, 2013; Satyaki *et al.*, 2014
	Hybrid Sterility	*Odysseus (Ods)*	*D. simulans/ D. mauritiana*	Hybrid male sterility	Ting *et al.*, 1998; Sun *et al.*, 2004; Bayes and Malik, 2009
		JYAlpha	*D. melanogaster/ D. simulans*	Hybrid male sterility	Masly *et al.*, 2006
		PR domain-containing 9 (PRDM9)	*Mus musculus musculus/Mus musculus domesticus*	Hybrid male sterility	Mihola *et al.*, 2009
		Overdrive	*Drosophila pseudoobscura pseudoobscura/ Drosophila pseudoobscura bogotana*	Hybrid male sterility	Phadnis and Orr, 2009

Genes were selected to illustrate the breadth of isolation barriers for which speciation genes or strong candidates have been characterized, and the table is not intended to be comprehensive. Although compelling evidence linking genotype to phenotype has been provided in all cases, the direct impact of allelic variation on RI may not be fully demonstrated for some candidates (asterisks (*)). That is, an impact on the prevention of fertilization or hybrid dysfunction is assumed based on the phenotypes changed by these alleles but reproductive isolation has not been explicitly examined following allelic replacement by transformation or introgression for these candidates.

Diverse Evolutionary Models Supported

Because many evolutionary models in the field of speciation genetics are grounded in specific molecular mechanisms, identifying speciation genes is essential to test their biological merit. In addition, knowing key sequences facilitates the application of population genetic tests to determine whether drift, selection, and/or migration have been the predominant forces driving the evolution of RI. The speciation genes identified to date lend support to diverse processes.

Ecological speciation

A classic model of speciation – ecological speciation – postulates that RI evolves as a by-product of ecologically based divergent natural selection (Schluter and Conte, 2009). In other words, the mechanism by which individual populations differentially adapt to local selection pressures is genetically linked to the evolution of RI between populations. Pleiotropy, tight physical linkage, capture by a chromosomal inversion, or one-allele assortative mating all represent alternative mechanisms by which recombination between the loci contributing to locally adaptive phenotypes and the loci causing RI may be sufficiently frustrated to allow the joint evolution of both traits (Nosil, 2012).

Speciation genes provide ample empirical evidence that supports this model for prezygotic or extrinsic postzygotic barriers. For instance, *cis*-regulatory changes that eliminate expression of mFAS, a fatty acid synthase responsible for methyl-branched cuticular hydrocarbon production, in the humid habitat specialist *Drosophila birchii* relative to the habitat generalist *Drosophila serrata* are pleiotropic (Chung *et al.*, 2014; Chung and Carroll, 2015). They alter both desiccation sensitivity and mate choice. Likewise, allelic differences that specialize plants to different pollinators or to alternative mating systems necessarily also reduce gene flow between plant species (e.g., Hoballah *et al.*, 2007; Byers *et al.*, 2014; Li and Chetelat, 2015). In *Heliconius* butterflies, wing color patterns are essential for both predation avoidance through mimicry and mate choice (Jiggins *et al.*, 2001). Thus, genetic differences that have evolved in response to divergent selection favoring

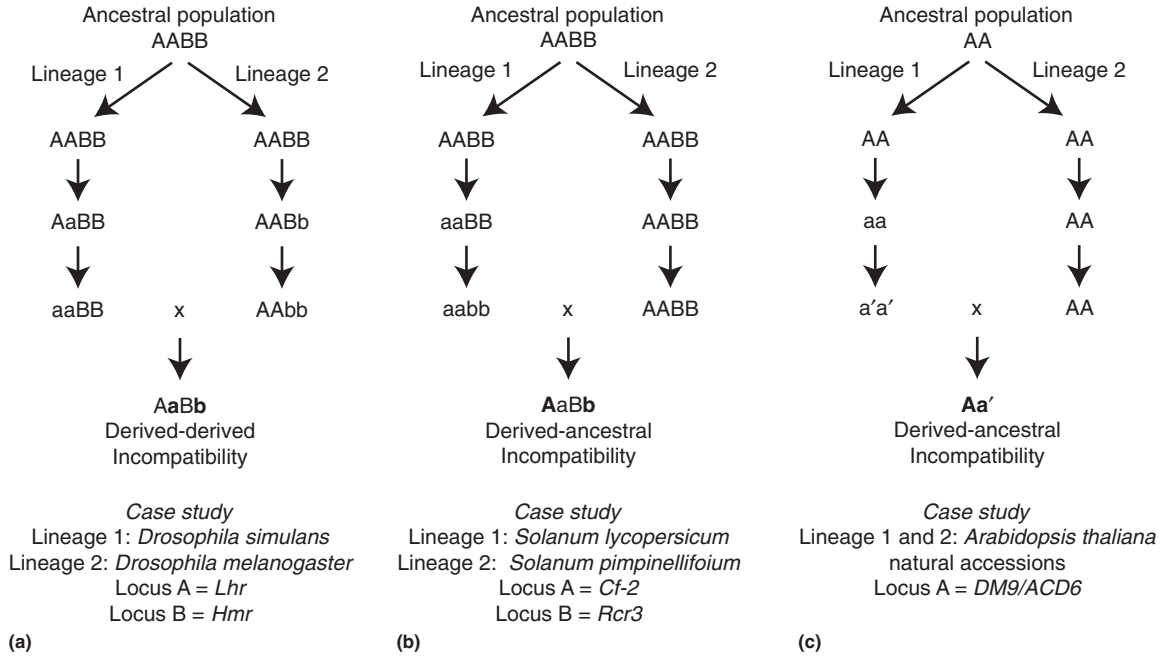

Figure 2 BDM incompatibilities evolve by multiple evolutionary mechanisms. (a) Classic BDM model where incompatible derived substitutions fix at alternative loci in each lineage, as observed for F_1 hybrid male lethality in crosses of two *Drosophila* species (Brideau *et al.*, 2006). (b) Substitution of a derived allele at Locus A permits the evolution of a second derived allele at Locus B in the same lineage, leading to incompatibility with the ancestral allele at Locus A. In the case study, hybrid necrosis arises in 3/16 of F_2 progeny of crosses between wild tomato species, because bb homozygotes are incompatible with AA or Aa genotypes (Rooney *et al.*, 2005). (c) A succession of substitutions at a single locus leads to the evolution of an incompatibility between a derived and ancestral allele. Some loci involved in incompatibilities that cause hybrid necrosis in intraspecific crosses among *Arabidopsis thaliana* accessions likely evolved by this mechanism (Chae *et al.*, 2014; Todesco *et al.*, 2010). Incompatible alleles are highlighted in bold.

alternative mimicry patterns (Kronforst *et al.*, 2006; Kronforst and Papa, 2015) may lead to behavioral isolation between color pattern races as well as extrinsic postzygotic isolation since hybrids with intermediate, non-mimicking color patterns are more susceptible to predation.

Theoretical models and experimental evolution studies both provide strong evidence that intrinsic postzygotic RI can evolve through ecological speciation as well (Dettman *et al.*, 2007; Gavrilets, 2004; Schluter and Conte, 2009). Although several speciation genes exhibit evolutionary patterns consistent with this process, their histories may also be consistent with other models or their contribution to interspecific barriers remains to be fully affirmed (Chae *et al.*, 2014; Lee *et al.*, 2008).

Evolutionary arms races, mutation pressure, and hybrid incompatibilities

Although multiple processes may drive the fixation of alleles within lineages that cause postzygotic incompatibilities between lineages, incompatibilities are predicted to arise more rapidly if selection is involved. Consistent with this expectation, many speciation genes known to be involved in BDM incompatibilities appear to rapidly evolve within lineages due to ongoing evolutionary arms races. These patterns of substitution and counter-substitution seem to be largely driven by mutation pressure and selection to resolve genomic conflicts rather than ecological pressures (Presgraves, 2010). Within lineages, selfish genetic elements may parasitize host genomes through elevated transposition rates or biasing transmission in their favor through meiotic drive and gamete-killing segregation distortion. Host genomes respond to these strong selection pressures by evolving mechanisms that suppress these activities or compensate for their deleterious effects. If parasitic elements are separated from their corresponding suppressors or if different host genome compensatory mechanisms are incompatible in hybrid genetic backgrounds, dysfunction may manifest.

For instance, the speciation genes *Lhr* and *Hmr* interact as part of a protein complex that represses satellite DNA and transposable elements (TEs), and epistatic interactions between *Lhr* and *Hmr* in *Drosophila melanogaster* × *Drosophila simulans* hybrids lead to mis-expression of TEs and consequently hybrid lethality (Brideau *et al.*, 2006; Satyaki *et al.*, 2014; Thomae *et al.*, 2013). Rapid coevolution of repetitive DNA regions and the proteins that regulate their segregation during meiosis and mitosis, and other systems that compensate for mechanisms that distort chromosomal segregation patterns, have also been implicated in intrinsic postzygotic barriers (Bayes and Malik, 2009; Ferree and Barbash, 2009; Fishman and Saunders, 2008; Phadnis and Orr, 2009), providing support for a prescient mechanistic model (Henikoff *et al.*, 2001). The evolution of CMS and restorer genes reflects a similar case of postzygotic RI that evolves due to genomic conflict within lineages (Rieseberg and Blackman, 2010). The speciation genes involved in these types of arms races – as well as host–pathogen systems related to hybrid necrosis – exhibit high levels of coding sequence divergence, often in tandem

with copy number evolution. Whether the cumulative effects of all substitutions are necessary for BDM incompatibilities, or whether substitutions that cause incompatibilities are rare and only these types of genes evolve rapidly enough to hit upon them, remains an open question.

Relaxation of purifying selection, particularly following gene or genome duplication, may also accelerate rates of substitution through genetic drift. In the case of gene or genome duplication, if resolution of functional redundancy among recent duplicates occurs by gene silencing or subfunctionalization within populations such that different descendant lineages maintain function in separate map locations, postzygotic RI may also result (Lynch and Force, 2000; Werth and Windham, 1991). In this scenario, F_1 gametophytes or F_2 generation hybrids may inherit a chromosome set that lacks either a full complement of ancestral functions or any functional copy period. Examples of speciation genes consistent with this form of RI arising from gene movement driven by passive mutational silencing of gene duplicates have been observed in intraspecific crosses in *Arabidopsis* and interspecific crosses among rice and *Drosophila* species (Bikard *et al.*, 2009; Masly *et al.*, 2006; Yamagata *et al.*, 2010).

Hybridization as a driver of speciation

Reinforcement, allopolyploid speciation, and homoploid hybrid speciation are documented ways that hybridization may foster speciation. Speciation gene sequences have revealed an additional, perhaps surprising way that hybridization may actually promote the cessation of gene flow. In several cases, gene flow has facilitated the spread of alleles contributing to the evolution of RI between lineages. For instance, *optix* sequences involved in wing pattern divergence have been passed among *Heliconius* species and repeatedly reused in the independent evolution of mimetic races (Heliconius Genome Consortium, 2012; Reed *et al.*, 2011). In the threespine stickleback, the *Eda* allele that confers adaptation to freshwater through loss of lateral plates, and that may contribute to behavioral isolation between marine and freshwater populations due to effects on growth rate in a species that assortatively mates based on size, was likely transported to many freshwater populations worldwide through the marine gene pool (Barrett *et al.*, 2009; Colosimo *et al.*, 2005; McKinnon *et al.*, 2004; Schluter and Conte, 2009). It remains to be determined whether alleles that initiate or resolve genomic conflicts similarly introgress among species and, if so, whether gene flow of such alleles would facilitate or impede the speciation process.

Speciation Genomics

P Michalak, Biocomplexity Institute, Virginia Tech, Blacksburg, VA, USA

Glossary

Adaptive radiation Process in which organisms rapidly diversify into a plethora of new forms, particularly when a change in the environment makes new resources available, creates new challenges, and opens yet-environmental niches.

Allopatry Geographical separation enabling genetic divergence of populations and taxa in isolation.

Assembly, genome assembly Computational reconstruction of the genome sequence; typically involves collapsing reads into contigs, joining contigs into scaffolds, and linking scaffolds into chromosomes.

Bioinformatics Interdisciplinary field that develops methods and software tools for understanding biological sequence data.

de Bruijn graph assemblers Software programs for genome assembly based on a set of a number of symbols and dimensions. For genomics applications, the set of symbols consists of four characters ('A,' 'C,' 'T,' 'G') and dimension is equivalent to the chosen k-mer size.

Comparative genomics Branch of genomics in which genome features of different organisms are compared.

Contigs, contiguous sequence Genomic fragment generated by a genome assembler, based on overlapping reads.

Dobzhansky–Muller incompatibilities Genetic incompatibilities that evolve between populations or closely related species without going through an adaptive valley. It requires changes in two or more loci, where a new allele arises at one locus in one population, but is incompatible with another new allele that evolved independently in the second population. When combined in hybrids, these incompatibilities cause reduced fitness.

Greedy assemblers Software programs for genome assembly based on greedy algorithms, i.e., those finding the shortest common supersequence for a set of sequence fragments.

Linkage disequilibrium (LD) The nonrandom association of alleles at two or more loci. Such associations are facilitated by the physical proximity of genes on a chromosome (linkage) and/or by strong interactions of alleles with one another that affect the fitness of an organism more strongly than either allele alone (epistasis). Strong epistasis can cause LD between genes without them being closely physically linked on a chromosome.

Next-generation sequencing (NGS) High-throughput (massively parallel) methods of DNA sequencing, provided by such technologies as Illumina, 454, and Pacific Biosciences, enabling whole genome analyses.

Reproductive isolation Barriers to gene exchange between populations or species.

Secondary contact Recent geographic overlap of two or more divergent evolutionary lineages (i.e., populations or species) after a period of geographic isolation, which allowed for some degree of differentiation to occur from a common ancestor.

Smith–Waterman algorithm Local sequence alignment, in which similar regions between two strings or nucleotide or protein sequences are computationally determined.

Overview: Speciation Genomics – Toward the Periodic Table of Speciation

In the process of writing his famous book, *The Principles of Chemistry*, Dmitri I. Mendeleev (Mendeleyev and Lawson, 1891) created the Periodic Table of Elements that listed the majority of then-known elements according to increasing order of atomic weights. When he organized the table into horizontal rows, a system of elements became apparent – but only if he left blanks in the table. With the empty classes included, later to be filled with newly discovered elements, a distinct pattern of elements with similar physical and chemical properties emerged at regular intervals – periodically – in vertical columns of the table. It turned out that the properties of elements were accounted for, or at least correlated with, a single organizing variable, namely the positive charge of the nucleus, which in Mendeleev's times could be only approximated by atomic weight.

Compared with the Periodic Table, biological classification systems, including taxonomy, fall short. The human genome project and the origin of genomics, leading to the plethora of complete or near-complete genome sequences for multiple organisms across the tree of life were believed by many to hold promise of a new organizational understanding. To uncover new guiding principles, a systems approach known as systems biology, lying at the interface of genetics, genomics, and bioinformatics, was created. Systems biology has been less appealing to evolutionary biologists who were skeptical that categorizing and organizing principles other than evolutionary process itself can be informative or even feasible. Indeed, the most common and natural reason for hierarchical organization in biological systems is evolution by descent with divergence from the common ancestor.

As exemplified by the Periodic Table invention, when we examine a large amount of data, what we see depends a lot not only on what we want to see, but also on how we organize the data. Similarly, when we analyze multiple genomes, which are in the realm of comparative genomics, our perspective and novel ways of visualization determine what we will notice. One of the uncharted areas of comparative genomics is

 doi:10.1016/B978-0-12-800049-6.00081-0

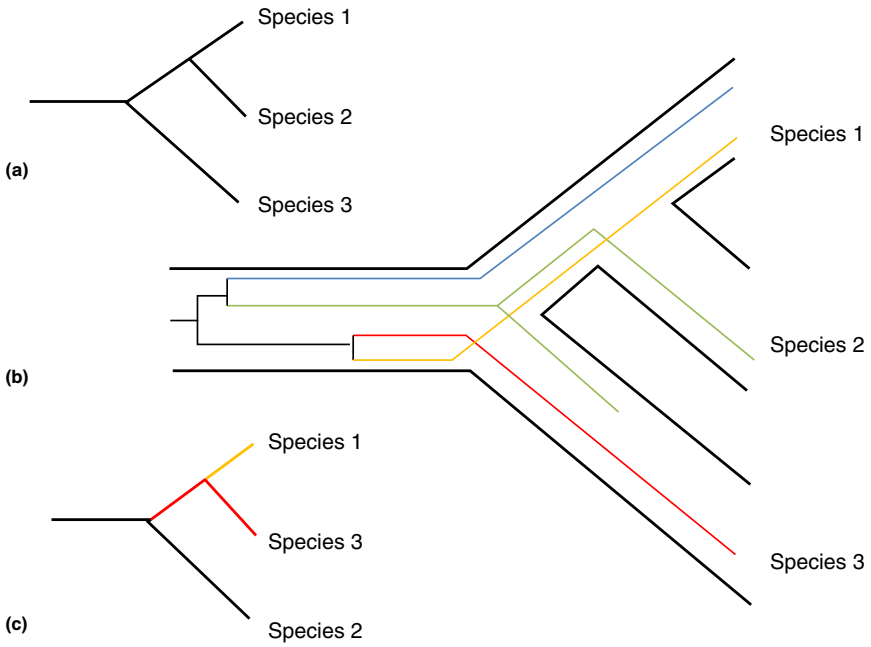

Figure 1 Speciation and incomplete lineage sorting that leads to gene genealogies incongruent with the species phylogeny (a). As the common ancestor diverges into Species 1, 2, and 3, not all ancestral alleles will end up in founding populations of the new species (b). For example, the most recent common ancestor of Species 1 and 2 has by chance lost the red allele, while the founding population of Species 3 did not have blue and orange alleles and then lost the green allele as well. Phylogenies constructed on the basis of the present day allele similarities between the three modern species will thus produce different species histories, some of which will be incongruent with the species phylogeny (a), dependent on which gene lineage we look at. For example, the orange allele in Species 1 is most related to the red allele in Species 3, so according to this allele Species 1 and 3 will be clustered together as most closely related (c).

inference of speciation, or the origin of new species, "the mystery of mysteries" as Darwin called it (Darwin, 1859). Speciation occurs as genetically-based barriers to gene flow evolve and cause previously interbreeding populations to become reproductively isolated from one another (Coyne and Orr, 2004). Reproductive isolation, either pre- or postzygotic, and its genetic determinants are thus central to describing and understanding speciation, at least in its formulation consistent with the prevalent Biological Species Concept (de Queiroz, 2005; Seehausen *et al.*, 2014). Most, if not all, discoveries in the field of speciation genetics, such as the identification of genes responsible for hybrid incompatibilities (Orr *et al.*, 2004; Presgraves, 2010; Rieseberg and Blackman, 2010), involved traditional experimentation, genetic mapping, and single candidate gene approaches, which necessarily limited the research to a handful of experimentally tractable organisms. On the other hand, comparative genetics for a long time was focused on model organisms and phylogenetically distant, 'flashy' representatives of major taxonomic groups, thus failing to provide a finer evolutionary timescale necessary for addressing questions related to speciation.

As next-generation sequencing (NGS) technologies are becoming increasingly available at a lower cost, comparative genomics has recently expanded to multigenome analysis of divergence between closely related species, as well as polymorphism within populations, laying the foundations for, respectively, phylogenomics and population genomics. 'Speciation genomics' is budding at the interface between these two areas of research (as well as functional genomics), but novel ways of thinking, data analysis, and visualization will be required to surface before this new field flourishes (Seehausen *et al.*, 2014). Reconstructing the sequence of speciation events and identifying speciation-driving genes in closely related and potentially hybridizing species is extremely challenging due to such processes as incomplete lineage sorting and interspecific gene flow. These processes result in local gene genealogies that differ in their topology from the species tree, and analyses of different loci with a single sequence per species are likely to produce conflicting or even misleading results (**Figure 1**). Moreover, if hybridization is involved in speciation and adaptive radiation, and we do keep finding out more and more that hybridization is a widespread phenomenon producing evolutionary novelties (e.g., Heliconius Genome, 2012; Martin *et al.*, 2013; Lamichhaney *et al.*, 2015), a simple tree is no longer an ideal representation of evolution, and more complex graphs or multidimensional tables will need to be explored instead. Most sequence divergence between species that we observe today has accumulated either before or after a speciation event, and even if it happened precisely at the tree bifurcation moment (node), it can still be coincidental rather than causative with respect to isolating mechanisms or local adaptations. Conversely, especially in species that diverged in separation (allopatry), some genes that differentiated after a speciation event are predicted to be a part of negative epistatic interactions known as Dobzhansky–Muller (hybrid) incompatibilities, essential for postzygotic reproductive isolation upon secondary contact and reinforcement of sexual isolation (Coyne and Orr, 2004). Also in the case of sympatric

speciation due to host shifting and ecological divergence, genetic variation responsible for new local adaptations that accumulated in populations after parting of their way may be considered a causative speciation factor. Therefore, it is critical for speciation genomics to employ gene-function annotation tools, genetic interactions information (pathways and networks), as well as population genetics tools, such as McDonald–Kreitman tests (Mcdonald and Kreitman, 1991; Messer and Petrov, 2013) and Pool-hmm (Boitard *et al.*, 2013) for dissecting adaptive sequence changes from neutral changes. The following sections will give a brief introduction to available methods and present two case studies that exemplify how advances of comparative genomics and phylogenomics provide new insights into speciation.

How are Whole Genomes Analyzed?

The ultimate goal of genome projects is to provide an organism's complete genomic sequence information but 100% completeness is still barely achievable in organisms other than microbes. The first genomes were sequenced with the classical Sanger (chain termination) method, employing its capillary-based, semi-automated implementations, while new genome projects rely more and more on the next generation, massively parallel sequencing technologies, primarily Illumina which has largely dominated today's market. Since most sequencing methods produce relatively short strands of 100–1000 base pairs, longer chromosomal sequences are partitioned into smaller fragments that can be sequenced separately, and subsequently reassembled to provide the original genomic sequence. The assembly process is one of the most challenging steps in *de novo* genome sequencing projects and involves either a laborious process of 'chromosome walking' that progresses through the entire strand piece by piece or faster but computationally demanding 'shotgun sequencing' that randomly breaks up DNA into numerous short segments, or a combination of both. Resequencing genome projects are easier, once a genome scaffold exists and can be used as a reference for mapping new genomes from the same species. Shotgun sequencing is largely dependent on redundant coverage, in which on average every nucleotide is sequenced many times over, as required to produce a high-quality assembly with a minimum number of gaps. Another benefit of redundancy is greatly increased accuracy in terms of the sequencing error control: Where a single read has an error rate of 1%, eightfold coverage produces an error rate as low as 10^{-16} when eight high-quality reads agree with one another (Schatz *et al.*, 2010). High coverage is also required for sequencing polymorphic sites within diploid or polyploid genomes.

A major challenge in the assembly process, even under high sequence coverage, is to reconstruct repetitive sequences, such as mononucleotide stretches, microsatellites, minisatellites, transposable elements, and clusters of tRNAs and rRNAs, since these sequences are very abundant in eukaryotic genomes, and tend to be longer than the read length. The best solution to resolving repetitive sequences is use of sequencing technologies (e.g., Pacific Biosciences) that generate long reads, the longer the better. Since NGS long-read solutions are not cost-effective, many genome projects have employed hybrid approaches combining long reads, mate-pair information, and high volumes of shorter reads (Illumina). Early genome assemblers were based on a simple 'greedy' algorithm, in which all pairs of reads are compared with each other, and the ones that overlap most are merged first. To allow for sequencing errors, assemblers generate these overlaps with a variant of the Smith–Waterman algorithm (Smith and Waterman, 1981) that allows for a small number of differences (1–10%) in the overlapping sequence. Once all overlaps are recovered, the reads with the longest overlap are concatenated to form a contiguous sequence (contig). The process then cycles, each time merging the sequences with the longest overlap until all overlaps are used (Schatz *et al.*, 2010). While greedy assemblers perform well with long reads and compact genomes, they fail to process shorter reads, especially from genomes enriched in repetitive sequences. To address these and other challenges of NGS, new assemblers replace the overlap algorithm with a de Bruijn graph, in which the reads are decomposed into k-mers becoming the graph nodes, edges between nodes are drawn, and nonbranching paths are translated into unambiguous contigs.

Although generating draft assemblies from NGS is relatively easy, finishing a genome to the chromosome level is still difficult and costly. Post-assembly genome processing involves quality assessment, gene prediction and annotation, as well as finishing steps, such as closing gaps through targeted Sanger sequencing, and integrating sequence information with genetic mapping, restriction maps or *in situ* hybridization results. Comparative genomics then establishes the level of homology between two or more genomes and expands formerly gene-oriented methods to a new genome-wide perspective. However, comparative genomics in the era of complete genomes is not only 'more of the same.' The entire genome level provides unprecedented opportunity to develop new methods, models, and statistical tests, such as the four-taxon ABBA/BABA test for introgression across genomes (**Box 1**), originally developed for estimating gene admixture between modern human and Neanderthal populations from single nucleotide polymorphism patterns (Green *et al.*, 2010; Sousa and Hey, 2013). The discovery of Neanderthal and Denisovan admixture with modern humans through ancient interbreeding (Reich *et al.*, 2011; Skoglund and Jakobsson, 2011) has been one of the most unexpected findings of comparative genomics and human genetics lately ($\sim$2.7% of the author's genome is estimated to derive from Neanderthals).

Genome-Wide Evidence for Speciation with Gene Flow in *Heliconius* Butterflies

The closely related neotropical butterfly species *Heliconius melpomene*, *Heliconius cydno*, and *Heliconius timareta* are distasteful to predators and often exhibit Müllerian mimicry to more distantly related species (Martin *et al.*, 2013). All three species include various wing pattern forms, or races, which can be viewed as incipient stages of speciation, as it seems that selection for Müllerian mimicry can lead to wing pattern divergence and color-based assortative mating with no geographic separation (Chamberlain *et al.*, 2009). *Heliconius cydno* and *H. timareta* together form a clade that is sister to

Box 1 The ABBA/BABA introgression test

Whole genome sequence information from closely related taxa may be used for identification and estimation of recent gene admixtures between populations or species. One of the methods, known as the four-taxon ABBA/BABA test, relies on comparing the taxa tree (assumed to be known) with the gene trees inferred at a specific site. Incongruent patterns between the population tree and the gene tree can be due to unequal mutation rates (rather unlikely), incomplete lineage sorting (shared ancestral polymorphism that by chance does not make it to all considered taxa) or to gene flow (introgressive hybridization). A certain statistic, called '*D*,' was specifically designed to detect introgressions from one population to another (Durand *et al.*, 2011; Sousa and Hey, 2013). Obtaining *D* estimates requires genome information from each of two sister populations (P_1 and P_2), a genome from a third population (P_3, a potential source of introgressed genes) and a fourth outgroup genome (O) to identify the ancestral state (identified as the A allele) and the derived state (B allele). If alleles at a specific site are scored in the order of P_1, P_2, P_3, and O, there are two phylogeny-incongruent allele patterns to be found: ABBA and BABA, with ABBA potentially originating from hybridization between P_2 and P_3, and BABA from hybridization between P_1 and P_3. Under the hypothesis of shared ancestral polymorphism, the number of tree topologies of ABBA and BABA are expected to be equal, and the expected *D* will be zero, which can be rigorously tested.

H. melpomene, but unlike *H. cydno*, several *H. timareta* races have *H. melpomene*-like patterns (**Figure 2**). Martin *et al.* (2013) provided evidence that 20–40% of the genome in *H. melpomene* shows a discordant phylogenetic pattern, consistent with admixture with *H. cydno* or *H. timareta* in sympatry. Estimates of admixture by means of the ABBA/BABA method increased with time period examined, implying continued gene flow during speciation as opposed to a recent burst. Additionally, linkage disequilibrium (LD) was strongest between derived alleles that were shared during the recent time period, indicating the existence of introgressed haplotype blocks that are yet to be broken down fully by recombination. Remarkably, blocks of shared sequence variation containing the *B*/*D* region, known to be responsible for red mimicry patterns between races of *H. melpomene*, were exchanged between postman *H. timareta* and postman *H. melpomene* (Heliconius Genome, 2012). Interspecific F_{ST} between sympatric species tended to be lower and more variable than between the corresponding allopatric populations, as expected under a model of admixture with variable selection against introgressing alleles. There was a significantly reduced signature of admixture on the Z chromosome compared with autosomes, which can be associated with Z-autosome incompatibilities known to cause female hybrid sterility in the system (Jiggins *et al.*, 2001; Naisbit *et al.*, 2003). Genomics thus provides empirical data for addressing the ongoing debate between recent proponents of sympatric speciation and the classical view of ubiquitous allopatric speciation.

The Genomic Landscape of Phenotypic Integrity in the Face of Gene Flow in European Crows

Carrion crows (*Corvus* [*corone*] *corone*) and hooded crows (*Corvus* [*corone*] *cornix*) are two European corvid [sub-]species with very distinct coloration (**Figure 3**) which fuels assortative mating (Poelstra *et al.*, 2014). The geographical distribution pattern of these species suggests a population history shaped by glaciation cycles during the Pleistocene, and is characterized by well-defined, narrow hybrid zones in the areas where the ranges meet, mostly across central Europe and Siberia. Extensive gene flow between hooded crows and the German carrion crow population was detected using whole-genome analyses, consistent with a scenario of admixture upon secondary contact (Poelstra *et al.*, 2014). All populations but Spanish showed signatures of expansion and had higher nucleotide diversity than that of the assumed refugial Spanish population.

A 1.95-Mb genomic region containing extreme genetic differentiation between carrion and hooded crows was mapped to a single chromosome. This region, potentially

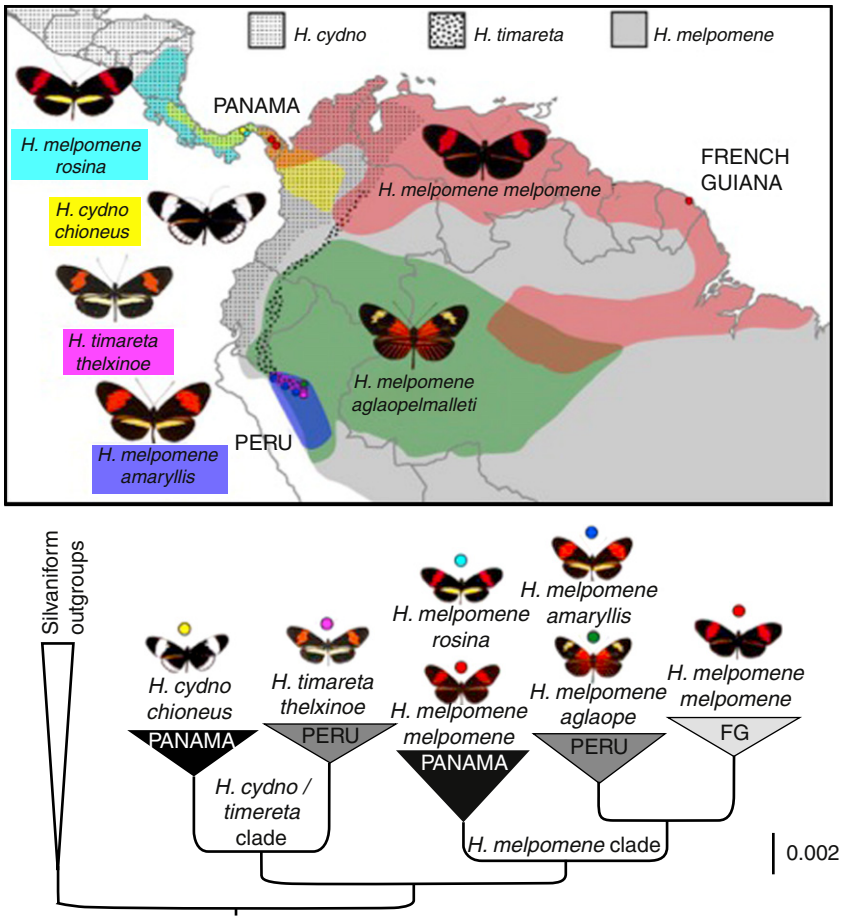

Figure 2 Distributions and phylogeny of *Heliconius* species and races. The phylogeny is a compressed version of the whole-genome maximum likelihood tree. Reproduced from Martin, S.H., Dasmahapatra, K.K., Nadeau, N.J., *et al.*, 2013. Genome-wide evidence for speciation with gene flow in *Heliconius* butterflies. associated with an inversion and harboring 81 of all 82 fixed sites between carrion and hooded crows, including 40 annotated protein-coding genes, was characterized by significantly reduced levels of nucleotide diversity and increased LD. A ~4.1 kb section of the region, associated with a local F_{ST} peak, had longer haplotype blocks and provided evidence for recent, hooded crow-specific, positive selection. This region turns out to contain a tandem array of voltage-dependent calcium channel subunits, including those encoded by members of the CACNG gene family responsible for transmembrane regulators of AMPA receptors, linked to the microphthalmia-associated transcription factor gene MITF, a central regulatory element of the melanogenesis pathway. The group (Poelstra *et al.*, 2014) also conducted an extensive gene expression profiling and found that at least 11 of the 21 melanogenesis genes underexpressed in gray hooded crow feather follicles were directly regulated by MITF (e.g., TYR, TYRP1, SLC45A2, RAB38, EDNRB2) or interacted with MITF in feedback loops (MC1R, HPGDS). This tentatively links gene expression, color phenotype, and a signature of divergent selection within a single divergence peak.

Another highly divergent 'island' within the region contained a hooded-derived fixed variant in the regulatory region of RGS9 (*regulator of G protein signaling 9*), a highly expressed gene in eyes (with lower expression in hooded crows), known to affect visual perception in vertebrates, as well as influence dopamine and opioid signaling in the brain (Martemyanov and Arshavsky, 2009). This finding is of special interest because it may point to a pleiotropy underlying color-based assortative mate choice promoting speciation in the system.

Conclusion

Thanks to the new methodological developments in genomics and bioinformatics the whole-genome perspective is a potential 'game-changer' to speciation studies. The field of speciation genetics may finally progress from approximations with model systems, such as hybrid inviability in crosses between relatively distant *Drosophila melanogaster* and *Drosophila simulans* (e.g., Barbash and Ashburner, 2003; Brideau *et al.*, 2006), to natural systems undergoing incipient speciation and adaptive radiation. The pattern that emerges from these and similar case studies is that gene flow between taxa is a pervasive feature of speciation and post-speciation processes, even including our own species, as well as island systems that so

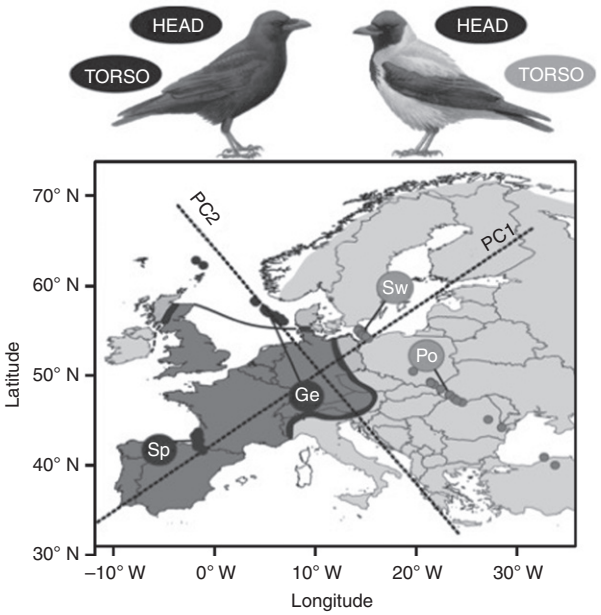

Figure 3 The European distribution of the carrion crow (dark gray area) and hooded crow (light gray area); the hybrid zone is shown as a black solid line. far have been used as textbook examples of allopatric speciation, such as Darwin finches (Grant and Grant, 2014; Lamichhaney *et al.*, 2015). Genomic signatures of speciation are being detected as local peaks of divergence (often called 'speciation islands' (Turner *et al.*, 2005; Feder *et al.*, 2012)) that exhibit resistance to gene flow, in addition to other sequence, structural, and functional features, including eroded LD, footprints of selective sweeps, enrichment in inversions, and mate choice- or reproduction-related genes.

Speciation, Geography of

JM Sobel, Binghamton University (State University of New York), Binghamton, NY, USA

Introduction

> Is not the biological laboratory which leaves out the ocean and the mountains and meadows a monstrous absurdity? Was not the greatest scientific generalization of your times reached independently by two men who were eminent in their familiarity with living beings in their homes? Brooks (1899, p. 41).

In all of evolutionary biology, few subjects have instigated such contention as the geography of speciation. It is well established that geographic isolation can facilitate the speciation process by removing the constraints on divergence imposed by gene flow (Mayr, 1942, 1963; Coyne and Orr, 2004). However, a long history of debate surrounds whether geographic separation is indeed required for species formation. It is now clear that divergence can be achieved despite substantial gene flow, resulting in highly discontinuous taxa in nature (e.g., Michel *et al.*, 2010). Arguments have thus shifted to the nature of the frequency distribution of speciation events across a spectrum of potential rates of gene flow. Some authors maintain that the vast majority of speciation events in nature occur without gene flow (Coyne and Orr, 2004), while others are convinced that speciation with gene flow may be quite common (Via, 2001; Nosi, 2008). Unfortunately, aspects of this debate are bound to continue for several reasons. First, for any given pair of closely related sympatric species, it is extremely difficult to determine whether a period of allopatry preceded current contact (Pinho and Hey, 2010). Second, in cases where highly differentiated, yet incompletely isolated taxa occur in sympatry, we do not know which will continue along the path toward becoming full species. These difficulties have spurred some to suggest that geographic context is not a useful categorization of speciation events (Kirkpatrick and Ravigne, 2002). However, one only needs to consider how vastly different the biodiversity of our planet could be if the 'oceans and the mountains and meadows' were arranged differently to appreciate the importance of geography to speciation. Therefore, regardless of how we classify each event, the topic of geography will undoubtedly continue to be vital in our understanding of the origin of species.

History

From Darwin to Jordan

Given the famous impact that island faunas had on both Darwin's (1859) and Wallace's (1880) thinking as they developed their ideas on evolution by natural selection, it is not surprising that early work favors geographic isolation as a potent force in the emergence of species. However, the beginning of a later controversy surrounding the geographic context of speciation can be detected at the very emergence of the field. Darwin notes that geographic isolation is important to divergence, stating "In a confined or isolated area … natural selection will tend to modify all the individuals of a varying species throughout the area in the same manner … Intercrosses, also, with the individuals of the same species, which otherwise would have inhabited the surrounding and differently circumstanced districts, will be prevented." (Darwin, 1859, p. 104). However, in considering the connection between patterns on islands and the diversity on continents, he goes on to say, "Although I do not doubt that isolation is of considerable importance in the production of new species, on the whole I am inclined to believe that largeness of area is of more importance, more especially in the production of new species…" As thoroughly explored by Sulloway (1979), Darwin's further discussions of 'partial' and 'ecological' isolation also suggest that he viewed speciation in sympatry as common.

At least partially in response to Darwin's perceived endorsement of sympatric speciation, several authors in the late nineteenth and early twentieth centuries, voiced dissenting views in strong support of allopatric speciation (see Sulloway, 1979). These arguments focused strongly on the biogeography of closely related species pairs, as determined by morphological analysis. The ichthyologist David Starr Jordan was particularly influential in advocating the role of geography in speciation, stating what would later be named Jordan's rule: "Given any species in any region, the nearest related species is not likely to be found in the same region nor in a remote region, but in a neighboring district separated from the first by a barrier of some sort…" (Jordan and Kellogg, 1907, p. 120). Jordan viewed the conditions for geographic isolation as ubiquitous in nature, perhaps influenced by his extensive work in freshwater fishes.

The Great Debate: Allopatric versus Sympatric Speciation

The modern synthesis made tremendous strides toward understanding the speciation process, largely through incorporation of Mendelian genetics and the articulation of the Biological Species Concept (BSC). Darwin's species concept was famously poorly developed; however, later workers such as Poulton initiated debate intended to more carefully define species (Poulton, 1908). With influences from many others, Mayr formulated the BSC as, "… groups of actually or potentially interbreeding natural populations, which are reproductively isolated from other such groups" (Mayr, 1942). Mayr also held firmly that geographic isolation was essential to the process, writing several scathing critiques of sympatric speciation (Mayr, 1947, 1963). In his view, physical barriers that confer geographic isolation act as indiscriminant external agents that separate emerging taxa while internal barriers to reproduction accumulate through time (**Figure 1**). Intrinsic reproductive isolation therefore stems from biological differences between organisms, and it is assumed to typically arise as a by-product of divergence during this allopatric phase (Coyne and Orr, 2004; Schluter, 2001). Dobzhansky (1937) and others additionally favored the idea that speciation is

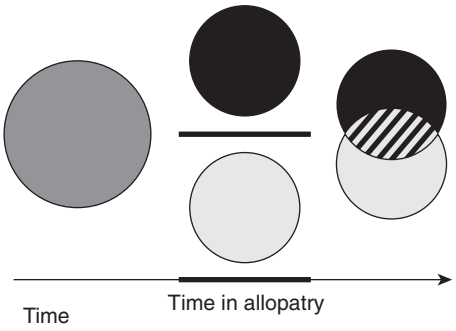

Figure 1 The traditional view of allopatric speciation. A formerly contiguous group of populations is separated by a physical barrier. During this time in allopatry there is no gene flow, and reproductive isolation arises as a by-product of divergence. Upon secondary contact, stable coexistence verifies that speciation is complete.

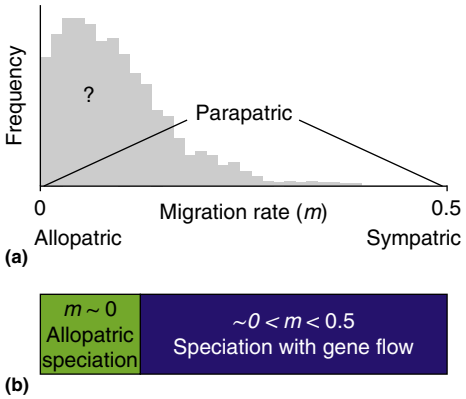

Figure 2 Redefining the geography of speciation. (a) A population genetic definition of the geography of speciation places allopatric and sympatric speciation at either extreme ends of a continuum in migration rate, while parapatric speciation describes everything in between. The geography of speciation may be approached by characterizing the unknown frequency distribution (?) of events across a range of potential migration rates (gray bars). (b) Because it will often be impossible to determine historic rates of gene flow or to rule out past episodes of allopatry, a rough dichotomy that separates events into fully allopatric speciation (green, $m \approx 0$) and speciation with gene flow (blue, $\approx 0 < m < 0.5$) may be more useful.

often completed through the process of reinforcement, which states that upon secondary contact natural selection may directly favor the evolution of early acting reproductive barriers due to the maladaptive nature of hybrids (Levin, 1970; Hopkins, 2013).

While this view of speciation dominated the literature throughout the mid-twentieth century, the vestige of sympatric speciation left by Darwin and other early workers (e.g., Walsh, 1864) never completely disappeared. In response to Mayr's criticisms, theoreticians explored potential conditions under which speciation could occur with gene flow (e.g., Maynard Smith, 1966), while empiricists sought to characterize potential examples. Guy Bush's experimental work on apple and hawthorn races of *Rhagoletis* fruit flies provided the most compelling case of sympatric speciation emerging from this period (1969). One of the key insights to the *Rhagoletis* system involves their mating behavior. Rather than forming a mating flight, *Rhagoletis* mate on their food source, providing a means for stable assortative mating to facilitate divergence. This work influenced the development of a number of similar empirical studies (e.g., Via, 2009), and there is continued speculation about whether host shifts in phytophagous insects are common examples of speciation with gene flow (Berlocher and Feder, 2002).

Redefining the Geography of Speciation

Mayr and others defined the geography of speciation spatially. Allopatric speciation occurs when geographic isolation is required, while sympatric speciation occurs when divergence happens in the same place, i.e., while each emerging species is within the 'cruising range' of each other (Mayr, 1963). Mayr also recognized parapatric speciation as an intermediate category that included examples where two taxa are mostly allopatric, but have abutting ranges with a narrow band of contact. More recently, these same terms have been defined from a population genetic point of view (Endler, 1977). The rate of migration (m) serves to indicate the magnitude of geographic isolation during speciation. Allopatric speciation is thus the subset of events where $m = 0$ throughout the process. The upper limit of migration $m = 0.5$ would occur if two taxa mated completely randomly at the onset of divergence, so this has been used as the condition of sympatric speciation. In contrast to the original spatial definition, parapatric speciation includes events where the value of m lies anywhere between the two extremes (**Figure 2(a)**).

Several criticisms of this approach provide motivation to redefine the geography of speciation. Allopatric speciation has been described by some as common and uncontroversial (Coyne and Orr, 2004). Colonization of oceanic islands following long distance dispersal to these isolated environments is regarded as an example. However, in order to truly achieve $m = 0$, no additional dispersal can occur to that 'isolated' environment during the entire time span of speciation. On the other end of the scale, criticisms have been levied against using $m = 0.5$ as the defining feature of sympatric speciation. For example, Mallet *et al.* (2009) argue that true panmixis of $m = 0.5$ is rarely, if ever, achieved in nature; therefore, it is a definition predetermined to fail. Instead, while acknowledging the potential importance of spatial separation in many cases, they favor defining sympatry less strictly, for example: Two populations are *sympatric* if individuals of each are physically capable of encountering one another with moderately high frequency. However, given the contentious history of this term, this redefinition seems unlikely to persist.

Given the perceived failures of categorization systems for the geography of speciation, a useful redefinition may be to examine events as either: (1) allopatric speciation (or nearly so), $m \approx 0$; or 2) speciation with gene flow ($0 < m < 0.5$). The former category would include events where geographic isolation is strong but potentially incomplete, such as long distance dispersal and subsequent colonization of isolated habitats. However, the defining feature would be consistently low or absent migration throughout divergence. The latter category would include those events for which gene flow has imposed a significant constraint on divergence. As Butlin *et al.* (2008) argue, migration rate can be viewed as a continuum,

and the value may fluctuate during different stages of the speciation process. In addition, past and future values of m are extremely difficult to estimate or predict. Therefore, rather than attempting to characterize a potentially unknowable frequency distribution (**Figure 2(a)**), a more useful approach may be to examine the dynamics of migration and selection in systems with ongoing gene flow (Butlin *et al.*, 2008), or to ask how often extant taxa exhibit the conditions favorable to the process (Bolnick and Fitzpatrick, 2007).

Speciation with Minimal Gene Flow ($m \approx 0$): Allopatric or Nearly So

Allopatric events include those for which migration is minimal throughout divergence. This would include both 'vicariant' and 'peripatric' subcategories of traditional allopatric speciation. Vicariant speciation refers to events in which a contiguous population is physically separated by some climatological or geologic event (Cracraft, 1982). Peripatric speciation is essentially the same with regard to gene flow, but occurs when small numbers of individuals in peripheral populations become separated from a progenitor through similar forces or long distance dispersal to isolated habitats (Coyne and Orr, 2004).

Theoretical support for allopatric speciation

Much of the theory associated with allopatric speciation focuses on the evolution of intrinsic postzygotic isolation (Dobzhansky, 1937, Muller and Pontecorvo, 1942). When emerging taxa are geographically isolated, two or more loci may fix for different alleles in each population. If these alleles produce negative epistatic interactions, hybrids between the taxa may be sterile or inviable (Orr, 2001). This form of isolation is often considered a hallmark of allopatric speciation because selection is expected to remove such negative interactions if they arose in the face of gene flow. While many other forms of isolation can also arise in allopatry, their evolution is often modeled indirectly. Indeed, theoretical treatment of allopatric speciation are simply models of sympatric speciation with the constraints imposed by gene flow removed. Felsenstein (1981) famously described the antagonism between selection and recombination when divergence occurs in the face of gene flow. His initial model considers a simplified case of two loci involved in divergent selection in alternate habitats. If mating is random, selection alone produces linkage disequilibrium between coadapted alleles; therefore, speciation cannot occur under these conditions unless selection is strong enough to remove every recombinant. If a locus conferring a pre-zygotic barrier is added in the form of assortative mating, speciation can occur; however, recombination severely limits favorable conditions by breaking up associations between assortative mating and adaptive loci. However, reductions in migration between alternative habitats facilitates the speciation process, with the lower extreme of allopatric speciation ($m = 0$) completely free of the constraints imposed by recombination.

Empirical support for allopatric speciation

Jordan's rule suggests that evidence for allopatric speciation should be ubiquitous, and it specifically proposes the most closely related species pairs as targets for assessing the geographic mode of speciation. Therefore, we might expect that the youngest species pairs are the most likely to exhibit allopatry, and this may often involve an obvious geographic barrier. Thus, phylogenetic studies of the time since speciation and the degree of range overlap might yield important insights into the geography of speciation. However, these studies, known as age-range correlations (ARCs), are very sensitive to mismatches between the timescales of speciation and range shifts, providing a limited glimpse into the process (see **Box 1**). Therefore, some of the best unambiguous examples of

Box 1 Age-range correlations

Age-range correlations (ARCs) aim to examine the geography of speciation by measuring the degree of geographic overlap in extant taxa across a range of different genetic distances (Barraclough and Vogler, 2000). Genetic distance serves as a proxy for time since speciation; therefore, the assumption is that the youngest taxa will reveal the nature of geographic distributions at the time of speciation. For example, if allopatric speciation is the norm, geographic overlap should be lowest for young taxa, and increase stochastically through time as range shifts and expand (**Figure B1(a)**). Alternatively, if speciation with gene flow is common, then many young species pairs will have overlapping geographic distributions (**Figure B1(b)**). These approaches have yielded mixed results, with signatures of allopatric speciation in some groups such as birds and mammals, and mixed results in groups such as phytophagous insects (Barraclough and Vogler, 2000). Despite the intuitive appeal of this approach, a number of significant criticisms have emerged (see Bolnick and Fitzpatrick, 2007; Warren *et al.*, 2014). For example, Losos and Glor (2003) argue that range shifts can be far too dynamic to be captured by this method. Indeed, range shifts associated with Pleistocene climatic fluctuations have likely produced frequent shifts between allopatry and sympatry across a timescale that is far too short for most speciation events (Fitzpatrick and Turelli, 2006). This method is also highly sensitive to the species concepts employed in taxonomic treatment of different groups. For example, sessile organisms with morphologically defined species may lead to the overprediction of allopatric speciation events. At best, this may therefore be a one-directional test, which should be interpreted with caution.

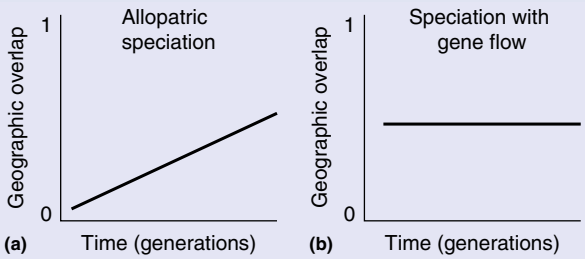

Figure B1 Age-range correlations examine the degree of geographic overlap between taxa over evolutionary time scales. (a) If allopatric speciation is common, geographic overlap should be low for the most recently diverged species pairs, and increase through time as ranges change. (b) If speciation with gene flow is common, geographic overlap may be high at the earliest stages, and post-speciation range shifts may stochastically impact geographic overlap.

allopatric speciation come from known geologic events that likely resulted in simultaneous allopatry for multiple species pairs. For example, as the Isthmus of Panama arose approximately 3 million years ago, many formerly contiguous marine species were completely isolated by this major geologic event. Several well-described examples of emerging species pairs exhibit additional forms of reproductive isolation, suggesting that speciation is either occurring or complete in many of these taxa (Knowlton *et al.*, 1997; Lessios, 1998).

Similarly, the highly isolated nature of oceanic islands provides ample opportunity for long distance colonists to diverge, either mostly or completely unimpeded by gene flow. These examples also illustrate the power and importance of geographic isolation to promote evolutionary divergence, with spectacular examples of island floras and faunas with extremely high rates of endemism (e.g., Amadon, 1950; Templeton, 1979). Further emphasizing the importance of spatial separation, *in situ* speciation on islands appears to be relatively rare (Coyne and Price, 2000). For example, Igea *et al.* (2015) find that among the 33 endemic plant species on the highly isolated Cocos Island, none are the result of *in situ* speciation, but rather result from mainland colonization and subsequent divergence.

Speciation with Gene Flow ($\sim 0 < m < 0.5$)

Speciation that occurs in the presence of recurrent gene flow faces significant constraints. Specific conditions may impact the probability of speciation with gene flow, such as polyploidy or homoploid hybrid speciation; however, these topics are covered elsewhere (Ramsey and Schemske, 1998; Abbott *et al.*, 2013). In recent years, genomic studies have helped illustrate the heterogeneous nature of genetic variation when divergence and gene flow occur simultaneously (Nosil *et al.*, 2009). Indeed, these studies have been instrumental in illustrating the maintenance of substantial phenotypic differentiation despite apparent introgression at neutral loci. However, others have demonstrated the need for caution in inferring patterns of gene flow and isolation from indirect evidence (e.g., Noor and Bennett, 2010; Cruickshank and Hahn, 2014), providing fodder for continued debate over whether the the current enthusiasm for divergence with gene flow is warranted (Coyne and Orr, 2004). Therefore, it is important to examine the theoretical and empirical support for speciation with gene flow critically.

Theoretical support for speciation with gene flow

As mentioned above, Felsenstein (1981) elegantly described the difficulties associated with divergence with gene flow due to the antagonism between selection and recombination. As a result, the subsequent theoretical work focuses on describing conditions that would overcome these difficulties (reviewed in Bolnick and Fitzpatrick, 2007; Gavrilets, 2003). For example, many theoretical models have been proposed that invoke pleiotropy or tight genetic linkage to prevent recombination (Ortiz-Barrientos *et al.*, 2002; Butlin, 2005; Bolnick and Fitzpatrick, 2007). For example, so-called 'one-allele' models describe situations such as Bush's (1969) *Rhagoletis*, whereby a single adaptive allele simultaneously impacts fitness on a new resource and assortative mating (Ortiz-Barrientos and Noor, 2005). Critics have labeled these 'magic' traits; however, others suggest this may be more common than expected (Servedio *et al.*, 2011). Models of speciation with gene flow that incorporate two or more loci are perhaps more realistic, and they demonstrate increased difficulty for the process. When recombination can breakup emerging associations, speciation with gene flow requires the strength of selection to be very strong or genetic loci involved to be very closely linked (**Figure 3**). However, in considering migration as a continuum, varying amounts of migration will alter the probability of speciation in emerging taxa. Low, but nonzero values of migration may often be surmountable, and the strength of selection or the degree of genetic association will have a positive impact on the potential for speciation (**Figure 3(b)**).

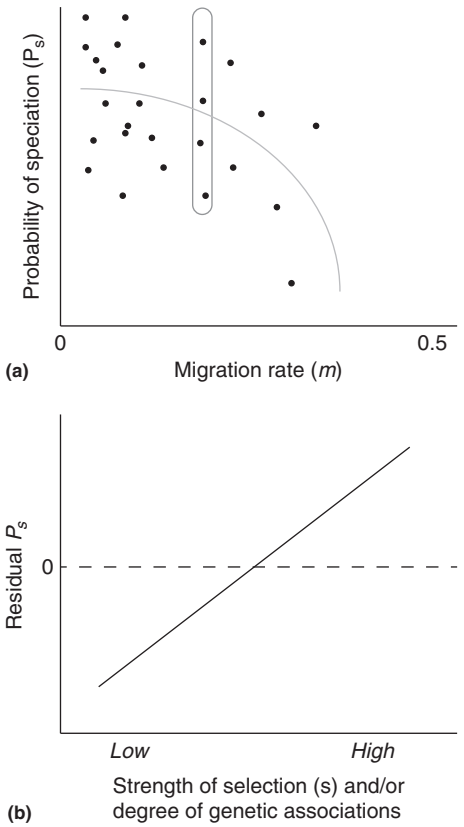

Figure 3 Factors impacting speciation in the face of gene flow. (a) Increasing migration will generally impede speciation, with higher rates of migration impeding divergence with gene flow. Residual variation in the probability of speciation is shown by the gray oval. (b) Two of the key factors impacting speciation in the face of gene flow are the strength of selection and the degree of genetic associations between loci involved in local adaptation and assortative mating. Residual variation in speciation probability is expected to have a positive relationship with these factors. For example, strong selection will facilitate speciation for a given degree of migration.

Empirical support for speciation with gene flow

The most common forms of evidence proposed for cases of speciation with gene flow comes from isolated environments

that are unlikely to provide the conditions of allopatry (Coyne and Orr, 2004; Bolnick and Fitzpatrick, 2007). While it may be impossible to determine the previous rate of migration between emerging taxa in these conditions, the geographic structure of isolated environments suggests that migration between groups was initially high before reproductive isolation emerged. Undeniably, it is often very difficult to unambiguously rule out periods of allopatry from any putative case of speciation with gene flow (see **Box 2**), but these cases provide some of the most compelling candidates. Examples have been proposed in fish species flocks inhabiting isolated lakes (Schliewen *et al.*, 1994) or plants on isolated islands (Savolainen *et al.*, 2006). For example, on Lord Howe Island, a species pair of palm trees occurs in sympatry on this remote oceanic outcrop (Savolainen *et al.*, 2006). These trees appear to be capable of hybridizing, but habitat and temporal isolation are strong enough to maintain these distinct taxa in nature. Interestingly, in contrast to the Cocos Island example above, Lorde Howe Island appears to have a relatively high rate of *in situ* speciation, suggesting that this island may provide unique conditions favoring divergence with gene flow (Papadopulos *et al.*, 2011).

While these examples appear compelling, a number of issues prevent ruling out an impact of geographic isolation completely. First, multiple invasion events from a source taxon may facilitate divergence (Gray and Cavers, 2014). For example, the first colonists to reach an island may establish a population and begin to diverge from the progenitor. If a second group of colonists arrive later, their success may depend on establishing in a different habitat from the original colonists. Even low levels of hybridization between the two groups could make them appear to be each other's closest relative, and the ecological character displacement that occurs due to competition may produce two stably differentiated taxa (Schluter and McPhail, 1992). Another issue with putative cases of divergence with gene flow is the potential for standing genetic variation to impact divergence (Seehausen, 2002). For example, in Bush's *Rhagoletis* fruit flies, a chromosomal inversion that arose in allopatry may explain how recombination is prevented between coadapted allele combinations (Feder *et al.*, 2005). Sympatric divergence may not be possible without this inversion, so this appears to be a case where the lines between sympatric and allopatric speciation are blurred.

Indeed, the most interesting speciation events may involve a mixture of processes in both geographic isolation and in sympatry (e.g., Heliconius Genome Consortium, 2012; Martin *et al.*, 2015; Stankowski and Streisfeld, 2015). Mayr's notion of parapatric speciation, with taxa exhibiting abutting ranges, represents just one simple case where gene flow may be high in some regions and low in others. For example, Mallet *et al.* (2009) describe 'mosaic sympatry' in which patchy alternative habitats for diverging taxa produce a mix of physical isolation and contact. Host shifts, as in phytophagous insects may represent one relatively common example of this form of divergence (Nosil, 2007). In plants, edaphic specialization is similarly a process that must commonly begin in sympatry, and produces a patchy arrangement of contact and isolation between diverging taxa (Kay *et al.*, 2011). Fluctuations in geographic range through time may also result in contact and gene flow in some periods, and extensive physical separation

Box 2 Difficulty in distinguishing primary from secondary contact

While speciation with gene flow and allopatric speciation are debated as opposite ends of the spectrum in the geography of speciation, they can be surprisingly difficult to diagnose from patterns of genetic variation (Noor and Bennett, 2010; Cruickshank and Hahn, 2014). In the traditional view of allopatric speciation, adaptive alleles that arise in each emerging species will become differentially fixed, and other loci in linkage disequilibrium with these causal mutations will follow suit (Via and West, 2008). Genetic drift is also expected to result in differential fixation of alleles in each taxon, and many loci across the genome are expected to be highly differentiated (Via, 2001). **Figure B2(a)** shows an example of allopatric speciation. The lower panel represents genetic differentiation with selected loci (solid black line) and other regions throughout the genome (dashed black line). Alternatively, if two taxa emerge in the face of gene flow, adaptive alleles are expected to become highly differentiated, while the rest of the genome exhibits weak patterns of differentiation (lower panel **Figure B2(b)**). This dichotomous view rests on two assumptions: (1) allopatric divergence will be complete before the establishment of secondary contact ('stable coexistence of discontinuous taxa'), and (2) many shared polymorphisms at the initiation of speciation will be lost during the allopatric phase. Secondary contact followed by even small amounts of gene flow may homogenize nonadaptive loci (gray dashed line and arrows), and shared polymorphisms that remain from the progenitor population may also resemble the pattern expected for divergence with gene flow.

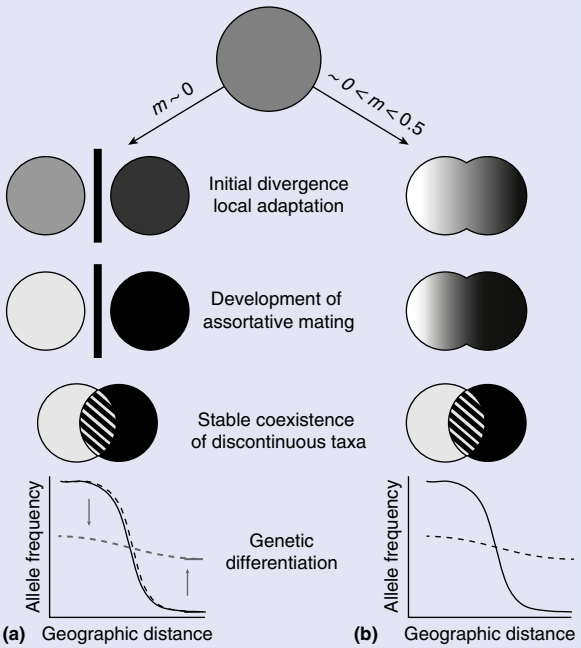

Figure B2 Primary and secondary contact between diverging lineages may produce similar genomic signatures. (a) Two taxa become highly differentiated in allopatry and are maintained after secondary contact despite hybridization. Allopatric divergence impacts all loci simultaneously, but secondary contact results in homogenization of neutral regions of the genome (arrows and dashed lines), while selected loci remain differentiated (solid line). (b) Two taxa arise via divergence with gene flow. Selected loci show strong levels of differentiation (solid line), while neutral loci will be more freely exchanged (dashed line).

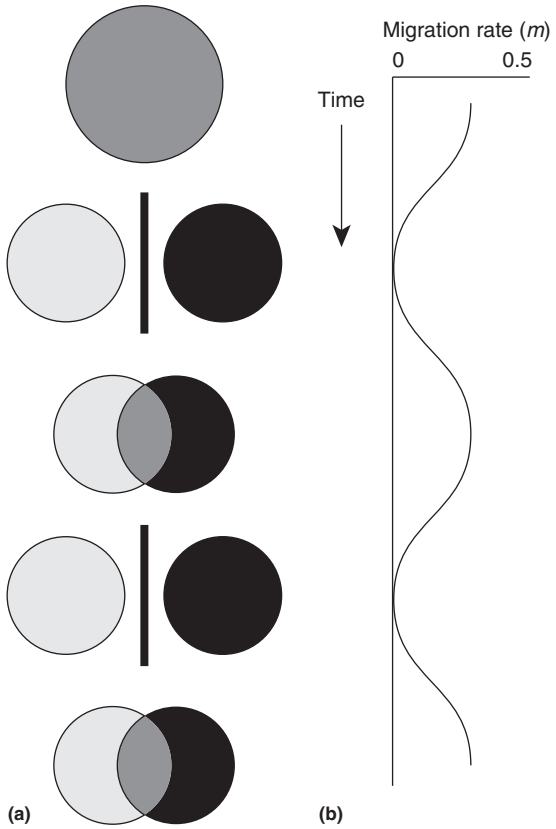

Figure 4 Fluctuating geographic context of speciation. (a) Through time physical barriers may arise and recede repeatedly during the speciation process. (b) Migration rates fluctuate as physical barriers rise and fall. These cases represent a mosaic of allopatric and sympatric factors influencing the potential for divergence.

in others (Butlin *et al.*, 2008; **Figure 4**). While these cases fit into the category of divergence with gene flow, physical separation also plays a key role.

Sources of Geographic Isolation

Given the importance of spatial separation to both purely allopatric speciation and many presumed cases of speciation with gene flow, it is instructive to examine the source of spatial separation in examples besides vicariance. Indeed, while Mayr and others refer to geographic isolation as a purely external factor, the degree to which geographic features impact gene flow is the result of the interaction between biological traits of organisms and the landscape they are found in. For example, the biology of organisms may determine dispersability, which can be highly variable across species. Therefore, whether reaching an isolated habitat represents a rare long distance dispersal event or a frequent stopover may depend on intrinsic characters as well as extrinsic factors. Similarly, the geographic ranges that organisms occupy represent the simultaneous outcome of historical, biological, and geographic factors (Endler, 1982; Thorpe *et al.*, 2008). Therefore, studies of speciation have much to be gained by examining the interaction between biology and geography.

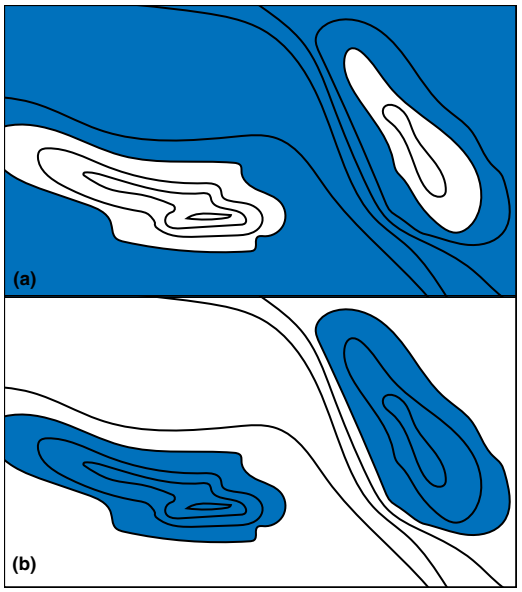

Figure 5 Niche conservatism leads to geographic isolation. (a) A hypothetical topographic map of a region with species range indicated in blue. (b) During periods of climatic warming, niche conservatism leads to range contraction of the previously contiguous species into higher elevations. Thus, retaining niche characteristics can lead to an increase in geographic isolation when suitable habitat becomes spatially constricted.

Niche conservatism

Niche conservatism refers to the notion that ecological niches are likely to experience phylogenetic inertia, and change somewhat slowly (Wiens and Graham, 2005). While it may seem paradoxical to consider how a lack of change in the niche can impact divergence between species, niche conservatism is hypothesized to impact the initial development of allopatry in some cases (Kozak and Wiens, 2006). Climatic fluctuation may change the arrangement of suitable habitat across a landscape over time, resulting in variation in the interconnectedness of habitats. If populations retain their ecological tolerances via niche conservation, they may migrate in order to seek conditions consistent with their retained niche. This can potentially result in increases in allopatric separation between previously connected populations. For example, in mountainous regions, contiguous lowland populations could be driven to higher elevations during periods of climatic warming, producing allopatric separation (**Figure 5**). Although biological differences must accumulate between populations to initiate speciation (Sobel *et al.*, 2010), geographic isolation via niche conservatism may play an important role in facilitating subsequent divergence.

Ecogeographic isolation

In direct contrast to niche conservatism, adaptations to the abiotic or biotic environment may produce shifts in the ecological tolerances of populations, leading to niche divergence (**Figure 6**). Shifts in ecological niche between lineages may have concurrent impacts on the geographic distribution of taxa when alternate suitable habitat is spatially disjunct across the landscape (Sobel *et al.*, 2010). The reduction in gene flow that

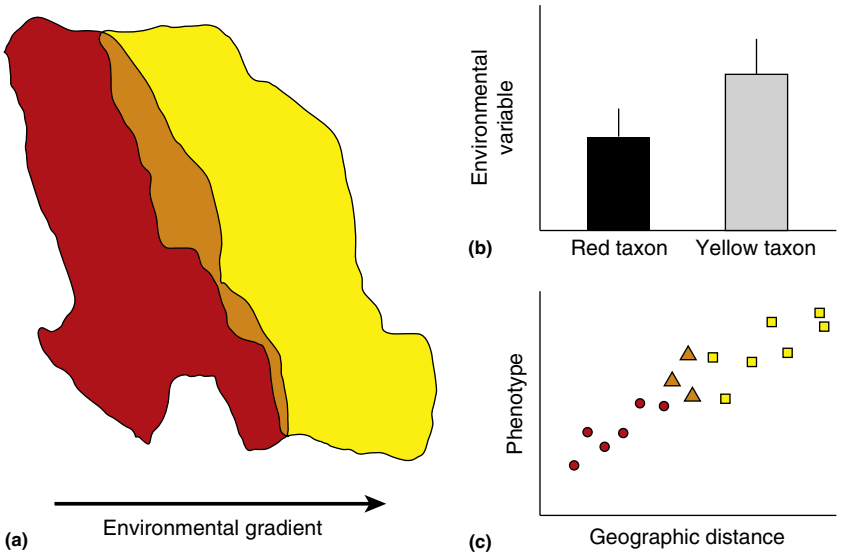

Figure 6 Ecogeographic isolation as a result of niche divergence. (a) Species distribution modeling shows a nonrandom arrangement of suitable habitat for a red and yellow sister taxon pair along an environmental gradient. Ecogeographic isolation is strong but incomplete with a hybrid zone formed where the ranges meet. (b) Environmental variables exhibit significant differences at sites occupied by the two taxa. (c) Ecophysiological phenotypes vary across space, verifying the presence of ecogeographic isolation.

occurs by this process is referred to as ecogeographic isolation (Ramsey *et al.*, 2003; Sobel *et al.*, 2010). The phenotypes involved can be thought of as so-called 'magic traits' from the point of view of divergence with gene flow (Servedio *et al.*, 2011), because local adaptation may simultaneously produce multiple forms of reproductive isolation including assortative mating, immigrant inviability (Nosil *et al.*, 2005), and extrinsic postzygotic inviability (Hatfield and Schluter, 1999).

Ecogeographic isolation can be measured in a variety of ways. In one approach, species distribution modeling (SDM) can be employed to predict biological differences between taxa, and ecogeographic isolation is estimated from the overlap and exclusivity of predicted suitable habitat for each taxon (Sobel, 2014). These models are built using a combination of remote sensing data of environmental conditions and population collection records from museums or herbaria (Elith and Leathwick, 2009). As such, SDMs can be used to reveal differences in the environmental conditions experienced by a pair of taxa, but it does not directly measure ecological differences between them (Warren *et al.*, 2014). The most powerful approach to assess ecogeographic isolation is therefore to measure biological differences between emerging taxa that impact geographic distributions, either by reciprocal transplant experiments (Angert and Schemske, 2005) or via variation in ecophysiological traits (Sheth and Angert, 2014). Local adaptation and clinal variation are well documented in a variety of organisms (Clausen *et al.*, 1940). Therefore, it is perhaps not surprising that ecogeographic isolation appears to be strong in the groups that have been examined (Sobel, 2014).

Conclusions

The topic of the geography of speciation has been marked by fierce debate over whether full geographic isolation is required to initiate the process. The history of the debate goes back at least to Darwin, and survives to this day. We now have empirical examples and theory that suggest the conditions for speciation with gene flow may sometimes be satisfied in nature; however, we will probably never know what frequency of speciation events that occur in allopatry or in contact. However, even in our most compelling cases of speciation with gene flow, geographic isolation may continue to play a crucial role. Therefore, speciation studies are likely to benefit from continued focus on the processes that produce spatial separation, and the topic of the geography of speciation is far from outliving its utility.

Speciation, Sexual Conflict and

JJ Ting and AD Cutter, University of Toronto, Toronto, ON, Canada

Glossary

Chase away model The evolution of exaggerated secondary sexual characteristics through sexually antagonistic coevolution.

Interlocus sexual conflict Occurs when the expression of a locus in one individual compromises the fitness of its mate with expression of different loci acting to counteract the negative effects. One possible outcome is sexually antagonistic coevolution.

Intralocus sexual conflict Occurs when the same combination of alleles exert opposite effects on fitness when expressed in a male versus a female.

Reproductive isolation Any factor that restricts gene flow to produce independently evolving populations that, in the extreme, yields distinct species. Barriers may act prior to mating (premating isolation), after mating but prior to zygote formation (premating, prezygotic isolation (PMPZ), gametic isolation), or after zygote formation (postzygotic isolation).

Sexually antagonistic coevolution A possible outcome of interlocus sexual conflict whereby selection on one sex favors reproductive traits that induce a fitness cost on its mates. Selection on the mate, in response, favors evasive adaptations to reduce the negative effects, leading to a cycle of male and female trait evolution.

Sexual conflict Differing optimal reproductive strategies of sperm donor and recipient individuals that induces opposing selective pressures on the sexes.

What is Sexual Conflict?

The kernel of the idea that those traits shared between the sexes can experience different fitness optima in each sex – sexual conflict – traces to Darwin (1871), and yet reproduction was, nevertheless, widely viewed as an entirely cooperative endeavor prior to the 1970s. As we now recognize, the fitness interests of mating partners are seldom harmonious in all aspects of the 'economics' of reproduction (Parker, 1979), and instead, male and female reproductive interests often conflict. The fundamental root of conflicting interests between the sexes lies in the production of different sized gametes (anisogamy): smaller male gametes (sperm) essentially parasitize the larger, resource-rich female gametes (eggs) (primordial sexual conflict: Parker *et al.*, 1972; Parker, 1978). This asymmetry in gametic investment in reproduction sets the stage for further layers of conflict to arise between males and females in any traits that elevate the reproductive success of one sex at the expense of the other. Students of sexual selection now apply the term 'sexual conflict' to these disparities between the sexes in their fitness interests, the resulting selective pressures, and evolutionary responses (Parker, 1979; Arnqvist and Rowe, 2005).

Sexual conflict is widespread across taxa (Arnqvist and Rowe, 2002), with conflict over parental investment taking many forms, including mating rate (Rice and Holland, 1997; Holland and Rice, 1998; Rice *et al.*, 1998), sperm selection by females (Ball and Parker, 2003), and epigenetic control of development (Rice *et al.*, 2012). These antagonistic interactions between the sexes contrast with exaggeration of secondary sexual traits through other forms of sexual selection that involve female preference and male–male competition. Rapid nonantagonistic trait evolution mediated by Fisher's (1930) runaway selection model or Zahavi's (1975) handicap 'good genes' hypothesis can contribute to interpopulation divergence and the evolution of reproductive isolation. Likewise, evolutionary responses to sexual conflict also can promote trait exaggeration, via the chase away model involving sexually antagonistic coevolution (Holland and Rice, 1998), to produce population divergence and speciation in a manner potentially even more potent than other modes of sexual selection (reviewed in Gavrilets, 2014). Distinguishing sexual conflict from other forms of sexual selection, however, remains a challenge (Rowe and Day, 2006).

Sexual conflict generates sexually antagonistic selection that discriminates among heritable variation in male traits and in female traits (Rice, 1984), whereby selection favors one trait value to maximize the reproductive success of one sex and a different trait value for the other sex. For example, more numerous matings typically will improve male reproductive success disproportionately greater than female reproductive success because female reproductive output often is limited by total offspring production, independent of the number of matings (Bateman, 1948). Consequently, selection will favor alleles that confer on males a propensity to mate numerously and promiscuously, as well as favoring alleles that enable females to engage in few, select 'high-quality' matings. This tension can lead to the evolution of mating rates that are suboptimal from the point of view of one or both sexes, or can instigate coevolutionary arms races in traits that influence the balance of sexual costs and benefits for each sex (Arnqvist and Rowe, 2005). The roles of which sex inflicts and receives disproportionate fitness costs depend on the organism and its stage in the coevolutionary process, sometimes with females inflicting higher fitness costs on males (e.g., sexual cannibalization of male mantids: Lelito and Brown, 2006) or vice versa (e.g., traumatic insemination of female bedbugs: Stutt and Siva-Jothy, 2001). However, sexual conflict need not necessarily result in harmful behavior, nor is harm a required feature for sexually antagonistic coevolution to occur (see Rowe *et al.*, 2005; Lessells, 2006).

The vocabulary employed for concepts in sexual conflict are tailored toward organisms with distinct and separate sexes

 doi:10.1016/B978-0-12-800049-6.00071-8

(gonochorism or dioecy: see Schärer *et al.*, 2014). However, sexually antagonistic selection also occurs in hermaphroditic mating systems, which provided some of the first observations and insights into sexual conflict (Charnov, 1979). Recently, Schärer *et al.* (2014) defined and clarified the nuances of sexual conflict theory in hermaphrodites in order to bring attention back to them as powerful examples of sexual conflict, coming from simultaneously hermaphroditic organisms in which an individual expresses both sexes at the same time, such as the 'love dart' in snails (Koene and Schulenburg, 2005), as well as from sequential hermaphrodite species in which a single individual changes from one sex to the other over time (reviewed in Abbott, 2011). Given that hermaphroditism is taxonomically widespread, with ~70% of animal phyla and >90% of plant genera containing hermaphrodite representatives (Renner and Ricklefs, 1995; Jarne and Auld, 2006), neglecting sexual conflict in hermaphrodites could impede progress toward deciphering general principles and implications of sexual conflict for the production of biodiversity (Schärer *et al.*, 2014). The dual connections of evolutionary transitions in reproductive mode with speciation itself (Goldberg and Igić, 2012) and with shifts in the cost-benefit structure of sexual conflict suggest that consideration of both of these factors simultaneously might prove fruitful in discerning the driving forces in species diversification.

Despite the prevalence of circumstances like multiple mating and sex chromosomes that are conducive to sexual conflict across organisms (Charlesworth, 1991; Zeh and Zeh 1996, 1997; Baur *et al.*, 1998; Michiels *et al.*, 1998; Jennions and Petrie, 2000), sexual conflict is unlikely to provide a prominent selective pressure in several key types of systems. In particular, organisms with reproductive modes dominated by asexuality and parthenogenesis, extremely high self-fertilization, and true monogamy should severely limit the extent to which sexual conflict can contribute to evolutionary change. For example, species with true lifelong genetic monogamy, such that mating with other individuals is not possible for either sex, display completely codependent reproductive success for the two sexes and so escape most sexual conflict (Wedell *et al.*, 2006); any strategy that decreases partner fitness will simultaneously reduce self-fitness, and consequently be opposed by selection. The extreme rarity of monogamy in animals has led to doubts about the existence of this ideal in nature (Birkhead, 1997; Wedell *et al.*, 2006; Hosken *et al.*, 2009b), although asexual and selfing reproduction arise commonly in both plants and animals (Jarne and Charlesworth, 1993).

How Can Sexual Conflict Promote Speciation?

Speciation results from the accumulation of genetic divergence between populations, which fosters the evolution of reproductive isolation. As populations evolve independently, incompatibilities amass and manifest as mismatches in mating behaviors or morphologies, ecological preferences, postmating gametic interactions, or as fitness deficiencies in genetically admixed, hybrid individuals. Sexual selection on mating traits can drive them to diverge rapidly from preexisting genetic variability, but the distinctiveness of such daughter populations may be temporary as they are susceptible to subsequent fusion (Servedio and Bürger, 2014). Similarly, while extrinsic genotype-by-environment interactions can represent a powerful selective pressure to restrict gene flow, transience of environmental conditions can collapse multiple nascent species back into a single evolutionary unit (Seehausen *et al.*, 2008; Futuyma, 2010). While such ecological speciation is most typically framed in terms of divergent local adaptation (Rundle and Nosil, 2005), modulation of the strength of sexual selection by ecological conditions could influence population divergence under sexual conflict in a similar way under some circumstances (Seehausen *et al.*, 1997). By contrast, a permanent reproductive barrier to enforce restricted gene flow evolves when population divergence involves new, derived alleles that create genetically intrinsic reproductive isolation by way of reduced viability or reproductive success of hybrid offspring, for example, via Dobzhansky–Muller incompatibilities affecting development or behavior (Dobzhansky, 1937; Coyne and Orr, 2004; Gavrilets, 2004). Rapid coevolution that results from sexually antagonistic selection provides an intuitively appealing way to explain how trait divergence can foster the production of new reproductively isolated populations or maintain restricted gene flow between nascent species that originated from other evolutionary circumstances.

Sexually antagonistic coevolution has the potential to provide a more potent and rapid source of interpopulation divergence compared to other forms of intersexual selection such as female mate-choice or assortative mating (Panhuis *et al.*, 2001; Kirkpatrick and Ravigné, 2002). A perpetual arms race between the sexes that follows from sexually antagonistic coevolution can bring about rapid and potentially limitless evolutionary change (Parker, 1979), for example, through iterated female evolution of resistance adaptations in response to male persistence adaptations. By comparison, other forms of intersexual selection typically involve an evolutionary response in female preference favoring an exaggerated male trait rather than resistance to an exaggerated male trait. The evolutionary tethering of the expression of female preference to those male traits that provide an indirect or direct benefit to females leads to trait responses constrained within the scope of females' ability to perceive them (Fisher, 1930; Berglund *et al.*, 1996). By contrast, female evasion of male traits under antagonistic coevolution, rather than trait tracking, creates more opportunity for the evolution of novelty and, subsequently, population divergence in allopatry (Gavrilets, 2000; Gavrilets *et al.*, 2001; Martin and Hosken, 2003) or even in sympatry (Gavrilets and Waxman, 2002). Sexually antagonistic coevolution also predicts the evolution of multiple male traits under a wide range of conditions (Arak and Enquist, 1995; Gavrilets *et al.*, 2001) and a greater number of genetic trajectories for the sexes and populations to pursue, resulting both in rapid exaggeration and diversification (Gavrilets, 2000). In some cases, such sexual traits could be co-opted for ecological innovation and provide the basis for divergent natural selection and so indirectly contribute to the origin of new species (Bonduriansky, 2011).

It is straightforward to see how gene flow may be disrupted in early stages prior to mating or in later stages after zygote formation: easily observable traits like species-specific

courtship songs in birds (Grant and Grant, 2010) and sterile hybrids in *Drosophila* (Masly *et al.*, 2006) provide compelling and clear-cut bases of reproductive isolation. By contrast, reproductive barriers that occur midway through the reproductive process at the gametic level – following mating, but prior to zygote formation, termed postmating, prezygotic reproductive (PMPZ) barriers – can involve phenotypically subtle but reproductively crucial divergence, owing to coevolution between the gametes or between the female reproductive tract and the sperm or components of the seminal fluid (Eady, 2001). As we discuss the ways that sexually antagonistic selection can participate in the speciation process, one must consider the potential for evolution of reproductive isolation to manifest through any of these phases: premating barriers, PMPZ incompatibilities, and postzygotic isolation.

The Dual Genetic Bases of Sexual Conflict

Two genetic pathways can produce sexual conflict, whereby sex-specific selection can occur between different loci (interlocus conflict) or within a locus (intralocus conflict). Interlocus conflict can induce an evolutionary arms race between the sexes, while intralocus conflict results in an evolutionary tug-of-war for each sex to reach their own fitness optimum. Both modes may derive from either simple (one- or two-locus systems) or complex (polygenic, quantitative genetic) genetic architectures. Below we differentiate between the two types of sexual conflict and discuss how each can facilitate, or restrain, the process of speciation.

Interlocus Conflict and Speciation

Conflict over the outcome of male–female interactions that are mediated by genetic factors encoded with different loci is known as interlocus sexual conflict. Conflicts between the sexes can occur over a diversity of traits, with commonly considered traits including mating rate, parental investment, remating behavior, and female reproductive rate. Different traits encoded by loci with sex-biased expression in each sex enable males and females to reach their sex-specific fitness optima in a given intersexual context (Rice *et al.*, 1998). As the intersexual context changes, interlocus conflict can drive continuous selective pressure for allelic replacement at the interacting loci in both sexes (Rice and Holland, 1997). Such recurrent conflictual selection will potentially spur a sexually antagonistic coevolutionary arms race between one set of loci that confers benefits to one sex at the expense of the other sex, and a distinct set of loci that control responding traits in the alternative sex. If given the opportunity for a male trait and female response to coevolve under sexual conflict, 'unresolvable evolutionary chases' might result, whereby neither sex reaches their optima (Parker, 1979). Under such conditions, sexually antagonistic coevolution can promote rapid evolutionary change (Parker, 1979).

Such a perpetual arms race that involves multiple loci promotes divergence between separated populations that evolve along independent evolutionary trajectories of trait change and counter-change (Rice, 1996; Rice and Holland, 1997; Holland and Rice, 1998; Rice *et al.*, 1998; Chapman *et al.*, 2003). When new mutations arise with sex-limited expression at sexually antagonistic loci subject to interlocus conflict, selection in one sex will favor their fixation and the same allele will be selectively neutral when it occurs in the other sex. Consequently, iterated over time, sex-limited selection can lead to repeated fixation of new sexually antagonistic alleles. Allopatric divergence accrues between populations as their trait evolution traces independent genetic trajectories, with coevolution driving distinct genotypic solutions to ongoing sexual conflict involving sex-biased adaptations and counter-adaptations. Because any source of evolutionary divergence, especially divergence involving new derived mutations (Orr, 2005), will increase the probability of genetic incompatibilities arising that could impede gene flow between populations, an interlocus genetic basis to sexual conflict can facilitate speciation (Rice *et al.*, 1998).

A perpetual arms race between the sexes represents just one possible evolutionary outcome of interlocus sexual conflict predicted by theory (reviewed in Gavrilets, 2014). Another possibility is the accumulation of many alleles at loci expressed in each of the sexes (Gavrilets and Hayashi, 2005; Härdling and Bergsten, 2006; Hayashi *et al.*, 2007; Härdling and Karlsson, 2009), that can potentially lead to sympatric speciation (Gavrilets and Waxman, 2002; Hayashi *et al.*, 2007). Other evolutionary outcomes of interlocus sexual conflict can generate elevated genetic variation in the population, but not facilitate formation of new species (Gavrilets, 2014), such as evolution toward an equilibrium (Kondoh and Higashi, 2000; Gavrilets *et al.*, 2001; Kimura and Ihara, 2009), and cyclic evolutionary dynamics (Gavrilets *et al.*, 2001; Haygood, 2004). Additionally, stochastic perturbations like genetic drift have the potential to switch the attracting evolutionary regime expected by deterministic theory (Gavrilets and Hayashi, 2005; Hayashi *et al.*, 2007). An alternative outcome to sexually antagonistic coevolution is that females can evolve indifference to male traits rather than resistance, and in extreme cases may select against these traits (Rowe *et al.*, 2005). The indifference that females express to male traits could halt the coevolutionary process, thus preventing further divergence that would otherwise facilitate the speciation process (Rowe *et al.*, 2005).

Intralocus Conflict and Speciation

Intralocus sexual conflict, as a mode of sexually antagonistic selection, favors alternative alleles at the same locus differentially between the sexes and generally acts as a force promoting maintenance of genetic variation (Rice and Holland, 1997; Parker and Partridge, 1998). In intralocus sexual conflict models with a one-locus two-allele genetic system, the strength of selection determines the evolutionary outcome: whether a population reaches an evolutionary compromise between the sexes or, instead, the population reaches an equilibrium that optimizes the fitness of only one sex (reviewed in Gavrilets, 2014). With a polygenic trait subject to intralocus sexual conflict owing to a sex-by-genotype interaction, the same combination of alleles exert opposite effects on the fitness of each sex (Fisher, 1930; Lande, 1980). The resulting conflicting

selection acting to produce an optimal phenotype in males thus, collaterally, impedes selection for the optimal phenotype in females (Rice, 1996). This scenario results in an evolutionary tug-of-war in which neither the male nor female trait value might obtain their sex-specific optima, owing to the evolution of an intermediate phenotype for both sexes and maintaining genetic variation for the trait in both sexes.

Importantly in the context of speciation, this tendency of intralocus sexually antagonistic selection to maintain polymorphism, rather than to drive individual alleles to fixation, will retard the accumulation of divergence between populations. Consequently, we should expect this genetic architecture of sexual conflict to impede, or at least not facilitate, the speciation process. However, sexual antagonism via intralocus conflict might not be able to maintain genetic variation effectively at more than a very small number of loci (Turelli and Barton, 2004), suggesting that the scope for intralocus conflict to constrain divergence might have been overstated in extrapolations of single-locus models unless epistasis among intralocus conflict loci is pervasive (Arnqvist *et al.*, 2014). Intralocus conflict also can impede divergence between populations by interfering with coevolutionary dynamics mediated by interlocus conflict (Pennell and Morrow, 2013). Nevertheless, intralocus sexual conflict could promote speciation when one sex experiences sufficiently strong directional selection, as it could drag traits expressed in the other sex across sex-specific maladaptive troughs of fitness, potentially fostering formation of new species (Bonduriansky and Chenoweth, 2009). Also, interestingly, epistasis among loci that each experience intralocus conflict can lead to 'equity effect' allelic fixation at different loci that could contribute to population divergence if different allele combinations fix in different populations (Arnqvist *et al.*, 2014), though it is unclear whether secondary contact of divergent populations might simply resurrect the sexual conflict rather than contribute to reproductive isolation between them.

Resolutions to intralocus sexual conflict can evolve that alleviate the selection pressure for maintenance of alternative alleles at a locus that confer sex-limited costs and benefits. Specifically, translocation mutations of loci to a sex chromosome, regulatory mutations that induce sex-limited expression, gene duplication that permits each gene copy to evolve to sex-specific fitness optima, or genetic imprinting can all provide evolutionary routes to eliminate intralocus conflict (reviewed by Bonduriansky and Chenoweth, 2009; Stewart *et al.*, 2010). The consequences of such evolutionary solutions to intralocus sexual conflict, however, might then themselves foster the evolution of reproductive isolation, as the resulting genetically decoupled male and female trait evolution respond independently to selection (Parker and Partridge, 1998; Pennell and Morrow, 2013). For example, when the evolution of sex-specific gene expression resolves intralocus conflict to create sexual dimorphism in a trait like body size, further selection on dimorphism can drive diversification whereby the dimorphic population can access and exploit previously inaccessible resources (De Lisle and Rowe, 2015). Moreover, as the sexes evolve independently, exaggeration of a male trait to an extent that it compromises female fitness could then spark a sexually antagonistic coevolutionary arms race via interlocus conflict. For example, genes with different expression between males and females (sex-biased genes), especially for paralogous copies of duplicates, could represent the resolution of intralocus sexual conflict (Wyman *et al.*, 2012; Ingleby *et al.*, 2015), as there can be rapid turnover in sex-biased gene expression (Harrison *et al.*, 2015). In this circuitous manner, the resolution of intralocus sexual conflict might ultimately predispose populations to evolution by interlocus conflict and lay the genetic groundwork for interpopulation divergence (Pennell and Morrow, 2013).

In turn, the independent evolution of separated populations for such evolutionary resolutions to sexual conflict, involving unique genetic causes, would provide the raw substrate for forming genetically intrinsic reproductive incompatibilities through Dobzhansky–Muller interactions in hybrid individuals (Orr, 1995). As a by-product of hybrid genetic incompatibilities, female choosiness in selecting mates might promote premating isolation under secondary contact that could subsequently evolve to an exaggerated extent by reinforcement or reproductive character displacement (Servedio, 2001). Because sexually antagonistic genes might contribute much of the genetic variation in fitness within a population, these loci offer plausible substrates for divergent selection to generate intrinsic incompatibilities between emerging species (Gavrilets, 2014).

How Can the Genetic Architecture of Sexually Antagonistic Selection Impact Evolutionary Responses?

Interlocus conflict provides a more effective potential source of population divergence and reproductive isolation than does intralocus conflict (Gavrilets, 2014). Such disparity between these two genetic modes of sexual conflict arises because of the tendency for intralocus selection to maintain polymorphism, rather than to drive allelic fixation, and for interlocus conflict to generate coevolutionary arms races between alleles with sex-biased expression at different loci. These conclusions ought to hold true regardless of the simplicity (one or two loci situations) or complexity (polygenic, quantitative genetic situations) of the genetic architecture of sexually antagonistic loci (Gavrilets, 2014), with the caveat that polymorphism maintenance via intralocus conflict for polygenic traits might not be stable in the absence of epistasis (Turelli and Barton, 2004; Arnqvist *et al.*, 2014). Whether sexually antagonistic selection operates primarily on standing genetic variability or on new mutations also represents a critical determinant of the potential for sexual conflict to generate irreversible constrictions on gene flow between populations. Responses to selection will always be more rapid when genetic differences are immediately available, meaning that trait divergence can accumulate especially quickly. But such rapid shifts in trait means from selection on additive genetic variation may easily be undone (Servedio and Bürger, 2014). The persistence of divergent populations as genetically distinguishable entities requires that barriers to hybridization are not leaky, and it is genetically intrinsic reproductive incompatibilities from new mutations that are more likely to enforce restricted gene flow even in the face of mating between nascent species, owing to irreversible hybrid dysfunction. Given that new mutational input might be

a rate-limiting step, even for conflict loci for which selection greedily favors novel alleles, it remains a challenging problem to assess the importance of distinct contributors to the genetic architecture of sexual conflict in the accretion of enduring divergence.

What Signatures of Sexual Conflict Reveal Its Influence on Speciation?

It remains a pernicious challenge to discriminate evolution by sexual conflict from other modes of sexual selection (Rowe and Day, 2006), making it especially difficult to demonstrate empirically an association with speciation. Compelling examples of rapid genetic changes in experimental populations owing to sexual conflict nevertheless do not generally make direct links to diversification and the accumulation of reproductive isolation (e.g., mating rates in *Drosophila*: Rice, 1996; Holland and Rice, 1999; Pitnick *et al.*, 2001a,b; Rice *et al.*, 2005). Despite a few examples illustrating proof of principle (but see Martin and Hosken, 2003; Hosken *et al.*, 2009a), given the inability of laboratory evolution to mimic natural conditions (Arbuthnott *et al.*, 2014) and other studies failing to demonstrate divergence coupled to reproductive isolation (e.g., Wigby and Chapman, 2006; Gay *et al.*, 2009; Gagnon and Turgeon, 2011), it remains unclear empirically how broadly antagonistic coevolution might apply to the speciation process.

An alternative to experimental evolution for inferring processes of male–female coevolution and their influence on speciation is to conduct interpopulation or interspecies crosses and examine traits indicative of reproductive isolation, such as mating rate, offspring production, and survivorship (Parker and Partridge, 1998; Andrés and Arnqvist, 2001). Genital structures evolve most rapidly and divergently by intersexual selection as genitalia typically differ, even between closely species (Arnqvist, 1998, reviewed in Hosken and Stockley, 2004). In particular, the male genitalia of *Drosophila* varies across the genus (Bachli and Vilela, 2002), within the *Drosophila melanogaster* species subgroup (Yassin and Orgogozo, 2013), and even within a natural population (Andrade *et al.*, 2009). Sexually antagonistic coevolution can explain why male genitalia are divergent between some species of *Drosophila* (Kamimura and Mitsumoto, 2012), but not all (see Eberhard and Ramirez, 2004). For example, females of *Drosophila yakuba* have coevolved structures (cavities with sclerotized platelets) to minimize infection risk caused by wounding with sclerotized spikes on the male genitalia (Kamimura, 2012), in contrast to females from the sister species *Drosophila santomea* that lack these cavities, as they have coevolved with males with rounded genitalia (Kamimura, 2012). Interspecies matings revealed enhanced mating costs from the risk of microbial infection, owing to genital mismatch and indicating sexually antagonistic coevolution within each species. Similarly, interspecies matings of *Caenorhabditis* nematodes revealed dramatic fitness costs, manifesting as sterilization and premature death to maternal nematodes (Ting *et al.*, 2014). Gametic barriers to fertilization define a potent contribution to reproductive isolation between *Caenorhabditis* species, mediated by heterospecific male sperm that induce the harmful effects by displacing conspecific sperm and by mislocalizing within the maternal gonad and to nonreproductive tissues (Ting *et al.*, 2014). The findings implicate a role of sexually antagonistic coevolution whereby female resistance adaptations to aggressive sperm evolved along different trajectories in different species. However, it remains unclear whether conflictual selection might have occurred during speciation per se or after other drivers of reproductive isolation had already created 'good species.' Moreover, caution must be taken in interpreting interpopulation crosses, as some outcomes are not necessarily unique to or required from sexually antagonistic coevolution (Rowe *et al.*, 2003).

Comparative phylogenetic analysis provides yet another avenue to evaluate a role for sexual conflict in species diversification. One such analysis identified higher species richness in clades with polyandrous compared to monandrous species, as a proxy for sexual conflict (Arnqvist *et al.*, 2000). Despite being consistent with a role for sexual conflict in promoting speciation, additional and more fine-grained analyses are warranted that might better distinguish conflict from other modes of sexual selection, incorporate quantitative measures of reproductive isolation (Rabosky and Matute, 2013; Yukilevich, 2013), and that exploit recent advances in partitioning speciation and extinction rates on phylogenies (FitzJohn, 2010).

How Might Sexual Conflict Hinder Speciation?

Speciation represents a compelling possible evolutionary outcome of sexual conflict and sexually antagonistic coevolution (see Lessells, 2006; Gavrilets, 2014). Sexual conflict could instead hinder speciation, however, and increase the risk of extinction (Rowe and Day, 2006; Rankin *et al.*, 2011). Sexual conflict could elevate extinction rates by reducing the mean fitness of populations (Doherty *et al.*, 2003; Rowe and Day, 2006), which can also occur when unresolved intralocus conflict impedes genetic divergence (Lande, 1980; Bonduriansky and Chenoweth, 2009). Populations can also be driven to extinction when sexual conflict over mating is a 'tragedy of the commons,' whereby traits favored by antagonistic selection are simultaneously beneficial to individuals and costly to the group (Hardin, 1968; Rankin *et al.*, 2007). For example, in the pursuit of increasing mating rates, excessive harassment by males might directly compromise female survival, creating a male-biased population that feeds back in turn until the population collapses (Rankin *et al.*, 2011; Grayson *et al.*, 2014). A possibility worthy of further investigation is to what extent sexual conflict might promote both speciation and extinction, perhaps contributing to more rapid species turnover but little to net diversification.

Conclusions

The prevalence of sexual conflict across the tree of life, combined with its capability to propel rapid evolutionary change, motivates the logic that sexually antagonistic selection might play a creative role in the speciation process or in the maintenance of nascent species' integrity. However, the genetic architecture that underlies sexual conflict (intralocus vs.

interlocus conflict, few vs. many loci, standing variation vs. new mutation) can drastically alter the implications regarding the potential for and permanence of population divergence. Evolutionary responses to antagonistic selection can, in some circumstances, retard population divergence, increase the likelihood of population extinction, or contribute to post-speciation enforcement of restricted gene flow instead of providing the causative feature to species origination. More generally, it remains difficult to confidently ascribe a causal role to sexual conflict in the speciation process, despite the conceptual attractiveness of this idea, making especially important all future mechanistic studies of sexual conflict at premating, gametic, and postzygotic levels in the evolution of reproductive isolation.

Speciation, Sexual Selection and

JW Boughman, Michigan State University, East Lansing, MI, USA

Glossary

Antagonistic coevolution Coevolution in which the evolutionary interactions between two parties (two sexes or two species) impose costs on each other because of different evolutionary interests. The metaphor of an arms race is often used to describe the process and its outcomes.

Assortative mating Mating between individuals that are similar in a trait or set of traits, such as size assortative mating in which large males mate with large females and small males with small females. Also used to indicate preferential mating between individuals of the same species over individuals of other species.

Cryptic female choice Female choice that occurs after copulation.

Fisher's runaway sexual selection A model of sexual selection conceived by R.A. Fisher to explain the exaggeration of both male display traits and female preferences in the absence of benefits to females. Genetic correlation between male trait and female preference creates continual evolutionary exaggeration of both until the reproductive benefit of the exaggerated male trait is balanced by the cost of producing it.

Good genes sexual selection A form of sexual selection in which females obtain genetic benefits, or 'good genes,' from mating with particular males.

Mate preference The selection of mates based on criterion values of specific trait(s). Preference influences the propensity of individuals to mate with certain phenotypes.

Mating trait The secondary sexual traits involved in mating. These typically include display traits and competitive traits for males, and mate search and preference for females.

Reproductive character displacement refers to the greater difference of reproductive traits in regions of sympatry between two species than are seen in regions of allopatry.

Reproductive isolation Speciation occurs via the evolution of isolating barriers, which are characteristics of organisms that keep individuals in one population from exchanging genes with other populations. Reproductive isolation can occur by preventing individuals of separate species from mating (premating isolation) or by selecting against hybrids (postmating isolation).

Sexual conflict The occurrence of conflicting evolutionary interests and optimal strategies for reproduction between the two sexes, including aspects of reproduction such as mating rate.

Sexual isolation A form of premating isolation in which the choosy sex of one population or species (usually female) is less likely to accept members of the other population or species as mates.

Sexual selection Variation among individuals with different trait values in the number of mates acquired and in overall reproductive success, measured as the number of offspring produced. Intersexual selection involves choosiness by one sex for mates of the other sex based on trait values (often called female choice). Intrasexual selection involves competition within a single sex for access to the other sex, frequently through contests (often called male competition).

Signal A trait modified by selection to convey information and to influence the behavior of individuals receiving it. Signals can be in various modalities, including visual, auditory, olfactory, or tactile. Male display traits are signals.

Speciation The process by which one or more species evolves from another via genetic changes and the evolution of mechanisms that restrict gene flow.

Introduction

Background

The idea that *sexual selection* can contribute to *speciation* is an old one, going back more than 150 years at least to Darwin's (1871) book *The Descent of Man, and Selection in Relation to Sex*. The hypothesis is a natural outcome of the observation that in many taxa, the traits that differ most strikingly between closely related species are secondary sexual traits, and these same traits appear to hinder mating between species. Many sexual traits evolve because of their role in attracting and choosing mates or in garnering the resources necessary to do so and thus, sexual selection is at the root of this evolutionary change. As long ago as 1930, Fisher articulated the conditions under which sexual selection could cause speciation (Fisher, 1930) but the topic was then largely ignored while speciation research focused on the role of geography (Mayr, 1942) and then on natural selection (Schluter, 2000). The hypothesis was revived in a seminal paper by Lande (1981). In that work, Lande formalized Fisher's verbal model with a theoretical model of how coevolutionary change between female preference and male sexual traits could 'runaway' to ever more exaggerated forms. *Fisher's runaway sexual selection* has hence become the starting point for much of the theoretical work on sexual selection and speciation. In principle, the runaway exaggeration of both male mating traits and female preferences for those traits can easily lead to differences among allopatric populations because of the arbitrary nature of sexual traits (they are not adaptive with respect to natural selection). This means they are free to vary in many directions and likely to differ between populations (Turelli *et al.*, 2001). If populations subsequently

 doi:10.1016/B978-0-12-800049-6.00070-6

encounter one another, they are unlikely to mate because males in one population express trait values that females in the other population do not find attractive. This increases *sexual isolation*, a key component of *reproductive isolation* and thought to be one of the primary barriers isolating species in many taxa (**Figure 1**; West-Eberhard, 1983).

Empirical Case Studies Offer Support

Diverse in-depth studies have shown that sexual selection does contribute to speciation in many taxonomic groups. These empirical studies focus on the evolutionary mechanisms by which sexual selection causes speciation in particular groups of taxa, using observational data and manipulative experiments to test how sexual selection contributes to the process of speciation. For example, compelling evidence from neotropical frogs shows that populations differ in mating traits because of divergent sexual selection (where females prefer different traits causing sexual selection to act in different directions on males), and both genetic differentiation and reproductive isolation increase with greater difference in mating traits (Boul *et al.*, 2007). Another less direct line of evidence is when sexual traits differ substantially between species that are ecologically similar, such as that found in jumping spiders on Arizona mountaintops (Masta and Maddison, 2002), or *Laupala* crickets in Hawaii (Mendelson and Shaw, 2005). An outstanding question is whether these case studies represent a general pattern or are special in whether and how sexual selection acts to cause speciation.

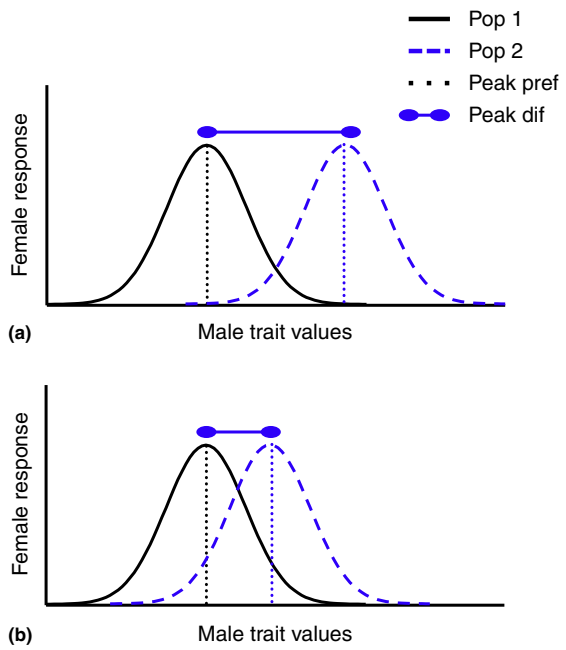

Figure 1 Female mate choice arises from underlying preferences for particular trait values. These can be described with preference functions, which consider how female sexual response depends on male trait values. The figure shows preference functions for two populations, which differ in the value of male trait preferred. Only where preference functions overlap is mating expected between two populations. (a) The populations differ substantially in trait values preferred (large peak dif). Low overlap means females from both populations will accept few males from the other population as mates, resulting in high sexual isolation. (b) The populations differ only a little in trait values preferred (small peak dif). High overlap means females from both populations will accept many males from the other population as mates, resulting in low sexual isolation.

Comparative Studies Are Equivocal

However evidence from comparative studies is much more mixed. These correlational studies explore the patterns of diversity and ask whether taxa in which sexual selection is present or strong have more species than those where sexual selection is absent or weak. Some studies report evidence in support (Owens *et al.*, 1999; Arnqvist *et al.*, 2000; Seddon *et al.*, 2013), others find no correlation (Gage *et al.*, 2002; Morrow *et al.*, 2003; Huang and Rabosky, 2014), and still others suggest that sexual selection may increase extinction rates more than speciation rates (Doherty *et al.*, 2003). Comparative analyses are done to test broad scale and general patterns, so if they succeed in doing so, then the equivocal results cast real doubt. In fact, these mixed results from comparative studies are a major reason why the hypothesis that sexual selection causes speciation is controversial (Panhuis *et al.*, 2001). However, comparative analyses typically use proxies for sexual selection (e.g., sexual size dimorphism or sexual dichromatism) and for speciation (e.g., species richness or number of species) and those proxies may be inexact or do not fully capture the action of sexual selection. These studies may then miss or gloss over real patterns. Recent work suggests that a refocus on the extent to which sexual selection differs among taxa will reveal cleaner answers than the historical focus on the strength of sexual selection (Rodríguez *et al.*, 2013). This makes sense, because most hypotheses suggest differences in mating traits are what causes isolation between species. Therefore, large differences in female preference are likely to cause large differences in male mating traits, whereas strong sexual selection may just speed up the rate of change (Rodríguez *et al.*, 2013).

Theory Is Equivocal

Results from theoretical work are likewise mixed. Theoretical work also focuses on generality, stripping away many biological details to reveal the basic principles and conditions where sexual selection will and will not facilitate speciation. A number of theoretical models strongly support a role of sexual selection in speciation. In some cases this is because of how environments affect the ability to detect male traits, related to sensory drive, as describe below (Higashi *et al.*, 1999; Kawata *et al.*, 2007). In other cases because antagonistic coevolution of male traits driven by *sexual conflict* leads to divergence (Gavrilets, 2000). However, other theoretical models suggest sexual selection is just as likely to hinder the process as facilitate it (Kirkpatrick and Nuismer, 2004; van Doorn *et al.*, 2004; Servedio, 2011). A landmark paper shows that Fisher's runaway on its own is unlikely to cause speciation, and that other mechanisms of sexual selection (and other theoretical approaches) are required (Servedio and Bürger, 2014). A few other models that incorporate *good genes*

sexual selection and which show that sexual selection can cause speciation are discussed below in the section 'Good genes'.

Sexual Selection versus Natural Selection

An additional controversy is over whether sexual selection can cause speciation on its own, or requires complementary natural selection. Proponents of sexual selection alone argue that because sexual selection is often far stronger than natural selection (Hoekstra *et al.*, 2001) and targets mating traits that have a direct role in determining whether gene flow occurs, it is likely to cause greater evolutionary divergence in mating traits and stronger reproductive isolation than natural selection (Svensson *et al.*, 2006; Boul *et al.*, 2007). Proponents of the counter argument acknowledge that greater evolutionary divergence may occur when both natural and sexual selection act in concert (Blows, 2002). This has the added bonus of generating differences in both mating traits to increase sexual isolation, and ecological traits to allow species to coexist (Kraaijeveld *et al.*, 2011). An important way to link sexual and natural selection and foster speciation is when females prefer traits that are also involved in divergent ecological adaptation (Podos, 2001; Servedio, 2004), essentially preferring the males that are well adapted to local environments (Welch, 2003; van Doorn *et al.*, 2009). This is related to the idea of magic traits, which also link mate choice to adaptation and makes speciation more likely. Of course, sexual and natural selection may oppose one another, which would retard divergence and impede reproductive isolation. This controversy requires further work to resolve.

How Sexual Selection Causes Speciation

Premating Isolation

Sexual selection should be especially important in the evolution of sexual isolation because of its importance in determining which individuals mate. Sexual isolation arises when males and females of different populations or species do not mate with each other, even when given the opportunity. Several forms of sexual selection could be involved in causing *mate preferences* and *mating traits* to diverge between populations. Focusing on the mechanisms of sexual selection causing speciation takes the study from descriptions of pattern to experimental tests of the process, giving far greater insight into the evolutionary process than correlational studies can provide.

Sensory drive

Sensory drive is a process that causes evolutionary change in communication systems – both in the sensory mechanisms needed to detect and discriminate communication *signals*, and in the structure of the signals themselves (Endler, 1992). The environment in which communication takes place affects the transmission of signals, selecting for those that transmit with minimal interference and degradation by habitat. Environments also select on properties of sensory systems to enable detection of predators, prey, and social partners (including mates). Even small differences in habitat can have substantial effects, causing both mating signals and sensory systems to adapt to local conditions, which leads to divergence between populations that live in different habitats (**Figure 2**). A natural outcome of this process is sexual isolation (Boughman, 2002). Speciation occurring due to this form of sexual selection has strong support from multiple taxonomic groups and studies.

Among the best worked out examples are African cichlid fish, where sensory drive on color perception, color preference, and color signaling is implicated in generating tremendous numbers of species – several hundreds in the African rift lakes of Victoria, Tanganyika, and Malawi (Seehausen *et al.*, 2008). Water color is the key aspect of the environment that mediates communication between male and female cichlids over mating. Differences in color perception are mediated by genes called opsins that influence how well specific wavelengths of light are detected and discriminated. Fish that live in clear shallow water express different opsins in their retinas than fish that live in red-shifted deep water, which leads females to prefer different color signals in their prospective mates. Water color also affects color and brightness contrast, which in turn affects signal detectability. Signals contrast when they are either different in color or different in brightness from the water color, and this contrast makes them easy to detect, especially when female eyes have evolved in response to water color as well. Males of the species found in the shallow clear water are blue and these females see blue well and prefer it, whereas males of the species found in deep red-shifted water are red and those females see red well and prefer it. Such divergent perception, preference, and signaling causes sexual isolation, as evidenced by color based *assortative mating* and genetic differentiation between the species (**Figure 2**).

Sensory drive is not limited to visual signals, because habitat also influences the transmission of other modalities, such as hearing and acoustic signals. A nice example of this is comparing rainforest birds that live in different types of forest (Tobias *et al.*, 2010). Species that live in bamboo forests produce songs with structure distinct from that of their close relatives that live in upland forest. The authors find that the pitch and pace of songs differs, with birds that live in dense bamboo singing songs of lower pitch, more complex structure, and faster pace than birds living in upland forest. This is consistent with predictions of sensory drive, because the song structure produced should resist degradation by the local habitat. Because song is important to mate choice it may also play a role in sexual isolation, although that has not been tested.

Good genes

A few studies have explored ways in which good genes sexual selection can contribute to sexual isolation. Good genes sexual selection occurs when females prefer males possessing alleles with high fitness (good genes), which makes females' choice of mates adaptive. Females typically use traits that correlate with genetic quality, or indicator traits, to identify those males. Two distinct mechanisms underlie this idea. The first is that the genetic benefits females obtain from their choice of mates is likely to depend on the environment – for example, obtaining genes for large offspring body size may be beneficial when resources are abundant and competition is fierce, but be costly

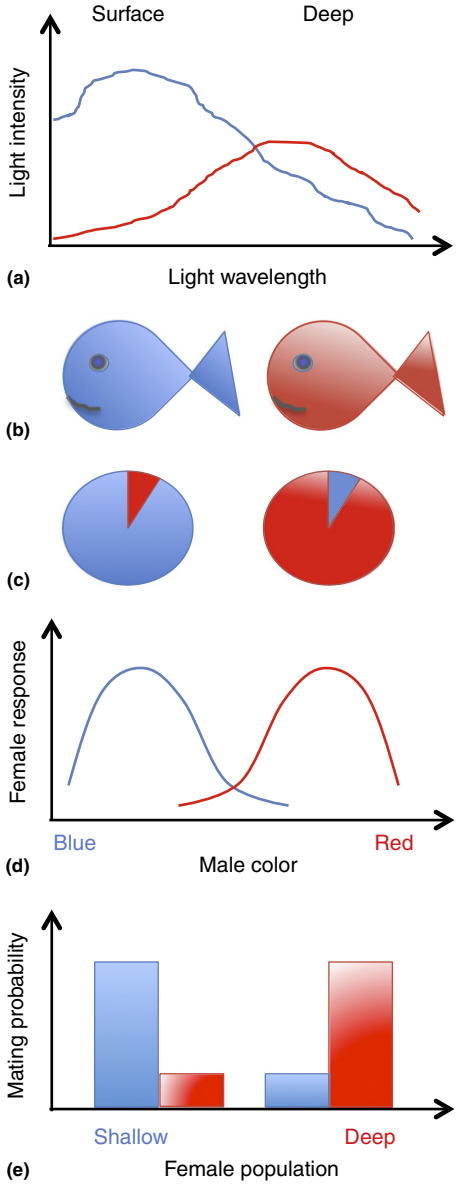

Figure 2 Sensory drive can cause sexual isolation as a by-product of adaptation to local signaling environments. Differences in signaling environment are likely to cause divergence in signals because of how they transmit in different environments; in sensory systems because of how environments affect detection of predators, prey, and mates; and in mate preference because it is affected by sensory abilities. The example shown is for water color and effects on fish diversification. On the left are data for a shallow water population and on the right for a deep water population. (a) Water color changes with water depth because of the way water attenuates light. The color spectrum in shallow water is bluish, whereas the spectrum in deep water is reddish. The curves shown are how light intensity varies across the light spectrum for surface and deep environments. (b) Male fish display colors that match the dominant water color, such that males are blue in shallow water and red in deep water. (c) Opsins expressed in the eyes of fish in shallow water consist predominately of the blue sensitive type, whereas opsins in shallow water are predominately red sensitive, making fish see those particular colors well. The pie charts show the frequency of each opsin type in the eyes of fish from shallow and deep water. (d) Female fish prefer different colors because of their sensitivity to different wavelengths of light, thus favoring blue males in shallow and red males in deep water. The curves show preference functions indicating how female response depends on male color. (e) The combination of color preference and male color leads to sexual isolation between shallow and deep dwelling fish. Females from shallow water are likely to mate with blue males but not red males, and the reverse is true from females from deep water. The bars show the probability of mating with blue males (blue bars) and red males (red bars) for females in shallow and deep populations.

when resources are scarce. This is termed as context dependent benefits of choice (Welch, 2003). It means that females in populations or species that live in different environments may have preferences for different male traits because females will acquire for their offspring a different set of alleles that are favored in that particular environment. Thus, the genes that are 'good' vary with environment, and preferences should evolve in concert in order to reap the genetic benefits of choice (Qvarnström, 2001).

The second, related way arises from the condition dependent expression of mating traits. Only males in good condition express high values of mating traits such as bright color, large ornaments, and vigorous courtship, because males in poor condition lack the energetic and physiological resources to do so (Kodric-Brown and Brown, 1984). Female preferences are predicted to evolve to favor these condition dependent traits (Schluter and Price, 1993; Rowe and Houle, 1996). The way this connects to speciation is that, local males who are well adapted to the local environment because they possess locally good genes, will be in good physical condition and express high values of mating traits, making them attractive to females (**Figure 3**). Foreign males from another population with different environmental conditions will not be well adapted to the local conditions, will be in poor condition, and express low trait values. Thus, with preferences for condition dependent traits, females will prefer males from their own population who are locally adapted, selecting against males who have migrated from populations in other environments because their poor condition means they express unattractive mating traits. This should increase sexual isolation even if female preferences do not differ between the populations (van Doorn *et al.*, 2009). This mechanism seems likely to be important in the context of climate change, because it is expected to result in range movement (Hickling *et al.*, 2005; Hitch and Leberg, 2007), potentially making this a widespread phenomenon.

Sexual conflict

Sexual conflict arises because males and females achieve high reproductive fitness in different ways. The consequence is that when females are at their fitness peak, males are not. Therefore, when females evolve to their fitness peak, this exerts selection on males to evolve traits that increase male fitness. The reverse is also true, that when males evolve to their fitness peak, this exerts selection on females. This tug of war results in continual *antagonistic coevolution* between the sexes. The direction of evolutionary change is not determined by environment (contrary to sensory drive), but instead, by the interactions between the sexes. Sexual conflict may easily cause

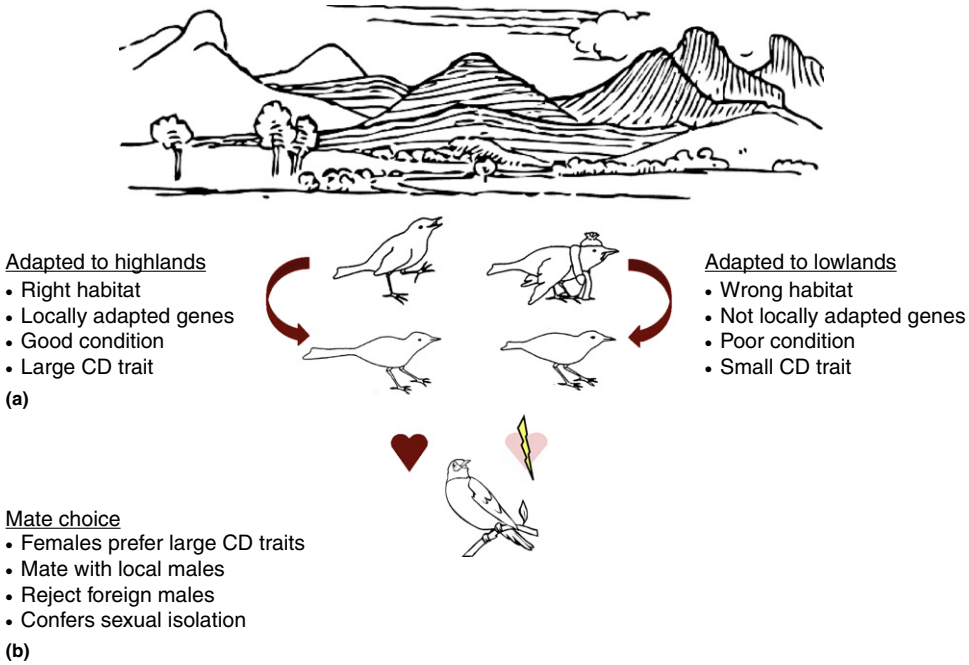

Figure 3 Condition dependent traits and preferences can lead to sexual isolation. (a) Long tail feathers and bright colors are condition dependent traits. Both highland and lowland males in their native habitat possess the genes that confer local adaptation, thus they are in good condition and have long tails. However, if lowland males migrate to the highlands they will not be locally adapted and are likely to be in poor condition. As a consequence, they will have short tails (a condition dependent trait). Thus, condition dependent traits function as indicators of local adaptation. (b) Females in both highland and lowland populations prefer long tailed males. Therefore, females are likely to reject foreign males who have immigrated because their poor condition gives them unpreferred trait values, or short tails. This results in sexual isolation between highland and lowland populations, simply due to condition dependent trait expression and preference for condition dependent traits.

allopatric populations to evolve in different directions. Subsequently, if populations come into contact males and females from the two populations are not likely to mate, increasing sexual isolation, and may even have reproductive incompatibilities, increasing postmating isolation. There is some theoretical support (Gavrilets, 2000), some comparative support (Arnqvist *et al.*, 2000), and some empirical support (Martin and Hosken, 2003) for sexual conflict increasing overall reproductive isolation. The route to speciation through sexual conflict is not completely clear however. Antagonistic coevolution leads to divergence and possibly speciation when females evolve resistance to male traits because this selects for exaggerated male traits to overcome resistant females, which perpetuates the coevolutionary cycle. If instead females evolve indifference to those male traits or even evolve discrimination against them, sexual isolation would contribute little to speciation. Other studies suggest that speciation is the least likely manner in which to ameliorate the conflict between the sexes (Rowe *et al.*, 2005); therefore, the role of sexual conflict in speciation requires further work.

Postmating Isolation

Sexual selection affects not only premating or sexual isolation, but also postmating isolation. Although much less studied than sexual selection on premating isolation, nonetheless, a few studies suggest this can occur through multiple avenues, including *cryptic female choice*, heterospecific sperm doing poorly in competition with conspecific sperm, hybrids having poor mating success, and even genetic incompatibility because of rapid evolution for genes that underlie reproductive traits (Birkhead and Pizzari, 2002).

Cryptic female choice and sperm competition

Cryptic female choice could contribute to postmating isolation in a few ways, because hybrid males are not likely to be preferred by females, but instead represent low-quality mates. In some species females can eject sperm from unpreferred males after copulation but before fertilization (Dean *et al.*, 2011), and it stands to reason that females would be especially likely to eject heterospecific sperm. Females can also alter their investment in offspring and thus, lower the survival and fitness of offspring from unpreferred partners (Burley, 1988; Sheldon, 2000; Loyau *et al.*, 2006). Competition among males for fertilization can also contribute to postmating isolation. When females mate with multiple males, the sperm of those males compete to fertilize the female's eggs, known as sperm competition (Parker, 1970; Birkhead and Pizzari, 2002). Studies have shown that conspecific sperm often have higher fertilization rates than heterospecific sperm. This can be caused by conspecific sperm just being better at fertilizing conspecific eggs (Price *et al.*, 2001), or by females mediating sperm competition and preferentially using sperm from conspecifics (Tyler *et al.*, 2013).

Sexual selection against hybrids

Even if all these other mechanisms fail so that hybrids are formed and survive to adulthood, hybrid males are likely to

BOX 1

A few studies suggest that occasionally, mating with heterospecifics can be adaptive. This occurs when there is little or no intrinsic postmating isolation, such that hybrid offspring are likely to survive, and when the heterospecific species has traits or alleles that are beneficial in particular environmental circumstances. A well-known example is in spadefoot toads, which breed in ephemeral ponds. When water levels are low, ponds may dry out before tadpoles can metamorphose, favoring rapid development. In these conditions, females from the slow maturing species *Spea bombifrons*, can benefit from mating with rapidly maturing *Spea multiplicata* because their hybrid offspring are more likely to reach metamorphosis (Pfennig, 2007).

have secondary sexual traits that are unusual combinations of trait values or intermediate to the pure species that produced them. Sexual selection against hybrids is a natural extension of sexual selection within species because females often evolve strong preferences for particular trait values. Given that females have often evolved to be quite selective in which males are acceptable as mates, their mismatched or intermediate phenotypes are likely to make hybrid males unattractive to females of both pure species, who instead find conspecific males more attractive. Thus, sexual selection acts against these hybrids, which have low mating success and thus low reproductive fitness. This has been seen in hybrid flycatchers (Svedin *et al.*, 2008), in hybrid butterflies (Naisbit *et al.*, 2001), and in hybrid sticklebacks (Vamosi and Schluter, 1999). It can contribute substantially to overall reproductive isolation, for example, comprising 25% of the total postmating isolation in flycatchers (Svedin *et al.*, 2008; but see **Box 1** for counter examples).

Female Choice and Male Competition

Most of the work to date focuses on how sexual selection generated from female choice contributes to speciation, but sexual selection also arises from males competing with each other for mating opportunities. Increasingly, scientists are asking whether and how male competition contributes to speciation. The most commonly considered mechanism for male competition in speciation is that if males are more likely to be aggressive to males who are similar to them, males with rare phenotypes will escape most aggression. This creates frequency dependent disruptive selection that favors divergence (Seehausen and Schluter, 2004; Qvarnström *et al.*, 2012). Essentially, males who have average phenotypes receive the most aggression, and males with rare phenotypes (at the extremes of the phenotypic distribution) the least. The general pattern is similar to how competition for food resources favors rare types which then generates disruptive selection (Dieckmann and Doebeli, 1999). Empirical tests of this idea are mixed; however, with some studies showing this effect is insufficient to cause speciation (Dijkstra *et al.*, 2007). Perhaps more promising is the idea that it's not rareness per se, but that certain combinations of phenotypes are successful in male competition, and that there is more than one way to beat your rivals (Keagy *et al.*, 2015). For example, large and aggressive males can win contests, but so can brightly colored and quick males. Therefore, two different types can have high fitness through male competition. Which males win competitive contests may also vary with habitat, suggesting that male competition can lead to divergent selection between habitats (Lackey and Boughman, 2013).

A related idea is the role that male competition can play in *reproductive character displacement* when two formerly allopatric species come into contact (Grether *et al.*, 2009). Males who are sufficiently different are not recognized as competitors, thus avoiding the costs of competitive interactions. For example, several species of damselflies differ in whether male wings are clear, black, or ruby spotted. Males direct aggression to other males who share their wing color pattern, so when two species are similar, they 'waste' aggression on heterospecific males. Much better is to reserve energy and time for driving off only conspecific males who are truly competing for conspecific females. This selects for differences between species in sympatry, resulting in reproductive character displacement to facilitate recognition of competitors (Anderson and Grether, 2010).

Male competition and female choice are the two halves of sexual selection, which interact to determine the overall direction and strength of sexual selection. Whether they work in concert to favor the same divergent set of phenotypes or in contrast to favor different sets of phenotypes will affect how much sexual selection contributes to overall diversification and isolation. Little theoretical work has been done to investigate this, but one model found that when the traits that confer success in male competition are also attractive to females, divergence and sexual isolation are enhanced (van Doorn *et al.*, 2004).

Learned Mate Choice and Speciation

Recent work is highlighting the potential for learning to foster speciation, although it can sometimes hinder the process (Verzijden *et al.*, 2012). Mate preferences can be either genetically encoded or acquired by learning, and the traits used to attract mates can also be either genetic or learned. Mate preferences can be learned through imprinting, where juveniles learn the phenotypes of parents, and choose mates later in life who match those parental phenotypes. This is fairly well known in birds, where for example, great tits raised by foster blue tit parents in the wild, grew up to sing like blue tits and preferred mating with blue tits (Slagsvold *et al.*, 2002; Johannessen *et al.*, 2006). Imprinting is less well understood in other taxa, but may be widespread. For example, in sticklebacks, females raised by foster fathers imprint on traits that are targets of divergent natural selection, thereby learning to prefer mates of the foster father species over conspecifics and causing increased sexual isolation (Kozak *et al.*, 2011).

Mate preferences can also be learned through experience with potential mating partners. Learning can be involved for both sexes, but males and females will often differ in what is learned. Studies show that females often learn to prefer familiar phenotypes, which should promote sexual isolation (Kozak and Boughman, 2009). When mate preferences are learned, either through imprinting or prior experience, speciation is promoted (Verzijden *et al.*, 2005; Servedio *et al.*, 2009), because such learning enhances the fidelity with which

females choose mates like themselves. This has the effect of keeping the ecological and mating traits together, enhancing divergence and maintaining trait-preference correlation.

Males may modify courtship behavior based on experience, courting familiar phenotypes based on positive responses from conspecific females, and avoiding unfamiliar phenotypes based on negative responses from heterospecific females, as was shown for *Drosophila* (Dukas, 2008). Both of these effects should facilitate speciation. However, when the traits males use to attract mates are learned, such as birds learning song, this often inhibits speciation because learning disconnects the phenotype from genotype. For example, if a young male finch learns the song of a heterospecific, he will be unattractive to conspecific females and more likely to mate with heterospecifics. This is likely to lead to hybridization, and undermine sexual isolation.

Sexual Selection and Speciation in Plants

Sexual selection occurs not only in animals but also in plants (e.g., Bernasconi *et al.*, 2004). Although the particulars are different, the principles are shared. For example, both animals and plants attract potential mates through elaborate display: in animals through exaggerated secondary sexual traits such as plumes or song that potential mates find attractive, whereas in plants this may be through elaborate floral traits such as petal color or nectar rewards that potential pollinators find attractive. These pollinators are essential to actual mating in outcrossing plants. Another shared mechanism is competition to fertilize ovules: in animals through sperm competition and in plants through pollen competition. Male traits may influence success in sperm and pollen competition (e.g., how quickly sperm/pollen reach the ovules, or how many sperm/pollen grains are transferred), and may thus experience strong sexual selection through male competition. Females may not be passive in this process, and may influence which sperm/pollen fertilize their eggs through cryptic female choice.

To what extent does sexual selection in plants contribute to speciation? Some high profile cases have provided evidence that floral traits which differ between species will attract different pollinators or cause variation in pollen placement, resulting in pollinator isolation (reproductive isolation mediated by animal pollinators, which is akin to sexual isolation in animals) (e.g., Schemske and Bradshaw, 1999; Bradshaw and Schemske, 2003; Ramsey *et al.*, 2003). Such pollinator isolation can create substantial barriers between species and recent work finds this barrier is strong in a number of systems (Baack *et al.*, 2015). Whether this mechanism is solely responsible for speciation is questioned in a review by Kay and Sargent (2009), who suggest that although pollinator isolation occurs, it is often combined with other isolating mechanisms. Their arguments are reminiscent of the debate on whether sexual selection alone or in combination with natural selection is more powerful and/or more likely to cause speciation. Further work will be needed to resolve these questions, but it seems that multiple barriers contribute in almost all systems studied to date; not surprising given that speciation is a complex process that may unfold over long periods of time. Pollen competition can also contribute to reproductive isolation when conspecific pollen are more likely to fertilize ovules than heterospecific pollen. This is termed conspecific pollen precedence, and can occur if conspecific pollen tubes grow more rapidly or germinate at higher rates than heterospecific pollen, as seen in several plant systems, such as *Iris* (Carney *et al.*, 1996), *Helianthus* (Rieseberg *et al.*, 1995), and *Mimulus* (Ramsey *et al.*, 2003). Cryptic female choice can contribute to these patterns as well, if female traits have evolved to mediate competition between conspecific and heterospecific pollen, thus favoring the production of conspecific offspring (Baack *et al.*, 2015). Moreover, heterospecific seeds may be selectively aborted, a process similar to differential allocation in animals (Sheldon, 2000). These mechanisms may be widespread, given that about half the plant taxa investigated by Lowry *et al.* (2008) show strong pollinator isolation and/or pollen competition, and pollinator isolation is one of the strongest barriers. Thus, sexual selection may be a key mechanism generating reproductive isolation in plants, and deserves more intensive study.

Conclusion

Given the many ways in which sexual selection can contribute to the process of speciation and its power to cause evolutionary change, it almost certainly plays a role in generating the diversity we find around us. Exactly what that role is, and under what conditions speciation requires sexual selection to proceed are areas of very active research.

Speciation-with-Gene-Flow

SP Egan, Rice University, Houston, TX, USA
GR Hood and JL Feder, University of Notre Dame, Notre Dame, IN, USA

Glossary

Divergence hitchhiking The process by which physical linkage to a gene under divergent selection increases genomic divergence for adjacent regions along a chromosome. Divergence hitchhiking creates a localized region of reduced gene flow, enhancing the potential to maintain or accumulate differentiation at linked sites, both neutral and those under selection.

Divergent selection Selection that acts on genetically based traits in different directions between two populations, including the special case where selection favors two extremes within a single population (i.e., disruptive selection).

Dobzhansky–Muller incompatibilities Genetic incompatibilities that evolve between populations or closely related species without going through an adaptive valley. It requires changes in two or more loci that cause reduced fitness within hybrids. For example, if an ancestral population is homozygous at two loci (AABB) and divides into two populations, a new allele arises and fixes at one locus in one population (population 1 = aaBB), but is incompatible with another new allele that arises at the second locus in the second population (population 2 = AAbb). When combined in hybrids, these incompatibilities cause reduced fitness in the hybrids (AaBb).

Genome hitchhiking The process by which genetic divergence across the entire genome is facilitated, even for loci unlinked to those under selection, by a global reduction in average genome-wide gene flow caused by selection.

Genome-wide congealing A process associated with the combined effects of genes throughout the genome during adaptive divergence that results in a rapid and nonlinear transition from one ancestral genome into two distinct genomes and one population into two reproductively isolated species.

Host races Ecologically divergent, partially reproductively isolated, sympatric populations of plant-feeding insects, the presumed initial stage in speciation-with-gene-flow.

Linkage disequilibrium (LD) The nonrandom association of alleles at two or more loci arising from physical proximity of genes on a chromosome (linkage) and/or by strong epistatic interactions of linked or unlinked alleles that affect the fitness of an organism more strongly than either allele alone (epistasis).

Parapatry Two or more populations or species (or other taxonomic unit) whose geographic ranges partially overlap or are immediately adjacent to each other. In parapatry, populations or species may exchange genes to some degree.

Primary contact When two or more divergent evolutionary lineages (i.e., populations or species) evolve differences while in geographic contact.

Recombination In eukaryotes, a process by which a piece of DNA is broken and then joined to a different piece during meiosis via crossing over which leads to the offspring having different combinations of alleles from those of their parents.

Reinforcement A process by which natural selection favors the increase of reproductive isolation between two evolutionary divergent populations that geographically overlap, either in primary or after secondary contact, in response to the production of maladapted hybrids.

Reproductive isolation Barriers to gene exchange between populations or species is called reproductive isolation.

Secondary contact Recent geographic overlap of two or more divergent evolutionary lineages (i.e., populations or species) after a period of geographic isolation, which allowed for some degree of differentiation to occur from a common ancestor.

Selection–recombination antagonism A term that describes how recombination breaks up associations between selected loci related to ecological adaptation and loci causing reproductive isolation related to assortative mating, impeding genetic divergence across the genome and constraining speciation-with-gene-flow.

Sympatry Two or more species (or other taxonomic unit) that geographically overlap in the same locality where taxa have the opportunity to exchange genes (i.e., gene flow).

Overview: The Major Issues of Speciation-with-Gene-Flow

Speciation occurs as genetically based barriers to gene flow evolve and cause previously interbreeding populations to become reproductively isolated from one another (Mayr, 1963). One of the biggest debates about speciation concerns whether populations can diverge into new species when they geographically overlap and are connected by gene flow (termed speciation-with-gene-flow; Berlocher and Feder, 2002; Coyne and Orr, 2004; Bolnick and Fitzpatrick, 2007). Generally speaking, speciation-with-gene-flow includes situations in which populations overlap entirely in their ranges (sympatric) or only partially (parapatric; **Figure 1**). It also includes cases in which populations evolve in the face of continuous gene flow and have always been in contact (primary contact) or have experienced periods of geographic isolation (allopatry; **Figure 1**) and episodes of subsequent gene flow (secondary

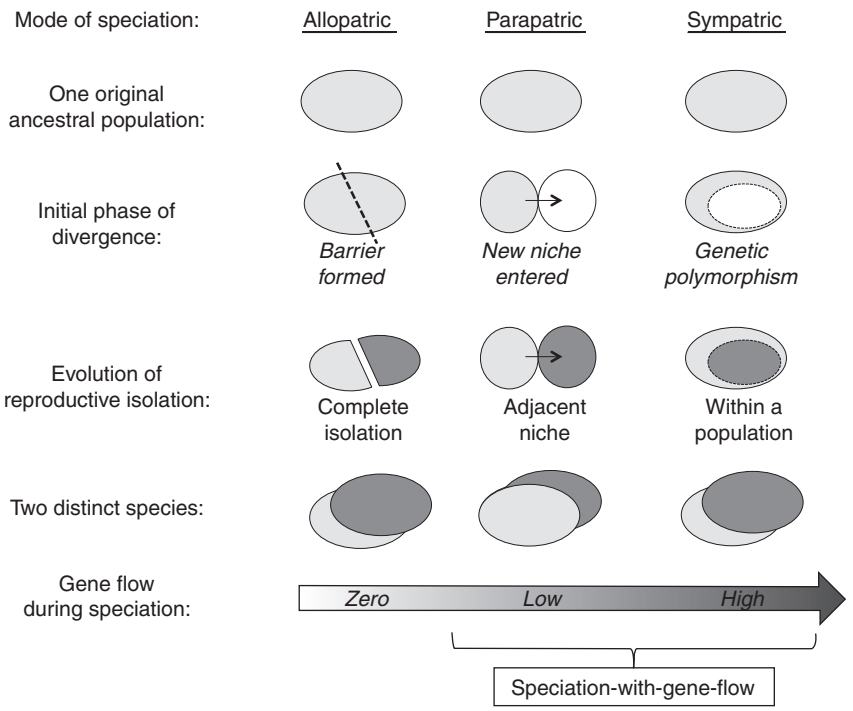

Figure 1 Different geographic scenarios of speciation highlighting the opportunity for gene flow during the speciation process.

contact). The key issue is whether additional reproductive isolation can evolve that culminates in speciation when gene flow is occurring between populations.

The most contentious question concerning speciation-with-gene-flow is whether the process can occur *de novo* in populations in primary contact (termed sympatric speciation; Coyne and Orr, 2004). However, there has also been considerable debate about whether additional prezygotic reproductive isolation (i.e., barriers to gene flow acting before zygotes are formed) can evolve between populations in secondary contact (termed reinforcement; Noor, 1999; Ortiz-Barrientos *et al.*, 2004). In this latter case, a degree of post-zygotic reproductive isolation (i.e., genes causing the inviability or sterility of hybrids) has accumulated between populations during the period when they were geographically separated. Once they reestablish contact and hybridize, selection could then act to directly favor traits that reduce the degree that individuals from the different populations interbreed because of the reduced fitness of their offspring. Although sympatric divergence and reinforcement may not be as common as other forms of speciation, accumulating evidence over the last 20 years (see below) has increasingly shown that these processes can occur and are not as uncommon as once thought.

History

The debate about speciation-with-gene-flow dates back to Benjamin Walsh, a colleague of Charles Darwin, who proposed that plant-eating insects may undergo speciation without geographic isolation (i.e., in sympatry) by shifting and adapting to new host plants (Walsh, 1864). The key to Walsh's hypothesis of speciation-with-gene-flow is that strong divergent selection imposed by different habitats or environments acts as an ecological barrier to gene flow and initiates speciation. Populations cannot simultaneously adapt to the contrasting selection pressures imposed by different habitats to be jack-off-all-trades generalists. Traits that result in individuals surviving better or garnering more mates in one environment have detrimental consequences in other habitats (i.e., fitness tradeoffs exist). Consequently, migrants moving between habitats or hybrids between individuals from different populations do not thrive compared to resident parental types. Thus, an ecological reproductive barrier is generated that, if strong enough, can result in speciation.

The Selection–Recombination Antagonism

An important consideration that has been argued to constrain speciation-with-gene-flow is called the 'selection–recombination antagonism' (Felsenstein, 1981). While divergent selection can create alternate combinations of genes adapted to different habitats, migration and hybridization between individuals from different populations, coupled with subsequent recombination during meiosis, can break these suites of genes apart, homogenizing populations and impeding progress toward speciation. As a result, it has been argued that strong divergent selection must act on genes closely physically linked together in the genome affecting different aspects of ecological adaptation (e.g., for plant-eating insects, loci encoding traits for performance and choice of a specific host plant) in order for speciation-with-gene-flow to proceed. Such strong selection

may be rare in nature and genes effecting ecological adaptation may only fortuitously, and not commonly, be closely linked in the genome.

Given these considerations, some evolutionary biologists have argued that divergence-with-gene-flow may be rare in nature compared to allopatric speciation (Mayr, 1963; Futuyma and Mayer, 1980; Coyne and Orr, 2004). The reason is that geographically isolated populations can evolve independently and unopposed by gene flow. Thus, there is no constraint imposed by the selection–recombination antagonism. Because hybrids do not form, diverged combination of genes that form in allopatry are not broken down. Moreover, divergent and directional natural selection, sexual selection for mating preferences, and even random genetic drift can all contribute to population differentiation in allopatry. In comparison, divergent ecological selection is the primary process initiating speciation-with-gene-flow in primary contact. Post-zygotic isolation due to 'intrinsic' genomic incompatibilities between genes (aka Dobzhansky–Muller incompatibilities) is more likely to evolve in allopatry. In this case, new mutations may be favored by natural selection in the genetic background of the population they arise in. However, if these populations were to ever come back into secondary contact and hybridize, the mutations may interact negatively and cause inviability or sterility when mixed for the first time with those of the other population. It is generally thought that intrinsic reproductive isolation cannot evolve readily during the initial stages of speciation-with-gene-flow because migration and interbreeding between populations would immediately expose the negative fitness effects of incompatibility causing mutations in hybrids, resulting in their rapid elimination. Thus, the presence of Dobzhansky–Muller incompatibilities between geographically overlapping and hybridizing populations would indicate either (1) a case of secondary contact, or (2) that substantial 'extrinsic' ecological reproductive isolation has already accumulated in primary contact to allow for intrinsic post-zygotic to evolve.

Evidence for Speciation-with-Gene-Flow: The Apple Maggot Fly

The greater number of ways that reproductive isolation can evolve and the reduced importance of linkage for divergence when populations are geographically isolated imply that speciation is easier in allopatry than in the face of gene flow. However, this should not be taken to indicate that speciation-with-gene-flow cannot happen and is exceedingly rare. Indeed, just as Benjamin Walsh had predicted over 100 years earlier (Walsh, 1864), empirical evidence began to accumulate in the 1980s that ecologically divergent, sympatric host races of plant-feeding insects, the presumed initial stage in non-allopatric speciation, could form in the face of gene flow (Berlocher and Feder, 2002; Dres and Mallet, 2002).

One example argued by Walsh (1867) and later by Bush (1969) to be a prime example of speciation-with-gene-flow is the apple maggot fly, *Rhagoletis pomonella*, which historically infested the fruits of native hawthorne trees (*Crataegus* sp.), but a genetically distinct host race has evolved in the last 150 years to infest apples, *Malus domestica* (Bush, 1966; Bush, 1969). *Rhagoletis* flies infest the fruits of many different species of host plants from many different plant families. Host fruits are typically available for a discrete window of time over the growing season and each fly species having one generation per year (Dambroski and Feder, 2007). Adult flies meet exclusively on or near the host fruits to mate, females lay eggs into the host fruit, larvae consume the fruit, then burrow into the soil to pupate, and enter a pupal diapause that lasts until the following year. Thus, phenological matching of fly to host plant fruiting is critical to fly fitness. Over 25 years of genetic and field studies have demonstrated that *R. pomonella* flies from apple and hawthorne trees represent partially ecologically reproductively isolated host races, the hypothesized initial stage of speciation-with-gene-flow (Filchak *et al.*, 2000). There is no evidence for intrsinic, non-host-related reproductive isolation between the host races (Linn *et al.*, 2004) and mark-recapture studies have determined that flies migrate between apples and hawthorne trees at a gross rate of ~4–6% per generation (Feder *et al.*, 1994). Thus, gene flow has been continuous between the host races since their origin and geographic isolation (allopatry) can be discounted as a factor contributing to the build up of genomic divergence (Feder *et al.*, 2013). Diapause and differential fruit choice are two major host-related adaptations ecologically reproductively isolating apple and hawthorne flies (Feder *et al.*, 1997; Linn *et al.*, 2003). Apple varieties that are commonly infested by *R. pomonella* flies produce fruit about three weeks earlier than hawthorne trees during the late summer or early autumn (**Figure 2**). Associated with this ecological difference, the apple fly race has evolved earlier emergence times and changes in diapause phenology. As a result, apple and hawthorn flies mate at different times of the season and display a degree of allochronic isolation. In addition, hawthorne flies generally prefer the odor of the

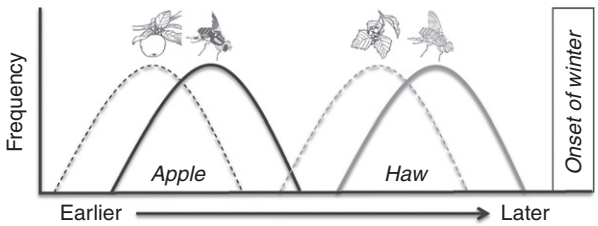

Figure 2 A textbook example of speciation-with-gene-flow: the ancestral hawthorn (gray lines) and recently derived apple-infesting (black lines) host races of the tephritid fruit fly *Rhagoletis pomonella*. *Rhagoletis* flies infest the fruits of many different species of host plants from many different plant families. Host fruits are typically available for a discrete window of time over the growing season (dashed lines) and each fly species (solid lines) having one generation per year. Adult flies meet exclusively on or near the host fruits to mate, females lay eggs into the host fruit, larvae consume the fruit, then burrow into the soil to pupate, and enter a pupal diapause that lasts until the following year. Thus, phenological matching of fly to host plant fruiting is critical to fly fitness and divergent selection between populations on different trees is strong enough to drive speciation in the face of gene flow. Illustration credit: *R. pomonella* – Chris Brown; host plants – Erin Kelso. Redrawn from Egan, S.P., Ragland, G.R., Assour, L., *et al.*, 2015. Experimental evidence of genome-wide impact of ecological selection during early stages of speciation-with-gene-flow. Ecology Letters 18, 817–825.

volatile compounds emitted from ripe hawthorne fruit and use this as a cue to find and orient to hawthorne trees while avoiding apples, whereas the reverse is true for apple flies (Linn *et al.*, 2003; Forbes *et al.*, 2005). Because adults mate on host fruit, the differences in host preference translate directly into mate choice and prezygotic reproductive isolation between hawthorne and apple flies. Recent work comparing allele frequency changes across the genome induced by a selection experiment with allele frequency differences observed between sympatric haw and apple host races in nature demonstrated that natural selection affects large fractions of the genome during divergence (Egan *et al.*, 2015).

Other Textbook Examples for Speciation-with-Gene-Flow

Evidence from other plant-feeding insects (e.g., goldenrod gall flies, leaf beetles, and treehoppers; Abrahamson and Weis, 1997; Wood, 1980; Funk, 2010; reviewed by Berlocher and Feder, 2002; Dres and Mallet, 2002), from parasites attacking specialist insects, as well as from other animals and plants (e.g., cichlid fish and palm trees; Barluenga *et al.*, 2006; Savolainen *et al.*, 2006; reviewed by Bolnick and Fitzpatrick, 2007), further strengthened the case that taxa could diverge in sympatry in the face of gene flow. The finding that reinforcement could promote the evolution of additional reproductive isolation between populations following secondary contact, for example, between *Drosophila* fruit flies (Noor, 1999), has also led to a greater appreciation that all of the genetic differences contributing to speciation need not arise in allopatry. Finally, other examples of ecologically based speciation that appear to involve differences not wholly evolved in allopatry, such as stickleback fish, lake whitefish, pea aphids, and sunflowers (reviewed by Feder *et al.*, 2013), have also helped shift debate from the feasibility of speciation-with-gene flow to how prevalent it is in nature and what are the most important factors promoting and constraining the process.

New Theoretical Insights

At the same time that empirical evidence was accumulating for speciation-with-gene-flow, new theoretical insights widened the conditions under which reproductive isolation could evolve in sympatry and parapatry (Dieckmann and Doebeli, 1999). For example, if assortative mating is based on habitat preference rather than differentially choosing mates in a common mating pool or if the same allele causes assortative mating in both populations, then the selection–recombination antagonism can be alleviated (Felsenstein, 1981; Servedio *et al.*, 2011). Moreover, when divergent selection occurs and migration is not completely random between populations, a degree of disequilibrium can be established between performance genes even in the absence of genetically based habitat choice and physical linkage among loci.

Other arguments have been made that 'divergence' and 'genome' hitchhiking can increase the effectiveness of divergent selection and facilitate the evolution of reproductive isolation in the face of gene flow (Feder and Nosil, 2010). In divergence hitchhiking, selection on an already diverged gene reduces the effective migration rate locally for regions of the genome around the selected locus. This makes it easier for new divergently selected mutations to 'hitch' a ride with the diverged gene and become established because they are not opposed by as high a rate of gene flow as implied by the gross migration rate of individuals between populations. Genome hitchhiking occurs when several genes are diverged in the genome. In this case, the collective effect of multifarious selection on these genes results in a global, genome-wide reduction in effective migration rate. As a result, new mutations, even those not under strong divergent selection, can begin to accumulate across the genome without being tightly physically linked to already diverged loci (Feder *et al.*, 2012).

We caution that recent results should not be interpreted as meaning that population divergence is easier in sympatry or parapatry than allopatry. However, for many organisms that experience their environments on fine spatial and temporal scales, divergence in the face of some gene flow may be fairly common and not as limited by theoretical considerations, as previously thought. Moreover, even if speciation is not primarily initiated in sympatry or parapatry, many populations may not completely diverge and speciate in allopatry. Mixed modes of speciation in which populations experience periods of allopatry interspersed with secondary contact and gene flow may be frequent. Indeed, in certain cases like sticklebacks and *Rhagoletis* flies, genetic variation that arose in the past in allopatry may be present at high standing levels in extant populations to help fuel rapid divergence-with-gene-flow when new ecological opportunity presents itself (Schluter, 2000; Schluter, 2001; Feder *et al.*, 2003; Bolnick, 2011).

Next-Generation Sequencing: Testing the Role of Genome Structure in Speciation-with-Gene-Flow

New empirical and theoretical findings have shifted the emphasis of researchers from testing whether speciation-with-gene-flow can occur (it can) to investigate in more detail the conditions and factors facilitating the process. In this regard, a focal point of study investigates the role that genome structure may play in making speciation-with-gene-flow more or less likely (Seehausen *et al.*, 2014), which has been enabled by advances in next-generation DNA sequencing. When there is no limit to the number of mutations and traits under strong divergent selection, in principle, speciation will progress relatively unimpeded, even in the face of gene flow. Here, genome structure is not imperative because the direct effect of selection on individual mutations is sufficient for them to establish and differentiate populations. However, when this is not the case, which may be typical, then divergence and genome hitchhiking take on increased significance and genome structure can be an important consideration for speciation-with-gene-flow (Feder *et al.*, 2012).

Next-generation sequencing has helped enable this line of enquiry by allowing genomic differentiation to be characterized between populations at varying stages of the speciation process, thus, providing a means to test for patterns of divergence consistent with hitchhiking. It is generally thought

that speciation-with-gene-flow will generate a heterogeneous pattern of genetic differentiation across the genome between diverging populations (Nosil *et al.*, 2009). Regions that contain genes under divergent selection and tightly linked neutral markers will show differences, while the remainder of the genome will tend to be homogenized by gene flow. This has given rise to a metaphor of 'genomic islands of divergence,' where a genomic island is any gene region which exhibits significantly greater differentiation than expected under neutrality (Turner *et al.*, 2005). Divergence hitchhiking may be important for allowing differentiation to build from these initially isolated islands to successively encompass more of the genome (Via and West, 2008; Via, 2012). Thus, divergence hitchhiking predicts that populations very early in the speciation-with-gene-flow process should display only a few regions of exceptional divergence in genome scans (Feder *et al.*, 2012). Additional mutations contributing to ecological adaptation and reproductive isolation should subsequently accumulate almost exclusively in these genomic islands, as population progress further in speciation, until they eventually spread to cover the entire genome. Recent theoretical analyses have suggested, however, that windows of reduced effective migration around selected sites may be narrower than has been argued (Feder and Nosil, 2010), implying that while divergence hitchhiking may provide a boost in certain circumstances, the process is not essential for speciation-with-gene flow. An exception may be chromosomal inversions and translocations, which can decrease recombination rates across larger stretches of the genome and, thus, may qualitatively increase the potential for divergence hitchhiking to occur compared to collinear regions where gene order is the same along chromosomes (Noor *et al.*, 2001).

In contrast, genome hitchhiking predicts that not just a few strongly selected genes, but many more weakly selected loci across the genome, are often and principally involved in divergent ecological adaptation (Flaxman *et al.*, 2013). When a critical threshold number of these genes accumulate to reduce effective migration genome-wide, populations will show a rapid, nonlinear transition from comparatively low to high levels of adaptive genetic divergence, and between locus linkage disequilibrium. Reproductive isolation essentially becomes an increasing characteristic of the genome rather than of individual genes, as the genomes of populations congeal into the alternate adaptive entities we recognize as species. Hence, genome hitchhiking predicts that many genes across the genome will be found to show low level differentiation in early stages of speciation-with-gene-flow followed by a marked and dramatic increase in levels of divergence between populations that have moved into the genome-wide-congealing phase of the process (Flaxman *et al.*, 2014).

Genome scans in a range of organisms, including *Timema* walking sticks (Soria-Carrasco *et al.*, 2014), *Heliconius* butterflies (Nadeau *et al.*, 2012), *Anopheles* mosquitos (Lawniczak *et al.*, 2010), *Rhagoletis* fruit flies (Michel *et al.*, 2010), *Gasterosteus* threespine sticklebacks (Jones *et al.*, 2012), *Coregonus* lake whitefish (Gagnaire *et al.*, 2013), and *Helianthus* sunflowers (Scascitelli *et al.*, 2010), have revealed extensive genetic differentiation between populations even at the early stages of ecological divergence. These taxa may therefore have the capacity to undergo genome-wide congealing during speciation-with-gene-flow (Flaxman *et al.*, 2014). Manipulative transplant and selection experiments on key conditions or traits known to differentially affect natural populations of *Rhagoletis* (Michel *et al.*, 2010; Egan *et al.*, 2015) and *Timema* (Soria-Carrasco *et al.*, 2014) also imply that numerous loci having moderate to weak effect relative to gene flow contribute to divergent ecological adaptation. Also, population comparisons of butterflies have revealed what looks like nonlinear increases of divergence through time (Nadeau *et al.*, 2012). However, much further research is required to confirm that divergence hitchhiking and genome-wide congealing resulting from the consequences of numerous small effect genes are important genome-level processes facilitating speciation-with-gene-flow.

Conclusion

New research on speciation-with-gene-flow is currently yielding novel insights into the origins of biodiversity. This understanding is being forged from accumulating evidence from nature on speciation-with-gene-flow involving many different forms of life in combination with next-generation DNA sequencing of the genome. By comparing taxa at varying stages in the speciation continuum from partially isolated races to near completely separated taxa, progress is being made in characterizing how genes are arrayed and collectively diverge during speciation. This research will indicate whether different stages of the speciation-with-gene-flow process exist, how different genome structures evolve and are influenced by divergence being initiated in sympatry versus parapatry versus allopatry, and how genome structure affects the potential for further population divergence through processes such as divergence and genome hitchhiking. The study of speciation-with-gene-flow has therefore progressed from research primarily documenting the process to analyses of genome-level processes facilitating population divergence.

Species Concepts and Speciation

D Ortiz-Barrientos, The University of Queensland, St Lucia, QLD, Australia

Introduction

Sexual recombination and mutation often produce continuous distributions of traits in a population (Galton, 1889; Wright, 1931; Fisher, 1958). However, as students of nature can confirm, continuity of form often breaks down as populations move through environmental gradients (Barton and Hewitt, 1985), migrate over geographical obstacles such as rivers and mountains (Mayr, 1942b), or coexist with related organisms that compete for resources or mates (Darwin, 1859; **Figure 1**). Although these circumstances immediately suggest that evolutionary forces like natural and sexual selection as well as genetic drift cause the decoupling of variation within and between populations (Coyne and Orr, 2004), the biological meaning of the resulting morphological gaps is less obvious.

Understanding the origins of discrete phenotypes among populations is one of the most fundamental and enduring problems in evolutionary biology; it not only underpins our understanding of the origins and maintenance of biodiversity, but also forms the conceptual basis of the species problem. This article provides a brief introduction to our current understanding of what species are and how they originate. It discusses the species problem (Mallet, 1995; Coyne and Orr, 2004; Lowry, 2012) and reviews the relationship between gene flow and the origin of new species, while discussing the likelihood of speciation under different geographical settings (Dobzhansky, 1940; Futuyma and Mayer, 1980; Gavrilets, 2000; Coyne and Orr, 2004; Bolnick and Fitzpatrick, 2007). This article also describes the various forms of reproductive isolation that accumulate as species originate, and it highlights some integrative questions about the speciation process that require further development.

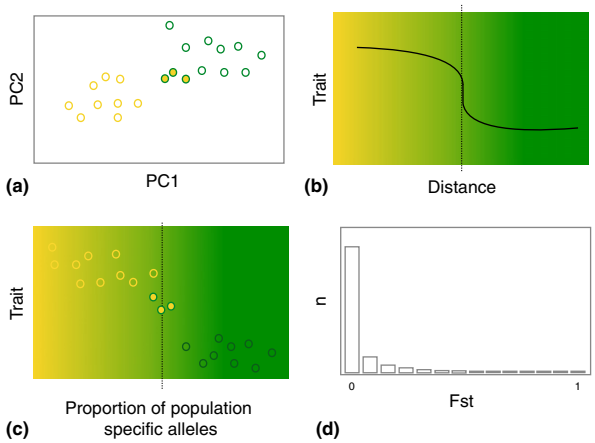

Figure 1 Phenotypic variation in nature is discontinuous. The principles of genetics suggest that sexual recombination should create a continuous distribution of phenotypes. However, careful examination of trait variation suggests that organisms cluster into groups of well-defined morphologies. (a) Morphological clusters often arise as populations colonize contrasting habitats (yellow and green landscape). (b) Traits may cline or abruptly step into different morphospaces. Alleles, or linked variants, responsible for the trait difference sort into each habitat. (c) Individuals found in one habitat contain a large fraction of such alleles (yellow circles), whereas individuals found in the other habitat contain alternative alleles responsible for their specific phenotypic value (green circles). In (a), (c) a few individuals may have mixed fractions of specific alleles from the two populations as shown with the green circles filled with yellow. How striking the proportions of mixed and non-mixed genotypes reflect the relative strength of divergent selection and homogenizing gene flow in a given trait. (d) Frequency distribution of Fst values between two populations. Because this process likely reflects the early stages of speciation, genomic differentiation between populations is likely to be low and to reflect similarity due to ancestral polymorphism, although in some cases can reflect homogenization by gene flow.

The Nature of Species

The origin of new species can be understood in two major ways. On one hand, speciation is the set of processes that create morphological and genotypic discontinuity in populations. Darwin was the first to provide a meaningful explanation for this process by suggesting that natural selection is responsible for the phenotypic gaps seen in nature (Darwin, 1859). These gaps arise from the elimination of unfit individuals with intermediate phenotypes, which leads to the origin of forms often distinguished by multiple traits and by their inability to occupy each other's niche. More recently, these ideas have been extended to include the formation of genotypic gaps between populations, or the formation of genotypic clusters in sympatry (Mallet, 1995). Although these 'Darwinian species' are probably common, many could be short-lived given that environmental conditions can be unstable over long periods of time, and the homogenizing effects of gene flow can often overpower the differentiating effects of natural selection.

On the other hand, species originate when interbreeding groups of individuals can no longer reproduce with other such groups (Dobzhansky, 1937, 1940; Mayr, 1942a, 1963). In this view, reproductive gaps, and not necessarily morphological ones (e.g., sibling species are nearly identical), define biological species, and neither environmental fluctuations nor hybridization can eliminate the genetic differences that have accumulated between them. (Coyne and Orr, 2004; Rieseberg *et al.*, 2006). These two major solutions to the species problem, Darwinian and biological species, have helped us understand how natural selection and other evolutionary forces play a role in the origin of biodiversity. However, the two solutions assign a different emphasis to the role of evolutionary forces: while Darwinian species arise by divergent natural or sexual selection during primary contact, many different evolutionary forces acting in a variety of geographic

 doi:10.1016/B978-0-12-800049-6.00061-5

Box 1 Speciation and gene flow

Sympatric and parapatric speciation, as well as reinforcement of reproductive isolation, are difficult because gene flow antagonizes the forces that create divergence (such as drift and natural selection). Gene flow can be present since the beginning of sympatric and parapatric speciation (primary contact), or during the completion of allopatric speciation (when populations come into secondary contact). Although primary contact may never lead to divergence of populations, and secondary contact can fuse them, theoretical models suggest that strong divergent selection, physical linkage between genes responsible for adaptation, and stable genetic associations between prezygotic and postzygotic reproductive isolation can facilitate speciation with gene flow in both cases. Sympatric and parapatric speciation are likely to always lead to the origin of Darwinian species, but perhaps less likely to the origin of biological species.

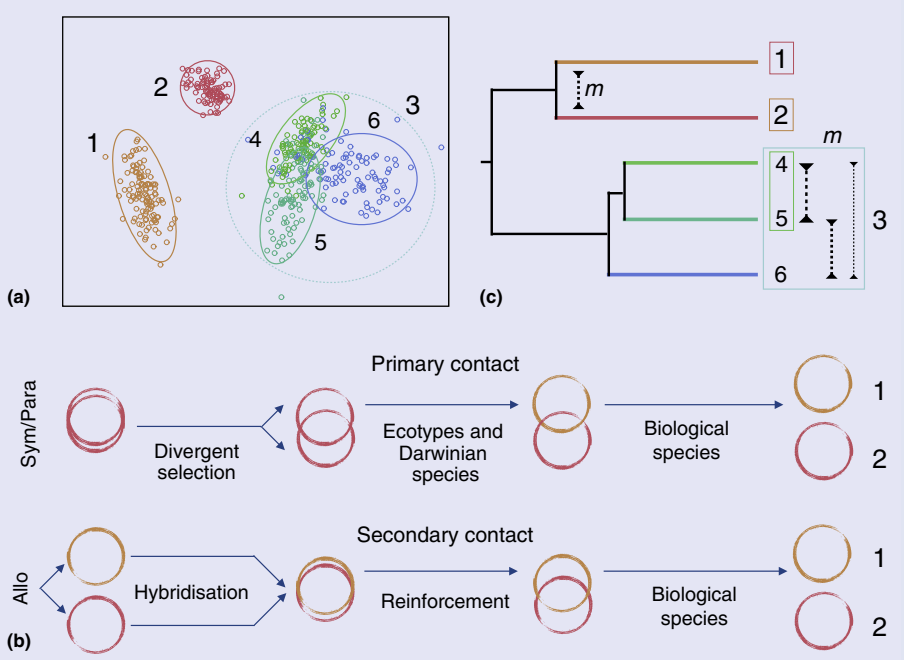

Figure Box 1 Speciation with gene flow during primary and secondary contact. (a) Populations showing strong associations between phenotype and habitat often form clearly defined clusters in multivariate trait space (clusters 1 and 2), and are likely to be reproductively isolated. (b) However, some populations may partially overlap in morphology, either because they are in the early stages of speciation, or because they have come back into contact after a previous period of allopatric divergence (clusters 4–6). Natural selection can resolve these stages and lead to the formation of populations clearly separated by complete extrinsic or intrinsic reproductive isolation. (c) Examination of variability in multiple genetic markers is expected to reveal the history of their divergence, although patterns of gene flow can distort relationships amongst populations. *m* represents migration rate between populations, and its strength is denoted by the thickness of the inverted arrows connecting a population pair.

settings (including secondary contact) can fuel the origin of biological species (**Box 1**; **Figure 2**).

Different from its sexual counterparts, asexual organisms are difficult to sort into these views (Holman, 1987; Cohan, 2002, 2006; Barraclough *et al.*, 2003; Cohan and Koeppel, 2008; Tang *et al.*, 2014). However, given that natural selection often favors single asexual genotypes that replace the entire population in a given habitat, asexual species can be better understood in terms of their adaptations, and perhaps as genotypic clusters suited to particular environments. This is because complete replacement of genetic variability leads to a correlation between genotype and phenotype, and thus to organic discontinuity. In groups of organisms where both sexual and asexual reproductions is rampant (agamic complexes; e.g., Krak *et al.*, 2013), organic discontinuity does not arise, suggesting that the origin of species is intimately related to the mode and prevalence of sexual reproduction in any given system.

Reproductive Isolation

Speciation studies investigate the evolution of genotypic clusters and of biological species. In other words, they seek to understand how divergent natural and sexual selection create the morphological and genotypic gaps of Darwinian species, and how reproductive isolation evolves and leads to the irreversible formation of biological species. Studying the origin of genotypic clusters and biological species often requires performing ecological (Hatfield and Schluter, 1999; Rundle and Schluter, 2004; Rundle and Nosil, 2005, e.g., Thibert-Plante and Hendry, 2009), behavioral (e.g., Noor, 1995; Noor *et al.*, 2001; Moehring *et al.*, 2006) (depending on the organism), and genetic experiments between populations that grow suboptimally in each other's habitat (e.g., Lowry *et al.*, 2008b; Lowry and Willis, 2010), fail to recognize heterospecific partners (Ortiz-Barrientos *et al.*, 2004), or fail to produce fertile or viable hybrid offspring (Presgraves *et al.*, 2003;

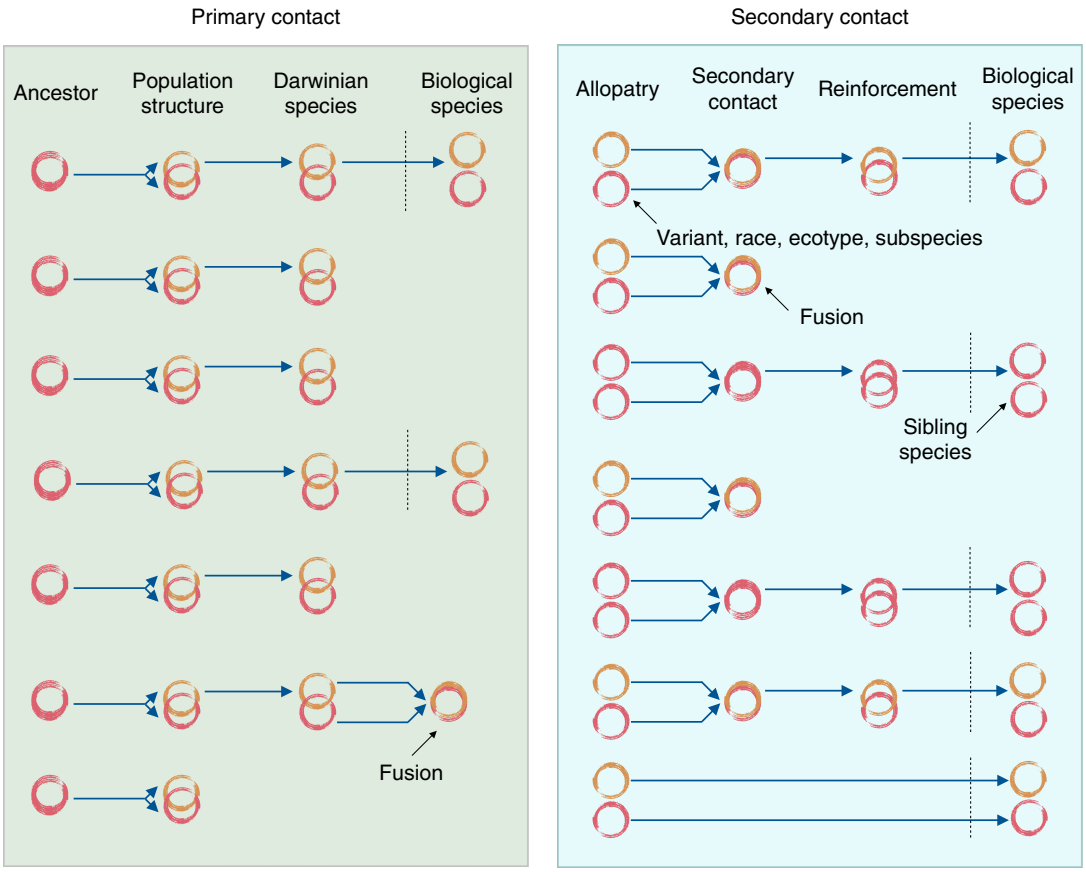

Figure 2 Primary and secondary contact speciation, and the distribution of speciation events. The left panel shows primary contact speciation, where divergent natural selection, mainly leads to the creation of Darwinian species, and less often to the formation of biological species. The transition from Darwinian to biological species might occur only if there is either the right genetic architecture for linking extrinsic and intrinsic reproductive isolation or gene flow fully ceased between Darwinian species so intrinsic isolation can evolve unimpeded by homogenizing gene flow. Fusion and lack of divergence are also possible outcomes. The right panel shows secondary contact speciation, where previously allopatric populations come into contact and either fuse, remain separated by a hybrid zone, or complete the speciation process via reinforcement of reproductive isolation. Allopatric populations might have differentiated via natural selection (either divergent or uniform) or drift, and the outcomes of speciation do not necessarily lead to morphologically distinct species (i.e., sibling and cryptic species). Dotted vertical line represents the moment at which speciation becomes irreversible.

Presgraves, 2010a; Moyle, 2007). Despite the differences between Darwinian and biological species, these experiments on speciation address whether reproduction works as effectively between populations as it does within populations, and whether the kind of reproductive isolation that evolves is dependent on the ecology of the organism (see Sobel and Chen (2014) for a recent discussion on how to measure reproductive isolation). To understand the genetic, behavioral and ecological basis of speciation, the various forms of reproductive isolation that arise when populations become new species must first be described (Sobel *et al.*, 2010).

Reproductive Isolation *before* the Formation of Heterospecific Zygotes

Prezygotic reproductive isolation evolves when traits facilitating access to mates and gametes diverge between populations. Well-known prezygotic isolating barriers include the evolution of flowering time differences in plants (e.g., Hall and Willis, 2006; Savolainen *et al.*, 2006), the evolution of female preferences for male songs in insects and frogs (Blair, 1974, e.g., Littlejohn and Watson, 1985; Pfennig, 2003; Pfennig and Pfennig, 2010), and habitat isolation in response to adaptation to contrasting environments in plants (Ramsey *et al.*, 2003; Angert and Schemske, 2005; Sobel *et al.*, 2010; Schemske, 2010; Sobel, 2014; Sobel and Streisfeld, 2015; Baack *et al.*, 2015; Nakazato *et al.*, 2010). Because of the distinction between finding mates, and gametes finding each other after copulation, it is appropriate to call reproductive barriers that affect fertilization but not mating postmating-prezygotic isolation in animals (Price, 1997; Howard, 1999; Servedio, 2001; Matute, 2010b), and postpollination-prezygotic isolation in plants (Baack *et al.*, 2015). A common and important form of postmating-prezygotic isolation is called conspecific gametic precedence: here, mixed loads of pollen or sperm from two populations result in offspring ratios biased toward conspecific over heterospecific individuals (Rieseberg *et al.*, 1995; Price, 1997; Chang, 2004).

Reproductive Isolation *after* the Formation of Heterospecific Zygotes

If heterospecific zygotes form, hybrids might not be as viable and fertile as their diverged parents. Any change in development that reduces viability and fecundity of hybrid individuals represents a form of postzygotic reproductive isolation (Sasa *et al.*, 1998; Price and Bouvier, 2002; Presgraves, 2002; Lijtmaer *et al.*, 2003; Moyle, 2007). However, hybrids may suffer in more subtle ways, like when they fail to mate with other hybrids or parental types even though they are viable and fertile (Noor, 1997). Because the causes could in principle be so vast, the study of hybrid inviability largely relies on genetic experiments that isolate the causal genes of hybrid death, coupled with subsequent experiments that find the normal function of the gene in the parental species (Presgraves *et al.*, 2003; Barbash *et al.*, 2003; Orr *et al.*, 2004; Presgraves, 2007b; Phadnis *et al.*, 2015). The reasons for hybrid sterility are perhaps more restricted and might relate to normal variation found in reproductive genes within populations (e.g., Sun *et al.*, 2004; but see, Masly *et al.*, 2006).

Although hybrids tend to show reduced fitness compared to their parents, this need not be the case. In plants, it is common to find hybrid vigor (Lowry *et al.*, 2008a; Baack *et al.*, 2015), where hybrids show higher fitness than their parents; this can weaken some ecological forms of postzygotic reproductive isolation (see next section) and perhaps divergence during the early stages of speciation. Hybrids can also form new populations in areas where their parents cannot grow and reproduce, and therefore become new hybrid species (Barton, 2001; Greig *et al.*, 2002; Gross and Rieseberg, 2005; Rieseberg and Willis, 2007; Abbott *et al.*, 2013; Baack *et al.*, 2015). Finally, in some cases of primary and secondary contact between populations with adjacent habitats, hybrids can exist in intermediate environments, or ecotones, and form phenotypic and genetic clines that serve as conduits of genetic exchange between the diverged populations (Barton and Hewitt, 1985; Jiggins and Mallet, 2000; Abbott *et al.*, 2013). Whether hybrid zones often resolve in complete reproductive isolation, extrinsic or intrinsic, remains to be empirically explored.

Extrinsic and Intrinsic Reproductive Isolation

Extrinsic reproductive isolation refers to barriers to reproduction that arise from heritable variation that interacts with environmental conditions (Rundle and Whitlock, 2001; Rundle, 2002; Rundle and Nosil, 2005). These barriers manifest only in the habitats of the two diverging populations (**Figure 3(a)**). The opposite is true for intrinsic reproductive isolation, where barriers manifest in any environmental condition where hybrid formation occurs (**Figure 3(b)**; Coyne and Orr, 2004). The genetic changes responsible for intrinsic barriers are also expected to accumulate non-linearly ('snowball') with time (Moyle and Nakazato, 2010; Matute *et al.*, 2010; Orr, 1995), thus making the evolution of biological species difficult to reverse. One key difference between the two forms of barriers is the inexorable involvement of natural selection in extrinsic but not necessarily intrinsic reproductive isolation. Extrinsic barriers are predicted to evolve when divergent natural selection drives traits apart to the extent that any intermediate phenotype would be maladapted in the habitat of the two parents (Rundle, 2002), and any migrant phenotype would fail to survive in the alternative habitat of the other population (Nosil *et al.*, 2005).

Although intrinsic barriers may evolve as a by-product of divergent natural selection acting on traits within populations (Nosil, 2012), genomic conflict and, meiotic drive (Presgraves, 2010a,b), and gene transposition (Masly *et al.*, 2006) can also create hybrid sterility and inviability. Extrinsic barriers are the quintessential feature of Darwinian species, whereas intrinsic barriers are the critical component of biological species as they create irreversibility of divergence between populations. Although the study of these barriers has historically been split between ecologist and geneticists, respectively, modern speciation research aims to integrate the study of both, making it easier to understand the origin of both Darwinian and biological species, and the transitions across the speciation continuum (**Figure 4**; Wu, 2001; Lowry, 2012; **Box 2**).

Questions about Reproductive Isolation

How Important Is Genetic Drift in Speciation?

The role of natural selection and genetic drift in speciation can be easily perceived: divergent natural selection can trigger speciation events or complete them via reinforcement, whereas genetic drift leads to the inexorable accumulation of genetic differences between allopatric populations that create reproductive isolation between populations. Less obvious it is how genetic drift plays a role during colonization of new areas (e.g., via founder effects, Mayr, 1942a; Templeton, 1980; Coyne, 1994; Matute, 2013) or during speciation with gene flow (Via, 2009, 2012; Feder *et al.*, 2012; Nosil, 2012). A founder effect occurs when dramatic reductions in population size restructure the gene pool of a population after colonization of a new area. Some of these changes are expected to alter the mean value of traits causing reproductive isolation between populations, thus leading to what is known as founder speciation. Although some theoretical scenarios suggest that reproductive isolation may evolve directly from changes in population size (Slatkin, 1997; Uyeda *et al.*, 2009), experimental and observational evidence shows that the principal consequence of founder effects, inbreeding, leads more often to extinction than to speciation, suggesting that founder speciation exists in nature but might be rare (Matute, 2013).

Divergence arising from genetic drift is unlikely when populations diverge in the face of gene flow. This is because migration leads to the recombination of parental genomes during meiosis in hybrids and therefore to the eventual homogenization of allelic frequencies between populations (Felsenstein, 1981). However, neutral alleles can accumulate in regions that are recalcitrant to homogenization, which often are under strong divergent natural selection (Nosil *et al.*, 2009). Because of their physical proximity, recombination during meiosis in hybrids cannot decouple the neutral allele from the selected allele. Therefore, the neutral allele diverges together with the selected allele, in a process termed divergence hitchhiking (Via, 2012). Theory also suggests

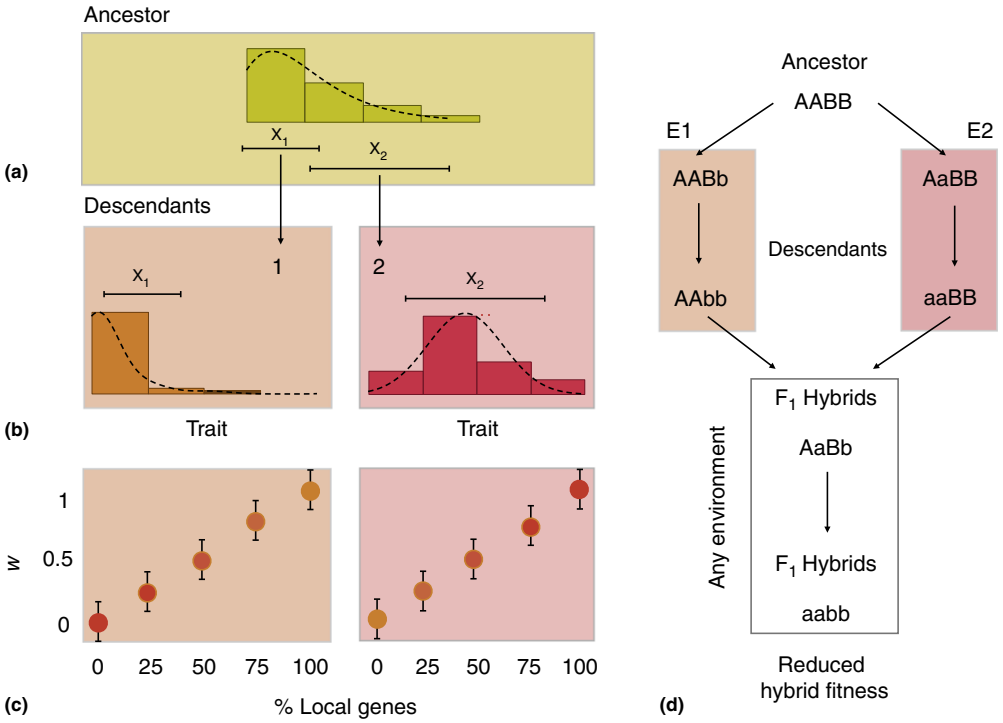

Figure 3 Extrinsic and intrinsic postzygotic reproductive isolation. (a) Trait distribution in an ancestral population that occupies the yellow habitat. The population colonizes two abutting and contrasting habitats where different mean trait values are favored (X_1 and X_2). (b) As divergent natural selection shifts trait means apart, populations start manifesting extrinsic reproductive isolation. (c) The strength of extrinsic reproductive isolation is a function of the proportion of local genes in the individuals exposed to each habitat. Migrants (i.e., 0% local genes) have reduced fitness (W) in the alternative habitats (immigrant inviability). F_1 hybrids, in the absence of dominance show an intermediate fitness response, whereas the two types of backcrosses (25% and 75%) shift rank in fitness across the two environments (note that the backcross type containing 25% of local genes in one environment would contain 75% of local genes in the other environment). This pattern is consistent with the effects of ecology-based divergent natural selection being responsible for the origin of reproductive isolation between populations adapting to contrasting environments. Other forms of selection (e.g., uniform selection) can also create reproductive isolation, but they would not lead to this pattern (see Nosil, 2012 for a review). (d) The evolution of Dobzhansky–Bateson–Muller genetic incompatibilities. An ancestral interaction between loci A and B evolves to fix alternative alleles of one of the loci in two populations found in two different environments; however, natural selection or genetic drift can drive the process. Hybrids between the two populations will experience reduced fitness because the alleles *a* and *b* have not been tested against each other (note that these are only a subset of all fixed differences that accumulate between the two populations).

that unlinked neutral alleles may diverge beyond neutral expectations if natural selection is quite strong, in a process termed genome hitchhiking (Feder *et al.*, 2012).

The effect of selected sites on neutral variability is also problem fundamental to the formation of hybrid zones. Hybrid zones establish when there is a balance between natural selection and migration (Barton and Hewitt, 1985), and this determines the movement of neutral alleles across the zone. The strength of selection creating the hybrid zone is visualized in terms of gradients that reflect how quickly phenotypes and genotypes change per unit of geographic distance (i.e., phenotypic and genetic clines, Harrison, 1993). The movement of neutral alleles across the zone largely depends on how close they are to the selected loci, and on the strength of selection (Barton and Bengtsson, 1986). Strong barriers to gene flow in a hybrid zone can delay the movement of neutral alleles for hundreds of generations, thus facilitating genetic differentiation in the face of gene flow (Barton and Gale, 1993), and possibly the accumulation of additional barriers to gene flow between the populations (Nosil *et al.*, 2009). Whether hybrid zones resolve into irreversible species or not, remains an active question of speciation research (Rudman and Schluter, 2016).

Is There a Genetic Link between Extrinsic and Intrinsic Reproductive Isolation?

Ecology-based divergent natural selection leads to the accumulation of extrinsic reproductive isolation (Schluter, 2001, 2009; Rundle and Nosil, 2005; Schluter and Conte, 2009; Nosil, 2012). Theoretically, hybrids will display intermediate trait values that would render them unfit in parental habitats (Rundle and Whitlock, 2001). Similarly, migrants will fair poorly in each other's habitats (Nosil *et al.*, 2005). Different from extrinsic postzygotic isolation (that relies on additive genetic variance for fitness), intrinsic postzygotic isolation relies on the evolution negative epistatic interactions amongst loci derived from two populations (Orr, 1995; **Figure 3(b)**). As mentioned before, intrinsic reproductive isolation manifests in any environment where hybridization occurs, including the laboratory, and regardless of the evolutionary

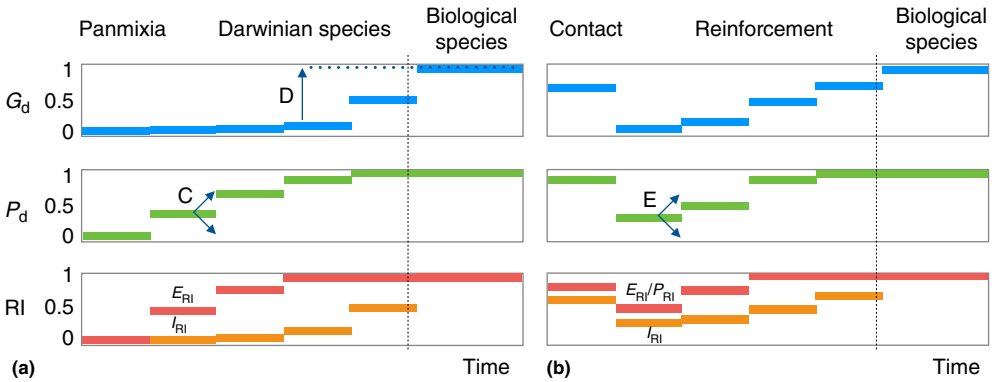

Figure 4 The evolution of genetic and phenotypic differentiation and the accumulation of reproductive isolation between populations. (a) Species may originate in sympatry or parapatry if natural selection is relatively stronger than the amount of gene flow between the two populations. Populations start in panmixia where genetic (G_d) and phenotypic (P_d) differentiation is minimal, and intrinsic reproductive isolation (I_{RI}) is absent. If natural selection is creating differentiation despite gene flow, then extrinsic reproductive isolation (E_{RI}) will become stronger in the system and both migrants and hybrids will be removed from the populations. Darwinian species arise when multiple traits and genes clearly define phenotypic and genetic clusters. Extrinsic reproductive isolation can be quite strong at this stage, thus reducing gene flow to minimal levels and facilitating divergence between populations due to drift and selection. Intrinsic reproductive isolation can now freely evolve without the homogenizing constraints of gene flow, thus creating evolutionary independence and species irreversibility. (b) A similar process occurs when two previously allopatric populations come into secondary contact (but this may be difficult to distinguish if it happened long ago). Levels of genetic and phenotypic divergence as well as the evolution of reproductive isolation are initially moderate, eventually increasing in strength as speciation proceeds. One way in which this can happen is via reinforcement. Here, maladaptive hybridization creates a strong selective pressure for favoring individuals that prefer conspecific over heterospecific individuals. C and E represent the points at which divergent selection favors the evolution of alternative traits, including behavioral ones. D represents the special case in which entire genomes start to diverge dramatically as a consequence of very strong selection acting on many loci (Feder *et al.*, 2013; Flaxman *et al.*, 2014).

forces that drove the fixation of alternative interacting alleles. The negative epistatic interactions that reduce fitness in hybrids are called Dobzhansky–Muller–Bateson (DMB) genetic incompatibilities (Bateson, 1909; Muller, 1942; Dobzhansky, 1934), and they have been the intense focus of genetic research in the last decades (Presgraves, 2010a). Although relatively few genes causing DMB incompatibilities have been identified, it appears that in most cases natural selection and genomic conflict have driven their rapid evolution (Presgraves *et al.*, 2003; Presgraves, 2007a). But, is it possible to reconcile the role of natural selection in creating both forms of reproductive isolation?

One viable scenario that links the evolution of extrinsic and intrinsic reproductive isolation by natural selection is via a special form of divergence hitchhiking, which in this article is referred to as isolation hitchhiking. Under divergence hitchhiking, neutral alleles linked to divergently selected alleles also become highly differentiated between the two diverging populations. This occurs because gene flow cannot breakdown the genetic association between adaptive and neutral alleles that arises from their proximity along a chromosome. Although most neutral mutations will be harmless in hybrids, a fraction of them will be part of a genetic incompatibility, and therefore will create intrinsic reproductive isolation. Isolation hitchhiking therefore refers to the evolution of intrinsic isolation as a by-product of DBM incompatibilities evolving in tight linkage with those genes causing extrinsic reproductive isolation. It remains unclear whether the genetic variability necessary for isolation hitchhiking exists, but recent work in monkey flowers from the genus *Mimulus* suggests that is possible (Presgraves, 2013; Wright *et al.*, 2013).

In the absence of linkage within a chromosome, mechanisms that suppress recombination between these two kinds of mutations could facilitate their genetic association (**Figure 5**). For instance, if a population carries the locally adapted genotype *AABB* and a second population the locally adapted genotype *aabb*, recombinant genotypes are expected to display reduced fitness. Consequently, any modifier allele that reduces recombination between A and B will be favored (Lenormand and Otto, 2000), including chromosomal inversions (Kirkpatrick and Barton, 2006). Once in place, this region of suppressed recombination, which contains the genes responsible for extrinsic postzygotic reproductive isolation, facilitates the accumulation of the alleles responsible for the evolution of DBM incompatibilities and therefore of intrinsic postzygotic reproductive isolation. This mechanism of isolation hitchhiking has an advantage over the linkage model explained before: because some modifiers of recombination, such as inversions, can suppress recombination rates over long stretches of a chromosome, they also increase the mutational availability for the evolution of DBM incompatibilities. Both models predict co-localization of quantitative trait loci for extrinsic and intrinsic forms of reproductive isolation, which should map to regions of suppressed recombination.

Even though suppression of recombination facilitates speciation with gene flow, extrinsic and intrinsic reproductive isolation could be genetically independent, and evolve sequentially under specific circumstances. For instance, intrinsic reproductive isolation may evolve once extrinsic reproductive isolation has reduced gene flow to nil levels (Seehausen *et al.*, 2014). Different from scenarios of suppressed recombination, this would facilitate the accumulation of DMB incompatibilities across most of the genome (**Figure 5**). Note that this

Box 2 Phylogenies, genealogies and reproductive isolation

A major consequence of population differentiation is the sorting of ancestral alleles into independent lineages and thus the eventual formation of groups where allelic ancestry is confined to the lineage and not to other such (**Figure 4**). Achieving this level of lineage-specific allelic ancestry (i.e., monophyly) can take a long time, particularly in large populations where loci can remain polymorphic for many generations. Therefore, the historical relationships of some genes may not reflect the relationships arising from the speciation process (Avise and Wollenberg, 1997; Pagel, 1999; Edwards and Beerli, 2000; Beltran *et al.*, 2002; Brumfield *et al.*, 2003; Leache *et al.*, 2014; Edwards *et al.*, 2016).

The use of phylogenies, where only one individual per type is sequenced, and genealogies, where many individuals per population are sequenced, are some of the most common approaches to establish taxonomic relations across the tree of life. Although phylogenies and genealogies arise from the same principles that create species, the population genetics of ancestral and new mutations make it difficult to create straightforward equivalences between phylogenetic or genealogical species and Darwinian or biological species. However, phylogenies and genealogies can provide insights as to the basic role of speciation versus extinction in creating diversification (Reddy *et al.*, 2012; Rabosky *et al.*, 2013; McGuire *et al.*, 2014; Rabosky, 2015), reveal the tempo of speciation in swift evolutionary processes such adaptive radiations (Rundell and Price, 2009; Gavrilets and Losos, 2009; Agrawal *et al.*, 2009; Rabosky and Glor, 2010; Reddy *et al.*, 2012).

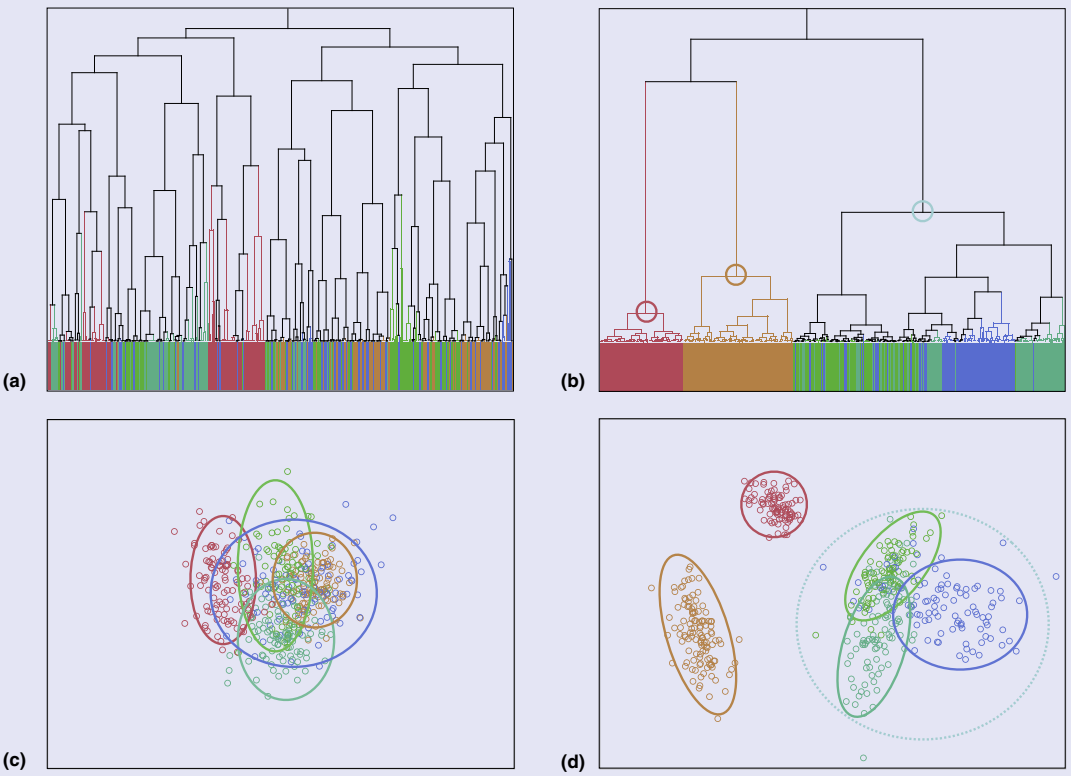

Figure Box 2 Clusters, genealogies, phylogenies, and reproductive isolation. As fewer traits are shared between them and populations become discrete, their phylogenetic relationships also change. For instance, transitions from continuous variation (a), (c) to discontinuous variation (b), (d) can lead to clustering of phenotypic forms that might be associated with particular environmental conditions as shown by the multiple colored sets inside the dotted circle in (d). Nodes in (b) represent where reciprocal monophyly can be observed between biological species (red vs. orange vs. blues and greens) or Darwinian species (green and blue clusters). (d) Also shows that Darwinian species share individuals with similar genotypes and trait values as a consequence of recent common ancestry. Biological species are less affected by incomplete lineage sorting than Darwinian species, but reciprocal monophyly is likely to manifest after speciation has been completed. Reciprocal monophyly, like complete reproductive isolation, is seemingly a definite point in time. However, and different from the biological species, reciprocal monophyly can be affected by incomplete sampling of individuals across the range of an organism.

expectation is also found in allopatric speciation where suppression of recombination is not directly related to the probability of speciation. However, and different from speciation with gene flow, there is no a priori expectation that extrinsic or intrinsic reproductive isolation should evolve first during allopatric speciation.

Can Speciation Repeat Itself?

Across the geographic range of a species, genetic drift cannot create an association between traits and environment, and therefore its role on the evolution of reproductive isolation is unpredictable. In contrast, natural selection can create strong

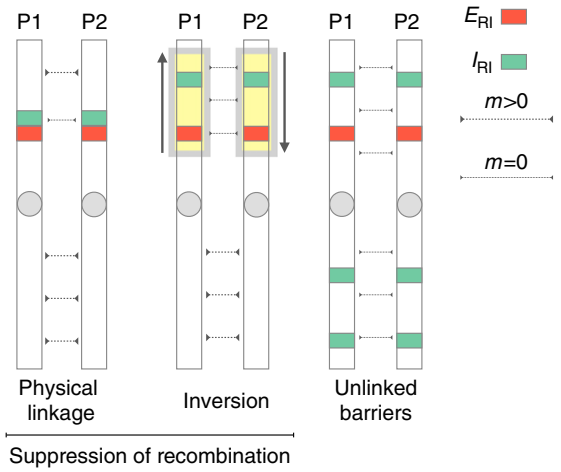

Figure 5 The evolution of extrinsic and intrinsic reproductive isolation during primary speciation with gene flow. Three general models for the isolation hitchhiking of extrinsic and intrinsic reproductive barriers to gene flow between populations. P1 is population one, and P2 is population two. Rectangles and the circle in the middle represent a metacentric chromosome. The green rectangles are locations in the genome containing genes that are members of a DBM genetic incompatibility that reduces fitness in hybrids and creates intrinsic reproductive isolation (I_{RI}). The red rectangles are locations in the genome containing genes under ecology-based divergent natural selection and causes extrinsic reproductive isolation (E_{RI}). The large yellow rectangles and associated arrows represent a chromosomal inversion separating the two populations. The inverted arrows represent varying levels of gene flow along chromosomal regions, *m*, between the two populations. The first model (physical linkage) assumes tight linkage (i.e., little recombination) between the genes responsible for the two forms of reproductive isolation, whereas in the second model (inversion) a chromosomal inversion suppresses recombination between otherwise unlinked loci responsible for the two forms of reproductive isolation. Model three (unlinked barriers) assumes that gene flow stopped across the entire genome and now is free to evolve by both genetic drift and natural selection. In this model, isolation hitchhiking arises after Darwinian species evolved (i.e., extrinsic reproductive isolation reduced gene flow between the two populations completely).

associations between environment and phenotype and thus create repeated patterns of divergence amongst the populations of a species. Parallel speciation is a deterministic case of speciation where ecology-based divergent natural selection leads to the evolution of reproductive isolation repeatedly and independently between populations adapted to contrasting environments (Schluter and Nagel, 1995). Populations inhabiting the same habitat are expected to remain reproductively compatible for longer periods of time compared to populations found in contrasting habitats. Therefore, typical tests of parallel speciation involve phylogenetic approaches that evaluate independence and number of origins, genetic crosses both between populations adapting to the same environment and between populations adapting to different environments, and finally, experiments that link trait variation with variation in reproductive isolation (Ostevik *et al.*, 2012). Although there are several convincing cases of parallel speciation in animals (e.g., in snails (Johannesson *et al.*, 2010); stick insects (Soria-Carrasco *et al.*, 2014); and stickleback fishes (Schluter and Nagel, 1995), there are relatively few putative ones in plants, perhaps suggesting that the consequences of divergent natural selection across kingdoms might be different, or that the right tests have not yet been performed in plants (Ostevik *et al.*, 2012).

Can Reinforcement of Reproductive Isolation Complete the Speciation Process?

Natural selection can complete the speciation process by reinforcing reproductive isolation in response to maladaptive hybridization between two populations (Dobzhansky, 1940). However, this is rather difficult: gene flow can randomize the associations between the genes causing maladaptive hybridization and those causing prezygotic (or extrinsic) reproductive isolation, and thus causing the two populations to fuse. More problematic, as prezygotic isolation spreads in the population, maladaptive hybridization becomes rare, effectively removing the pressure for evolving further prezygotic isolation. As a consequence, reinforcing selection can be self-defeating. Despite these and other seemingly fatal arguments (Servedio and Noor, 2003), recent experimental evidence for reinforcement suggests that it could be quite common in nature (Ortiz-Barrientos *et al.*, 2004; Hoskin *et al.*, 2005; Lukhtanov, 2010; Lemmon and Lemmon, 2010; Matute, 2010a,b; Yukilevich, 2012; Hopkins, 2013; Nosil, 2013; Pfennig and Rice, 2014).

Models of reinforcement illustrate how the antagonism between gene flow and natural selection can be tipped in favor of natural selection and therefore speciation. Felsenstein (1981) used a simple model where alleles at two loci, B and C, controlled fitness in two habitats. In one population the fittest genotype was *bc* and in the other one it was *BC*. Hybrids between them, *bC* and *Bc*, had low fitness. A third locus, A, controlled the mate preferences for *A* or *a* individuals. Although recombination between the loci B and C would favor speciation, but recombination between A and BC would antagonize it. The reason was simple: recombination between B and C would help restore the fittest genotypes, whereas recombination between A and BC would lead to preference for mates that would not be fit in the habitat where choice took place. Because the A locus had two preference alleles, these models are referred to as two-allele models for the evolution of mate preferences. Two-allele models suggest that speciation with gene flow would be difficult unless mechanisms suppressing recombination between A and BC evolved, or recombination between these A and the BC loci were unnecessary.

Felsenstein (1981) suggested that a single allele for mate preferences at the A locus could provide a solution. The mate preference would act as an enhancer locus of a previously present preference, or as an assortative mating locus that would favor mating between conspecific individuals. For instance imagine two groups of individuals that fail to see each other well and often misidentify members of each group. If they were both given glasses that enhanced the ability to distinguish group members, the exchange of the glasses (i.e., the same allele) would enhance the ability to correctly identify the identity of each individual. These models are

called one-allele models for the evolution of assortative mating, and recombination in the ABC system does not hamper speciation. Theoretical models, as well as the empirical evidence for speciation by reinforcement have been recently reviewed in plants and animals (Hopkins, 2013; Ortiz-Barrientos *et al.*, 2009).

Is Recombination Suppression Necessary for Speciation with Gene Flow?

Suppression of recombination may sometimes favor divergence during speciation (**Figure 5**). In the Felsenstein model, suppression of recombination would favor mating between individuals that survive well in the habitat where the mate choice took place. Recently, work on speciation with gene flow has revealed that chromosomal inversions play an important role in speciation by suppressing recombination between loci contributing to various forms of reproductive isolation. For instance, Noor *et al.* (2001) suggested that inversions would lock DBM genetic incompatibilities into place thus preventing their elimination from the population. The consequences were simple but powerful: first, inversions would maintain maladaptive hybridization levels over long periods of time, thereby facilitating the evolution of prezygotic isolation until the completion of speciation. Second, inversions would create conditions for genetic associations between loci responsible for prezygotic and postzygotic isolation, thus alleviating the antagonism between recombination and speciation by natural selection. A related model, proposed by Rieseberg (2001) suggested that inversions could amplify the effects of reproductive isolating genes by extending their effects over larger regions of the genome. More recently, it has become clear that allelic modifiers of recombination, or those alleles responsible for natural variation in recombination within species, can also play a role in during the early or late stages of speciation with gene flow by preserving favorable allelic combinations in each locally adapted population (Ortiz-Barrientos *et al.*, 2016). However, suppression of recombination might be unnecessary in several models of speciation (Ortiz-Barrientos *et al.*, 2016). For instance, if divergent natural selection is very strong since the early stages of speciation, the frequency of maladapted hybridization would be low and the conditions for the evolution of suppressed recombination would not occur.

What are Speciation Genes?

Studies of reproductive isolation have attempted to isolate the genes responsible for reproductive isolation. However, the very definition of what a speciation gene is makes it difficult to agree how many speciation genes have been found, and whether they reveal patterns of speciation (Rieseberg and Blackman, 2010; Presgraves, 2010a,b). Under the view that speciation is the evolution of reproductive isolation, it is clear that genes whose alleles contribute to some form of reproductive isolation can be considered a speciation gene (Nosil and Schluter, 2011). On one hand, there are genes contributing to DBM genetic incompatibilities, and therefore to the evolution of intrinsic reproductive isolation (hybrid sterility and inviability). On the other hand there are genes responsible for local adaptation and the evolution of extrinsic reproductive isolation (immigrant inviability and extrinsic postzygotic isolation), and those responsible for gametic recognition, for male–female interactions, and mate choice. In this sense, the list of speciation genes that have been discovered is perhaps larger than anticipated; yet they still have not clearly revealed whether there are special categories of speciation genes.

Questions about the contribution of a particular gene to speciation are similar to those applied to measurements of reproductive isolation. It would be important to know when the speciation gene arose, and whether or not speciation genes create full or weak reproductive isolation (Nosil and Schluter, 2011; Coyne and Orr, 2004). In relative terms, a speciation gene causing strong reproductive isolation might see its effects reduced to a very small magnitude if it arose very late in the speciation process. In a similar fashion, a gene whose expression is late during the life cycle of the organism (e.g., hybrid sterility), might also contribute relatively little to total reproductive isolation if genes expressed earlier during development (e.g., genes responsible for seed germination in plants) already produced high levels of isolation between populations.

Why are There Species?

The fundamental principles of population genetics determine the patterns of genetic variation in nature. However, it is less clear how they lead to the emergence of species. Darwinian species are perhaps best understood in terms of the action of disruptive and ecology-based divergent natural selection (Mallet, 1995), whereas biological species ultimately rely on the evolution of DBM genetic incompatibilities (Coyne and Orr, 2004). These proximate causes form the basis of the research program to understand the origin of species but they do not answer the question as to why there are species and not just a continuum of diversity in nature. As discussed by Maynard Smith and Szathmary (1995), one putative answer is that genetic variation occupies a discontinuous ecological and geographical space. As individuals colonize and adapt to such conditions the complex interrelation amongst genes leads to the emergence of trade-offs that make it difficult to occupy other environments. In this sense, the reason for the existence of species leads to the natural formation of Darwinian species. However, as it has been discussed before, ecological divergence need not be the last step of the formation of new species and therefore other features of the world (in addition to environmental and geographic heterogeneity) must explain the existence of both Darwinian and biological species.

Sexual recombination and mutation are perhaps the missing ingredients, which incidentally are also the major sources of genetic variation in nature. A combination of heterogeneous landscapes and sexual recombination of new mutations might inexorably lead to the formation of both Darwinian and biological species (Coyne and Orr, 2004). This is because, over time, new genetic variation sorts into new niches via the action of both drift and natural selection. However, some of this variation is incompatible with the occupation of specific areas across space and environment (the evolution of extrinsic reproductive isolation), and sometimes in an irreversible way

(the evolution of intrinsic reproductive isolation). Biological species sometimes may not need to evolve in this environmental grid, but in sexual selection grids, or neutrally evolving grids. In each one of these grids, phenotypes sort into clusters via different evolutionary forces, mostly in allopatry, and then genetic incompatibilities evolve leading once more to the production of irreversible biological species and the facilitation of coexistence in sympatry.

Acknowledgments

The author is grateful to Eric Baack for detailed and insightful comments about the ideas presented in this article. Maddie James and Thomas Richards provided useful comments to previous versions of this manuscript. The author is also grateful to Paula Davies, Justin Taylor and Richard Kliman for their sustained and encouraging support and guidance throughout the editorial process of the encyclopedia. This article is by no means exhaustive so the author apologizes for the many references that could have also been cited.

Glossary

Combination therapy A treatment consisting in the simultaneous administration of two or more drugs.
Complementation within mutant spectra The increase in virus progeny production by gene products supplied by different members of the same mutant spectrum.
Consensus sequence The one that at each position has the residue (nucleotide or amino acid) which is most abundant at the same position in the set of aligned sequences.
Defective viral genome The one that cannot complete a replication cycle, or that completes it with a substantially lower efficiency than the corresponding standard virus.
Error catastrophe Loss of genetic information due to an excess of mutations.
Error threshold An average error rate above which a virus cannot maintain its infectivity.
Fitness The replicative capacity of a virus mutant, population or isolate, measured relative to a reference mutant, population or isolate of the same virus.
Interference In the quasispecies context it means the capacity of a viral mutant or population to inhibit the replication of higher fitness genomes. Interference by a mutant spectrum is the converse of complementation within a mutant spectrum (see term above).
Lethal defection Loss of viral infectivity mediated by a class of defective genomes termed defectors.
Lethal mutagenesis Extinction of a virus due to an excess of mutations.
Master sequence The highest fitness genome in a viral quasispecies.
Monotherapy Treatment with a single drug.
Mutant spectrum (also termed cloud, distribution, or swarm) The ensemble of mutants that constitute a viral quasispecies.
Mutation frequency The average number of mutations per nucleotide in a mutant spectrum.
Mutation rate The frequency of occurrence of mutations during replication of a viral genome.
Rate of evolution Increase in the number of mutations in a viral genome population as a function of time. Generally the mutations are counted in the consensus sequence.
Viral quasispecies A distribution of related genomes subjected to genetic variation, competition, and selection, and that act as a unit of selection.

Introduction: Theoretical and Experimental Quasispecies

The term viral quasispecies refers to a population structure of RNA viruses whose major feature is the presence at any given time of multitudes of viral mutants that can approach a dynamic equilibrium when the population size is large and the environment constant. In practice, a true equilibrium is not attained because population size is finite and environments are variable. The absence of population equilibrium favors the unpredictable change of frequency of multitudes of dynamically arising and decaying mutants that altogether offer a rich substrate for virus adaptability. The quasispecies concept had two independent origins, one theoretical, coming from the field of biophysics; and another experimental, coming from molecular biology. The theoretical quasispecies were founded by Manfred Eigen in a pioneer mathematical study that addressed the evolution of molecules that replicated with the regular production of error copies (Eigen, 1971). The theory was completed by Manfred Eigen and Peter Schuster, and its objective was to develop a model for self-organization and adaptability of primitive replicons that are thought to have been at the origin of life on earth (Eigen, 1992, 2013; Eigen and Schuster, 1979). In this treatment, the replicating molecules are organized around a dominant or most fit (with maximum replicative capacity) sequence termed the 'master' sequence (terms defined in the Glossary). The mutants around the master sequence are ranked according to fitness, with higher fitness corresponding to molecules with a sequence closer to the master. The information conveyed by the mutant distribution is lost if the average error rate during replication exceeds a threshold value. Violation of the error threshold leads to loss of information. Quasispecies was initially formulated as a deterministic theory, meaning that the mutant distributions were of infinite size in equilibrium, and the evolutionary outcomes predictable. This was a mathematical necessity amply accepted in the formulation of theoretical models. Extensions of the original quasispecies theory to the more realistic situations of finite populations in variable fitness landscapes have been developed (as recent review, see Domingo *et al.*, 2012). These extensions approximate quasispecies to real biological entities that often display a stochastic (i.e., with an unpredictable chance component) rather than deterministic (predictable) behavior.

The experimental origin of quasispecies was the discovery that populations of the RNA bacteriophage Qβ were composed of complex spectra of mutants rather than a defined virus with a precise nucleotide sequence, as it was thought at a time at which a virus isolate was synonymous with a nucleotide sequence. The estimate was that in populations of bacteriophage Qβ the subset of genomes without mutations (what could be

considered the master or more abundant sequence) did not amount to more than 15% of the total; the rest were mutants (Domingo *et al.*, 1978). This observation on the population structure of bacteriophage Qβ was in striking agreement with the main precepts of quasispecies theory (Domingo *et al.*, 2001, 2012; Eigen and Schuster, 1979). The fact that RNA virus (and many DNA virus) populations consist of dynamic (continuously changing) mutant distributions has been amply confirmed by application of new ultra-deep sequencing techniques that have greatly facilitated analyses of viral populations; the more deeply mutant spectra are analyzed the more dramatic their complexity turns to be (Acevedo *et al.*, 2014; Domingo *et al.*, 2012; Lauring and Andino, 2010). No exceptions to a quasispecies genomic structure have been found among the RNA viruses. Mutant clouds replicate in humans infected with HIV-1, influenza virus, hepatitis C virus (HCV), or Ebola virus. Pathogenic and nonpathogenic RNA viruses are quasispecies (Holland, 2006). Presently, quasispecies are defined in virology as dynamic collections of different but closely related genomes subjected to a continuous process of genetic variation, competition and selection, and that act as a unit of selection (Domingo *et al.*, 2012).

Implications of the Quasispecies Population Structure

There are two major classes of consequences of viral populations existing as quasispecies: (1) of a theoretical nature regarding how should viruses be defined, and (2) of a practical nature derived from the mechanisms by which viruses adapt to changing environmental conditions, and ensuing difficulties for viral disease prevention and treatment (Holland *et al.*, 1982).

With regard to the definition of virus, the main departure of quasispecies from previous views is that the 'wild type' can no longer be considered a genome with a defined sequence, of the type currently cataloged in data banks. Instead, a wild type is a distribution of related but different sequences, that is, a rather indeterminate average of related sequences. This is an important conceptual novelty since the term 'wild type' still used in many microbiology and virology textbooks has only an evanescent meaning in that it should be defined for each isolate, for each clone and even for each experiment in laboratory designs. The connection among sequences of the same replicative unit is often established by mutation, but it can be also made by recombination and segment reassortment in the case of viruses with a segmented genome. Quasispecies theory is compatible with any mechanism of genome variation fueling the genetic change for competition and selection to act on any mutant or mutant ensemble.

A second implication that pertains to the way viruses should be defined originates from internal interactions that are frequently established among components of the same mutant spectrum, and the influence of such interactions in virus behavior. The first experimental result that pointed at intrapopulation interactions was that individual biological clones isolated from a population of bacteriophage Qβ displayed lower fitness than the total population from which the clones were isolated (Domingo *et al.*, 1978). The same result was obtained with biological clones of vesicular stomatitis virus (Duarte *et al.*, 1994). Other observations both in cell culture and *in vivo* on the collective behavior of viral quasispecies are summarized in **Table 1**, and have been reviewed (Domingo *et al.*, 2012; Lauring and Andino, 2010). Thus, mutant spectra that are generated during viral replication are not merely an

Table 1 Evidence of collective behavior of viral quasispecies

Virus	*Observation*	*References*

MV	Two mutants together (but not each individually) mediate membrane fusion	Shirogane *et al.* (2012)

Abbreviations: FMDV, foot-and-mouth disease virus; LCMV, lymphocytic choriomeningitis virus; MV, measles virus; Qβ, *Escherichia coli* bacteriophage Qβ; PV, poliovirus; VSV, vesicular stomatitis virus.

aggregate of mutants as a result of mutation-selection (the traditional Wright–Fisher view of population genetics) in which the mutants coexist independently of the others. Rather, the population is an aggregate whose composition is influenced not only by mutation-selection acting on the dynamically arising variants, but also by the acquisition of new phenotypes through interactions among mutants (Shirogane *et al.*, 2012). There is a sort of 'coevolution' of population structure and selection forces, as if intrapopulation interactions modified the environment. In other words, and in agreement with the initial quasispecies theory, in viral quasispecies an ensemble of mutants, not the individual components, is the target of selection. In some cases, however, the behavior of individual mutants may prevail over the ensemble. Part of the current research on viral quasispecies aims at distinguishing those properties of mutant spectra that depend on individualities from those that depend on collectivities, with the objective of better understanding viral population dynamics and viral disease mechanisms, to design more effective antiviral strategies.

Quasispecies as Reservoirs of Phenotypic Variants

Mutant spectra (also termed mutant distributions or clouds) are a rich reservoir of genetic and phenotypic variants, as can be intuitively gathered from examining **Figure 1**, and considering that an individual infected with an RNA virus can attain 10^{10} to 10^{12} (in some cases even more) potentially infectious particles at any given time during an acute infection (about one billion pages filled with the genomes related to those depicted in **Figure 1**). Mutations can impact viruses in different ways. A mutation is considered neutral when it does not have a significant effect in the biology of the virus harboring it. If the mutations depicted in **Figure 1** were neutral, the behavior of a virus would be independent of their presence. It turns out that a large proportion of mutations (difficult to tell how many, but probably the majority) are not selectively neutral. Many mutations are deleterious to various extents, and they will be either eliminated or their frequency reduced as a result of negative selection. However, some mutations present in a mutant spectrum have the potential to rescue the virus from a selective constraint, for example, to overcome an immune response (neutralizing antibodies or cytotoxic T cells), or an antiviral agent administered to control the infection.

Very few out of the entire repertoire of mutations will be adequate to confront a specific constraint, but the accumulation of mutations in a large mutant spectrum endows the ensemble with the capacity to respond to many constraints. The virus population size, also referred to as viral load, is an important determinant of virus adaptability (Domingo and Perales, 2012). Host antibody responses or inhibitors administered during antiviral treatments constitute selective constraints that are easy to recognize and to quantify (**Table 2**). Viruses in the multiple intracellular and extracellular stages of their life cycles face multiple selective constraints that are not easy to identify. Some, however, are essential to ensure short-term and long-term virus survival in nature. Changes in host cell tropism and host range, or variations in virulence that favor virus spread among host populations are examples of essential variations that occur regularly during virus spread. A common feature to the mechanisms of response to most selective constraints is that they often require one or a small number of mutations in the virus genome to be operational. In other terms, quasispecies distributions, with the likely prevalence of single and double mutants over multiple mutants, are the ideal object for selection of relevant traits to occur. From a historical perspective, this should not be surprising since viruses probably exist because they have evolved means to respond to such constraints. Any virus that would require 100 precisely located mutations in its genome to overcome an antibody response would have been extinguished long ago by the types of immune systems we see today. Viruses are confined to one or a few hosts, and they are amenable to classification, because the number of mutations needed to infect other types of phylogenetically distant hosts is not within reach of their mutant spectra. Thus, except in rare cases (e.g., large evolutionary jumps through recombination) phenotypic flexibility is confined to traits whose modification requires a limited number of mutations.

Exploration of Sequence Space, Viral Fitness, and Viral Load

Nucleotide sequence space means the number of genomic sequences available to a replicating entity, be it a virus or a cell. The term was first used by John Maynard Smith for amino acid sequences, and extended by Manfred Eigen and colleagues to nucleic acids and to viral evolution (Eigen and Biebricher, 1988). The theoretical sequence space available to a virus is a huge quantity; for a 10 000 nucleotide genome it is calculated as $4^{10\,000}$ (4, number of different types of nucleotides to the power of the length of the viral genome). Only a minority of the theoretical sequence space can be occupied by a virus because most of the sequences have no biological meaning since they fail to encode the regulatory and coding regions with functional sequences at the required genomic positions. The key issue here is that transitions among minority sequences compatible with representing a viral entity can give rise to viral forms with altered properties. There are continuous movements in sequence space in components of RNA viral quasispecies, even those components that represent minority subpopulations present at low frequency (Tsibris *et al.*, 2009). Such movements are fueled by high-mutation rates (in the range of 10^{-3} to 10^{-5} mutations produced per nucleotide copied (Domingo *et al.*, 2012)), and guided by fitness differences. Fitness is relative to the environment. A pathogenic human virus can be attenuated by extensive replication in cell culture. By increasing its fitness in cell culture as a result of repeated passage, a virus may lose its fitness for humans. Fitness and virulence are not necessarily directly correlated (Herrera *et al.*, 2007 and references therein), but for some pathogenic viruses fitness, population size, and population heterogeneity are relevant to disease progression. Viral load has long been recognized as a predictive parameter in clinical virology: the higher the load of a pathogenic virus in an infected individual the higher the probability of disease

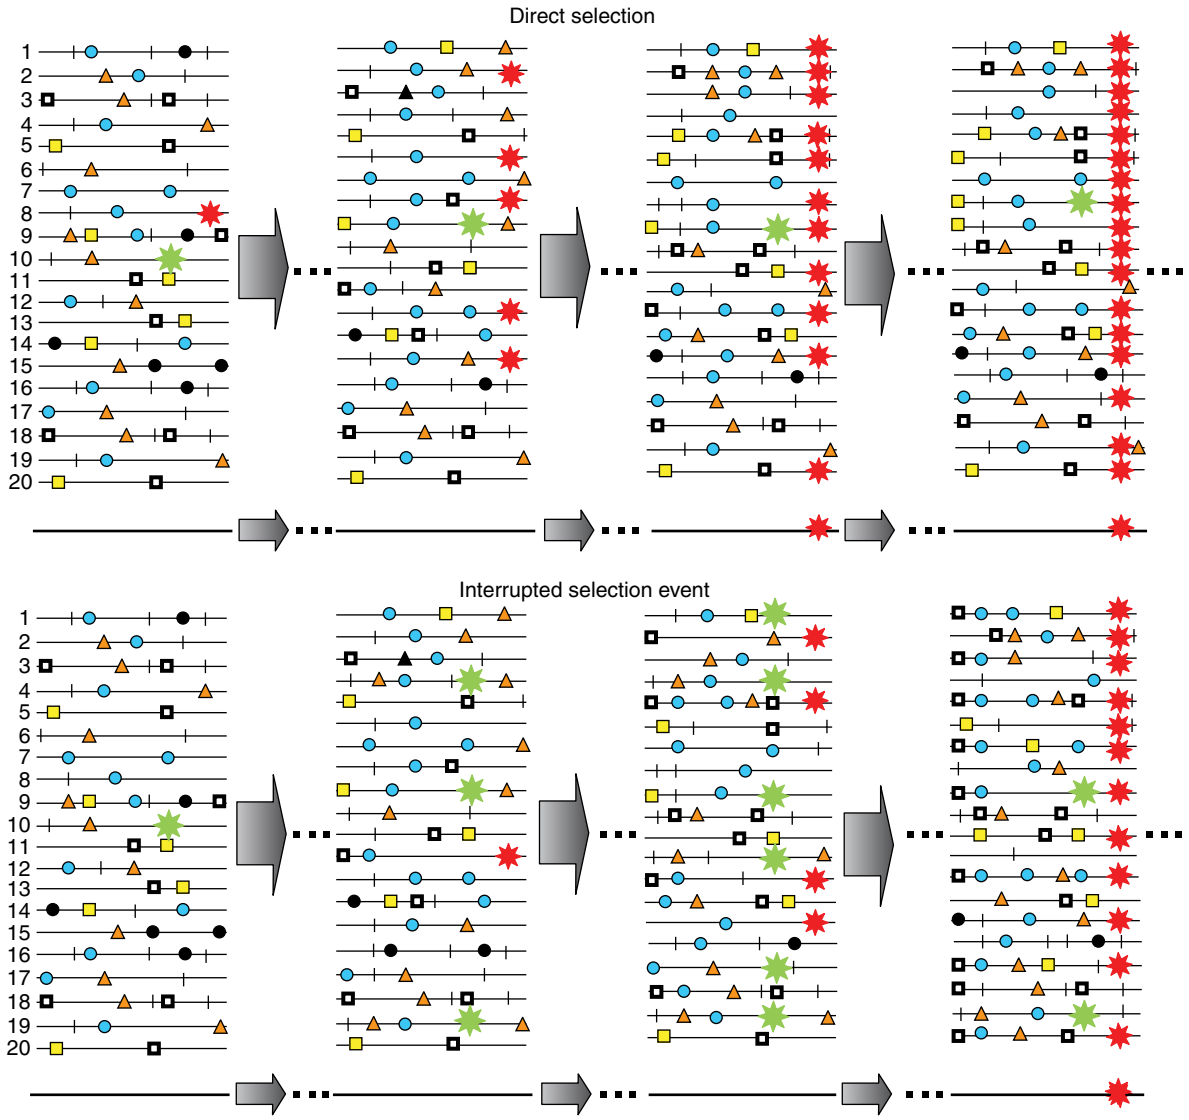

Figure 1 The complexity of viral mutant spectra, and selection dynamics. Individual genomes are depicted as horizontal lines, and mutations as different symbols on the lines. Below each mutant distribution, the consensus sequence is also represented by a horizontal line. In the top series direct selection of genomes harboring the mutation represented by the red asterisk occurs and the mutations becomes part of the consensus. In the bottom series, an interrupted selection of the mutation depicted by a green asterisk is represented. Because of the continuous dynamics of appearance of new mutations, the mutation that was in its way to dominance is overgrown by a newly arising mutation (red asterisk) that finally becomes part of the consensus. Application of deep sequencing is revealing multiple unsuccessful or interrupted selection events in viral populations (see text).

progression. The connections between replication rate, exploration of sequence space, and viral fitness with regard to viral disease potential have been reviewed (Domingo *et al.*, 2012). In simple terms, the process by which quasispecies dynamics plays its role in viral pathogenesis and persistence can be expressed as follows: rapid replication and high-mutation rates imply efficient exploration of sequence space for fitness gain; fitness gain optimizes replication in the considered environment, with the consequent increase of viral load and further exploration for adaptability; variant sequences able to replicate in new environments become more likely when the repertoire of sequences increases (**Figure 2**). Fitness can also be a determinant of multidrug resistance, as suggested by studies with HCV in cell culture (Sheldon *et al.*, 2014). Thus, the dynamics that allow the replicative optimization of a virus may also endow it with phenotypic pluripotency, further supporting the selective advantage of quasispecies behavior. Once the implications of quasispecies for viral infections were understood, clinicians realized how important it is to limit the viral load by initiating treatment as soon as a disease is diagnosed (for AIDS treatment, the title of an article by David Ho illustrates this point (Ho, 1995)). Thus, despite being seemingly of a theoretical nature, the conceptual body derived from quasispecies theory impinges on problems of a practical nature, particularly therapeutic designs, as summarized next.

Table 2 Some types of selective internal and external constraints recognized to act during a virus life cycle

Type of constraint	*Quantification*	*References*
Virion stability in extracellular environments. Genome packaging constraints	Indirect, through calculations based on structural information or determinations of infectivity following exposure to altered environment (temperature, ionic conditions, etc.)	Mateu (2013) and Ojosnegros *et al.* (2011a)
Different cell types, host species	Difficult to quantify mutants with altered cell tropism or host range, but they can be selected from evolving quasispecies	Baranowski *et al.* (2001), Baranowski *et al.* (2003), Ruiz-Jarabo *et al.* (2004), and Domingo *et al.* (2012)
Neutralizing antibodies	10^{-2} to 10^{-6} is the usual range of frequencies of monoclonal antibody-resistant viral mutants	
Inhibitors used in therapy	Frequencies in the range of 10^{-3} to 10^{-5} depending on genetic and phenotypic barrier, and viral fitness	Domingo (1989), Richman (1996), Domingo *et al.* (2012), and Sheldon *et al.* (2014)

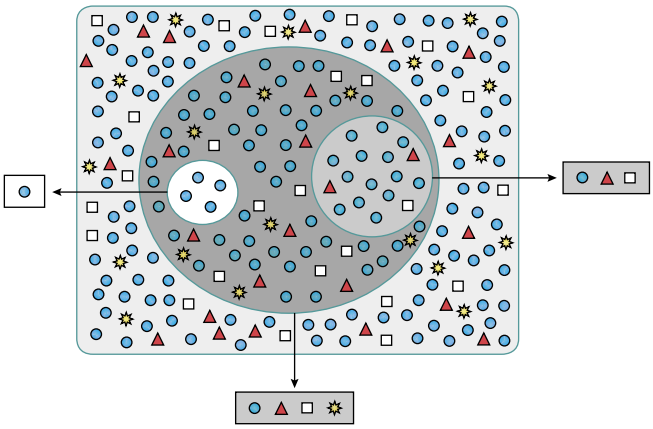

Figure 2 A simplified representation of sequence space and the importance of population size. The large rectangle includes many types of variants, the most relevant highlighted by four symbol types. Depending on the population size (delimited by circles of different size) the repertoire of variants available for selection or other evolutionary events varies (variants depicted in small rectangles). It must be considered that immediately after replication of the variants takes place, a new mutant distribution is formed. Reproduced from Domingo, E., Sheldon, J., Perales, C., 2012. Viral quasispecies evolution. Microbiology and Molecular Biology Reviews 76, 159–216, with permission from the American Society for Microbiology, Washington DC, USA.

Antiviral Designs to Counteract the Adaptive Response of Viral Quasispecies

In pharmacology, only a few decades ago the combined use of several drugs was against basic principles of good practice. Yet, in the last years, the efficacy of combination therapies over monotherapy has become evident in cases in which the agent to be controlled undergoes dynamic adaptive variations derived from the Darwinian mechanisms that are part of quasispecies theory. The need of combination therapies is now amply recognized to treat genetically variable viruses and to control cancer, and it might be also recognized in the future for prion diseases, also subjected to Darwinian dynamics (Domingo *et al.*, 2012; Mas *et al.*, 2010; Ojosnegros *et al.*, 2011b; Weissmann, 2012). Combination therapy is one among several alternative treatment designs that have been suggested or are under investigation to counteract the adaptive potential of viral quasispecies (reviewed in Domingo *et al.*, 2012).

As a general principle, for a mutant virus to be resistant to two or more drugs that target different steps of the virus life cycle, it should acquire at least two or more specific mutations (at least one mutation per each administered drug) to survive the treatment. For basic statistical reasons, the probability of occurrence of two specific mutations in the same viral genome equals the product of the probability of occurrence of each of them separately. Taking as a reasonable estimate a frequency of escape to one drug of 10^{-4}, the frequency mutants resistant to two, three, or four drugs is expected to be of the order of 10^{-8}, 10^{-12}, and 10^{-16}, respectively. Soon a probability is reached whose reciprocal value is lower than the viral population size in the infected organs targeted by the drugs. It is very unlikely that the viral quasispecies reaches a position in sequence that harbors resistance to three or more drugs. Highly active

antiretroviral therapies (HAART) for AIDS are based in this principle; HAART has dramatically decreased AIDS-related deaths, and has converted HIV-1 infection largely into a chronic condition. Procedures to eradicate HIV-1 from the organism are under investigation. Several books and review articles have addressed the problem of drug resistance in viruses in its theoretical, experimental, and clinical aspects (Domingo *et al.*, 2012; Richman, 1996; and references therein).

An antiviral strategy that was developed as a consequence of one of the corollaries of quasispecies theory is termed virus entry into error catastrophe or lethal mutagenesis. As mentioned in the Introduction, the inheritable information conveyed by any replicative system is lost if the error rate increases over a threshold value. In support of this prediction, John J. Holland and colleagues were the first to prove experimentally that mutation frequencies at specific sites of viral genomes could be increased at most by 2.8-fold, and that increases in mutation rates were detrimental for infectious progeny production (Holland *et al.*, 1990; Lee *et al.*, 1997). It is worth noting that despite the recognized fact in that most mutations on well adapted viruses and organisms are likely to be deleterious, the result of Holland and colleagues was not obvious. *A priori*, higher than basal mutation rates might be advantageous. It has been described that mutator bacteria that display 10^2- to 10^3-fold higher mutation rates than their parental populations, have enhanced adaptive capacity relative to their standard counterparts. Also, contrary to the results of Holland and colleagues, the reversion frequencies at several defined sites of the *Escherichia coli lac Z* gene could be increased 10^2- to 10^3-fold by chemical mutagenesis with good survival levels (discussed in Holland *et al.* (1990)). The reason that enhanced mutation rates are detrimental for RNA viruses is that they replicate very close to the error threshold for maintenance of genetic information. If they did not, additional mutational loads would have been beneficial for adaptation. Even if the molecular mechanisms by which viruses cross an error threshold are not the same as implied by the original quasispecies theory, the basic concept and its consequences are very similar (Domingo *et al.*, 2012).

Experiments on virus extinction through increased mutagenesis were pursued by Esteban Domingo, Pedro Lowenstein, Juan Carlos de la Torre, and their colleagues using foot-and-mouth disease virus and lymphocytic choriomeningitis virus as model systems in cell culture and *in vivo* (Eigen, 2002; Grande-Pérez *et al.*, 2002; Ruiz-Jarabo *et al.*, 2003; Sierra *et al.*, 2000) and by Larry Loeb, Jim Mullins and colleagues with HIV-1 (Loeb *et al.*, 1999). These authors coined the term lethal mutagenesis, the expression most used in virology. Important developments have occurred in the theory and practice of lethal mutagenesis, opening new prospects of antiviral designs.

Sequential Antiviral Treatments Based on Lethal Mutagenesis

Initial experiments with HIV-1 and FMDV indicated that combinations of mutagenic agents and non-mutagenic antiviral inhibitors were more effective to extinguish virus than a mutagenic agent alone, particularly when the virus had high-replicative fitness (Pariente *et al.*, 2001; Tapia *et al.*, 2005). In principle, this result was expected from the observations and arguments in favor of combination therapy outlined in Section 'Antiviral Designs to Counteract the Adaptive Response of Viral Quasispecies'. However, experiments by Celia Perales and colleagues in which alternative protocols of administration of

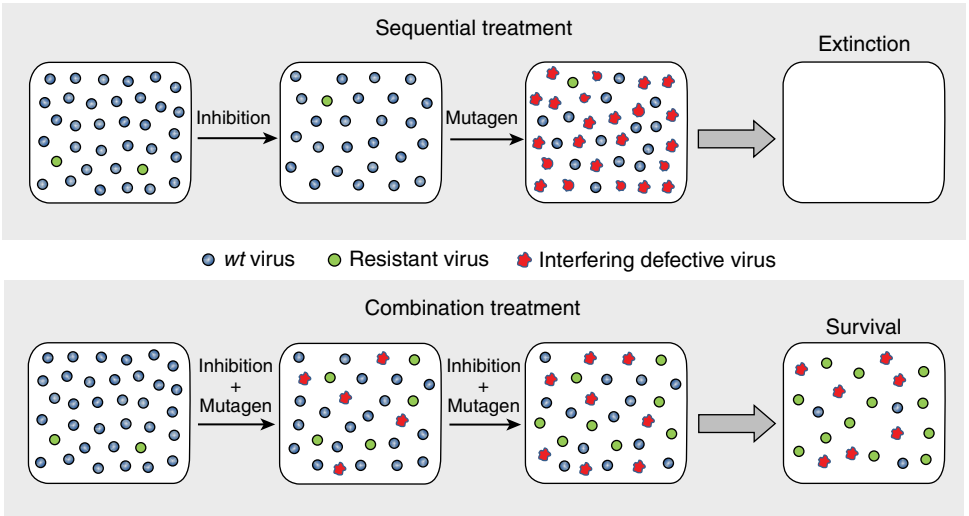

Figure 3 Schematic representation of the effect of a sequential versus combination treatment on a viral population. Top: A viral population contains some inhibitor-resistant mutants (green circles). Administration of an inhibitor diminishes the viral population size prior to a significant increase of inhibitor-resistant mutant frequencies. Subsequent mutagenesis results in the generation of defectors (rough red circles) that interfere with replication of the ensemble and can lead to virus extinction. Bottom: Administration of an inhibitor together with a mutagen may reduce the viral load, inhibit replication of defectors thereby attenuating their interfering activity, and increase the frequency of inhibitor-resistant mutants thus permitting viral survival. The advantage of a sequential versus combination administration to achieve virus extinction depends on the concentrations of inhibitor and mutagen (see text).

mutagens and inhibitors were compared indicated that a sequential administration of an inhibitor first, followed by a mutagen could have an advantage over the corresponding combination or the administration first of the mutagen and then the inhibitor. For each virus–host system there is a range of concentrations of inhibitor and mutagen at which either the sequential or combination administration are more effective (Iranzo *et al.*, 2011; Perales *et al.*, 2012). The advantage of the sequential protocol has been documented with several viruses that use different replication strategies such as FMDV, LCMV, and HCV, and new antiviral protocols are now under investigation (review in Perales *et al.*, 2012; **Figure 3**). Therefore, quasispecies dynamics has practical consequences regarding the design of antiviral strategies, documenting the value of basic research to open practical possibilities.

Conclusions and Prospects

Quasispecies is a theory of molecular evolution adequate to describe the behavior of replicating entities characterized by high-mutation rates. It has found its maximum interest in the interpretation of adaptability of RNA viruses, chiefly with the recognition that populations of RNA viruses consist of complex mutant spectra, as predicted by the theory. Although the term quasispecies applies mostly to RNA viruses, the concept is also valid for other biological entities. Some DNA viruses that are replicated by low-fidelity DNA polymerases display a dynamics comparable to that of RNA viruses. Quasispecies behavior has been also observed with subviral replicons such as viroids and with RNA molecules evolving *in vitro*, or cellular collectivities such as mutator bacteria, bacterial biofilms, or cancer cells. More recently, the Darwinian behavior of prions has been attributed to conformational heterogeneity of the prion protein, with strain modifications ('mutations') being associated with conformational transitions. This is a new development that will require an extension of quasispecies theory to non-replicative systems, in which mutations are based on conformational changes. Thus, quasispecies theory has been extremely important as an experiment-provoking incentive to understand the dynamics of many biological systems (overview in Domingo (2016)).

Species Trees, Inference of

S Edwards, Harvard University, Cambridge, MA, USA

Nomenclature

θ The neutral mutation parameter, in diploid organisms equivalent to four times the effective population size multiplied by the mutation rate of the gene in question.
N Effective population size.
μ Mutation rate.
τ A measure of time in coalescent units, usually applied to branches of a species tree.
t The number of generations along a branch of a species tree.

Glossary

Anomaly zone A type of species tree with internal branch lengths that are so short (in coalescent units) that the most common gene tree produced is topologically different from the species tree.
Coalescent unit A unit of time measurement in coalescent theory. When speaking of diploid organisms, usually one coalescent unit is equal to 4N generations, where N is the effective population size and the generation time is specific to the organisms being studied.
Deep coalescence Looking from the present to the past down the branches of a species tree, a situation in which two gene lineages do not coalesce before the next common ancestral species is encountered. Two lineages are said to coalesce deeply when they do not coalesce within the branch designating their common ancestral species. Usually deep coalescence occurs when branches are short in coalescent units.
Effective population size The size of an ideal population whose genetic dynamics are similar to the actual population being studied. An ideal population is one that is experiencing no migration or selection, undergoes random mating and whose genetic variation is neutral. The effective population size of a species is usually smaller than its census size.
Incomplete lineage sorting Looking forwards in time, from the past to the present, a situation in which gene lineages to not come to fixation within a species before that species diverges into two species.
Gene tree A phylogenetic tree of alleles sampled from one or more species.
Multispecies coalescent model A model providing probability distributions of gene trees sampled from phylogenetic trees consisting of multiple species. Both the branch lengths and the topologies of gene trees are predicted by the multispecies coalescent model. These parameters are in turn predicted by the sample sizes of alleles within each species and the topology, branch lengths, and effective population sizes of the species tree.
Single-nucleotide polymorphism (SNP) A DNA polymorphism at a single site or nucleotide. Generally gene trees cannot be constructed from a single SNP but a SNP can designate a bipartition among species or alleles in a dataset.
Species tree A phylogenetic tree of species, each of which consists of alleles at one or more loci.

As outlined in other articles in this section, phylogenetic trees are an essential tool for mapping the history of biodiversity, reconstructing evolutionary events, and depicting evolutionary relationships among species. Additionally, although there continue to be debates about the relative utility of morphological and molecular data in phylogenetic analysis, systematics of extant or recently extinct species in the twenty-first century is largely, although certainly not exclusively, based on molecular data. With the advent of new ways of generating molecular data using next-generation sequencing and other genomic technologies, molecular data increasingly comes in the form of DNA sequence data consisting of many loci, each with multiple single-nucleotide polymorphisms, or SNPs (Lemmon and Lemmon, 2013; McCormack *et al.*, 2013). There has also been a rapid increase in datasets consisting of many individual SNPs, each characterized across a set of populations or species (Peterson *et al.*, 2012). With these new and increasingly large molecular datasets come challenges of handling the stochasticity and randomness inherent in such datasets, especially at the level of the genealogy of genes or DNA sequences. Such stochasticity is a major reason for the advent of so-called 'species tree' methods of phylogenetic inference (Edwards, 2009; Nakhleh, 2013; Szöllősi *et al.*, 2015).

Species tree methods are best thought of as a general framework for handling phylogenetic data from multiple loci. This framework includes methods such as concatenation or supermatrix methods, in which separate loci are concatenated into a single 'supergene' for analysis; in this way, concatenation can be thought of as a special case of the more general models employed in species tree inference (Liu *et al.*, 2015; **Figure 1**). In turn, species trees – being based primarily on models solely involving divergence (isolation) events from common ancestors, can be thought of as special cases of even more general isolation-migration or network models, which assume some level of gene flow between descendant lineages (**Figure 1**). Although currently species tree methods focus exclusively on molecular data, and specifically on DNA sequence and SNP data, in the future, the species tree framework will

 doi:10.1016/B978-0-12-800049-6.00220-1

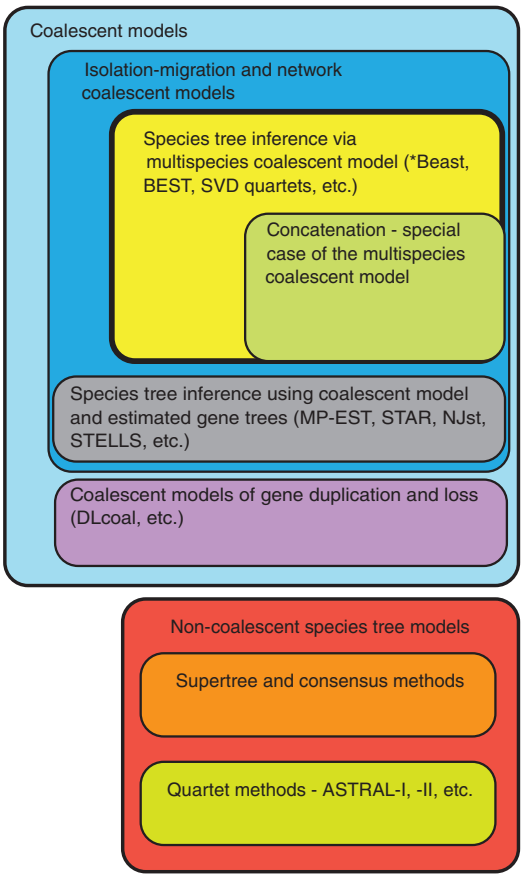

Figure 1 Relationships among coalescent models and species tree methods. This article focuses on models in the yellow box. Species tree methods are viewed as based either on coalescent models or arbitrary models. Species tree methods are seen as specific instances of models that include both isolation and migration, i.e., species tree methods are network or isolation-migration models with no migration among lineages. Concatenation or supermatrix methods are in turn seen as specific instances of species tree methods in which gene trees are identical across genes. With reference to both species trees and concatenation methods, these specific instances are likely to be most often violated in any given dataset. Additional models for gene duplication and loss in multigene families also employ the multispecies coalescent model. Supertree and consensus methods are viewed as non-coalescent methods in so far as they are usually not grounded in any specific biological model. Similarly, species tree methods such as ASTRAL are based on simple heuristics and do not reference coalescent theory directly.

likely include analysis of morphological data and other types of molecular data such as rare genomic events and insertions and deletions. Thus species tree inference can be thought of as synonymous with the general problem of phylogenetic inference, providing a general and inclusive framework for inferring the history of life (Figure 1).

Historical Background to Species Tree Inference

Phylogenetic analysis has undergone major changes in the last few decades. The first widely used phylogenetic methods focused on distance and parsimony approaches in the late 1960s, followed in the early 1980s by maximum likelihood, and Bayesian methods in place by the mid-1990s (reviewed in Felsenstein, 2003; Rannala and Yang, 2008). Each of these updates were driven by the need to handle larger and more complex datasets that better accommodate the statistical properties of the data used to build phylogenetic trees. Species tree methods are no different. In the case of species tree methods, the statistical properties that were ignored by previous methods included the recognition that the different loci used for phylogenetic analysis in multilocus datasets could often have different topologies from one another, even in the absence of complicating factors like gene flow between species or molecular events such as horizontal gene transfer (HGT) or gene duplication (Maddison, 1997; Nakhleh, 2013). The phenomenon known as 'incomplete lineage sorting' (ILS), a major source of gene tree heterogeneity in phylogenetic analysis, was first recognized and the term coined by John Avise in his studies of mitochondrial gene trees in a related field known as phylogeography, which focuses on the history of closely related species and populations within species (Avise *et al.*, 1987). Avise realized that there were cases in which the topology observed and clearly supported by mitochondrial data sometimes conflicted with the pattern of relationships clearly suggested by phenotypic data of the species or populations being studied. Working with Joe Neigel and others in the mid-1980s (Neigel and Avise, 1986), Avise also realized that such conflict did not necessarily have to arise from demographic events such as hybridization between species, but could in principle arise from purely stochastic processes such as genetic drift as species diverge from one another. The variety of sources of discordance between gene trees and species trees was synthesized in a seminal review in 1997 by Maddison (1997), who coined the term 'deep coalescence' to describe the phenomenon of ILS, but looking backwards in time, from the present to the past, rather than from Avise's perspective, which saw the process proceeding 'forwards' from ancestral to descendant populations (Figure 2). Whereas events such as HGT, gene duplication, or hybridization require specific molecular or population forces to be realized, the only criterion for ILS to arise is the finiteness of populations – a criterion which of course applies to every species and lineage in any clade, from bacteria to plants to humans (Edwards, 2009). Only in the imaginary situation when genetic drift is so severe that fixation of ancestral variants occurs instantaneously could ILS be ruled out in principle. Hence ILS is now recognized as the most prevalent of the major sources of incongruence between gene trees and the relationships of species in which those gene trees are embedded. As such it is the most important, but by no means the only, statistical issue that arises when multiple loci are analyzed.

Deconstructing Incomplete Lineage Sorting and Deep Coalescence

A good (nonmathematical) way to understand the phenomena of ILS and deep coalescence is to imagine a field of marbles of two different colors, with each color representing an allele in a single, ancestral population (Figure 2(a)). The two alleles in the ancestral population describe a simple gene tree, one with just

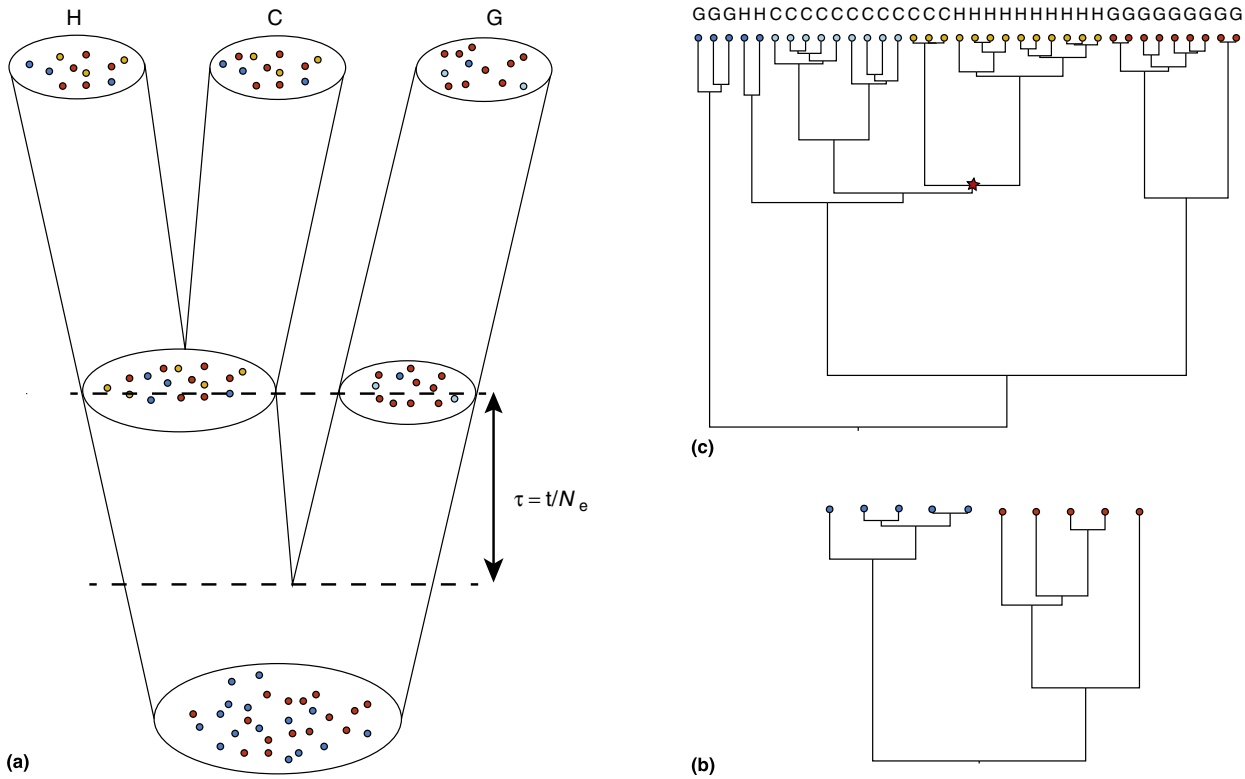

Figure 2 Illustration of the concept of incomplete lineage sorting or deep coalescence. (A) Species tree showing diversification of three lineages from a common ancestor. Alleles present in the common ancestor are retained in all three descendant lineages because of branches that are short in coalescent units. The length of the internode (τ) in coalescent units is indicated. (B) Gene tree of 12 alleles sampled from the ancestral population in A. The coalescent tree was generated using the R package Phybase (Liu and Yu, 2010). The single population used to generate the gene tree had a value of $\theta = 4\ N\mu$ of 0.01. (C) Gene tree of 12 alleles sampled from each of three populations, again using Phybase. The designations for the three species from which alleles are sampled are H, C, and G. Colored balls are qualitative designations of each allele corresponding to general relationships of alleles in the gene tree. The species tree used to generate the gene tree was: ((H:0.00402#0.01, C:0.00402#0.01):0.00304#0.01,G:0.00707#0.01))#0.01. The units of branch lengths of the species tree are substitutions per site and the values of θ appear after the pound sign. This gene tree displays substantial incomplete lineage sorting or deep coalescence. The interspecific coalescent event that occurs closest to the present (indicated by a star) is between alleles sampled from H and C, suggesting the species tree in A according to the method of Takahata (1989).

two lineages designating the two alleles (**Figure 2(b)**). An absolute barrier sundering the ancestral population into two spatially and phylogenetically distinct populations will result in both sets of alleles being found on either side of the barrier. To the extent that the two populations on either side of the barrier represent incipient species that will continue to diverge, the barrier immediately causes population para- and polyphyly of gene lineages to arise, a type of gene tree species tree conflict. The 'conflict' or discordance arises because the two populations no longer display reciprocal monophyly of gene lineages (Neigel and Avise, 1986). The conflict is also evident because we have sampled more than one allele per population. Had we sampled only a single allele per population, no such discordance would arise; either we would sample the same allele on both sides of the barrier, in which case the two alleles are identical, or we sample different alleles, in which case the gene tree simply reflects the historical divergence between the two alleles. In the latter case, the gene tree simply has two tips and no discordance with the 'species' tree is evident.

By the time one of the two descendant populations itself undergoes another population divergence, genetic drift may have caused allele frequencies in the two populations to have diverged and additional mutations may or may not have resulted in additional alleles (**Figures 2(a)** and **2(c)**). The second divergence event and consequential ILS in one of the two ancestral populations proceeds as the first one, with the diversity of alleles being found on either side of the second barrier, and discordance arising if multiple alleles have been sampled. However in this case, even if only a single allele has been sampled from what are now three descendant populations (or species), discordance is now possible. This discordance under three populations can occur if genetic drift prior to the second speciation event has not caused allele frequencies to shift significantly enough so that one or another allele is completely lost from one of the two populations (Pamilo and Nei, 1988). A key result of classical population genetics is that the average conditional fixation time of a new neutral allele in a population is 4N generations, where N is the effective population size of a diploid species with 2 N chromosomes (Kimura and Ohta, 1969). In the parlance of coalescent theory, we might say that the average coalescence time of two neutral alleles in a population is also 4 N

generations (Hudson, 1990). If the time in generations between our two speciation events is less than 4 N, there is a good chance that the alleles in the lineage comprising the internode in the species tree will not have gone to fixation, with the result that polymorphism still exists once the second speciation event comes about. If this is the case, the probability of discordance of the allelic genealogy, even when a single allele is sampled, is substantial and ILS can occur. Even if fixations have occurred, there is some chance that they would have proceeded in such a way as to cause discordance with the species tree. Going backwards in time according to coalescent theory, if the length of the internode between two speciation events is short on the scale of the population size (again, <4 N generations), then there is a higher chance that the two alleles sampled from sister lineages in the species tree will not have coalesced once one reaches the first speciation event, and ILS again is likely. The probability of ILS is not dependent on the absolute length t (in generations) of the internode, but rather on the ratio of t/N_e). Additionally, although a major impetus for species tree theory, ILS is not required for most species tree methods to apply.

Species Trees and the Multispecies Coalescent Model

The above scenario is meant to help novices visualize the causes of ILS. All of the events described above can be assigned probabilities, which are central to species tree inference methods and have their roots in seminal results of coalescent theory. Pamilo and Nei (1988) and Takahata (1989) were among the first to take the rules of coalescent theory as applied to a single population and extrapolate them to calculate probabilities of gene trees sampled from multiple phylogenetically related populations. Rannala and Yang (2003) formulated a likelihood model for gene trees sampled from multiple populations by applying coalescent theory for a single population sequentially to the various branches of a species tree. This work comprised the origins of the multispecies coalescent (MSC) model, the theoretical basis for most methods of species tree inference (Degnan and Rosenberg, 2009). The MSC allows researchers to compute probabilities, and hence likelihoods, of a gene tree or a set of gene trees given a species tree. This likelihood was a conceptually important advance in species tree inference, because it clearly separated the likelihood traditionally used in phylogenetics, namely likelihood of DNA sequence data given a gene tree, from the additional likelihood incorporated in species tree inference, namely the likelihood of a set of gene trees given a species tree (**Figure 3**).

When a single allele is sampled from the tips of a three-species tree, the only relevant parameter for calculating the probability of ILS is the length in coalescent units of the internode between the two speciation events, and probabilities of gene tree topologies can be calculated easily by hand (Wakeley, 2008). When more than three species are involved or when branch lengths of gene trees are specified, then likelihoods of gene trees can be calculated using software packages such as COAL (Degnan and Salter, 2005) or Phybase (Liu and Yu, 2010). The MSC also facilitates easy simulation of gene trees from a species tree (Leaché and Rannala, 2011; Leaché *et al.*, 2014). Programs such as COAL can rapidly calculate entire distributions of gene trees from a species tree with arbitrary numbers of alleles sampled. For example, for a four-tip species tree (say human, chimp, gorilla, and orangutan) with a total of seven alleles sampled (three human alleles, two chimp, one gorilla, and one orangutan), there will be 10 395 distinct rooted gene tree topologies, even though the species tree itself can have only 15 possible rooted topologies. COAL can calculate the probabilities of each of these gene trees as well as the entire distribution. Other programs such as Treefix (Wu *et al.*, 2013) allow more accurate estimation of gene trees given a species tree, and are especially applicable to large numbers of gene trees from multigene families across the genome of a suite of species.

Recent History of Species Tree Inference

The years 2006 and 2007 saw important advances in the development of species tree methods and challenges to the concatenation paradigm that had dominated phylogenetics for the previous 20 years. Although the problem of gene tree discordance was well described and likelihoods for gene trees could be calculated on a species tree, no one had yet proposed statistical methods for inferring species trees, except in the

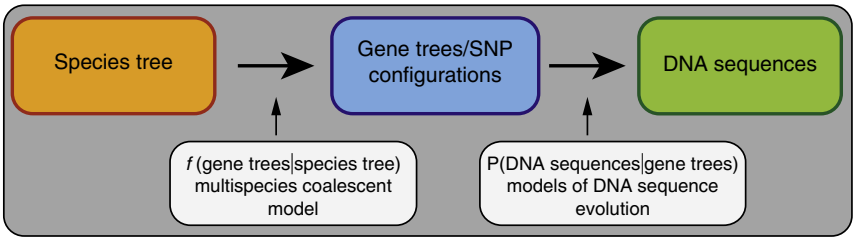

Figure 3 Processes generating parameters in species tree models and relationships among likelihoods in species tree models. The component of the overall species tree likelihood at the left is given by the probability density function (f) of the gene trees given the species tree and is based on the multispecies coalescent model. The more traditional likelihood in phylogenetics appears at right, the probability of the DNA sequence data given the gene tree. Many species tree methods combine these two likelihoods in order to estimate species trees from DNA sequence data. However, only Bayesian and SVD quartet methods estimate the species tree directly from DNA sequence data. Most other methods, such as STEM, MP-EST, STAR, and STELLS, employ a 'two-step' approach, in which the gene trees used to build the species tree are estimated separately and without reference to an overarching species tree. See **Table 1** for further details on each method.

simple case of three species (Pamilo and Nei, 1988; Takahata, 1989). Maddison and Knowles proposed minimizing deep coalescences (MDC) as a species tree method based on the principle of parsimony (Maddison and Knowles, 2006). Ané *et al.* (2007) proposed a method for summarizing Bayesian posterior distributions of gene trees and the concept of a concordance tree, a consensus tree with proportions on each branch indicating the proportion of the genome with a gene tree containing that branch. While the concordance tree idea was not based explicitly on the MSC and is strictly speaking not a species tree, it was still extremely useful for promoting the concept of and summarizing heterogeneity at the level of gene trees. Liu and Pearl (2007) proposed the first Bayesian method for estimating species trees, one that combined the likelihoods then available for calculating the probability of DNA sequence data given a gene tree and the probability of a set of gene trees given a species tree. Their software, Bayesian Estimation of Species Trees (BEST) (Liu, 2008) was the first widely used species tree method, one that employed a full Bayesian model. Other, simpler methods of species tree inference, such as GLASS, were also proposed (Mossel and Roch, 2010). Edwards *et al.* (2007) described using simulations and analysis of multilocus DNA sequence data some of the parameters for species tree estimation, showing that species trees could be estimated for a small or large number of loci depending on the shape of the species tree, in particular the length of the internodes. Kubatko and Degnan (2007) showed through extensive simulations that traditional maximum likelihood analysis of concatenated DNA sequence data could fail and was likely inconsistent if gene tree heterogeneity due to ILS was high. New insights into the behavior of alternative models of gene tree heterogeneity, such as that by Steel and Rodrigo (2008), quickly followed. The groundwork for species tree inference had been laid.

The anomaly zone: Another concept to emerge from this early work was the anomaly zone. The anomaly zone, first recognized by Degnan and Rosenberg (2006), is a region of species tree branch lengths that generate a distribution of gene trees in which the most common gene tree is actually different from the species tree. This paradoxical situation arises when essentially all gene lineages coalesce in the common ancestor of all species in the species tree, with the result that the topology of basal branches of the gene trees are dictated more by coalescent processes in the common ancestral lineage uniting all species rather than by the MCS. Although primarily a theoretical construct and apparently very rare in nature (Huang and Knowles, 2009), the anomaly zone has been proposed to apply in some empirical datasets (Linkem *et al.*, 2016). The anomaly zone is a useful analogy to the Felsenstein zone, a region of gene tree space leading to long-branch attraction and in which collecting more sequence data will positively mislead phylogeny inference with increasing certainty (Felsenstein, 1978). The anomaly zone is the gold standard for tests of the adequacy of a species tree method: if the method fails consistent inference in the anomaly zone, it cannot be said to be universally consistent. This criterion is often (Liu and Edwards, 2009; Liu *et al.*, 2009, 2010a) although not always (Mirarab *et al.*, 2014; Mirarab and Warnow, 2015) applied to newly proposed species tree methods.

Methods of Species Tree Inference

As of this writing, there are now numerous methods for estimating species trees (**Table 1**), reflecting a diversity of approaches and substantial research activity. The MSC has been exploited to take advantage of the diversity of DNA sequence data types as well as varying sophistication of statistical models employed. This diversity of approaches shows how the MSC can be used in all its complexity to infer species trees or can be distilled into simple rules that can guide species tree inference. The need for simpler models that do not employ the full likelihoods of the MSC quickly became evident as phylogenomic datasets grew in size (Liu *et al.*, 2015). For example, even the most sophisticated and popular Bayesian method for species tree inference in the PCR-era, *BEAST (Heled and Drummond, 2010), fails to converge with even moderate datasets consisting of a few tens of species and loci.

The various approaches highlighted in **Table 1** show both how flexible the MSC is and some of the practical challenges to implementation. For example, some methods, such as the MP-EST method, have thus far been developed to handle only one allele per species. Below is a brief summary of the logic behind some of the major pieces of software implementing species tree methods constraints and opportunities afforded.

Bayesian methods

Both *BEAST (Heled and Drummond, 2010) and BEST (Liu and Pearl, 2007; Liu, 2008) employ full and simultaneous likelihood estimation of gene trees and species trees. Both BEST and *BEAST take in DNA sequences as data and yield posterior distributions of gene trees, ancestral population sizes, and species tree branch lengths, as well as other parameters. The ability to study changes in effective population sizes over time is of general interest but has only rarely been used for testing various biological hypotheses, for example, in primates (Schrago, 2014a,b,c).

Maximum likelihood methods

Maximum likelihood species tree methods use estimated gene trees, rather than DNA sequence data, as input for species tree estimation. Thus they are sometimes called 'two-step' species tree methods (Liu *et al.*, 2015). MP-EST (Liu *et al.*, 2010a) is a popular pseudo-likelihood method that calculates the likelihood of a triplet of taxa in the species tree using gene tree triplets. It is a pseudo-likelihood method because the likelihood of the different triplets is not always independent, because they may share one or a pair of taxa (for example, triplet A, B, C is not independent of triplet A, B, D). Even the likelihood of two species tree triplets that do not share any taxa may not be independent if the genealogy of the two triplets shares branches internal to the species tree. Still, the pseudo-likelihood method has been shown to outperform concatenation methods in many situations, especially when gene trees are robustly estimated (Roch and Warnow, 2015). Other likelihood methods, including STEM (Kubatko *et al*, 2009) and STELLS (Wu, 2012), evaluate the likelihood of a set of gene trees. Whereas STEM uses branch lengths in the gene trees, STELLS focuses solely on gene tree topologies and a special peeling algorithm to estimate the species tree, which allows it to estimate large species trees rapidly from multiple

Table 1 Overview of methods of species tree inference. The table is not meant to be exhausted and highlights methods commonly used in the literature. Updated and expanded from Edwards (2009)

Method (References)	*Methodological basis*	*Basis in coalescent theory?*	*Data required*	*Accounts for stochastic variation or gene tree error?*	*Yields species tree branch lengths?*	*Yields effective population sizes?*	*Applicable to many loci?*	*Applicable to many taxa?*
Heuristic methods								
Species trees using average rank of coalescence time (STAR – Liu *et al.*, 2009)	Ranks of pairwise coalescence times	Yes	Coalescence times/Gene trees	Via bootstrapping	No	No	Yes	Yes
Specie trees using estimated average coalescence time (STEAC – Liu *et al.*, 2009)	Pairwise coalescence times	Yes	Coalescence ranks/gene trees	Via bootstrapping	No	No	Yes	Yes

*Branch lengths in coalescent or drift units.

loci. These methods can handle larger datasets than Bayesian methods in part because they do not simultaneously estimate gene trees and species trees.

Maximum tree and related methods

Coalescent theory leads to the inference that the depth of a common ancestor of taxa A and B in a species tree can be no greater than the most recent common ancestor for A and B detected across the set of estimated gene trees. A consistent estimate of the species tree therefore will be that species tree whose branch lengths are as long as possible given the minimum divergences among pairs of species in the set of gene trees. Liu (2010b) showed that if the gene trees are estimated in a consistent manner, the MT tree will be a consistent estimate of the species tree. A similar method called GLASS was proposed by Mossel and Roch (2010), and STEM (Kubatko *et al.*, 2009) is a maximum likelihood implementation of the MT approach.

Parsimony methods

The main species tree method implementing the principle of parsiomony is the MDC method, first proposed by Maddison and Knowles (2006) and implemented in the software Phylonet (Than *et al.*, 2008). MDC finds the species tree that minimizes the number of deep coalescence events across gene trees. Although a powerful method backed by sophisticated dynamic programming algorithms and accurate under a wide range of species tree space, it has been shown to be inconsistent in the anomaly zone (Than and Rosenberg, 2011).

Fast nonparametric methods

A variety of fast, nonparametric methods have appeared in recent years, including STAR, STEAC (Liu *et al.*, 2009), ASTRAL (Mirarab *et al.*, 2014; Mirarab and Warnow, 2015), NJst (Liu and Yu, 2011), and other methods. These methods all share the property of using gene trees as inputs for species tree estimation, although methods differ as to whether they use rooted (STAR, STEAC) or unrooted (NJst, ASTRAL) gene trees. Most methods are based on distillations of coalescent theory whereas ASTRAL is a heuristic method that minimizes a score of the number of quartet trees required by a given species tree. STAR and STEAC both take advantage of the fact that the average rank and divergence time, respectively, of a pair of species across a set of gene trees is a consistent estimator of the rank and divergence time of that same pair in the underlying species tree. These methods show considerable power to estimate the topology of species trees but require many gene trees and, in the case of STEAC, the estimated branch lengths in the species tree are biased (Helmkamp *et al.*, 2012).

Methods based on SNPs

SNPs constitute an increasingly common form of genetic data, especially with new next-generation sequencing methods such as Rad-seq or Genotype-by-sequencing (GPS). Even when sequence reads consist of more than 100-bp, many such loci only have a single, often bi-allelic polymorphic site, hence the tendency to reduce the dataset to SNPs. SNAPP ('SNP and AFLP Phylogenies': Bryant *et al.*, 2012) was the first species tree method specifically tailored to SNP data. SNAPP assumes the classic Wright–Fisher MSC model and uses a novel pruning algorithm and dynamic programming to calculate the likelihood of particular site patterns in the data given a species tree. Another species tree method, singular value decomposition (SVD) on quartets (Chifman and Kubatko, 2014), is applicable to both SNP and multilocus DNA sequence data and uses algebraic statistics and a matrix of site pattern probabilities to determine the validity of quartets of species. After inferring all or a random subset of possible quartet relationships, a quartet assembly method is used to construct the estimated species tree. SVD quartets can be applied to very large datasets and estimates the species tree quickly.

Gene Duplication and the Multispecies Coalescent

Gene duplication is also an important source of genomic information for inference of species trees and genome history (**Figure1**; Rasmussen and Kellis, 2012; Boussau *et al.*, 2013; Szollsi *et al.*, 2014; Wu *et al.*, 2014). Gene duplication and loss can be considered a specific instance of more general birth–death models, which can account for births (speciation, gene duplication, and HGT) as well as losses (species extinction, gene loss) (Szollsi *et al.*, 2014). Powerful models now exist for estimating the history of multigene families given a species tree through coalescent processes as well as gene duplication and loss (Rasmussen and Kellis, 2012). Such methods are increasingly useful for more accurately defining orthologs, paralogs, and the history of gene duplication and loss in genomes. Although not covered in detail in this article, such models are a useful complement to methods for inferring the history of species themselves.

Networks, Reticulation, and Species Trees with Hybridization

Several species tree methods have begun to incorporate hybridization, gene flow, and reticulation as part of the model of diversification (Nakhleh, 2013). This represents a significant step in the evolution of species tree inference methods because, while ILS is likely to be ubiquitous in nature, it alone cannot explain all the patterns observed in gene trees and DNA sequence data. Networks have been a consistent component of systematics for decades, and it had been routine to depict variation within single genes as networks, where the reticulations often signaled homoplasy in the DNA sequence. However, the concept of networks is much more powerful when analyzed at the level of populations, lineages, and species, i.e., in a species tree framework (Pickrell and Pritchard, 2012). In this context, however, distinguishing processes such as reticulation, HGT and hybridization from the ever-present patterns of ILS can be challenging, since both processes induce gene tree discordance. Special models are required to accommodate multiple processes simultaneously.

Justification for Species Trees

Although the intellectual foundation for species trees goes back several decades, methods for inferring species trees

represent fundamentally new approaches to estimating phylogenetic and population history and combining information from multiple loci. Unlike concatenation methods, they acknowledge the ubiquity of independent gene histories mediated by recombination – a universal aspect of eukaryotic and prokaryotic genetics. Species tree inference methods are applicable not only to situations in which ILS is evident or on recent timescales, but really in all situations, whether or not ILS is occurring. Although empirically they often yield estimates of history that are not as highly supported as a similar concatenation analysis, this discrepancy is often attributable to the model misspecification inherent in supermatrix methods and the slower rate at which signal accumulates when gene trees are considered as conditionally independent from one another (Edwards, 2009; Song *et al.*, 2012). Although species tree inference methods are far from perfect and still apply to only a limited number of speciation models, they are superior to concatenation methods in so far as they acknowledge and accommodate basic aspects of the genetics of populations that concatenation methods do not. No doubt the ensuing decades will see a further proliferation and empirical application of new species tree inference methods for diverse types of molecular and other data.

Sperm Competition

AG Rowley and JL Fitzpatrick, University of Manchester, Manchester, UK

Glossary

Monogamy A mating system in which both males and females mate with only one individual during a reproductive episode, most commonly a socially paired partner.

Polyandry A mating system in which a female mates with multiple males during each reproductive period.

Polygyny A mating system in which a male mates with multiple females during each reproductive period.

Promiscuity A mating system in which both males and females mate with multiple partners during each reproductive period.

Sperm competition Competition to fertilize egg(s) between ejaculates of different males that overlap spatially and temporally in the fertilization environment.

Sperm quality A composite measure of the ability of a male's sperm to successfully fertilize ova relative to other males in the population, as determined by sperm morphology, number, and performance.

Introduction

Darwin (1871) recognized that males who are better able to attract mates or out-compete rival males would leave more offspring to future generations, and would therefore be favored by evolution. Perhaps not surprisingly then, the pursuit of reproductive opportunities has led to the evolution of some of the most striking features in the animal kingdom. Males produce conspicuous ornaments (e.g., the peacocks tail) that are used to attract more mates than rivals or arm themselves with costly weapons (e.g., a stag's antlers) that are used to outcompete rivals for access to mates. However, for Darwin and evolutionary biologists who followed for the next century, competition among males ended at mating. We now know that this is not the case. Molecular evidence have revealed that females frequently mate with multiple males during a single reproductive period and different males commonly sire eggs from a single clutch (Birkhead and Møller, 1998). Such female promiscuity means that competition between males continues after mating in the form of sperm competition, the contest between sperm from rival males to fertilize an egg(s). The evolutionary significance of sperm competition was first recognized by Parker (1970), sparking a paradigm shift that resulted in an explosion of interest in the importance of sperm competition in shaping the evolution of reproductive behaviors and phenotypes.

The pervasive influence of sperm competition has played a vital role in the evolution and extraordinary diversification of reproductive traits. Adaptation to the intense selective pressures imposed by sperm competition has generated an astonishing variety of reproductive phenotypes, from male genitals that resemble medieval weapons (Crudgington and Siva-Jothy, 2000), to testes so large that they account for more than 10% of adult male body mass (Montgomerie and Fitzpatrick, 2009), to gigantic sperm measuring a remarkable 6 cm in length (20 times longer than the male who produced them!) (Pitnick *et al.*, 1995). Here we explore how sperm competition generates the tremendous diversity in reproductive traits by describing the conditions under which sperm competition occurs and examining how sperm competition influences the evolution of animal behaviors, anatomy, and physiology.

Among species, female mating behavior varies widely and this has important implications for the risk of sperm competition experienced by males (**Figure 1**). In species with monogamous females, who only mate with one male, the risk of sperm competition is low (or absent) and in these species sperm competition is unlikely to represent an important selective force shaping reproductive traits. However, genetic monogamy is exceedingly rare in animals. More often, socially monogamous females mate with, and produce offspring by, males outside of their social pairing. Furthermore, in many species female promiscuity is common, as females either seek out multiple mating opportunities or have little control over the number of males attempting to fertilize their eggs (as is often the case in externally fertilizing species). Therefore, the prevalence of female multiple mating means that males of the vast majority of species will experience sperm competition, albeit to varying extents, and researchers have capitalized on this variation in female promiscuity and animal mating systems to gain a better understanding of how sperm competition shapes reproductive traits.

As with females, males too have evolved a suite of behaviors that influence the risk of sperm competition (**Figure 1**). Males can actively guard their mates to prevent subsequent matings by rival males and thus reduce their risk of sperm competition. In an effort to prevent sperm competition males can even take the extreme action of detaching and lodging his genitalia inside the female to physically block access to the female's reproductive tract (Fromhage, 2006). In contrast, male reproductive behaviors can also increase sperm competition risk. For example, socially subordinate males who are unable to successfully attract females often adopt 'sneaking' behaviors (**Figure 2**), attempting to surreptitiously fertilize eggs without the knowledge of socially dominant males (Gross, 1996). Therefore, despite the best efforts of males to reduce their risk of sperm competition, both male and female reproductive behaviors ensure that sperm competition persists.

For internally fertilizing species, male genitalia, which deliver sperm to the female's reproductive tract, are at the front

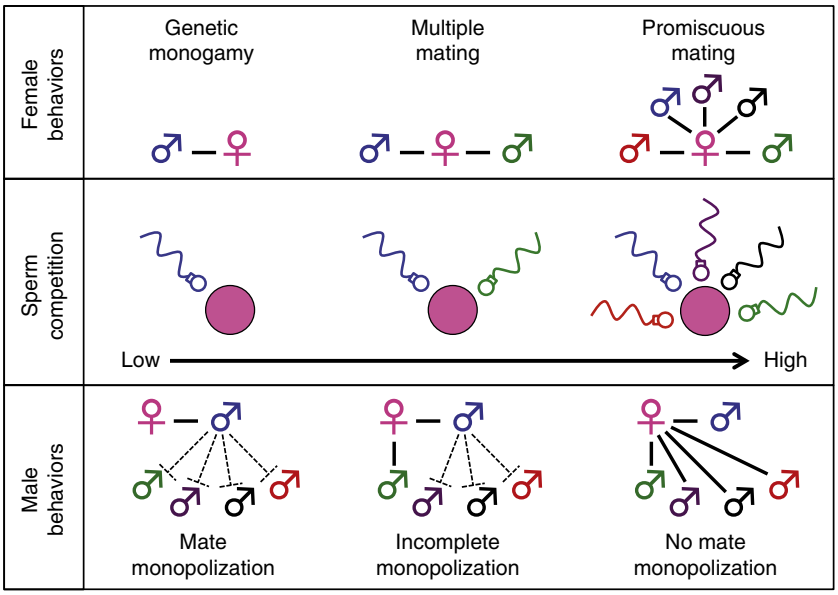

Figure 1 Summary of variation observed in male and female reproductive behaviors and how this variation influences the risk of sperm competition experienced by males. Male and female behaviors can work synergistically or antagonistically to influence sperm competition risk. Solid lines between males and females represent matings, while dashed lines represent thwarted mating attempts.

Figure 2 Sperm competition and sneaky matings. (a) Comparison of a large guarding male and a smaller sneaking male in plainfin midshipman (*Porichthys notatus*), a species with two alternative male reproductive tactics. Both males are reproductively mature. Guarding males court females, defend territories, and provide parental care for developing embryos, while sneaking males attempt to fertilize eggs surreptitiously and then leave the costly parental care to guarding males. Because sneaking males exclusively release sperm in the presence of a rival male they experience a higher sperm competition risk compared with guarding males. Testis size of a (b) guarding and (c) sneaking male demonstrating increased investment in testes in sneaking males, which represents a characteristic response to increased sperm competition risk. Photo credit: John Fitzpatrick.

line of competition among rival males. Male genital morphology is extraordinarily diverse (Figure 3), even among closely related species, and this diversity is attributable in large part to the selective pressures imposed by sperm competition (Hosken and Stockley, 2004). Male genitalia exhibit an astonishing variety of adaptations to maximize their chances of success in sperm competition. For example, male genitalia can displace sperm from previous matings, as is the case in the damselfly *Calopteryx maculata*, where male genitalia are covered in spines that remove almost all previously deposited sperm of rival males from the female reproductive tract, thereby virtually eliminating sperm competition (Waage, 1979). When looking across species, genitalia have more elaborate sexual 'weaponry,' including adaptations for sperm removal or displacement, in species where the risk of sperm competition is high compared with closely related monogamous species (Stockley, 2002). Similarly, populations of seed beetles (*Callosobruchus maculatus*) evolved under experimentally enforced monogamy

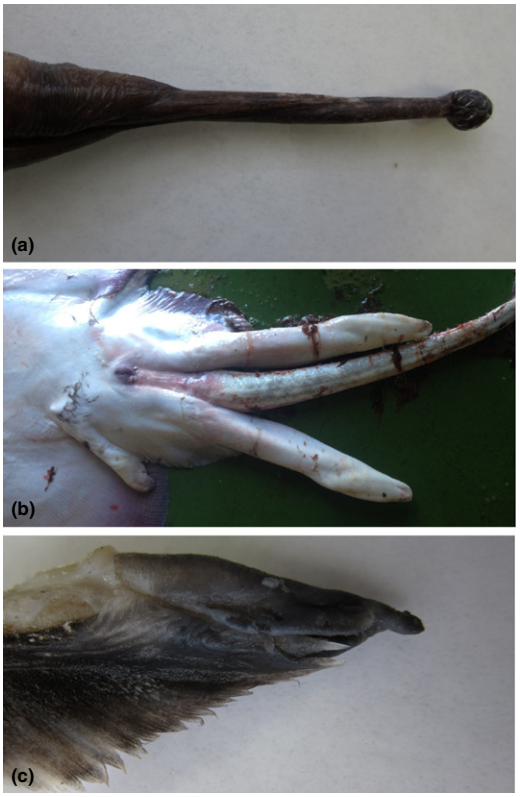

Figure 3 Diversity in genital morphology among cartilaginous fishes (sharks, skates, rays, sawfish, and chimaeras). Clasper (paired genitalia in cartilaginous fish) morphology differs dramatically in size and shape among (a) Australian ghostshark, *Callorhinchus milii* (Photo credit: Eduardo Garza Gisholt), (b) common skate, *Dipturus batis* (Photo credit: Amy Rowley), which shows paired claspers with the tail extending beyond the claspers and outside of the margins of the photo, and (c) New Zealand lanternshark, *Etmopterus baxteri* (Photo credit: Eduardo Garza Gisholt). Note the genital hooks and spurs observed at the terminal portion of claspers in (a) and (b).

show reduced genital spine length relative to polygamous populations (Cayetano *et al.*, 2011).

Sperm competition also influences genital size and shape. For example, in house mice (*Mus domesticus*), males maintained under breeding regimes where sperm competition occurred for 27 generations had thicker penis bones (baculum) than males maintained under enforced monogamy (Simmons and Firman, 2013). Across rodent and carnivores, the baculum is longer in species where sperm competition is prevalent (Ramm, 2007). There is good reason for genital morphology to respond to sperm competition risk, as several studies reveal that genital morphology predicts male reproductive success during sperm competition (Simmons *et al.*, 2009; Stockley *et al.*, 2013).

Following the release of sperm, either from male genitalia inside the female's reproductive tract or into the external environment in the case of internal and external fertilizing species, respectively, the sperm themselves are the primary combatants in male–male competition. Consequently, sperm are under intense selection, as those sperm traits that provide an advantage during sperm competition will be favored by selection. In particular, sperm competition influences the evolution of sperm number and sperm quality, both of which predict male fertilization success during sperm competition, albeit to varying degrees (Simmons and Fitzpatrick, 2012).

The number of sperm competing to fertilize an egg(s) can dramatically influence a male's competitive fertilization success. In many species, sperm competition is thought to follow a 'raffle principle,' where success in the raffle (in this case fertilizing eggs) is related to the number of 'tickets' (in this case sperm) a male holds (Parker, 1982). Under the raffle principle, all sperm have an equal chance of fertilizing eggs and therefore the probability of fertilization during sperm competition increases with the number of sperm transferred. Therefore, males are expected to invest more in sperm number when the risk of sperm competition is elevated (**Figure 2**; Parker, 1982).

The testes are the site of sperm production, and therefore an important target of selection for sperm number. Indeed, increases in testes size (in relation to body size) represent one of the most robust responses to sperm competition (**Figure 2**). The impact of sperm competition on testes size is especially well documented among primates (Harcourt *et al.*, 1981). For example, gorillas (*Gorilla gorilla*) experience a very low risk of sperm competition, as a single dominant male controls a harem of females and mates with them (almost) exclusively, and have remarkably small testes for their body size. In contrast, the closely related chimpanzee (*Pan troglodyte*) is highly promiscuous, facilitating very high levels of sperm competition, and has testes four times larger than those of a gorilla, despite weighing a quarter of a gorilla's body mass (Harcourt *et al.*, 1981). A similar pattern of increasing investment in testes in response to increase sperm competition risk is observed across a much broader range of primates (Harcourt *et al.*, 1981) and indeed across a wide range of other taxonomic groups, including birds, fish, amphibians, and reptiles (Simmons and Fitzpatrick, 2012).

Sperm competition not only selects for increases in sperm number but also influences the way males allocate their sperm during mating (Wedell *et al.*, 2002). While the costs of producing an individual sperm may be negligible, the ejaculate as a whole can be costly to produce (Dewsbury, 1982). Consequently, to maximize their reproductive success males are expected to strategically allocate their sperm during mating in response to cues of sperm competition (Wedell *et al.*, 2002; Parker and Pizzari, 2010). Males in many species indeed show strategic patterns of sperm allocation, but only under specific conditions. There is now clear evidence that males allocate more sperm when mating in the presence of a single rival male compared with matings where no rival males were present (Delbarco-Trillo, 2011; Kelly and Jennions, 2011).

However, sperm number is not the sole determinant of reproductive success during sperm competition, and under a broad range of conditions sperm quality (i.e., sperm morphology and performance) plays an important role in determining male fertility. Unique among cells, sperm must survive and travel outside the body in order to fulfill their function of fertilizing ova. Thus, as sperm moves toward the egg, various aspects of sperm quality, including sperm motility and swimming speed, will experience intense selection (Simmons and Fitzpatrick, 2012). For example, in domestic fowl (*Gallus domesticus*) and Atlantic salmon (*Salmo salar*), when females are artificially inseminated with an equal number of sperm

from two males, males with greater relative sperm velocity sire more offspring (Birkhead *et al.*, 1999; Gage *et al.*, 2004). Thus, in most species (but, for an exception see Dziminski *et al.*, 2009; Fitzpatrick *et al.*, 2012), sperm competition selects for increased sperm swimming speed (Simmons and Fitzpatrick, 2012).

Selection on sperm quality is predicted to impact on both sperm size and speed due to an assumed link between sperm swimming speed and sperm morphology, with longer flagella expected to generate greater propulsive force and allow sperm to swim faster (Gomendio and Roldan, 1991). While the underlying relationship between sperm morphology and swimming speed is far from clear (Humphries *et al.*, 2008; Fitzpatrick *et al.*, 2010; Simpson *et al.*, 2014), numerous studies have evaluated how sperm size responds to varying levels of sperm competition risk. In almost every taxonomic group studied to date (including mammals, birds, fish, reptiles, amphibians, and insects) there is evidence that sperm size increases with sperm competition risk (Simmons and Fitzpatrick, 2012). Moreover, a handful of recent studies have demonstrated that sperm competition also selects for faster swimming sperm across species, and this appears to be due to a positive relationship between sperm size and speed in these groups (Gomendio and Roldan, 1991; Fitzpatrick *et al.*, 2009; Lüpold *et al.*, 2009).

However, gaining a robust understanding of how sperm competition influences sperm size and speed has remained a contentious issue, as results contrary to the general pattern outlined above abound. Increasingly, efforts to understand how selection shapes sperm size and speed are focusing on better understanding the relationship and potential trade-off between sperm number and sperm size (Immler *et al.*, 2011). Although this work remains limited in scope, what is becoming increasingly clear is that sperm number, size, and speed are all important targets of selection by sperm competition, and which of these sperm traits are favored depends on the mechanism of sperm competition operating in a species (Immler *et al.*, 2011). For example, sperm are produced in greater numbers at the expense of size in large species with dilute female reproductive tracts where sperm competition adheres to the raffle principle. Conversely, where sperm displacement is the primary mechanism of sperm competition, as in many insects, selection acts to increase sperm size at the expense of producing greater sperm numbers (Immler *et al.*, 2011).

Increasingly, researchers are recognizing the importance of the non-sperm component of the ejaculate – seminal fluid – in mediating male reproductive success during sperm competition (Chapman, 2001). Sperm are released from males in the company of seminal fluid, a medium rich in proteins and other molecules produced by the accessory glands. These proteins exert a powerful influence on sperm competitive dynamics. First, seminal fluid proteins act on female physiology and behavior, which has knock-on effects for the risk of sperm competition faced by a male's ejaculate. For example, seminal proteins can reduce the risk of sperm competition experienced by an already inseminated ejaculate by reducing female receptivity to future matings (Chapman, 2001), aiding the displacement of rival males' sperm (Harshman and Prout, 1994), and contributing to the production of mating plugs that block access to the female's reproductive tract (Chapman, 2001). Second, seminal proteins can act to diminish the performance of sperm from rival males. In some social insect species, sperm perform better in the presence of the male's own seminal fluid than seminal fluid from a different, competing male (Den Boer *et al.*, 2010). However, the influence of seminal fluid on rival male sperm performance was not observed in monogamous social insect species, where sperm competition risk is low, indicating that seminal fluid function evolves in response to sperm competition risk (Den Boer *et al.*, 2010). Similarly, in the grass goby (*Zosterisessor ophiocephalus*), sperm of males using sneaky behaviors when attempting to fertilize eggs, and thus experiencing a higher risk of sperm competition, swim faster in the presence of the seminal fluid from a rival male, while sperm from males that use conventional courtship to woo females showed reduced fertilization rate when exposed to the seminal fluid of sneaky male (Locatello *et al.*, 2013). Thus seminal fluid has an important function during competitive matings and as such both the accessory gland and the proteins they produce evolve rapidly in response to sperm competition (Ramm *et al.*, 2005; Linklater *et al.*, 2007; Crudgington *et al.*, 2009).

In the four decades following Parker's (1970) recognition of the evolutionary significance of sperm competition, enormous advances have been made toward developing a comprehensive understanding of the evolutionary dynamics that govern sperm competition and its pervasive influence on male reproductive behavior, anatomy, and physiology. However, the study of sperm competition is still relatively young and many novel and exciting discoveries undoubtedly remain as advances in analytical tools and genomic approaches allow an ever widening set of questions to be addressed. Moreover, efforts to move the focus of sperm competition studies from the researcher's microscope to the female's reproductive tract (Manier *et al.*, 2010), the site of sperm competition in internal fertilizing species, promise to revolutionize our understanding of how sperm competition proceeds under 'real world' conditions. In this review, we focused our attention exclusively on evolutionary responses observed in males, paying particular attention to how sperm competition influences the evolution of male behaviors, genitalia, sperm, and seminal fluid. However, any discussion of sperm competition inevitably runs into the related topics of cryptic female choice, where females can influence the outcome of sperm competition by biasing fertility in favor of preferred males, and sexual conflict, where the evolutionary interests between the sexes differ. While these related topics are outside the immediate scope of this entry, we acknowledge their impact on shaping reproductive traits and encourage interested readers to follow up on these topics.

Supertree Methods, Phylogenetic

JG Burleigh, University of Florida, Gainesville, FL, USA

Supertrees

With the growth of evolutionary studies and consequently the availability of phylogenetic trees and data across many groups of taxa, there is increasing interest in combining insights from disparate sources to construct more comprehensive phylogenetic trees. Supertree methods and supermatrix methods are the two most common approaches to synthesize phylogenetic data. A supertree method combines a collection of phylogenetic trees with overlapping, but usually not identical, sets of taxa to create a single phylogenetic tree (i.e., the supertree) that, in most cases, contains all taxa from the input trees (**Figure 1**; e.g., Sanderson *et al.*, 1998; Bininda-Emonds *et al.*, 2002; Bininda-Emonds, 2004). In short, supertree methods generally combine smaller phylogenetic trees to build a larger phylogenetic tree (**Figure 1**), but any method to build a phylogenetic tree using other trees as input may be considered a supertree method. Consensus methods combine collections of trees with identical taxa (see Bryant, 2003). Thus, they may be considered a type of supertree method.

Although not designed specifically for phylogenetics, the BUILD algorithm (Aho *et al.*, 1981; but see Semple and Steel, 2003) is often described as the first supertree method. It builds a graph from a collection of input trees, and, if the trees are compatible, it outputs a tree that contains the topologies of all of the input trees. Numerous algorithms have enhanced or broadened the application of the original BUILD algorithm (e.g., Constantinescu and Sankoff, 1995; Ng and Wormland, 1996; Henzinger *et al.*, 1999; Daniel and Semple, 2004; Berry and Semple, 2006), but in practice, almost any collection of phylogenetic trees with taxonomic overlap will have topological conflict (i.e., no single tree can contain the topologies of all of the input trees). Algorithms such as MinCut (Semple and Steel, 2000), Modified MinCut (Page, 2002), and MultiLevelSupertree (Berry *et al.*, 2013) modified the BUILD or similar graph-based algorithms to combine incompatible trees. However, whether due to their complex, mathematical approach for resolving conflict among trees, questions about their performance on real datasets (e.g., Burleigh *et al.*, 2004; Eulenstein *et al.*, 2004; Chen *et al.*, 2006), or a lack of available, easy to use software implementations, these graph-based algorithmic approaches for supertree construction are seldom used in phylogenetics.

The matrix representation with parsimony (MRP) supertree problem provided the first pragmatic and intuitive method to construct supertrees (**Figure 2**; Baum, 1992; Ragan, 1992; see Baum and Ragan, 2004). For MRP, a collection of input trees is first transformed into a matrix of binary characters (**Figure 2**). Each column in the matrix represents a clade in an input tree. Usually taxa present in the clade are scored as '1,' and taxa not present in the clade, but otherwise present in the tree, are scored as '0'; the taxa that are not found in the input tree are scored as a '?,' representing missing data. After building the matrix, a phylogenetic tree (i.e., the supertree) is inferred from the matrix using maximum parsimony. With the availability of

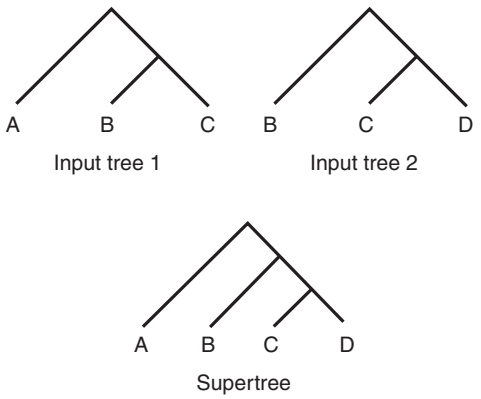

Figure 1 Supertree example. The two 3-taxon input trees on top can be combined to form a supertree that contains all four taxa found in input tree 1 and input tree 2. In this case, the supertree contains the topologies of input tree 1 and input tree 2, indicating that the two input trees are compatible. Interestingly, while the two input trees each contain information about one three-taxon tree (A|BC and B|CD, respectively), the supertree contains information about the relationships of four sets of three taxa (A|BC, A|BD, A|CD, and B|CD). Thus, the supertree induces two new sets of three-taxon relationships that are not present in the two input trees taken separately.

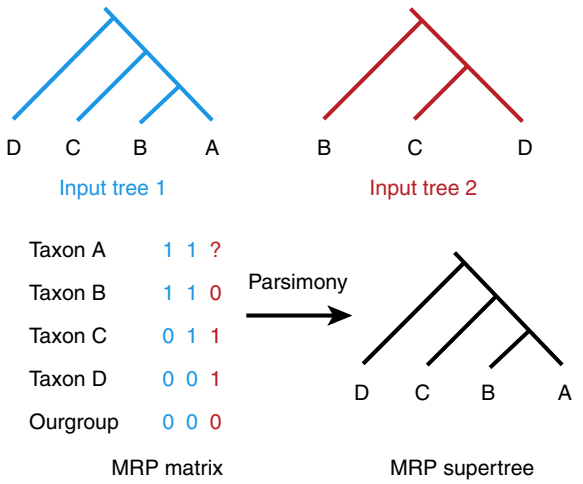

Figure 2 Matrix representation with parsimony (MRP). The two input trees can be coded as an MRP matrix. The first two columns of the MRP matrix describe clades in input tree 1 (a clade with A and B and a clade with A, B, and C), and the third column describes a clade in input tree 2 (a clade containing C and D, with taxon A missing). A maximum parsimony analysis of the MRP matrix will yield the supertree on the bottom right of the figure. Interestingly, even though input tree 1 and input tree 2 have conflicting topologies, the supertree is identical to input tree 1. This may be interpreted as a size bias for the MRP supertree method, in which the supertree more closely resembles larger input trees than smaller input trees.

 doi:10.1016/B978-0-12-800049-6.00222-5

fast and effective software for parsimony analyses, MRP quickly became the most commonly used supertree method. It has been used in some of the largest and best known supertree studies, including those for mammals (Liu *et al.*, 2001; Bininda-Emonds *et al.*, 2007), angiosperms (Davies *et al.*, 2004), dinosaurs (Pisani *et al.*, 2002; Lloyd *et al.*, 2008), and birds (Davis and Page, 2014). However, MRP also is the most commonly criticized supertree method (e.g., Pisani and Wilkinson, 2002; Gatesy and Springer, 2004; Goloboff, 2005). For example, there are numerous ways to code the input trees a matrix of binary or discrete characters, and these different codings can result in different supertree topologies (e.g., Purvis, 1995). Furthermore, it is not clear why a parsimony criterion would be appropriate or desirable for the MRP matrix, as the columns in the matrix generally represent membership in a clade, not any character (e.g., Rodrigo, 1993, 1996; Slowinski and Page, 1999). MRP can be biased, with the MRP supertrees reflecting the topologies of input trees based on their shape or size (**Figure 2**; Purvis, 1995; Wilkinson *et al.*, 2005), and the resulting MRP supertrees can include clades that are unsupported by all input trees (Bininda-Emonds and Bryant, 1998; Pisani and Wilkinson, 2002; Wilkinson *et al.*, 2004; Goloboff, 2005). Furthermore, if the input trees represent gene trees evolving through a coalescent process, MRP can be inconsistent, converging toward the incorrect species tree topology with more gene tree data (Steel and Rodrigo, 2008). Much of the debate surrounding MRP may be summarized as a difference in perspective between those who dislike MRP because it can fail versus those like MRP because it often does not (e.g., Bininda-Emonds, 2003). This is the paradox of MRP: although it is unclear why the optimality criterion is appropriate and there are numerous ways MRP can fail, MRP remains a popular supertree approach that often produces credible supertrees.

Matrix representation with flipping (MRF) is an error correction method to construct supertrees from the same binary character matrix of the input trees used in MRP (e.g., Chen *et al.*, 2002, 2003; Burleigh *et al.*, 2004; Eulenstein *et al.*, 2004). MRF assumes that the conflicts among input trees are due to error. However, these errors can be fixed by changing the character states in the binary character matrix (i.e., changing 0's to 1's or 1's to 0's) until the input trees are compatible. MRF seeks the supertree that implies the fewest changes (i.e., the least error) the binary character matrix. MRF appears to perform well compared to MRP in simulation and empirical analyses (Burleigh *et al.*, 2004; Eulenstein *et al.*, 2004; Chen *et al.*, 2006), but it has not been used as often as MRP.

Although matrix-based supertree methods like MRP and MRF often perform well, their results are based on a matrix representation of the trees, not the trees themselves, and their optimality criteria can be difficult to understand. Another class of supertree methods uses optimality criteria that directly seek to maximize the similarity between the input trees and the resulting supertree. There are a number of different ways to measure the similarity (or distance) between the input trees and a supertree. For example, the Robinson–Foulds supertree methods seek to supertree that minimizes the Robinson–Foulds distance between that input trees and the supertree, maximizing the number of clades shared between the supertree and the input trees (Bansal *et al.*, 2010; Chaudhary *et al.*, 2012, 2013). Other approaches use the triplet distance (Lin *et al.*, 2009; Ranwez *et al.*, 2010) or the SPR distance (Whidden *et al.*, 2014) to find the supertree that is most similar to the input trees. Each of these approaches appears to perform well in some contexts (but see Goloboff and Szumik, 2015), but it is difficult to know which distance measure is most appropriate and ultimately how the conflict among trees should be resolved.

Other supertree methods take a more conservative approach and do not attempt to resolve conflict among the species trees (Goloboff and Pol, 2002; Berry and Nicolas, 2007; Ranwez *et al.*, 2007; Scornavacca *et al.*, 2008). For example, semi-strict supertrees (Goloboff and Pol, 2002) or matrix representation with compatibility (MRC; see Ross and Rodrigo, 2004) seek cliques (clusters) of pairwise compatible characters in the MRP matrix, which are then used to construct supertrees of the uncontradicted groups in the input trees. Similarly, PhySIC (Ranwez *et al.*, 2007), and later PhySIC_IST (Scornavacca *et al.*, 2008), are veto methods that infer supertrees that contain only relationships in the input trees or induced by input trees. While these methods can reveal areas of conflict among input trees and may avoid some potential biases and undesirable properties of more liberal supertree approaches (e.g., Goloboff, 2005), the resulting supertrees also generally contain less phylogenetic information. As we add more input trees, more conflict will arise, and simply avoiding the conflict ultimately may not yield a useful synthesis.

It is not always clear how to choose among the tremendous diversity of supertree methods. Generally, there is a dearth of studies that have carefully characterized properties of different supertree methods (but see Steel *et al.*, 2000; Wilkinson *et al.*, 2004, 2007; Dong and Fernández-Baca, 2009). Instead, there have been two general approaches to evaluate supertree methods that represent distinct perspectives on what a supertree method should be. First, simulation experiments have been used to evaluate how well a supertree method can infer the species phylogeny (e.g., Bininda-Emonds and Sanderson, 2001; Eulenstein *et al.*, 2004; Piaggio-Talice *et al.*, 2004; Swenson *et al.*, 2010; Chaudhary *et al.*, 2013). These approaches generally simulate alignments from a 'known' species tree, construct input trees from these alignments, and then construct supertrees from the inferred input trees. The performance of the supertree method is based on how well the resulting supertrees reflect the original species tree. In the second approach, the supertree method is judged by how well the resulting supertree reflects the relationships in the input trees (e.g., Chen *et al.*, 2006; Lin *et al.*, 2009; Bansal *et al.*, 2010). For example, one might measure the average Robinson–Foulds or triplet distance between the input trees and resulting supertrees. This approach values the similarity of the supertrees to the input trees and penalizes the differences between the supertrees and the input tree.

Thus, ultimately users must choose whether the supertree should reflect the true biological species tree or the relationships within the input trees. For example, imagine inferring a supertree from a dataset consisting of a single, erroneous species tree. Should the supertree method return the true species tree or should it return the erroneous input species tree (which best reflects the input)? This is the difference between a phylogenetic inference method and a tree synthesis method. Although many

biologists ultimately want the true species tree, the optimality criteria of most of the traditional supertree methods are based on tree synthesis, seeking to retain the relationships from the input trees. In practice, the results from a tree synthesis method and a tree inference method hopefully will not differ greatly. In fact, recently developed maximum likelihood supertrees, which use a model of phylogenetic error to infer a supertree from a collection of input trees, essentially provide a synthetic tree that should reflect the true species tree (Steel and Rodrigo, 2008; Akanni *et al.*, 2015). Maximum likelihood supertrees also can be a statistically consistent method to build species trees from gene trees (Steel and Rodrigo, 2008).

For an approach designed to unite disparate phylogenetic data, supertree methods have been particularly divisive area of phylogenetics. Some of the criticism has focused on the properties or performance of specific supertree methods (e.g., Gatesy and Springer, 2004; Gatesy *et al.*, 2002, 2004; Goloboff, 2005; Wilkinson *et al.*, 2005; Goloboff and Szumik, 2015), but there also are general limitations to supertree approaches. For example, by using trees as input, rather than then underlying character data used to build the tree, they fail to capture a great deal of information that could help to resolve the phylogeny. Also, the quality (i.e., accuracy) of the input trees can greatly affect the results (Bininda-Emonds *et al.*, 2004). While all phylogenetic methods depend on the quality of the input data, supertree methods may be especially susceptible to input data error because the data are usually estimates of inherently difficult phylogenetic analysis problems. Furthermore, simply obtaining and finding published phylogenetic trees, either from the literature or even tree databases, can be difficult (e.g., Chen *et al.*, 2008; Stoltzfus *et al.*, 2012). Finally, nearly all supertree methods output topologies without branch lengths, which are necessary for many evolutionary analyses. Methods exist to add branch lengths to supertrees (e.g., Gittleman *et al.*, 2004; Vos and Mooers, 2004; Webb and Donoghue, 2004; Torices, 2010; Eastman *et al.*, 2013), but the original supertrees may have limited use for evolutionary analyses.

In spite of the limitations of supertree methods, there are several ways in which supertrees are a part of cutting edge phylogenetics work. Recently, a supertree approach was used to combine a taxonomy of named species with published phylogenetic trees to create a supertree of ~2.3 million species, by far the most comprehensive representation of the tree of life to date (Hinchliff *et al.*, 2015). Interestingly, this approach constructs the supertree from a graph database, which can be modified to build supertrees using approaches similar to the BUILD algorithm and other related supertree algorithms that addressed the original supertree problems (see Chaudhary *et al.*, 2015). Perhaps the most relevant use of supertrees methodology is in the field of species tree methods, in which the species tree topology is inferred based on variation in phylogenetic trees, usually using a gene coalescence or duplication and loss model (see Liu *et al.*, 2009; Knowles, 2009; Anderson *et al.*, 2012). Although not covered in this article, most species tree approaches are supertree methods, in which a species tree is inferred from a collection of input (i.e., gene) trees based on a biological criterion. The first species tree methods, gene tree parsimony, are very similar to the distance based supertree methods described above (e.g., Goodman *et al.*, 1979; Guigó *et al.*, 1996; Page and Charleston, 1997). They take a collection of gene trees and infer the species tree that implies the fewest number of evolutionary events, such as duplications and losses, lateral transfer, or deep coalescence events.

Supermatrix Methods

Supermatrix methods combine phylogenetic character matrices from different sources with overlapping, but usually not identical taxonomic coverage (**Figure 3**; e.g., De Queiroz and Gatesy, 2007). To build a supermatrix, individual phylogenetic character matrices are concatenated into a single matrix (i.e., the supermatrix), which can be analyzed using conventional phylogenetic methods such as maximum parsimony, maximum likelihood, or Bayesian approaches. These matrices often represent molecular sequences (e.g., Driskell *et al.*, 2004; Thompson and Shaffer, 2010), but some supermatrices combine both molecules and morphology (Gatesy *et al.*, 2003; Goloboff *et al.*, 2009). In practice, not all taxa will be found in all input character matrices, and consequently, the supermatrices often have much missing data, which could represent either unsampled or missing characters. Although extensive missing data can be problematic (Lemmon *et al.*, 2009; Simmons and Goloboff, 2013), credible phylogenetic trees have been constructed from supermatrices with extremely high percentages of missing data (e.g., Driskell *et al.*, 2004; McMahon and Sanderson, 2006; Thompson and Shaffer, 2010; Pyron and Wiens, 2011; Hinchliff and Roalson, 2013; Pyron *et al.*, 2013; Soltis *et al.*, 2013; Burleigh *et al.*, 2012, 2015). Today, almost any phylogenetic analysis of large

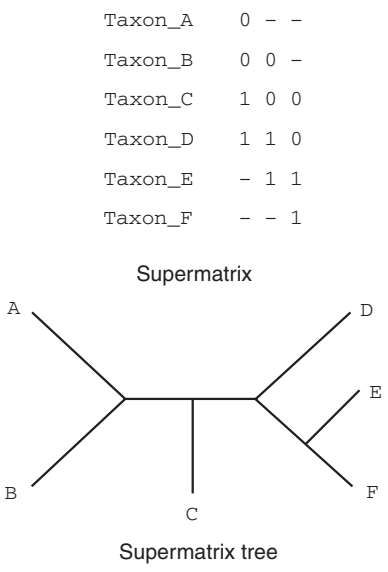

Figure 3 An example of a supermatrix analysis. The three columns in the supermatrix may come from different sources of data. Individually, each column can only describe the relationships among four taxa, but together the three columns can describe relationships among 6 taxa. Interestingly, if we remove data from Taxon_3 and Taxon_4, we cannot resolve the relationships among the remaining taxa. Only when we include data from Taxon_3 and Taxon_4 can we resolve the relationships among Taxon_1, Taxon_2, Taxon_5, and Taxon_6.

multi-locus or genomic data matrix may be considered a supermatrix, especially since, even with complete sampling, taxonomic sampling may not be even due to processes such as gene loss. Thus, there is often not an obvious distinction between a supermatrix and any combined data phylogenetic matrix.

Like supertree analyses, supermatrix analyses can induce relationships among taxa that are not apparent from analyses of any single data source (**Figure 3**). However, supermatrices have several seemingly intrinsic advantages over supertrees. First, they infer phylogenetic trees directly from the primary phylogenetic data, or characters. Thus, they can take advantage of sophisticated models of character evolution and phylogenetic inference software. Also, it is straightforward to quantify and interpret uncertainty for different tree nodes using either nonparametric bootstrapping or Bayesian posterior probabilities (e.g., Felsenstein, 1985; Huelsenbeck *et al.*, 2001). Finally, the output tree includes branch lengths, representing the number of substitutions, which can be easily transformed to represent time or make the tree ultrametric. This makes it easier to test rates and patterns of evolution and use the tree for phylogenetic comparative analyses.

Yet supermatrices are not without controversy. As supermatrices include more data, the data within the supermatrix will include more heterogeneity in rates and patterns of evolution. To encompass such heterogeneity within a single phylogenetic analysis, it may be necessary first to partition the supermatrices. Perhaps more worrisome is that the datasets may have different underlying trees due to processes such as hybridization/introgression or incomplete lineage sorting (e.g., Maddison, 1997), and combining datasets with different phylogenetic histories can lead to errors in the phylogenetic inference (e.g., Mossel and Vigoda, 2005; Kubatko and Degnan, 2007; Beiko *et al.*, 2008; Penny *et al.*, 2008). Thus, in some case, a species tree approach may be more appropriate than a supermatrix method.

While supertree and supermatrix methods may be viewed as competing methods for constructing large phylogenetic trees, they often have different objectives. Most applications of supertree methods seek a synthetic tree that best represents the relationships represented in the input trees. Thus, they are useful for representing the combined phylogenetic insights for a group of organisms. In contrast, supermatrix methods combine organismal character data to infer the species tree. Both approaches result in large trees, but the trees should be viewed or interpreted differently. However, some innovative new approaches for phylogenetics combine insights from both supertree and supermatrix methods. For example, with the growth of genomic data and a better understanding of the complexities of genomic evolution, it is clear that resolving a phylogeny often involves understanding not only patterns of variation among individual nucleotides, like a supermatrix method, but also patterns of variation among gene trees, like a supertree method. Thus, approaches that simultaneously infer gene tree from nucleotides and species trees from gene trees (e.g., Heled and Drummond, 2010; Bossau *et al.*, 2012) demonstrate that the solution to difficult phylogenetic problems may not be come from supertree or supermatrix methods alone, but by combining together the different perspectives from both approaches.

Support Measures, Phylogenetic Tree

E Susko, Dalhousie University, Halifax, NS, Canada

Glossary

Aligned sequence data A collection of amino acid, codon, or nucleotide sequences for organisms under study. Computer algorithms are used to align the sequence so that positions or sites are likely to be ancestrally related.

Alternative hypothesis A hypothesis of interest about the process or properties of the population that gave rise to data. In statistical tests, the probability of falsely rejecting a null hypothesis is controlled and small. Thus rejection of a null hypothesis suggests the alternative hypothesis is correct.

Bootstrap proportion The percentage of times a tree or split arose among trees estimated from bootstrapped alignments. Alternatively referred to as bootstrap support.

Bootstrapping Data-based simulation methods that are used to calculate *p*-values or confidence measures.

Conservative test A test is conservative if its actual false positive rate is smaller than its stated false positive rate.

False positive rate The probability of false rejection under the null hypothesis.

Likelihood The probability of observed data, treated as a function of the parameters in a model. Maximum likelihood estimation estimates parameters as those that maximize the likelihood.

Markov model A model for changes in discrete characters (e.g., nucloetides) over time where the probability of changes in the future depend upon past character states only through the current character state.

Nonparametric bootstrapping Bootstrapping where data sets are generated by sampling observational units at random and with replacement from the original data.

Null hypothesis A hypothesis of interest about the process or properties of the population that gave rise to data. In statistical tests, the probability of falsely rejecting a null hypothesis is controlled whereas the probability of falsely rejecting an alternative hypothesis is not. Thus failure to reject a null hypothesis is not usually considered evidence that it is correct.

Parametric bootstrapping Bootstrapping where data sets are generated using a parametric model, using parameters estimated from the original data.

Phylogenetic tree A graph showing evolutionary relationships between biological species.

Power The probability of correctly rejecting a null hypothesis when it is incorrect.

***p*-Value** The probability, calculated assuming a null hypothesis of interest, that a random test statistic is larger than the one observed in a study.

Split A partition of the taxa under study into two groups that are separated by an edge in a tree.

Test statistic A transformation of the data usually chosen so that values tend to be larger when the alternative hypothesis is correct than when the null hypothesis is correct.

Introduction

Modern methods of phylogenetic analysis use aligned sequence data to estimate evolutionary trees. A wide variety of methods are available for estimation. However, the information contained in aligned sequences varies substantially from study to study. Small sequence lengths or large evolutionary distances between sequences can lead to a great deal of uncertainty as to whether an estimated tree is correct. In this article methods for assessing uncertainty and their statistical properties will be discussed. One measure of support that will be considered is *p*-values coming from tests for significant evidence in favor of one tree by comparison with another. Another measure is bootstrap support for the claim that a set of taxa group together in the evolutionary tree. Due to its good statistical properties, maximum likelihood (ML) estimation is the most widely used method for estimating trees and some emphasis will be placed on measures of uncertainty associated with it. However, the bootstrap methods discussed apply more broadly to most methods for estimation.

Trees and Data

Figure 1 gives trees (Tree 1 and Tree 2A–2C) that might be considered possible for the $n=3414$-site mammalian mitochondrial data considered in Goldman *et al.* (2000):

		1	2	3	4	5	6	7	8	9		3414
0:	Mouse	I	N	I	L	T	L	L	V	P	…	L
1:	Opposum	I	N	L	L	M	Y	I	I	P	…	P
2:	Human	A	N	L	L	L	L	I	V	P	…	W
3:	Rabbit	I	N	T	L	L	L	I	L	P	…	W
4:	Harbor seal	I	N	I	I	S	L	I	I	P	…	W
5:	Cow	I	N	I	L	M	L	I	I	P	…	W

We will generally let x_i denote the data at site i; x_{ij} is the character state (nucleotide or amino acid, depending on the nature of the alignment). For instance $x_3=$ILLTII for the mammalian mitochondrial data.

Measures of support considered here include: (1) Two-tree tests: whether there is significant evidence against one specific tree in favor of another specific tree; for instance, against

 doi:10.1016/B978-0-12-800049-6.00212-2

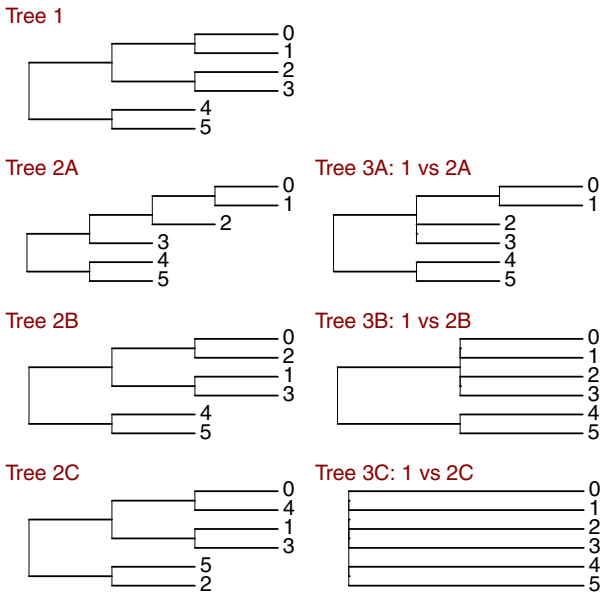

Figure 1 Tree 1 gives an example of a tree that significant evidence is being sought for. The trees 2A–2C give examples of trees that Tree 1 might be tested against with the KH test. The trees 3A–3C give the corresponding null trees obtained by collapsing edges in Tree 1 to make it equivalent to trees 2A–2C, respectively.

Tree 2A and in favor of Tree 1 in Figure 1. (2) Edge or split measures: whether there is significant evidence that a split in an estimated tree is truly present. For instance, one of the edges in Tree 1 can be described as splitting taxa 0 and 1 from the rest: 01|2345. The split 01|2345 is also present in Tree 2A, so one might be interested in whether that split is present without committing to either Tree 1 or Tree 2A as the correct tree.

Models and Methods

It is usually assumed that the observed character states at a site have been aligned in such a way that they are ancestrally related: the data that is observed at a position arose through a set of substitutions along the tree. Since algorithms like MAFFT (Katoh *et al.*, 2005) or PRANK (Löytynoja and Goldman, 2008) are used to convert raw sequence data into an alignment like the one for the mammalian mitochondrial data, there is some uncertainty about whether character states are correctly aligned to be ancestrally related, but this is a source of uncertainty that is usually ignored.

Treating the alignment as correct, and considering evolution at a particular site, most models make the reasonable assumption that given the ancestral character state for the immediate ancestor of an edge, evolution along that edge is independent of evolution along other edges. With this assumption, to model evolution at a site, it suffices to model evolution along an edge, which is usually assumed according to a time-homogeneous, continuous-time Markov chain (Felsenstein, 2004). Markov models require stationary frequencies as parameters and, in the case of nucleotide data, additional rate parameters are required; for amino acid models, empirical rate matrices derived from large databases are utilized to reduce the number of Markov model parameters requiring estimation. In most applications, additional parameters are required to allow different evolutionary rates over sites (Yang, 1994). A wide range of less commonly used, more complicated models and software are available allowing, for instance, variation of rates or substitution parameters across lineages (cf. Galtier, 2001; Jayaswal *et al.*, 2014). For the purposes of discussing tree support measures, the key issue is that there are a number of 'substitution model parameters' requiring estimation and providing additional sources of uncertainty: stationary frequencies of character states, rates-across-sites parameters, rate matrix parameters in the case of nucleotide data and, sometimes, additional parameters for more complex models.

Finally, most models assume that evolution across sites is independent. Because of interactions between sites in protein folding and other biological processes, this assumption is most likely not satisfied but, if the models of evolution at sites are reasonable, composite likelihood theory (Varin *et al.*, 2011) suggests treating sites as independent should still give reasonable tree estimates; the effect of ignoring site dependence on tree support measures is less clear and likely depends on the strength and nature of the dependence. In any case, the independence-across-sites assumption is convenient in that it yields a simple sum for the log likelihood or log probability of data:

$$l(\theta,\tau) = \sum_{i=1}^{n} l(x_i,\theta,\tau)$$

where $l(x_i,\theta,\tau)$ denotes the log of the probability of the aligned data at site i, τ is the tree that the probability is being calculated under and θ represents edge-lengths and substitution model parameters; θ_τ will be used to emphasize dependence on τ when it is important to do so. While most tree support measures adjust for uncertainty about edge-lengths, because of the wide variety of models, they sometimes do not adjust for uncertainty of all other parameters.

Tree support measures depend on the methods of estimating trees. ML estimation is perhaps the most frequently used method of estimation. It seeks to find the tree τ and substitution parameter estimates $\hat{\theta}$ that maximize $l(\theta,\tau)$. Packages available for ML estimation include PhyML (Guindon *et al.*, 2010) and RAxML (Stamatakis, 2014). Popular alternatives include parsimony and distance methods. Parsimony methods have a number of support measures like the consistency and retention indices that are specific to it. Distance methods start by considering the simplest ML problem: ML estimation for a pair of taxa. Because there is only one possible tree for a pair of taxa, ML estimation amounts to obtaining the evolutionary distance for the pair. Distance methods repeat this process for all pairs of taxa and then search for a tree for which the ML distances are well approximated by sums of edge-lengths over paths between taxa; one frequently used search strategy is the neighbour-joining algorithm (Saitou and Nei, 1987). Most of the measures of support considered here arise in an ML context. Bootstrapping methods apply generally to any method of estimation, including parsimony and distance methods.

Statistical Testing Concepts

Formal applications of hypothesis testing have a null hypothesis H_0 and an alternative hypothesis H_A. Given a suitable test statistic, T, chosen so that it tends to be large when H_A is true, an a-level test rejects the null hypothesis when $T > c_\alpha$ where c_α is chosen so that $P_{H_0}(\text{reject } H_0) = \alpha$. By definition, the test has probability of false rejection under H_0, alternatively referred to as the 'false positive rate,' that is controlled at α and is small. Since no control is provided over the probability of rejection when H_A is true, alternatively referred to as the 'power' of the test, H_0 and H_A are treated asymmetrically: if $T > c_\alpha$, it is unlikely H_0 is true but if $T \leq c_\alpha$, all that can be concluded is that it is not unlikely that T would have arisen under H_0; it remains possible that it was also not unlikely under H_A.

A specific example, whose relevance to tree tests will become clear later, is the z-test that a mean difference, μ, is 0 ($H_0{:}\mu = 0$) tested against $H_A{:}\mu > 0$. Such tests arise, for instance, when considering whether, say, the difference d in cholesterol levels of patients before and after some type treatment tends to be positive. Given a relatively large sample of differences, $d_1, \ldots, d_n$, under H_0, $z = \sqrt{n}\bar{d}/s_d$ should have an approximate standard normal distribution; here $s_d^2 = (n-1)^{-1}\sum_i (d_i - \bar{d})^2$. An α-level test rejects when $z > z_\alpha$ where z_α is the upper $(1-\alpha) \times 100$th percentile of the standard normal distribution. To have an $\alpha = 0.05$ false positive rate, the test must reject when $z > 1.64$. If $n = 100$ and the standard deviation of the d_i is 1, the power of the test is approximately 0.06, 0.64, and 0.99 when $\mu = 0.1$, 0.3, and 0.5.

In some cases, H_0 does not provide enough information to determine the false positive rate. For instance, a more natural H_0 for the cholesterol z-test example is $H_0{:}\mu \leq 0$ but different $\mu \leq 0$ give different false positive rates; in the example with $n = 100$, the false positive rate is 0.05 when $\mu = 0$ but 0.04 when $\mu = -0.1$. The convention in such cases is to require that the false positive rate be at most α for any parameters satisfying H_0, which usually amounts to requiring that the false positive rate be α at the boundary between H_0 and H_α. For the z-test, this criteria is satisfied if the false positive rate is α when $\mu = 0$; consequently the z-test is the same whether $H_0{:}\mu = 0$ or $H_0{:}\mu \leq 0$.

In theory, tests are designed to have known false positive rates, α. In practice, $P_{H_0}(\text{reject } H_0)$ often can only be calculated approximately, assuming a relatively large sample size. In some cases, while the false positive rate cannot, even approximately, be explicitly calculated, it can be said to be at most α. Such a test is referred to as 'conservative.' It will have less power than if the threshold, c_α, for rejection were determined so that the false positive rate is α. Nevertheless, knowing that a test is conservative is useful because it gives an upper bound on the false positive rate.

Finally, while it is natural to describe testing in terms of test statistics, T, it is convenient to calculate a p-value as $P_{H_0}(T > t_o)$, where t_o represents the observed test statistic. For instance, for the z-test, if the data gave $z = 1.3$, the p-value, $P = P(Z > 1.3) = 0.10$ where Z is standard normal. Note that since the test statistic T is a random quantity, the p-value, which is a transformation of the observed test statistic, is also a random quantity. Because $P_{H_0}(T > t)$ gets smaller as t increases, $t_o > c_\alpha$ if and only if $P = P(T > t_o) < P_{H_0}(T > c_\alpha) = \alpha$. Thus the α-level test that rejects when $T > c_\alpha$ is the same as the test that rejects when $P < \alpha$. Putting aside formal testing, it is useful to note that P is the probability of seeing a test statistic at least as large as the observed. If this is very small, either a rare event has been observed or H_0 is false.

Bootstrap Support

The 'bootstrap' broadly refers to data-based simulation methods that are most commonly used to obtain measures of uncertainty. Bootstrapping was originally described in Efron (1979) and introduced to phylogenetics in Felsenstein (1985). 'Nonparametric bootstrapping' is the most frequently used form of bootstrapping. The procedure generates a random sample of integers $i_1, \ldots, i_n$ with replacement from $1, \ldots, n$ which gives rise to a bootstrapped data set, $x_{i_1}, \ldots, x_{i_n}$. For instance, for the mammalian mitochondrial data, one might generate $i_1 = 3$, $i_2 = 6$, $i_3 = 3, \ldots, i_n = 9$ giving the alignment

		1	2	3		3414
0:	Mouse	I	L	I	…	P
1:	Opposum	L	Y	L	…	P
2:	Human	L	L	L	…	P
3:	Rabbit	T	L	T	…	P
4:	Harbor seal	I	L	I	…	P
5:	Cow	I	L	I	…	P

The term nonparametric is used because the procedure does not directly utilize the parametric model in simulations but rather the observed data. Bootstrapping is a class of 'resampling methods': methods that resample data from the original data.

For a given bootstrapped or resampled data set, parameter estimation can be done just as for the original data set. Estimates are denoted $\hat{\theta}^*$ and $\hat{\tau}^*$ to distinguish them from estimates for the original data. In applications of bootstrapping this is repeated many times, giving many data sets each in turn resulting in $\hat{\theta}^*$ and $\hat{\tau}^*$. The result is $\left(\hat{\theta}^*_{(1)}, \hat{\tau}^*_{(1)}\right), \ldots, \left(\hat{\theta}^*_{(B)}, \hat{\tau}^*_{(B)}\right)$ where the number of bootstraps B should, in principle, be large.

The results of bootstraping are commonly used to obtain a measure of support for tree τ as the percentage of $\hat{\tau}^*_{(b)} = \tau$, which is referred to as bootstrap support or 'bootstrap proportion' (BP) for the tree. The most common measure of uncertainty in phylogenetics is BP for splits, which is defined as the percentage of $\hat{\tau}^*_{(b)}$ that contained the split. Note that splits might arise in different trees. For instance, suppose that for mammalian mitochondrial data, only the trees 1, 2A–2B of Figure 1 were estimated among $B = 100$ bootstrapped data sets, and that Tree 1 arose 50 times while Tree 2 arose 10 times. Since these are the two trees with the split 01|2345, the BP for 01|2345 would be 60%.

If the value of B is small, BP will vary depending upon what particular bootstrapped data sets happened to arise through the random bootstrap generation, which is undesirable. For large B, it can be shown that BP will converge upon a value; denote it BP_c. The theory for bootstrapping is developed treating BP as if it were BP_c, so in principle, B should be as

large as possible. In practice, because phylogenetic estimation is computationally intensive, many applications take $B=100$. Binomial calculations can be used to obtain the chance that BP differs from BP_c by more than d% and are tabulated below

		BP_c(%)						
		50	60	70	80	90	95	99
$B=100$	$d=2$	0.62	0.61	0.59	0.53	0.40	0.25	0.02
$B=100$	$d=5$	0.27	0.26	0.23	0.17	0.06	0.01	0.00
$B=100$	$d=10$	0.04	0.03	0.02	0.01	0.00	0.00	0.00
$B=1000$	$d=2$	0.19	0.19	0.16	0.10	0.03	0.00	0.00

The table is symmetric around $BP_c=50\%$. For instance, if $BP_c=40\%$ and $B=100$, there is a 61% chance BP will differ from 40% by more than 2%. Since it is the more extreme BP_c values that are of particular interest, the relatively large chance of being more than 5% away from a correct BP of 50 or 60% need not be of concern. Nevertheless, one can see that using $B=1000$ leaves much less uncertainty as to whether results may be due to insufficient bootstrapping.

Adjusted Bootstrap Support

Bootstrap support is appealing because it can be applied to any estimation method whereas other tree support measures are tailored to the methodology used. Intuitively it is clear that large BP suggests strong support for a tree or split. If after deleting some sites and repeating others several times over, the same tree almost always gets estimated, it is likely the correct tree. Nevertheless, it would be nice to have a conventional statistical interpretation as a p-value, which would help to decide what constitutes large BP. For some time this was believed to be the case. Specifically, Efron *et al.* (1996) argued that 1-BP for a split could be considered a p-value for the test of H_0: the split is not present against H_a: the split is present. Under this interpretation, $BP>95\%$ should arise approximately 5% of the time when the split is not present. Susko (2009) showed that for ML estimation, due to the unusual nature of tree space, BP is actually conservative: $BP>95\%$ should arise less than 5% of the time. Through simulation it was found that the threshold required to have a 5% false positive rate depended upon the edge-lengths in the true tree and varied between 70–85%.

Susko (2010) provides an 'adjusted' BP, denoted aBP which is an approximation to $P(BP>BP_o)$ where BP_o is the observed BP and probability calculation is under H_0. As discussed in the statistical concepts subsection, $1-P(BP>BP_o)=P(BP\leq BP_o)$ can be interpreted as a p-value for the test of H_0 that uses BP as a test statistic; thus $1-aBP$ is approximately a p-value. Susko (2010) showed that $P(BP>t)$ can be approximated using simulations of normal random variables. The approach is a form of 'parametric bootstrapping.' It is parametric because the model for the data is implicitly used in generating normal random variables and bootstrapping because parameters in the simulation are estimated from the data.

An issue that needs to be borne in mind with most measures of support, including BP, is selection bias or the bias when splits for which support is obtained are selected post data collection; usually as splits in an estimated tree. BP for a split in an estimated tree can be expected to be larger than BP for a split specified prior to data collection. This makes sense, since for a fixed split, BP occasionally can be as low as 10% but this usually only occurs when that split was not present in the estimated tree. Distinctions can get blurry here as a split can be both a priori of interest and estimated. Considering the trees in Figure 1, imagine estimating separate trees from a large number of different alignments. The conservativeness of BP implies that BP for the split 01|2345, assuming it is not present, will tend to be larger than 95% less than 5% of the time. By contrast, the BP values for the splits in the estimated trees, which would change from alignment to alignment, might be larger than 95% far more frequently than 5% of the time.

RELL Resampling

An alternative type of bootstrapping that arises in phylogenetics is referred to as 'resampling estimated log likelihoods' or 'RELL resampling' (Kishino *et al.*, 1990). It is used in a number of statistical tests. We will illustrate its use for the Kishino–Hasegawa (KH) test developed in Hasegawa and Kishino (1989) and Kishino and Hasegawa (1989), which is the most widely used test for whether one tree is better supported than another. One tree (Tree 2) is fixed as true under H_0 and the other (Tree 1), the one for which significant evidence is sought, is the true tree under H_A; in principle, both trees should be specified prior to the collection of data. The KH test statistic is the average site log likelihood difference:

$$n^{-1}\{l(\hat{\theta}_1,1)-l(\hat{\theta}_2,2)\}=n^{-1}\sum_{i=1}^{n}\{l(x_i,\hat{\theta}_1,1)-l(x_i,\hat{\theta}_2,2)\}$$

$$=\sum_{i=1}^{n}d_i/n=\bar{d}$$

Expressed in terms of d_i, H_0:$E[d_i]=0$ and H_A:$E[d_i]>0$ and the test rejects when $\bar{d}$ is large.

As with the nonparametric bootstrap, in RELL resampling, a random sample of integers $i_1,\ldots,i_n$ is generated with replacement from $1,\ldots,n$. However, instead of selecting site patterns, $x_{i_1},\ldots,x_{i_n}$, to determine a new data set, the estimated log likelihoods, $l(x_{i_1},\hat{\theta}_j,j),\ldots,l(x_{i_n},\hat{\theta}_j,j)$ are resampled for the two trees, $j=1$, 2. A bootstrapped KH test statistic is then computed as $\bar{d}^*$, the average of the $d_k^*=l(x_{i_k},\hat{\theta}_1,1)-l(x_{i_k},\hat{\theta}_2,2)$. Because sites are being selected from the original data, the $\bar{d}^*_{(1)},\ldots,\bar{d}^*_{(B)}$ give the distribution for $\bar{d}$ that one would expect when data are generated from whatever the original process is, whether H_0 or H_A is correct. Because calculating a p-value requires the distribution for d when H_0 is true, the RELL version of the KH test replaces $\bar{d}^*_{(b)}$ with a centered version: $\bar{d}^*_{(b)}-B^{-1}\sum_b\bar{d}^*_{(b)}$. This ensures that mean of the distribution of $\bar{d}^*$ is 0 as required under H_0. A p-value is calculated as the proportion of centered $\bar{d}^*_{(b)}$ that are larger than the observed $\bar{d}$.

The original version of the KH test was effectively a z-test that the mean of a population is 0. As discussed earlier, if the d_i are independent and sequence length is relatively large, the z-test of H_0:$E[d_i]=0$ against H_A:$E[d_i]>0$, has p-value $P(Z>z)$ calculated with standard normal Z and $z=\sqrt{n}\bar{d}/s_d^2$ where

$s_d^2 = (n-1)^{-1}\sum_i (d_i - \bar{d})^2$. It can be shown that, as long as n is relatively large, the p-values using the original KH test or the RELL version will be almost identical, assuming B is large. For the types of sequence lengths encountered in practice, the RELL version is rarely worth the additional computation for the KH test.

Susko (2014) shows that the KH test is conservative (the false positive rate of an α-level test is usually much smaller than α) and provides a version that has an approximately correct false positive rate. Karin *et al.* (2014) provide a version of the KH that adjusts for alignment uncertainty.

A heuristic argument for the conservativeness of the KH test is that it is a consequence of using RELL in place of usual bootstrapping. In usual bootstrapping, the KH test statistic would be calculated as $\{l^*(\hat{\theta}_1^*,1) - l^*(\hat{\theta}_2^*,2)\}/n$ rather than the $\{l^*(\hat{\theta}_1,1) - l^*(\hat{\theta}_2,2)\}/n$ used in RELL resampling; here l^* denotes the log likelihood for a bootstrap sample. Because $\hat{\theta}_j^*$ is the ML estimate for the bootstrap sample, it makes $l^*(\theta,j)$ as large as possible; neither $l^*(\hat{\theta}_1^*,1)$ nor $l^*(\hat{\theta}_2^*,2)$ are likely to be very small. By contrast, $\hat{\theta}_1$ or $\hat{\theta}_2$ can occasionally be poor estimates for the given bootstrap sample, causing one of the $l^*(\theta_j^*,j)$ to be small, in which case a large or small KH test statistic will result. In short, RELL resampling is expected to occasionally produce more extreme bootstrapped KH test statistic, giving rise to more variability in the centered $\bar{d}_{(b)}^*$ and making it more frequent that the proportion of centered $\bar{d}_{(b)}^*$ will be larger than the observed $\bar{d}$.

Parametric Bootstrapping

For two-tree tests, the two trees can always be made equal by collapsing internal edges resulting in a tree referred to as the consensus tree. Figure 1 gives examples where the trees 3A–3C are the consensus trees obtained by collapsing edges in Tree 1 to make it equivalent to trees 2A–2C respectively. Recall that in testing the mean hypothesis, $H_0{:}\mu \leq 0$ against $H_A{:}\mu > 0$, p-values or critical values are determined by calculation at $\mu = 0$, the value on the boundary of the null hypothesis or the closest μ satisfying H_0 to values of μ under H_A. Consensus trees play this role in phylogenetics. Tree 3A, for instance, is on the boundary of tree space between the H_0 Tree 2A and the H_A Tree 1. Thus p-values or critical values should be determined by calculation under the consensus tree.

An alternative way of calculating p-values for the KH test statistic is through parametric bootstrapping. The idea is a general one applicable to any statistical test. Suppose the test rejects when test statistic T is large; for the KH test, T is the KH test statistic or difference in log likelihoods between Tree 1 and Tree 2. Parametric bootstrapping is similar to usual bootstrapping but instead of repeatedly generating bootstrap data sets from the original data, data sets with the same sequence length as the original data are generated from a model and assuming H_0 is true. For the KH test, data is generated from the H_0 tree, the consensus tree of trees 1 and 2, under whatever model was used to calculate likelihoods. Given estimated substitution model parameters and edge-lengths, software implementations like the seq-gen program of Rambaut and Grassly (1997) can generate simulated data on a tree. Let $T_{(1)}^*, \ldots, T_{(B)}^*$ denote the test statistic for each of the B bootstrap data sets. Then an approximate p-value is the proportion of $T_{(b)}^* > t_o$ where t_o is the observed test statistic. Similar comments as for usual bootstrapping apply as to how large B should be taken. Indeed, calculations are the same with BP_c and BP there replaced by 1 minus the correct and approximate p-value here.

Symbiogenesis, History of

N Gontier, University of Lisbon, Lisbon, Portugal

Glossary

Archaea Oldest Domain of Life, previously designated as Archaebacteria.

Bacteria Second Domain of Life, previously designated as Eubacteria.

Domains of life/ three-domain classification Based upon results obtained from comparative molecular phylogenetics, Woese *et al.* (1990) undid the prokaryote/ eukaryote and five-kingdom classification and instead distinguished three major domains of life: Archaea, Bacteria, and Eukaryota.

Eukaryota/Eukaryotes Third domain of life, containing the Protist, Fungi, Plant and Animal Kingdoms. Eukaryotic cells have a membrane-bounded nucleus that contains the genome, and the cytoplasm often contains various cellular bodies called organelles.

Flagellum/Flagella Whip-like extensions of prokaryotic cells that enable motility. Contrary to eukaryotic undulipodia, flagella are made up of flagelin proteins.

Hereditary symbiosis Symbiotic association that becomes permanent and irreversible, foundational for symbiogenesis.

Horizontal transmission Any type of exchange between distinct individuals that happens during their lifetime and outside of the germ line.

Kingdoms of Life/ five-kingdom classification According to Whittaker and Margulis (1978), life can be classified into five kingdoms: Prokaryotic Monera (containing the Archaebacteria and Eubacteria), Eukaryotic Protoctista (Protists), Fungi, Plants, and Animals.

Lateral gene transfer Horizontal gene exchange between distinct organisms or distinct genomes within the same organism.

Metamorphosis Pre-evolutionary idea that living organisms can transform, or change in form. Transformation and metamorphosis are precursors to transmutation and evolutionary theory.

Microbiome The complete community of microorganisms that inhabit or live on the surface of an organism. The term is sometimes used to specifically refer to the genomes of the microbiota.

Microtubules Tubulin protein structures.

Prokaryotes All Archaea and Bacteria, typified by a free-floating instead of nucleated genome.

Defining Symbiogenesis

Symbiosis occurs when distinct organisms live in close association with one another, while symbiogenesis is both a phenomenon and an evolutionary mechanism (Merezhkowsky, 1905, 1910; Famintsyn, 1907; Kozo-Polyansky, 1924/2010) that results from permanent and hereditary symbiosis (von Faber, 1912; Buchner, 1921, 1939; Wallin, 1927; Lederberg, 1952; Sagan, 1967). Margulis and Dolan (2000, p. 157) define symbiogenesis as the "origin of a new organ, metabolic pathway, behavior, tissue, or other feature as a result of long-term hereditary symbiosis and includes the process by which organelles of the eukaryotic cell evolved from ancient bacterial symbionts."

Symbiogenesis today is well recognized to underlie the origin of mitochondria and chloroplasts. Both are cellular organelles (organ-like bodies), found exclusively in eukaryotic life forms (prokaryotes lack them, **Figure 1**), where they reside inside the cytoplasm of the cell (**Figure 2**). Mitochondria are present in aerobe protist, plant, and animal cells, while algal and plant cells also contain chloroplasts. These organelles once used to be free-living bacteria that, around 2 billion years ago, entered some of the first eukaryotic life forms through phagocytosis (eating or engulfment). The organisms engaged in symbiosis, this became permanent and hereditary, and the once free-living organisms evolved into the organelles (**Figure 3**). The bacterial lineages wherefrom mitochondria and chloroplasts evolved still exist as free-living bacteria today.

That mitochondria and chloroplasts evolved by symbiogenesis has for the most part of history been suggested based upon morphological comparisons between the organelles and bacteria, as well as the fact that these organelles contain their own DNA and have a double membrane, suggestive of bacterial engulfment (Ris and Plaut, 1962; Nass and Nass, 1963). Genetic comparisons between the organellar DNA and the DNA of bacterial lineages has now confirmed their bacterial origin. Chloroplasts evolved from cyanobacteria, and mitochondria evolved from proteobacteria (Bonen and Doolittle, 1975; Bonen and Doolittle, 1976; Bonen *et al.*, 1977; Gray and Doolittle, 1982). Molecular gene-sequencing techniques have furthermore shown instances of lateral gene transfer between the organelles and the nucleus, in both directions. After symbiogenetic acquisition, mitochondrial and chloroplast DNA underwent considerable gene loss (Archibald, 2014; Martin and Herrmann, 1998).

Eukaryotic cells often have many more organelles, and their evolutionary origin remains uncertain. A bacterial and symbiogenetic origin for the lysosomes has been suggested by its discoverer, the Belgian cytologist De Duve *et al.* (1974).

According to Margulis, the nucleated cell also evolved by means of symbiogenesis. As such, it was symbiogenesis that enabled both the evolutionary transition from prokaryotes to eukaryotes, and the subsequent evolution of the four eukaryotic kingdoms.

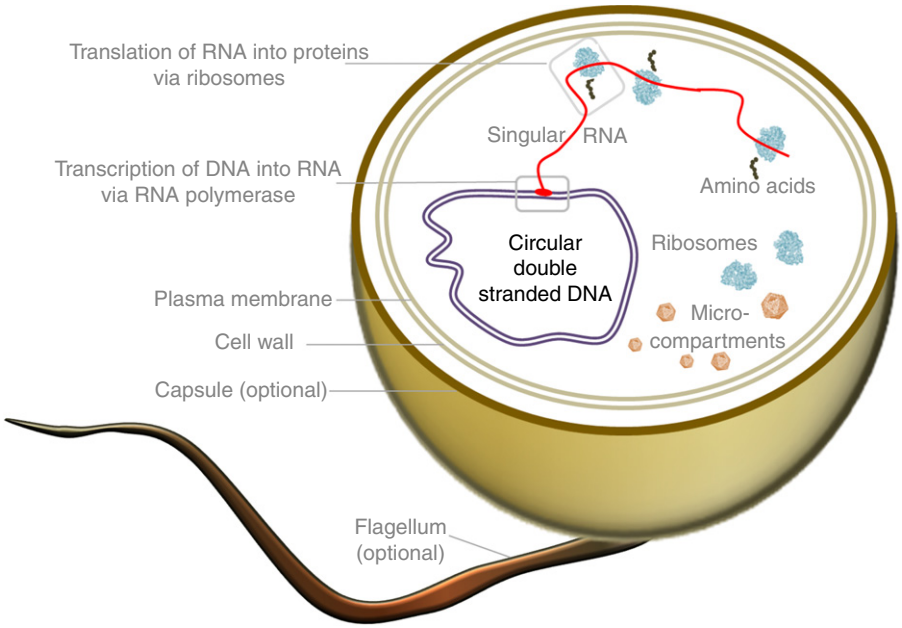

Figure 1 Schematic of a prokaryote. Prokaryotes neither have a membrane-bounded nucleus nor cellular organelles though they often contain micro-compartments that package enzymes and proteins.

From Hereditary Symbiosis to Symbiogenesis: The Origin of Mitochondria and Chloroplasts

Symbiosis research was often conducted in the margins of Darwinian evolutionary biology. Boveri (1904), for example, although a founder of chromosome theory, merely stated that Mendelian factors are transmitted via chromosomes. He also conjectured that the 'protoplasm' (cytoplasm) and chromosomes of the cell originated through symbiosis, an idea that was already introduced in 1893 by Shôsaburô Watasé (Sapp, 1994; Carrapiço, 2010, 2015).

Earlier in time, Schimper (1883, p. 112) suggested a single origin for "*Chlorophyllkörner*" (chlorophyll grains) and "*Farbkörper*" (pigment corpuscles) present in the plastids of plant and algal cells ("*plastiden*," subdivided into colorless "*leukoplastiden*," green "*chloroplastiden*" and yellow, orange and red "*chromoplastiden*"). He noted that they never arise *de novo* but develop from pre-existing 'protoplasmic' structures, and he thought they could divide and 'metamorphose' into one another. Because their protein structures ("*Proteïnkrystalle*") resemble those of 'living plasma' (bacteria), Schimper (1885, p. 202) later conjectured that chloroplasts might have resulted from a symbiosis between a colorless and chlorophyll-containing organism.

Merezhkowsky (1905, 1910, 1920a) identified these chlorophyll-containing bacteria as cyanobacteria ("*cyanophyceae*") and hypothesized that they underlie the evolution of all plant chromatophores ("*chromatophoren*," pigment-containing cells). Most importantly, Merezhkowsky argued that chloroplasts were different from their bacterial ancestors because they had evolved into new structures by a process he dubbed Symbiogenesis.

For Merezhkowsky (1910, p. 280, my translation), symbiogenesis is an evolutionary mechanism that forms part of a larger theory he introduced on the 'double' origin of life:

> All assumed and still assume today, that one plasma underlies all organisms, in other words, that out of non-being, life came forth from one root, from where one tree of organisms developed, first as a common trunk of protists, and then the tree split into two main axes – the plant axis and the animal axis. Until now, there was the general conviction, that the tree of life was a single one. The task set forth in this work, is to demonstrate that there are two trees of life, and that each tree originated on its own and independently from the other one, and this probably happened in different periods of earth's history. These trees partly developed on their own and independently from one another and partly stringed together and closely grew and developed together. Both trees are responsible for the diversity of organic beings. The idea of a unity of organic nature has to be abandoned in favor of the idea of nature's duality. (Merezhkowsky, 1910, my translation)

Life evolved from two distinct organismal types, each consisting of different 'protoplasms' ("*plasma-arten*"), "*Mykoplasma*" (Mycoplasma) and "*Amöboides Plasma*" (amoeba-like plasma). Mykoplasma is anaerobe, autotrophic, rich in phosphor and nucleic acid ("*nuclein*"), and experiments demonstrated a heat tolerance of up to 90 °C and a high resistance to poisons. Amöboplasma is aerobe and heterotrophic, low in phosphor and nucleic acids, it can only bear temperatures up until 50 °C, and it is easily poisoned. Based upon these features, Merezhkowsky (1910, p. 281) argued that "*Mykoplasma*" originated first because such organisms were better able to survive in the early earth's atmosphere and environment. Subsequently, and during different periods in time, these distinct life forms merged symbiogenetically. The first merger occurred between primitive bacteria and Monera and gave way to the evolution of amoebas. The second occurred when these amoebas merged with cyanobacteria (**Figure 4**).

Merezhkowsky thus pioneered in recognizing symbiogenesis' crucial role in the origin of complex life forms, and his

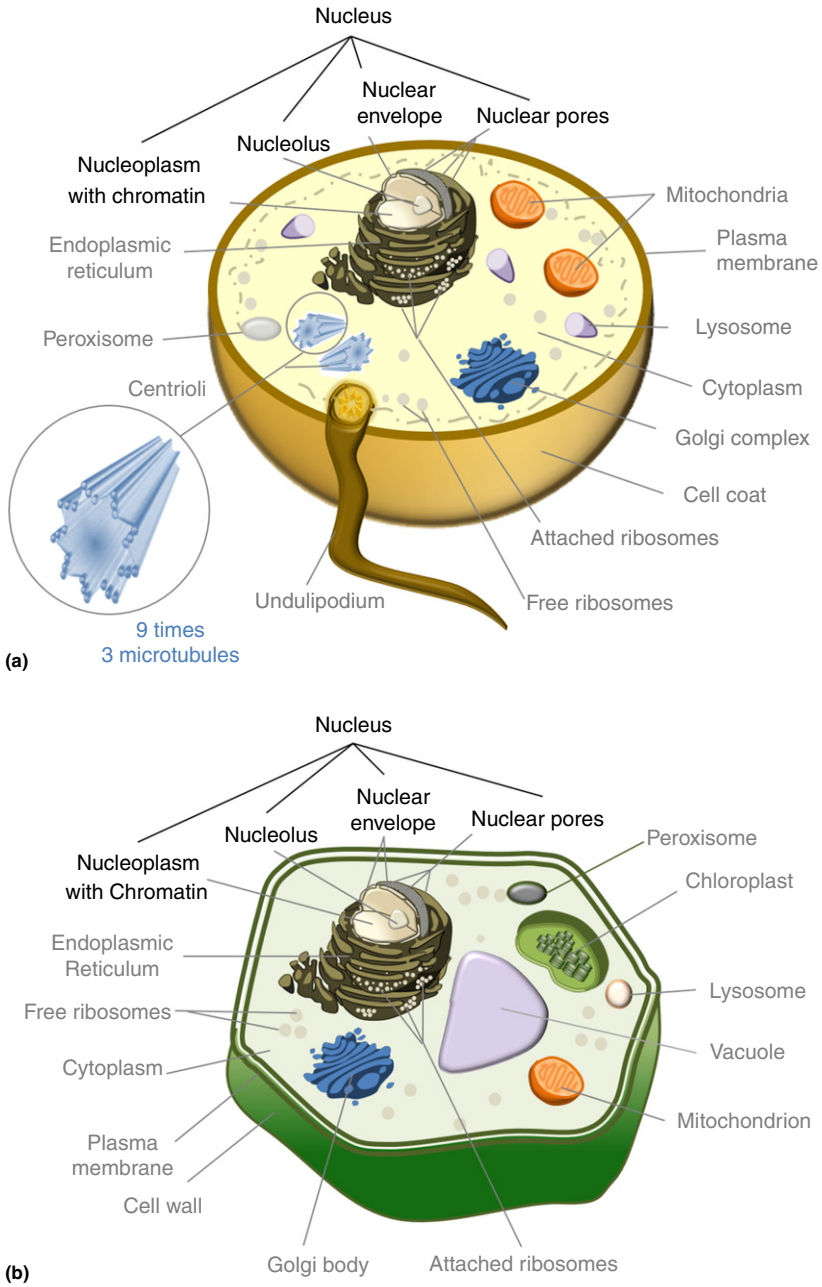

Figure 2 Schematic of an eukaryotic animal and plant cell. All eukaryotic cells have a membrane-bounded nucleus and many also possess numerous organelles.

double origin ideas made him recognize that a 'tree of life' needs to depict these symbiogenetic events.

Also Famintsyn (1907) and Kozo-Polyansky (1924/2010) developed ideas on symbiogenesis. Kozo-Polyansky understood evolution as the outcome of three phenomena: biotic potential or the ability to reproduce, symbiogenesis that generates variation and heritable novelty, and natural selection (Margulis, 1998, p. 1527).

The bacterial and symbiogenetic origin of mitochondria was first put forward by Kozo-Polyansky (1924/2010), Portier (1918) and Wallin (1923). Portier (1918) lived in France and when he suggested a symbiogenetic origin for mitochondria, he battled the successful Pasteur institute where bacteria became associated with disease (Sapp, 1994, 2003). In America, Wallin (1923) proposed that mitochondria evolved from oxygen-respiring bacteria, and he fought a similar battle against understanding bacteria merely as pathogens. For Wallin (1927), bacteria were the "building stones" or "primordial stuff from which all higher organisms have been constructed and modified," through *symbionticism*. Symbionticism is "the fundamental factor in the origin of species" because "microsymbiosis" can lead to new tissues and organs of such significance that they induce speciation.

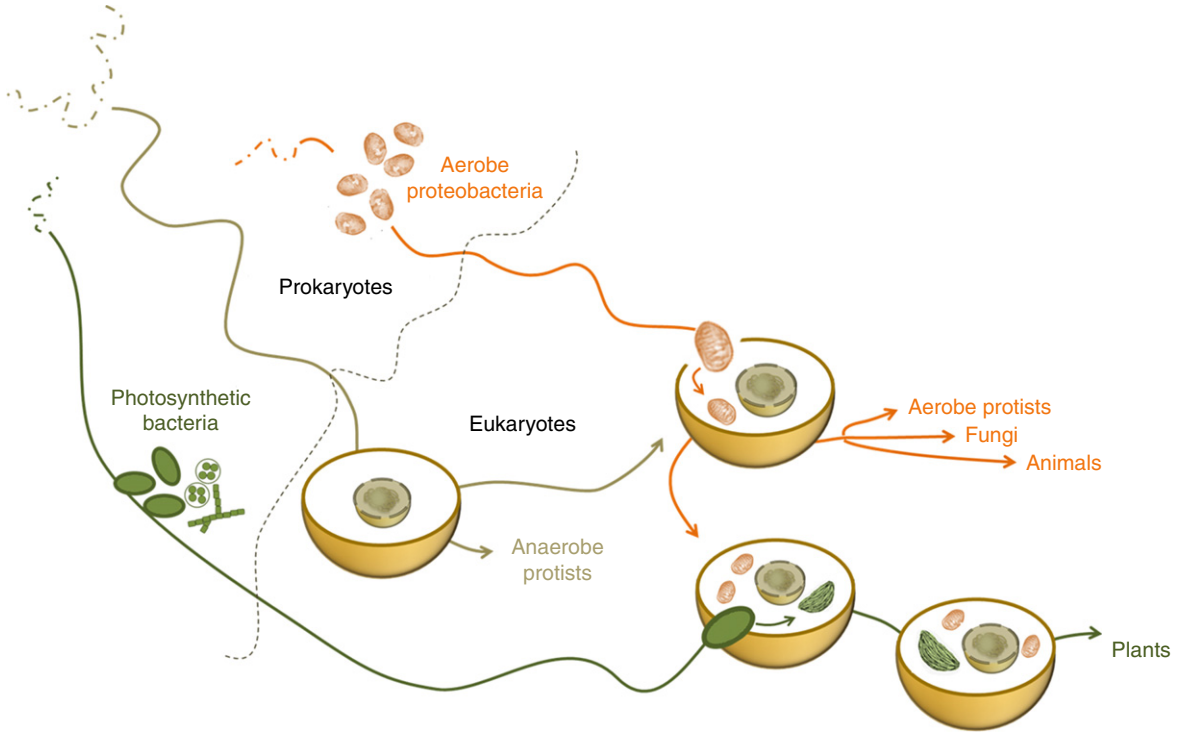

Figure 3 The origin of mitochondria and chloroplasts by symbiogenesis. Mitochondria evolved from aerobe proteobacteria, and chloroplasts from photosynthesizing cyanobacteria.

Earlier, von Faber (1912) had introduced the notion of "*erbliches Zusammenleben*," a concept Cowles (1915) translated as 'hereditary' and adopted by Buchner (1965). Also Wallin (1927) understood symbionticism as a 'hereditary mechanism.' Natural selection explained how species differentiate and evolve, but Darwin lacked clear theories on heredity and the origin of novel variation. For Wallin (1927, p. 121), symbionticism could complement Mendelian hereditary laws and theoretical genetics, because it introduces new genes and thus new hereditary variation: "on the basis of the new point of view that is associated with Symbionticism, we are forced to the conclusion that new genes must be acquired in organic evolution."

When Wallin suggested that mitochondria carry 'hereditary material' that can become part of the 'germ line,' 'genes' were still theoretical concepts presumably located on 'chromosomes.' Scholars that we now call adherents of 'cytoplasmic heredity' suggested that also the cytoplasm and the various organelles that house inside eukaryotic cells carry hereditary information.

One of them was Lederberg (1952), who in the 1940s reported on bacterial conjugation and transduction (**Figure 5**), two processes now characterized as mechanisms of horizontal gene transfer. For Lederberg (1952), however, both were instances of 'hereditary symbiosis' and 'infective heredity.'

Wallin and Lederberg's ideas that extrachromosomal, cytoplasmic structures such as plasmids or mitochondria carry hereditary material, and that these genes can become transferred to the nucleus were proven correct. Working at the Rockefeller Institute of Medical Sciences in New York, the Belgian cytoplasmic cell biologist Albert Claude, made the first electron-microscopy images of eukaryotic cells in 1945 (Palade, 1971). These enabled better visualizations of the cellular organelles and later, Ris and Plaut (1962) and Margrit and Silvan Nass (1963) respectively found DNA in chloroplasts and mitochondria, and linked it to symbiogenetic theories. Nonetheless, these ideas were overshadowed by the Modern Synthesis that advanced selectionist views of evolution. It was only through Margulis' work (Sagan, 1967) that data on symbiogenesis became widely recognized.

Lynn Margulis' Serial Endosymbiotic Theory

Our modern notions of symbiogenesis come from Lynn Margulis (Sagan, 1967), who from the 1960s onward, has introduced the Serial Endosymbiotic Theory (SET) (Sagan, 1967; Margulis, 1970, 1991, 1998; Margulis and Fester, 1991; Margulis and Dolan, 2001; Margulis and Sagan, 2002). Besides advancing a symbiogenetic origin for mitochondria and chloroplasts, according to SET also the eukaryotic nucleus evolved by symbiogenesis. In fact, according to Margulis, who endorsed a five-kingdom classification of life (Whittaker and Margulis, 1978; Margulis and Schwartz, 1997), all four eukaryotic kingdoms evolved as a result of three distinct symbiogenetic events (**Figure 6**).

SET gives the following chronological sequence of events (Margulis *et al.*, 2000; Margulis, 2010). In a first merger, fermenting thermoplasma-like archaebacteria (*Thermoplasma acidophilum)* merged with motile spirochete-like eubacteria, and evolved into the first anaerobe proto-eukaryotic cells (cells with a beginning nucleus). This first symbiosis is called motility symbiosis (**Figure 7**), because it presumably led to the

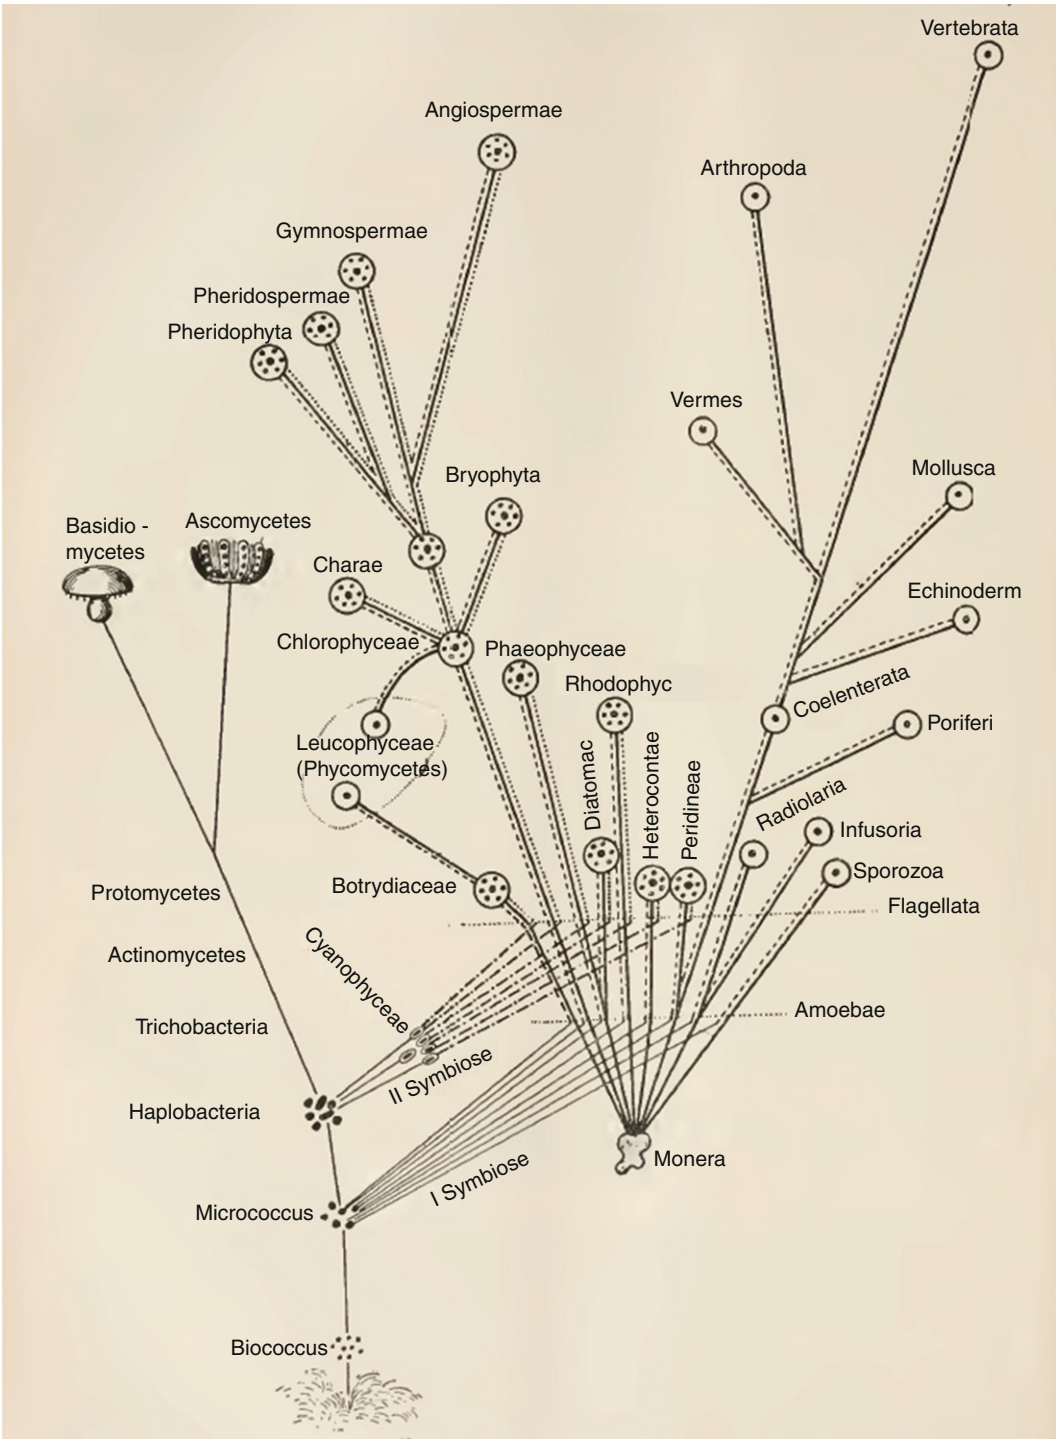

Figure 4 Merezhkowsky's polyphyletic tree of life (Merezhkowsky, 1910, p. 356). "*Mykoplasma*" is depicted by thin lines, "*Amöboplasma*" by thick lines, and the Cyanobacteria by interrupted lines. Mykoplasma evolved out of spontaneously generated biococci ("*Urbakterien*" or primitive bacteria), and this lineage evolved bacteria and fungi. Amöboplasma evolved out of spontaneously generated Monera. In a first symbiosis, Micrococcus on the Mykoplasma line merged with Monera resulting in the first Amoebae. A second symbiosis occurred between amoebae and Cyanobacteria (from the Mykoplasma line) resulting in flagellates. Consequently, he separated between three kingdoms: the kingdom of Mykoiden that never engaged in symbiosis (the thin line on the left); the animal kingdom resulting from a single symbiosis (the thick and interrupted lines); and the plant kingdom resulting from a second symbiosis event (thick, interrupted, and dotted lines). Leucophyceae were considered a side branch of plants.

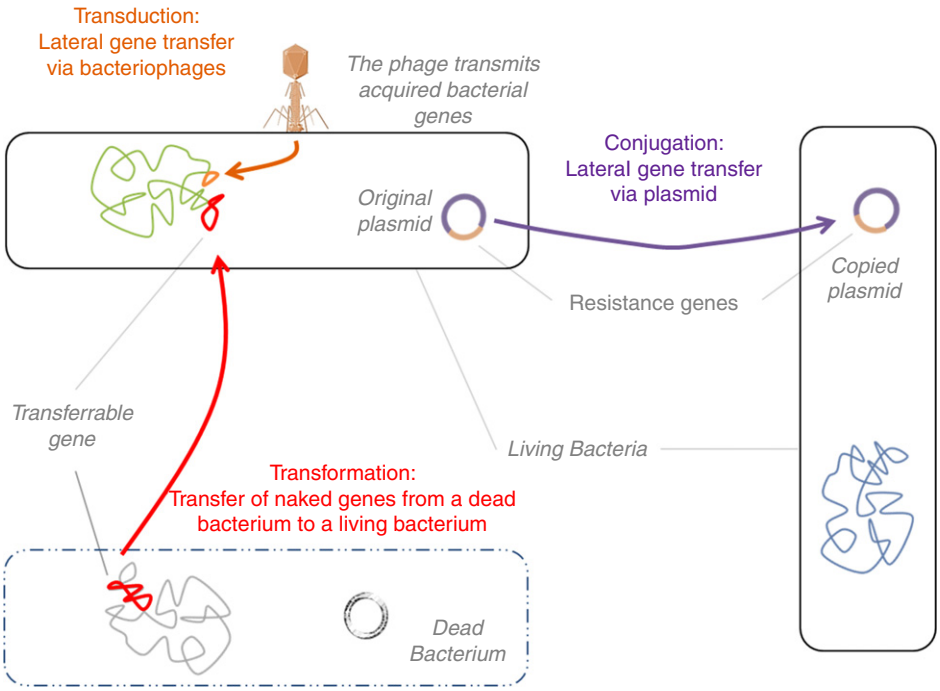

Figure 5 The three basic modes of lateral gene transfer amongst prokaryotes. In transduction, bacteriophages serve as vectors for the horizontal transmission of bacterial genes. In transformation, naked genes are picked up from their surroundings; and during bacterial conjugation, a single strand of a double-stranded plasmid (extrachromosomal DNA) is horizontally transferred from a donor to a recipient.

evolution of undulipodia and cilia (eukaryotic motility organelles that resemble tails and hairs) as well as centrioli (that form the centrosome which is the microtubule-organizing center that enables mitosis).

Evidence for motility symbiosis is found in the structure of undulipodia and centrioli. In cross section, centrioli are made up of microtubules organized according to a $[9(3)+0]$ pattern (**Figure 2(a)**). The same pattern is found in the cross section of the basal bodies (kinetosomes) of undulipodia and cilia (**Figure 8**). In their shaft (the axoneme), undulipodia and cilia have a $[9(2)+2]$ microtubular pattern. The structure of eukaryotic undulipodia is universal, and its morphological resemblance to the microtubular organization of centrioli makes Margulis assume that they share an evolutionary homologous origin, which she attributes to come from spirochete-like bacterial ancestors (Margulis *et al.*, 2000, 2006).

In a *second* merger, oxygen-respiring proteobacteria entered the cell's cytoplasm and engaged in permanent and hereditary symbiosis. The endosymbiotic bacteria evolved into mitochondria. Aerobic protoctists evolved, that, amongst others, includes amoebozoa and tailed (mastigote) cells, and from here all fungi and animals evolved.

In a *third* merger, early aerobic protoctists additionally engulfed photosynthesizing cyanobacteria that evolved into chloroplasts and gave way to the plant kingdom.

Wider Applications and Implementations of Symbiogenesis

Today, evidence is accumulating that endosymbiotic mergings occurred repeatedly. Sometimes the original merging bacteria as well as the organelles they evolved into were lost, and eukaryotes engulfed eukaryotes that already possessed organelles of bacterial origin. In this regard, scholars distinguish between primary, secondary, and tertiary endosymbiosis (Archibald, 2014; Raven, 1970; Stanier, 1974; Zook, 2015). In primary endosymbiosis, a prokaryote is engulfed by an eukaryote (a cyanobacterium enters a protist, leading to a photosynthetic eukaryote: a green algae). In secondary endosymbiosis, the product of primary endosymbiosis (the algae) is engulfed into another eukaryote where it wholly functions as an organelle (the transition from green to red algae); and in tertiary endosymbiosis, a eukaryote engulfs the product of secondary endosymbiosis (what happened when dinoflagellates evolved).

Nonetheless, an endosymbiotic origin for the eukaryotic nucleus remains debated. Some scholars assume that the outer membrane of prokaryotes merely folded inward thereby forming the membrane-bounded nucleus as well as the endoplasmic reticulum (Archibald, 2014). But these theories leave aside speculations on the origin of pro- and eukaryotic transcription and translation machineries that enable information to flow from DNA to RNA to proteins (**Figure 1**), as well as the origin of the eukaryotic chromosomes and mitosis.

Other scholars suggest that the eukaryotic nucleus evolved from viral symbiosis. For Livingstone Bell (2001), eukaryogenesis resulted from a symbiosis between a double-stranded DNA virus and a methanogenic Archaea. Villareal and Defilipps (2000) suggest that eukaryotic replication evolved from symbiogenetically acquired DNA viruses. The genes of these viruses and their host underwent hypercyclic organization and DNA compartmentalization into the complex eukaryotic chromosomes. Besides including virolution into the

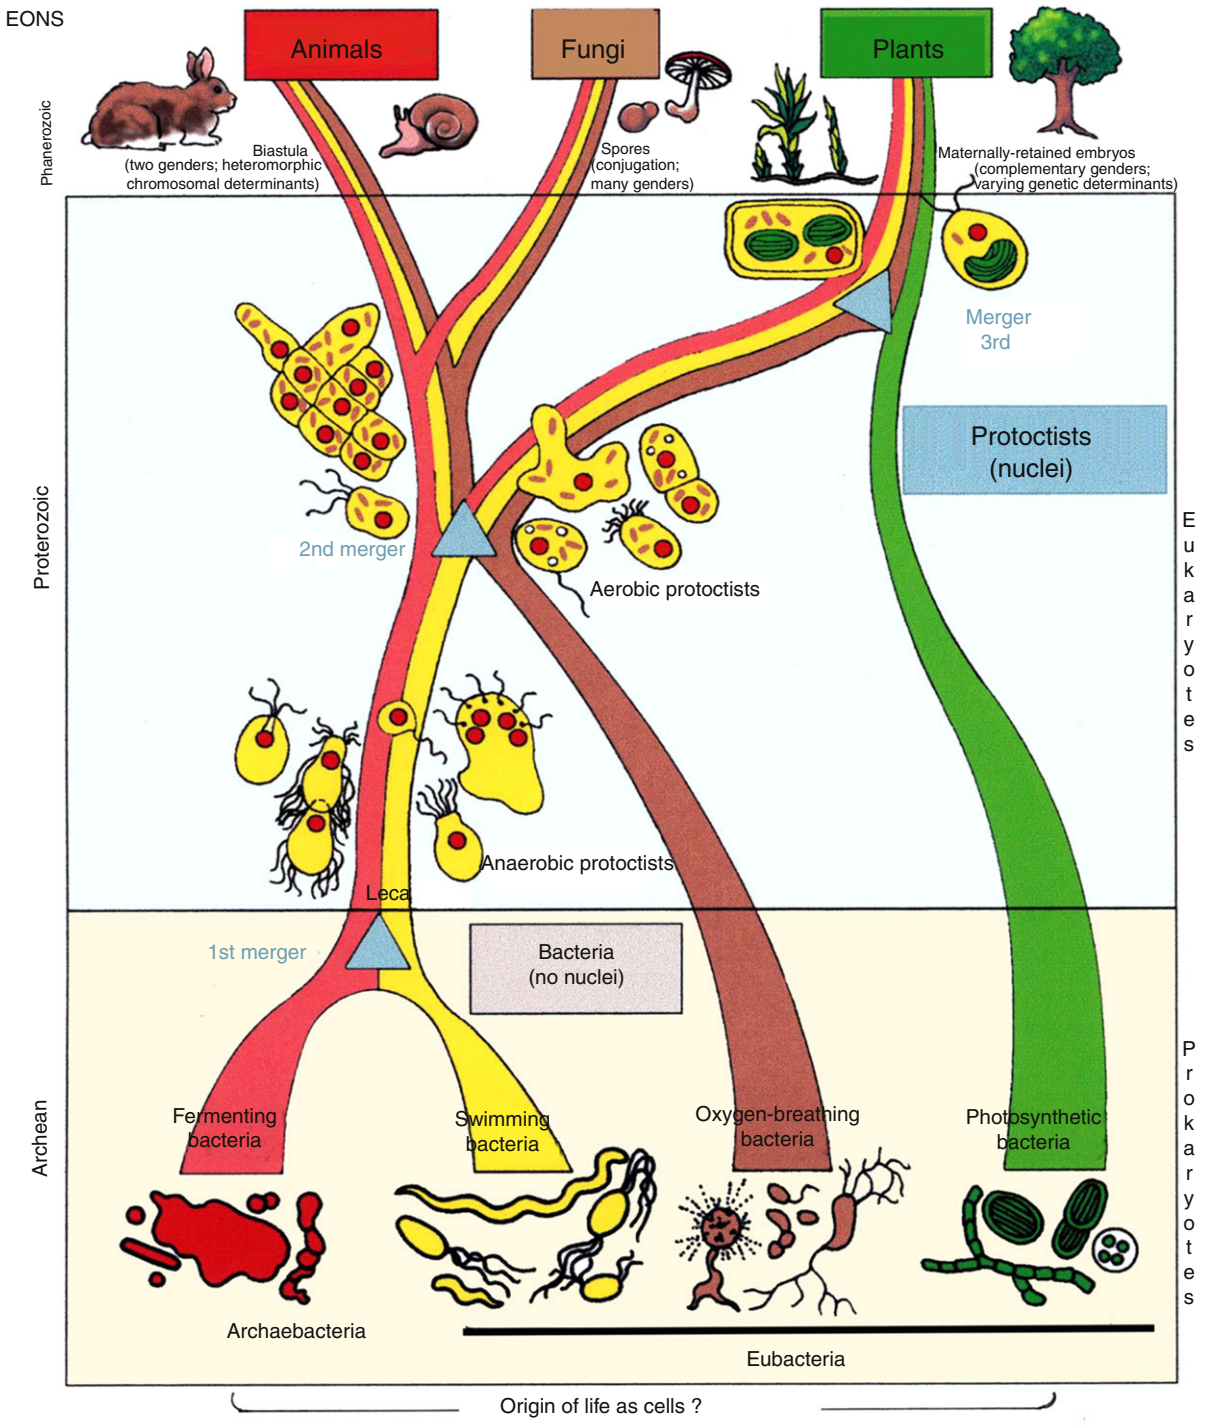

Figure 6 The origin of the four eukaryotic kingdoms according the Lynn Margulis' Serial Endosymbiogenetic Theory. The evolutionary transition from prokaryotes to eukaryotes happened because of symbiogenesis. Reprinted with permission and the courtesy of Ricardo Guerrero.

symbiogenetic framework, this research combines Eigen's (1996) theories on the origin of the genetic code with symbiogenesis theory, an idea already put forward in the 1980s by Dyson (1985).

Beyond eukaryogenesis, it is a fact that all eukaryotic life forms are prone to "viral colonization" (Villareal, 2000; Villarreal and Witzany, 2010, p. 699). Current microbiome and viriome projects are making scholars debunk the idea that viruses or microbial agents are mere pathogens or parasites. Rather, as mutual and commensal symbionts, these agents can introduce new genetic material that can become heredity and thus lead to symbiogenesis.

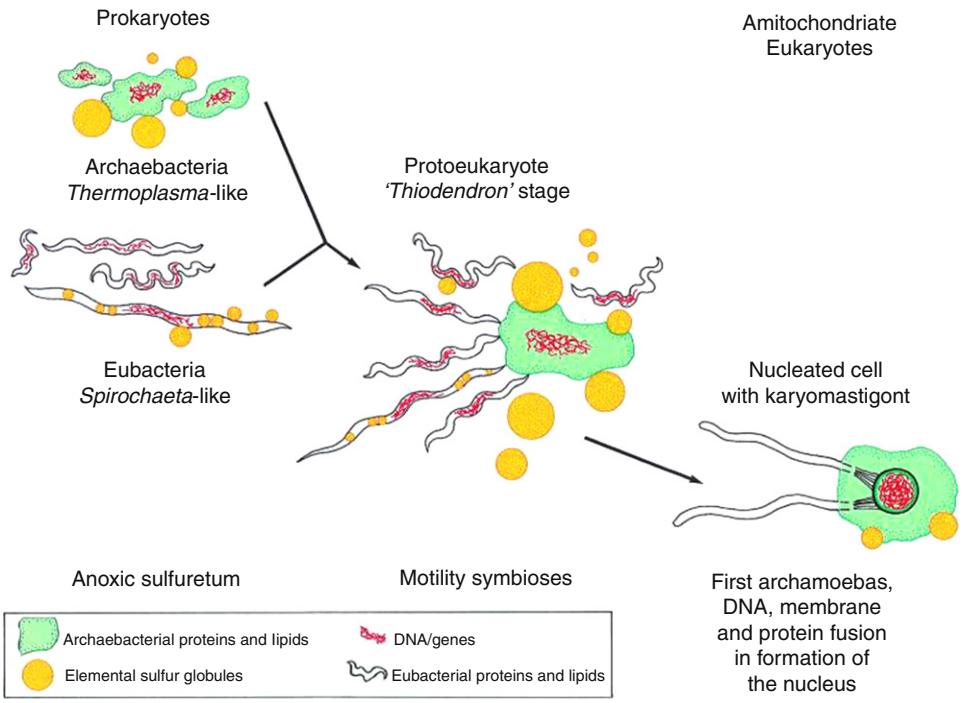

Figure 7 Schematic of motility symbiosis. The first symbiotic merger between spirochete and thermoplasma-like organisms enabled protoeukaryotic cells to acquire intra- and extracellular motility. Intracellular motility is necessary for the compartmentalization of genes into protein-rich chromosomes as well as for mitosis, the process whereby these chromosomes are doubled and pulled apart during division. Reprinted from Margulis, L., Dolan, M.F., Guerrero, R., 2000. The chimeric eukaryote: Origin of the nucleus from the karyomastigont in amitochondriate protists. PNAS 97 (13), 6954–6959, with permission and courtesy of Ricardo Guerrero.

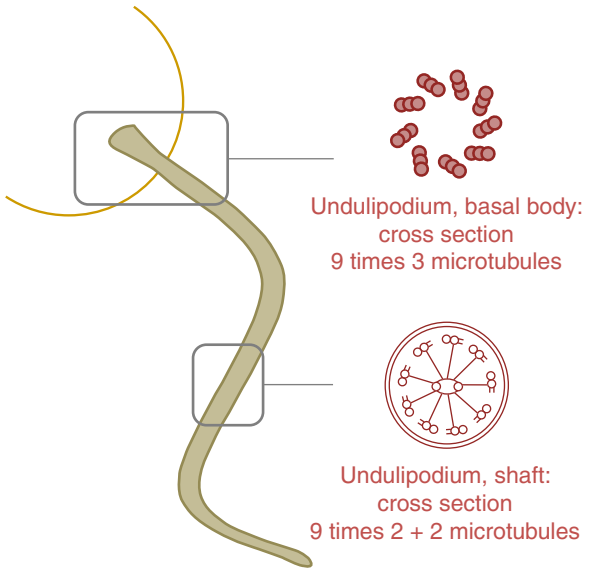

Figure 8 Cross section of a eukaryotic undulipodium. Its shaft has a 9 times 2 + 2 microtubular pattern while its basal body has a 9 times 3 microtubular pattern. The latter is identical to the icrotubular organization of centrioli, organelles that enable mitotic spindle formation (compare **Figure 2**).

Viruses mostly affect an organism's somatic cells during ontogeny. Upon infection, they either integrate into the host's DNA, or they use the host's metabolic apparatus to form new viruses, thereby destroying the cell upon release (Gontier, 2015a,b). Endogenous retroviruses (ERVs), however, are able to integrate into the germ line where they can influence phylogeny. Especially vertebrate genomes contain many remnants of ERVs, and ERVs in turn resemble mobile genetic elements (retrotransposons) that can become transferred laterally. This implies that ERVs "… have invaded the germ cell lines of every species of vertebrate. Here they replicate in Mendelian Fashion, as an integrated part of the sexual reproduction of the host, to inhabit the genome of all future generations" (Ryan, 2004, p. 560). Ryan (2002, 2004, 2009) considers such "… viral infection of host germ cells as a widespread but little-explored source of endosymbyotic creativity" (Ryan, 2006, p. 657), because the new symbiotic union can introduce new hereditary features.

Beyond influencing ontogeny and phylogeny, both symbiosis and symbiogenesis also impact evolution at the grand scale, by altering ecology from the environmental level all the way up to the biosphere. Winogradsky (1890, 1893) first discovered that the roots of legumes and the soil that surrounds these plants contain nitrogen-fixing bacteria. He later discovered the role these bacteria play in the earth's nitrogen-cycle. By launching 'microbial ecology' as a new research area, and by introducing the "*cycle of life*" concept (Ackert, 2007), Winogradsky helped bacterial research to transcend the medical disciplines.

Symbiogenesis also impacts the oxygen cycle. The Great Oxygenation Event marks the transition from an oxygen-low to an oxygen-rich atmosphere, estimated at 2.3 billion years

ago. The transition was induced by photosynthesizing cyanobacteria that originated 200 million years earlier. The new oxygen-rich atmosphere severely threatened the older obligate anaerobe Archaea and Bacteria. Oxygenation in turn caused methane to decrease which initiated the Huronian glaciation (Margulis and Fester, 1991). This environmental crisis triggered the first major extinction event (the oxygen catastrophe) as well as the evolution of aerobe bacteria. It also underlies the rise of symbiogenesis as an adaptive environmental response because some of the newly evolved aerobe bacteria became integrated as endosymbionts to subsequently evolve into cellular organelles.

As early as the twentieth century, such ecological and systems theoretical approaches led Reinheimer (1913) to provide a "*bio-economic*" view of life, wherein he introduced the concept of a "*web of life*" (Carrapiço, 2015). And many symbiologists today continue to link their theories to the idea that earth or 'Gaia' is a living superorganism (Lovelock, 1972; Lovelock and Margulis, 1974; Volk, 1998).

Reception of Symbiosis and Symbiogenesis in the Modern and Extended Synthesis

Ideas on symbiology first associated with sociopolitical ideologies and pre-evolutionary thought. After the introduction of natural selection theory, symbiology associated with vitalism, ecology, systems and hierarchy theory, cytoplasmic inheritance research, the biomedical sciences, and insight into the mechanisms of lateral gene transfer (understood as a form of hereditary symbiosis). These fields formed part of the 'eclipse of Darwinism' and developed in the margins of the Modern Synthesis that focused on selectionist, vertical-descent theories. From the onset, symbiologists have

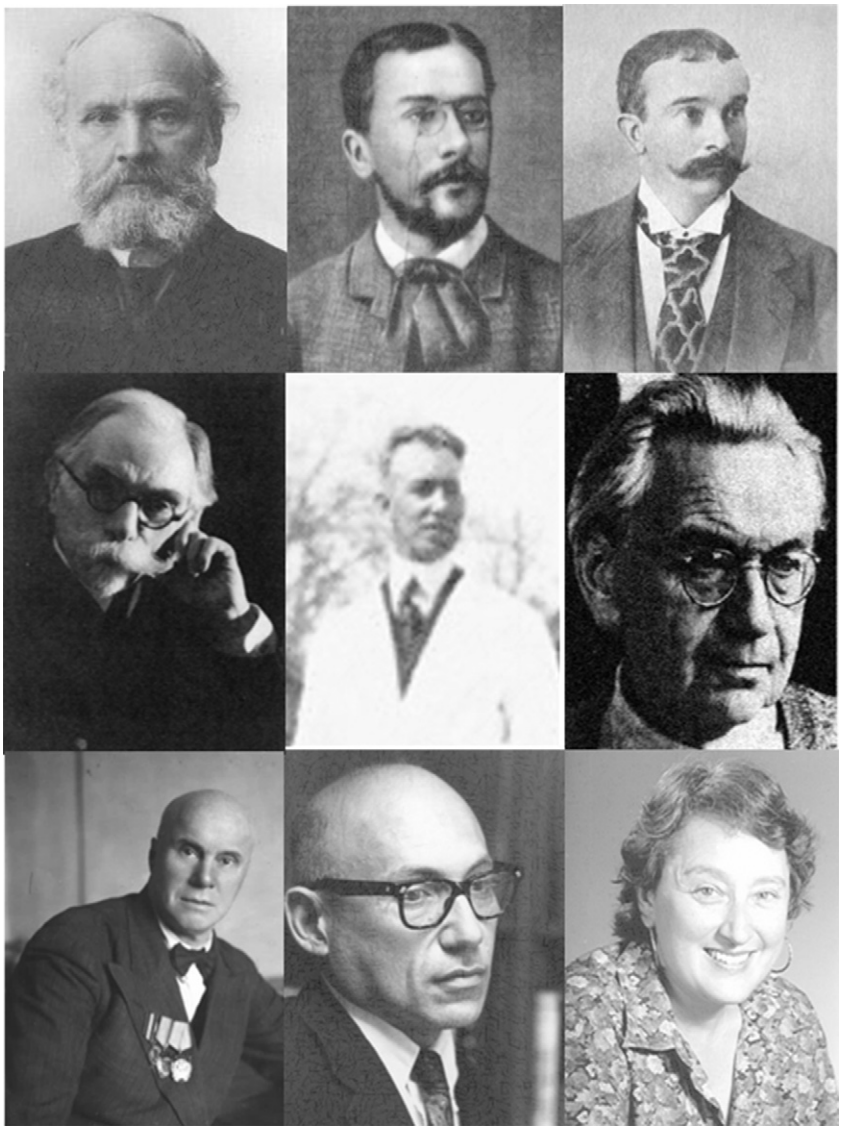

Figure 9 Pioneers in symbiogenesis research. From left to right and top to bottom: Andrey Sergeevich Famintsyn (1835–1918), Constantin Sergeevich Merezhkowsky (1855–1921), Andreas Franz Wilhelm Schimper (1856–1901), Paul Portier (1866–1962), Ivan Emmanuel Wallin (1883–1969), Paul Buchner (1886–1978), Boris Kozo-Polyansky (1890–1957), Joshua Lederberg (1925–2008), and Lynn Margulis (1938–2011).

in addition adhered to holistic, inter- and transdisciplinary stances, that counter the mechanical and reductionist approaches that characterized the division of the sciences at the turn of the twentieth century.

Its early associations with Western socialist thought (including Marxism) is not to be underestimated as a 'red flag' for neoliberal sociopolitical and Darwinian thought. In biology, symbiosis and symbiogenesis have often been typified as 'laws' of nature that either complement or contradict the 'laws' or 'mechanisms' of natural selection. Both presumed 'laws of nature' have been interpreted either in terms of struggle and competition, or cooperation and socialism, leading to both laws being understood as mutually exclusive. Nonetheless, by emphasizing cooperation and 'favoring' symbiosis over competition, symbiology too has, like competitive natural selection theory, been used to justify false believes on eugenetics, racism, hegemony, and national-socialism in order to obtain a 'higher good.' Early symbiologists and especially their critics often defined symbiosis in terms of parasitism, or as 'master–slave' relations (Sapp, 1994). Scholars such as Kropotkin, Reinheimer, Merezhkowsky, and Wallin understood symbiosis as a natural law necessary for progress, and especially Reinheimer and Merezhkowsky also saw symbiosis as a means for acquiring a 'higher good,' a 'better' and 'more cooperative' society that could be obtained by eugenetics. Merezhkowsky (1920b), for example, saw in symbiogenesis a justification for ethnic cleansing in order to develop a 'higher' society where mutualism would only arise amongst a select and chosen group (Sapp *et al.*, 2002).

Though both natural selection theory as well as theories on symbiosis and symbiogenesis find their historical roots in secular, Western sociocultural ideologies, both theories today are decoupled from such sociopolitical references. Nonetheless, the Serial Endosymbiogenetic Theory only became recognized post-synthetically, when molecular (phylo)genetics evidenced its basic morphologically obtained tenets.

Research on both symbiosis and symbiogenesis furthermore introduces new units and levels of evolution, including the *superorganism* (Spencer, 1876; Wheeler, 1928; Carrapiço, 2015), the *holobiont* (Margulis and Fester, 1991; Guerrero *et al.*, 2013), *symbiome* (Sapp, 2003), *symbiont* (Gontier, 2007), and *hologenome* (Rosenberg et al., 2007), as well as new means to draw evolutionary phylogenies (Brucker and Bordenstein, 2012), which today designates the rising field of *symbiomics* (after Sapp, 2003).

Currently, scholars associated with these disciplines are either pleading for an extension of the Modern Synthesis that incorporates the findings of symbiology with those of the Neo-Darwinian paradigm, while others are arguing for, or, a rupture with the latter in favor of a new evolutionary biology. The debates remain unsettled, but it is certain that increased genetic evidence for the symbiogenetic origin of life is causing for symbiosis and symbiogenesis to have finally received the scientific attention they deserve (**Figure 9**).

Symbiosis, History of

N Gontier, University of Lisbon, Lisbon, Portugal

Glossary

Deism The idea that the universe follows natural, mechanical laws even though it was created by a deity. The deity is presumed not to intervene after its original creation act. Deism was introduced by Natural Philosophers and is foundational for nineteenth century Natural History schools.
Ecology The study of the 'household' of organisms, broadly conceived as including biotic and abiotic environmental interactions, often depicted in hierarchy theories ranging from populations and species to ecosystems, biomes, and biospheres.
Metamorphosis Pre-evolutionary idea that living organisms can transform, or change in form. Transformation and metamorphosis are precursors to transmutation and evolution theory.
Symbiogenesis Evolutionary mechanism that results from hereditary symbiosis.
Symbiont Any organism that engages in a symbiotic relation with one or more organisms – often used to designate the smaller partner in the symbiosis.
Theism The idea that a supernatural being has created the universe and intervenes in creation at will. This belief is foundational for the Semitic religions as well as early Natural Theology schools.

Defining Symbiosis

Symbiosis refers to the phenomenon whereby two or more organisms with distinct genealogical, evolutionary histories live in close association with one another (de Bary, 1878, 1879). Together, the host and its symbionts form a new biological entity that is sometimes called a *superorganism* (Spencer, 1876; Carrapiço, 2015), *holobiont* (Margulis, 1991; Guerrero *et al.*, 2013), or *symbiome* (Sapp, 2003: 33); and this newly formed entity is considered to be a single unit, either of *natural selection* (through its hologenome, Rosenberg *et al.*, 2007; Zilber-Rosenberg and Rosenberg, 2008), or of other evolutionary mechanisms. Symbionts can be acquired both vertically (during phylogenesis) and horizontally (during ontogenesis). When symbiosis becomes obligate and hereditary, it can lead to evolution by symbiogenesis (Margulis and Dolan, 2000: 157). But even without causing symbiogenesis, symbiotic associations can affect an organism's adaptation, reproduction and fitness, species extinction or speciation, and symbiosis can influence ecological systems (Brucker and Bordenstein, 2012; Margulis, 1991; Zook, 2015).

Is Nature 'Red in Tooth and Claw' or 'Social' – Origins of Symbiosis Research in Natural History Research and Its Relation to the Sociopolitical Sciences

Research on symbiosis originated in nineteenth century European Natural History Research. Natural History Research marked the beginning of the modern sciences and encompassed the physical, biological, and cultural sciences (Gontier, 2011). Rather than adhering to 'divine laws' specified in religious writings, utopian scholars such as Thomas More or Bernard Mandeville, and moral philosophers such as Thomas Hobbes, Adam Smith, David Hume, and Jean-Jacques Rousseau would search for 'natural laws,' and transition from a theist to a deist worldview. These moral philosophers are called Social-Contract theoreticians because they founded sociopolitical, secular thought by debating the fair and just distribution of 'public goods' and 'natural resources' across nations, the 'natural' 'division of labor,' and the 'common goods' (shared belief states) that socially bond individual citizens into a 'common wealth' (a nation) (Gontier, 2009).

Their theorizing on the 'naturalness' by which humans 'live together,' and what the most righteous sociopolitical societal structure is, would come to define liberal and social thought and lead to the rise of the major secular sociopolitical doctrines of the nineteenth and twentieth centuries (libertarianism, liberalism, socialism, Marxism (communism), communitarianism, national socialism, and democracy). These sociopolitical ideologies were formulated by drawing idealized analogies with the animal world (often in the form of fables), which in turn founded preliminary researches on 'animal societies' that developed into naturalistic, and eventually evolutionary research on biological species.

It is well-known that Darwin (Burrow, 1972; Barrett, 1977; Bowler, 1983; Smocovitis, 1996) was inspired by:

1. Adam Smith's liberal idea of free-market economy and his metaphor of the 'invisible hand';
2. Thomas Malthus's notions of 'scarcity of resources' and 'struggle for existence';
3. Herbert Spencer and Thomas Huxley's liberal ideas on sociocultural 'progress';
4. Jean Baptiste Lamarck's ideas of 'adaptation' and teleological progress in biology;
5. Francis Bacon's 'induction theory';
6. Charles Lyell's 'uniformitarianism'; and
7. Wilhelm von Humboldt and Auguste Schleicher's 'natural genealogies' of the Indo-European languages.

The early Darwinists did not distinguish the natural from the sociocultural sciences, and their evolutionary theories were a natural extension of sociopolitical, liberal Hobbesian thought – how the latter ideology defined the 'natural'

condition as well as the sociocultural and political life of humans and animals. For Hobbes (1651/2010), humans were like wolves, who in a 'natural state' found themselves at 'war' with other humans because they wanted to defend their individual freedom. Early Darwinists extended these ideas to the whole of nature and, in the words of Alfred Lord Tennyson, they saw nature as 'red in tooth and claw.' A struggle for existence results from a scarcity of resources, leading to a natural selection of the fit, at the expense of the maladaptive (Huxley, 1888; Bouglé, 1909).

Etymological analyses of symbiosis jargon demonstrate that, prior to the introduction into biology, many of the foundational concepts were also used to define sociocultural human relations and sociopolitical ideologies (**Table 1**). Early symbiologists, however, applied less-liberal or non-liberal, often socialist and communitarian language to characterize the living arrangements present in the natural world – ideas that were inspired by Rousseau's social-contract theory. Rousseau (1762/2001) understood humans as 'good natured' and inherently social beings that became corrupted by artificial societies. The human family, one of the basic units of law, is typified by its sharing of resources, and societal living is ideally characterized by reciprocal exchange and a fair (re)distribution of natural resources. Reciprocal and altruistic social rule-following enables the formation of a 'social-contract' that in turn allows for the establishment of a 'higher, common good' that founds the resurrection of the welfare state. As members of the welfare state, persons become citizens that create a community where, for the sake of the whole, individuals give up part of their freedom to live together. These social ideas were further developed by Pierre-Joseph Proudhon (1840, 1849) under the form of 'mutualism' (**Table 1**), and by Pyotr Kropotkin's (1902) work on 'Mutual Aid.'

The Sociopolitical Life of Animals: Commensalism, Mutualism and Parasitism in the Economy of Nature

Research on symbiosis in the animal world followed as an extension of these sociopolitical theories. Linnaeus introduced the concept of an 'economy of nature' in the eighteenth century (Egerton, 2015), and Haeckel (1866) developed these ideas further when founding the field of ecology. The 'division of labor' concept was introduced by the French naturalist Milne-Edwards (1827), in the context of orthogenetic developmental laws, in order to describe the origin of complex anatomical forms in a hierarchical (systems theoretical) perspective (D'Hombres, 2012).

As a forerunner of ecological thought, Pieter Harting, working at Utrecht University, wrote a Dutch work in 1862, 'On the industry (economy) of animals: for all those who love nature,' wherein he discussed the numerous crafts found in the animal kingdom, ranging from 'carpenters' to 'architectural builders' and 'cleaners.' By applying sociopolitical terminology, Harting (1862) conceptualized the 'economy of animals' in terms of 'distributions' of 'common and public goods,' as well as 'divisions of labor' that underlie a hierarchically structured animal society.

Harting's work inspired the Belgian Zoologist and Paleontologist Pierre Joseph van Beneden, a student of Cuvier, which in turn specify the nature of the *social* lives of animals, in particular how they establish communal living and how they share their food resources. In this context, he would introduce the terms *commensalism* (*commensaux*), *mutualism and parasitism* (**Table 1**).

For van Beneden,

> When taking a closer look at the animal world, it does not take long to find more than one analogy with human society. If I'm allowed to say so, there is not one social position found in human society that is not also found in the animal kingdom. Most of the animals live peacefully from the fruits of their labors, and exercise a profession that gives them life. But, at the sideline of these honest industrials, we also find miserable ones, who cannot do without the assistance of their neighbors, some of whom establish themselves as parasites in their organs, others as commensals (*commensaux*) that take profit from the gains (labors) of the honest. (Van Beneden, 1875: 2–3, my translation)

Commensals or *messmates* are merely companions at the table, they are allowed to dine with the host and feed on their neighbor's catch. They can live inside or onside their host (what we today call *endo- or ectosymbiosis*), and they can either live independently or forever remain fixed (today called *facultative and obligate symbiosis*). *Parasites* are those animals who live at the expense of their neighbor, they take advantage of their host and can endanger its life. *Mutualists* are animals that live onto one another without being either *parasites* or *messmates*. They receive 'asylum,' and either return 'mutual services' or develop 'sympathetic bonds' which attracts them to one another (van Beneden, 1873, 1875). van Beneden described such associations to exist throughout the animal kingdom, and he dedicated a chapter on the nature of *parasites* as causative agents of disease (**Figure 1**).

The different social living arrangements of animals, for van Beneden, demonstrated the existence of a Great Chain of Being, which in turn evidenced divine providence. He did not use evolutionary vocabulary, but he did assume that especially the 'fixed commensals' undergo 'metamorphosis.'

With the dawn of evolutionary thought, two distinct paradigms, one of competition and one of socialism would emerge to characterize societal living of human and other animals. Both paradigms were well-recognized in both the biological and sociocultural sciences as valid means by which to describe the natural world. In a review article written by Bouglé (1909), for example, in a volume commemorating the 50th anniversary of Darwin's *Origin*, competition and socialism were presented as distinct and complementary 'laws' by which biological and sociological phenomena evolve.

Herbert Spencer (1876), famous for interpreting natural selection theory as leading to the 'survival of the fittest,' would write on the social living arrangements amongst distinct animals from within the competitive paradigm. Spencer introduced the concept of the 'superorganic,' and investigated how different 'life forms' (biological species but also sociopolitical, cultural, and linguistic systems), brought forth a division of labor and a hierarchical organization of the natural world that enables a unilinear and evolutionary progressive way of living or being in the natural world. For him, the superorganic structure comprises a higher, societal whole, of which he sought out the social laws.

Table 1 Etymology of symbiosis jargon

Term	*Etymology*	*First usage in biology*
Consortia	Plural for *consortium,* from Latin *consors* (partner, wife, companion) and *consortio* (having the same destiny), first introduced in French as *consorte* in the fourteenth century to designate a husband's wife, and later in England, where, from the fifteenth century onward, it first became a legal term for 'the right of a husband to access his wife,' and later a term to designate larger associations and societies that are bounded by duties and rights (e.g., in the form of divisions of labor)	Introduced in botany to characterize symbiosis by Reinke (1873) and Famintsyn (1907)
Commensalism	From the French word *commencaux*, derived from fifteenth century, Middle Latin *commensalis* (coming around a table), and *cum mensa* (eating at the same table)	Introduced in zoology by Van Beneden (1873, 1875) in that meaning, as *commensaux*. In a first English translation of his major 1975 work in 1976, the *commensaux* were translated as *messmates*, which either derives from Middle English *mes* (for table, dinner, food, and eating together at the same table), or from the old French word *mesme* or *même* (which means even, same or equal)
Mutualism	Introduced in French in the late fifteen century as *mutuel*, derived from the Latin *mutuus* (reciprocal exchange). Originally, the word was used to designate feelings of both love and hate between individuals. The term roots the French words *mutuel* and *mutuellisme*, first introduced by Pierre-Joseph Proudhon (1840, 1849), to designate societal socialism in human and animal societies; and a year later in Brittan as *communitarianism* by John Goodwyn Barmby, to designate societal, communal lifestyles (*consortia*) with social care (e.g., social justice such as health care)	First introduced in biology by van Beneden (1875) in that meaning, and today characterized as one type of symbiosis
Parasitism	From the Greek word *parásit*os (a person or organism who lives at the expense of another, who receives free nourishment and protection). Introduced in natural and medical sciences from the Greeks onward. First reintroduced in Medieval French as *parasite* in the sixteenth century	In biological and biomedical sciences fundamental to describe pathogens, though the first introduction in this sense remains obscure. de Bary (1878) in botany, and van Beneden (1875) in zoology, already identified several microorganisms as causal agents of disease, ideas that would become reintroduced as foundational for the germ theory of disease in the late nineteenth century
Symbiosis	From Greek *sumbio*sis (companionship) and *sumbioun* (to live together). First reintroduced in German and English languages in the early seventeenth century, to designate 'communal or social life,' including the union or living together of distinct individuals as companions, also in marriage (community) as husband and wife. From the seventeenth century onward used to describe societal, community life	First introduced in botany, by Frank (1877) as *symbiotismus* in 1877, and as *symbiosis* by de Bary (1878, 1879)
Symbiogenesis	*Symbio-* stems from the Greek *symbiosis* and *-genesis* from *genesis* (origin, birth, production, generation, creation). Symbiogenesis means generation or evolution by symbiosis	First introduced in biology by Merezhkowsky (1905) and later also by Kozo-Polyansky (1924/2010), by Wallin (1927) as *symbionticism*, and by Sagan (1967)
Hereditary symbiosis	A symbiotic association that becomes permanently transmitted to future generations, foundational for symbiogenesis	First introduced by von Faber (1912) in Germany as 'erbliche Zusammenleben' (hereditary living together) of bacteria inside tropical plants. Translated into English as 'hereditary symbiosis' by Cowles (1915), and later adopted by Buchner (1921, 1939), Wallin (1927), Lederberg (1952), and Sagan (1967)
Symbiont/Symbiote	Derived from symbiosis to designate an organism that entertains symbiotic associations, first known use in 1887 in Germanic languages, and from 1909 in French as *symbiote*	The term symbiote was first introduced by Paul Portier (1918) in France
Synergy	From the ancient Greek *Synergia* (working together, cooperation, joint work, assistance or help). First introduced in the middle of the seventeenth century. By the mid-nineteenth century, used to designate group cooperation and communal group living that advances effects unobtainable by the individuals, which is why the whole becomes more than the sum of its individual parts	First introduced in biology in bio-economic, systems theoretical and hierarchical approaches to life (see e.g., Corning, 2013, 2014)
	References: http://www.oed.com/; https://www.wiktionary.org/; http://www.etymonline.com/	(Carrapiço, 2015; Gontier, 2015; Sapp, 1994)

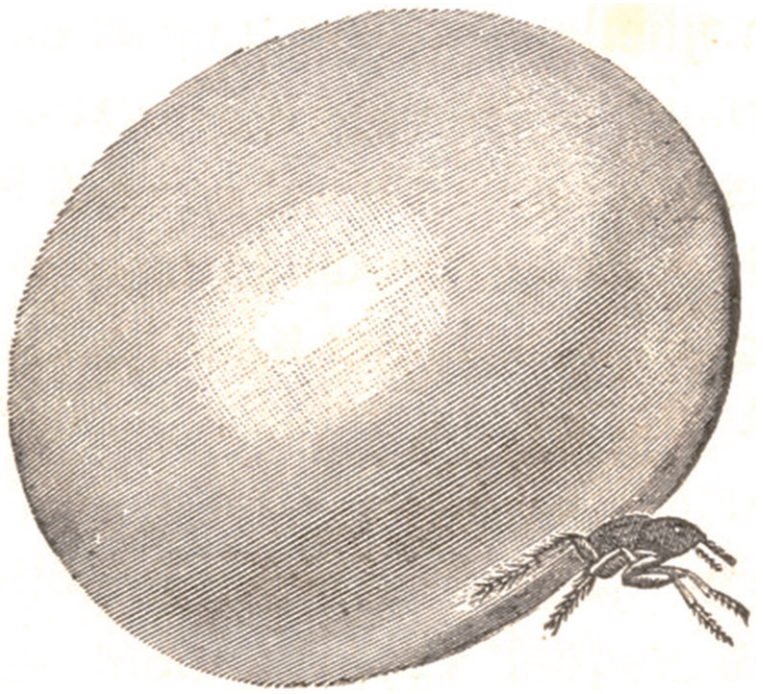

Figure 1 The swelling of a female chigoe flea (*Tunga penetrans*), a parasitic flea native to Latin America that partially penetrates the skin of mammals to breed, leaving an infectious blister. Used by Van Beneden (1875: 430) as an example of *temporary parasitism*.

Social Darwinians thus focused on competition, and many symbiologists understood these theories as direct extensions of liberal thought into biology. Symbiosis scholars critiqued by emphasizing that the sociopolitical and biological realms display many instances of social and mutualistic behavior, which they equally understood as 'lawful.'

Pyotr Kropotkin (1902) pioneered by understanding 'mutual aid' as a 'law of nature' that complements the principles or 'laws' of natural selection (Kropotkin, 1902). The first two chapters of his magnum opus focused exclusively on the 'mutual aid' found in animals. In the remaining chapters, from invertebrates to humans, he lists hunting and breeding associations as examples of socialism that contradict the sociopolitical ideas put forth by Hobbes, Malthus and Huxley. Battling, what Kropotkin (1902) called 'Huxley's (1888) gladiator show,' where organismal beings are characterized as 'naturally' amoral and asocial beings, Kropotkin instead makes the case that mutual aid and the division of labor is as 'instinctive,' and 'natural' as 'struggle for existence' is. For Kropotkin, the law of mutual aid helps eliminate competition and aids in the struggle for existence, enabling the establishment of social and political laws that bond organisms in communal lifestyles characterized by reciprocal altruism and cooperation (for a discussion see Dugatkin, 2011 or Sapp, 1994).

At the beginning of the twentieth century, parallels between the sociocultural and natural world appear to have come into disuse. An exception is Hermann Reinheimer (1913, 1915, 1920), who would continue to draw explicit parallels between the biological and social world. He developed a 'bio-economic' view of evolution and also identified symbiosis as a 'law of nature' (for a modern-day account on bio-economics and *synergy*, see Corning, 2013, 2014).

Today, and from within an extended synthesis, the similarities between reticulate biological and sociocultural evolution are being rediscovered (Gontier, 2007, 2012; Hird, 2010a,b; Kressing and Krischel, 2013).

Botanical Lichenology Studies and the Introduction of the Symbiosis Concept

Symbiosis research entered botanical studies through the study of lichens. Lichens are chimeric organisms composed of distinct symbionts (**Figure 2**). They grow on trees or rocks, and closer analyses of their foundational structures demonstrate thread-like, interwoven networks that resemble hair braids ('*Flechten*').

Lichens were first studied in pre-evolutionary times when German botanists including Georg Franz Hoffmann (1760–1826) and Georg Friedrich Wilhelm Meyer (1782–1856) attempted to provide morphological and taxonomic classifications of lichens. Hoffmann (1787, 1790–1801) classified lichens as plants and especially Meyer (1825) assumed that lichens arose 'spontaneously' while he interpreted the different morphological life-stages in terms of 'metamorphosis.' Both scholars' research perpetuated some of the basic terminology still used today to describe lichen morphology.

After the introduction of evolutionary thought, the works of Simon Schwendener (1828–1919), Christian Ernst Stahl (1848–1919), Johannes Reinke (1849–1931), Albert Bernhard Frank (1839–1900), and Heinrich Anton de Bary (1831–1888) and his students, would clarify the exact morphological nature of lichens (Kärnefelt *et al.*, 2012: 10).

Schwendener (1867, 1868a, 1868b) was the first to propose that lichens are 'new plants' with 'new characteristics' that

Figure 2 Lichens are chimeric organisms consisting of fungi that live in intimate symbiotic association with algae and/or cyanobacteria. These are some of Schwendener's (1868a) early drawings of lichens that demonstrate the dual nature of the organism.

originate from a reciprocal and intricate relation between two different organisms. For Schwendener (1868a: 3, my translation), lichens:

> enable insight into previously overlooked or completely misunderstood living relationships between two large plant groups, namely "algae" and "fungi" ("Pilze"). The algae are willing to serve as nutrition for the fungus that controls the algae. Despite these counterpropositions, however, the organisms are so intrinsically and reciprocally connected that through their penetration and merging, they constitute new plants with a clear individual character. For that reason, many authors classify them into an independent group as lichens ("Flechten").

The French scholar Jean-Baptiste Édouard Bornet (1828–1911), who first described the phylogeny of red algae, confirmed the dual nature of lichens experimentally. Bornet (1873, 1874) was able to separate the individual organisms, and noticed that when several of the fungal spores of the species he studies are disabled to establish associations with algae, they either die or are unable to reproduce because they germinate on the algae. He also noticed that such associations are formed rapidly during ontogeny (Fink, 1913), and thus outside the germ line.

Nonetheless, Schwendener's hypothesis and Bornet's experiments were fiercely criticized by their contemporaries (e.g., Kröber, 1874; and see Sapp, 1994), even though Famintsyn and Boranetski were also able to separate the individual organisms in 1876 (Khakhina, 1992), and experimental work by Stahl (1877) resulted in the laboratory formation of lichens from associating fungal spores with algae.

In the same year that Bornet conducted his experiments, Reinke (1873) had referred to the chimeric lichens in vitalist and sociopolitical terms, as a '*consortium*' ((**Table 1**), a concept that in turn relates to the *synergism* concept). This can be interpreted as a precursor of systems theoretical hierarchy theory and ecological thought in general as it would be developed by scholars such as Jacob von Uexküll and Ludwig von Bertalanffy in the beginning of the twentieth century. Reinke (1895, 1908), a scholar trained in both theology and philosophy, opposed both Darwin's selection theory as well as Haeckel's monism, and favored morphogenetic explanations for lichen development.

Two years after van Beneden had introduced his work on the social lives of animals, Frank (1877) characterized the association between the organisms that make up lichens as 'symbiotismus,' and defined it in terms of 'coexistence' (Sapp, 1994: 6). In the subsequent two years, de Bary (1878, 1879) reintroduced the ancient Greek concept of *symbiosis* (**Table 1**) to characterize the dual nature of lichens, and defined symbiosis as "the living together of unlike-named organisms." By basing himself upon the experimental work of his former students, Famintsyn and Stahl, de Bary developed the first theoretical framework on the appearance of symbiosis in the plant kingdom; a framework wherein he made direct reference to van Beneden's work. For de Bary, botanical symbiosis demonstrated the closest affinity to van Beneden's zoological mutualism concept (Seckback, 2002; **Figure 3**).

van Beneden and de Bary set the scene for all later theorizing on symbiosis because their work became available to a wide scholarly audience. The former's work was translated into English, and the latter's was summarized in the writings of his students and collaborators whom included Andrey S. Famintsyn (1835–1918), Sergei Winogradski (1856–1953), Martinus Beijerinck (1851–1931), and Ernst Stahl and Andreas Schimper (1856–1901). Scholars would opt for de Bary's symbiosis concept, and van Beneden's distinctions repeatedly became understood as types of symbiosis that specified the nature of the symbiotic relation.

Symbiosis in *All* Animals, Plants, and Protists and its Significance for Evolution

Microscopic advances steadily enabled better visualizations of pro- and eukaryotic cellular morphology, and botanists

Figure 3 Some of the pioneers in Symbiosis research, from left to right and top to bottom: Pierre-Joseph van Beneden (1809–1894), Simon Schwendener (1829–1919), Heinrich Anton de Bary (1831–1888), Andrey Sergeevich Famintsyn (1835–1918), Albert Bernhard Frank (1839–1900), Pyotr Kropotkin (1842–1921), Andreas Franz Wilhelm Schimper (1856–1901), and Paul Buchner (1886–1978).

identified the numerous cellular organelles found in plant cells. Between the 1860s and 1880s, Julius von Sachs (1859), Gottlieb Haberlandt (1876), and Schimper (1883) documented the role plastids (*'chlorophyllkörner'* or chlorophyll grains and *'Farbkörper'* or pigment corpuscles) play in the formation of starch and the coloring of the plant's leaves. Schimper (1885) furthermore noted that chlorophyll bodies (*'chloroplastiden'* or chloroplasts) divide in ways similar to bacterial division and suggested a symbiotic origin for the latter. As such, he first drew attention to symbiosis as an *intracellular* phenomenon, a theme that was later repeated and expanded by Paul Buchner (1921), who dedicated a full book on intracellular symbiosis (Sapp, 2002).

Andrey Famintsyn (1889a,b, 1892, 1907), the father of Russian plant physiology and a student of de Bary, studied both lichens and chloroplasts from a symbiotic point of view. Famintsyn is considered one of the pioneers of symbiogenesis theory, because he emphasized the adaptive role symbiosis plays in evolution by enabling the synthesis of new *consortia* (**Table 1**).

Symbiosis research also progressed from within the biomedical and bacteriological sciences where bacteria became understood as parasitic agents of disease. Ferdinand Cohn published a first systematic classification of bacteria in 1872; in 1876, Robert Koch associated the *anthrax* bacterium with the Anthrax disease ('Milzbrand-Krankheit') in cows; Pasteur's work on the germ theory of disease was read before the French Academy of Science in 1878; and Charles Louise Alphonse Laveran, the discoverer of the malaria parasite, was one of the first to, in 1880, recognize parasitic protozoa as causative agents of disease (Gontier, 2015b).

The positive effects of symbiosis also remained a topic of interest, especially in what regards its impact on ecology and the biosphere. Frank (1885) first described 'root symbiosis' (*'Wurzelsymbiose'*) that occurs between fungi and the roots of trees and plants, and he introduced the concept of *Mycorrhiza* (Carrapiço, 2015). At de Bary's lab, Winogradsky (1893, 1895) discovered nitrogen-fixing bacteria in the soil, which he called 'autotrophic' for their ability to synthesize chemical elements instead of devouring organic matter.

Beijerinck, another student of de Bary, also found *Rhizobia*, nitrogen-fixing, symbiotic bacteria present in the roots of legumes, and he was the first to point out their importance for agriculture (because rhizobia-rich roots and soil makes for fertile soil). Beijerinck is considered one of the founders of virology, and in nineteenth century academic circles, also de Bary (1861) was mostly known for his studies on plant diseases and for reporting on the life cycle of the fungus *Phytophthora infestans* that is parasitic on potatoes thereby causing potato blight (Gontier, 2015b).

Symbiosis found its way to America with the works of Roscoe Pound (1893) and Albert Schneider (1897) who integrated animal with plant studies in more general, and especially ecologically-oriented works on symbiosis (Sapp, 1994). Schneider (1897) first generalized de Bary's notion of symbiosis to *all* life forms, and he averred that symbiotic associations can occur between *more* than two individuals. He opens his work, 'On the phenomena of symbiosis' by saying that

> *All* living organisms manifest a more or less intimate biological interdependence and relationship. In fact, their very existence depends upon this condition, therefore no organism, no matter how simple or how complex its structure may be, is the result of a wholly independent phylogenetic development. (Schneider, 1897: 923, my emphasis)

Like Famintsyn, Schneider speculated about the evolutionary significance of symbiosis, when it first arose in

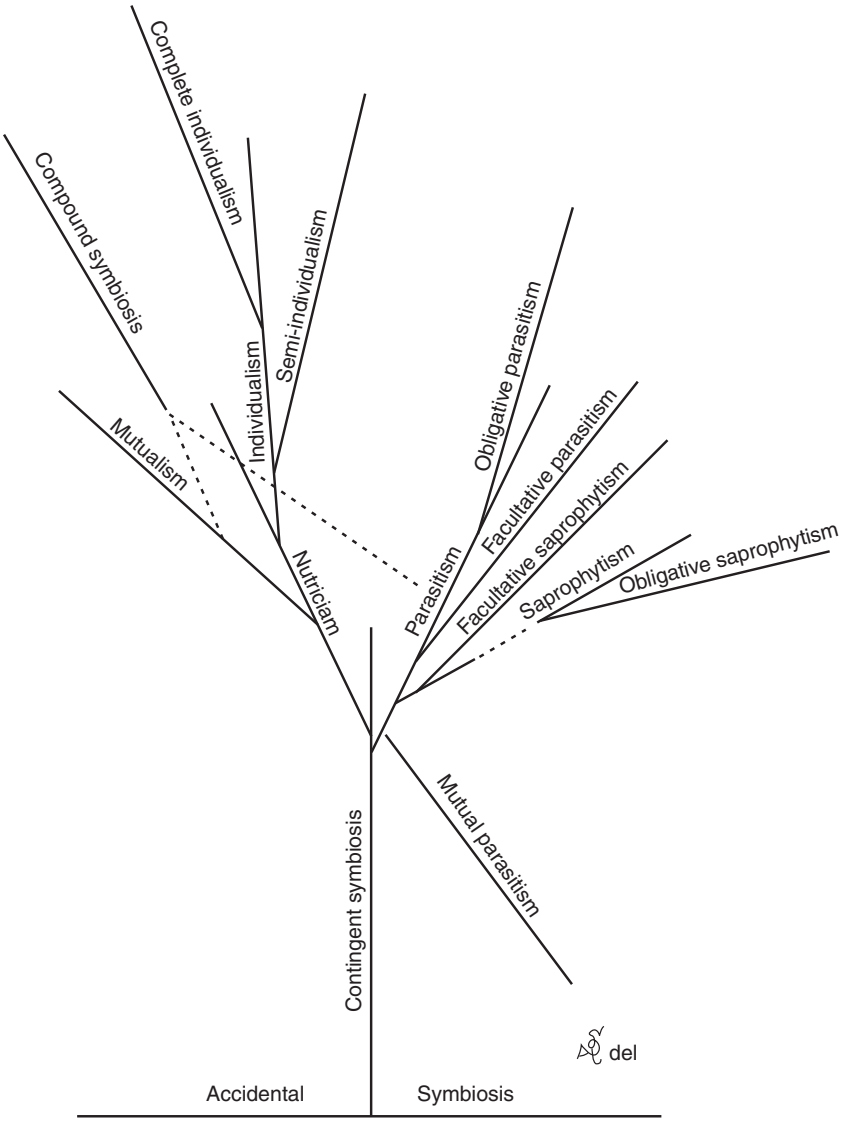

Figure 4 Schneider's phylogeny of the various types of symbiosis that evolved as an adaptive response to nutritional problems induced by the scarcity of resources and the struggle for existence.

time, and how it relates to natural selection. By associating symbiosis with a 'loss or acquisition of assimilated food-substances,' he understood symbiosis in nutritional terms, as an adaptive response to the struggle for existence that exists because of the scarcity of resources. In other words, for Schneider, it was hunger and a drive to reproduce ('food requiring and reproductive life-action of the organism'), that by necessity engaged organisms in forming symbiotic associations.

The emergence of symbiosis, for Schneider, was a process that required long periods of evolutionary time. He assumed that individual organisms evolved first, and because of their independent evolution, they were originally not equipped to form such relations, so they had to evolve them over the course of evolution. Schneider tried to synthesize natural selection theory with symbiology, in a 'coevolutionary,' 'ecological sense' *avant là lettre*. He described how symbiotic partners developed morphological adaptations to facilitate the symbiotic relationship, that went from parasitic and facultative to obligate and mutual.

Mimicry, for example, was a type of 'mutual adaptation,' a mutually evolved symbiosis. Other examples were the relation between the male and female reproductive cells, as well as the relation between mothers and their developing embryos. Schneider also brought symbiosis to entomology, by discussing numerous cases of symbiosis in insects and between insects and plants.

In his small but rich paper, he furthermore provided a layout for new terminology, by expanding the various types of symbiosis, and by pouring them into an evolutionary taxonomy (Figure 4). Schneider appears to have been engaged in reconstructing the evolutionary genealogy of the various types of symbiosis that evolved over the course of evolution.

Reduction of Symbiosis Studies to Ecology and Developmental Biology until the Advent of Symbiogenesis Theories

In 1885, Auguste Weismann developed his *Keimplasm* theory of descent that stated that hereditary traits are only transmitted through the germ line. It put a halt to neo-Lamarckian and evolutionary developmental studies, that because of their focus on ontogenetically acquired traits, became less and less understood as relevant for the study of evolutionary phylogenesis. Weismann's ideas were later synthesized with Theodor Boveri's and Walter Sutton's chromosome theory that identifies the chromosomes as bearers of hereditary traits. The rediscovery of Mendelian hereditary laws, and advances in theoretical and experimental population genetics as well as molecular genetics caused symbiosis to be studied from within fields such as ecology and developmental biology rather than evolutionary biology.

Symbiosis became understood as an ontogenetic or developmental, adaptive behavioral response to nutritional problems brought forth by the scarcity of resources and the struggle for existence. Nonetheless, in the margins of standard, Neo-Darwinian evolutionary theory, the evolutionary significance of symbiosis would remain studied by scholars who investigated cytoplasmic inheritance (for a discussion see Sapp, 2003; Gontier, 2015a) as well as ecological interactions (for a discussion see Egerton, 2015).

Some of the most important symbiologists at the beginning of the twentieth century were Frederick Keeble (1910), Paul Buchner (1921), Maurice Caullery (1922), George Nuttall who founded the *Journal of Hygiene and Parasitology* in 1901 and 1908, Lemuel R. Cleveland (1923).

Eventually, the recognition that 'hereditary symbiosis' can lead to symbiogenesis, and idea introduced by von Faber (1912) and brought to an English readership by Cowles (1915) and Buchner (1921), would reintroduce symbiosis studies into evolutionary biology.

Symbiosis, Introduction to

KM Oliver, University of Georgia, Athens, GA, USA
JA Russell, Drexel University, Philadelphia, PA, USA

Glossary

Aposymbiotic State in which a potential host lacks resident microbes.
Bacteriocyte Specialized host cells (sometimes called mycetocytes) for housing obligate bacterial symbionts.
Codiversification Corresponding lineage splitting between interacting partners, which signifies highly faithful interactions across evolutionary timescales and can be evidenced by matching host and symbiont phylogenies.
Facultative endosymbionts Maternally transmitted bacteria common in arthropods that are not required for host survival and reproduction. These have the potential for cross-species horizontal transfer, during which they move heritable traits to new hosts.
Metagenomics The study of the total genetic content associated with a particular environment, including the microbial communities associated with eukaryotic hosts.
Microbiome The assemblage of microbes associated with a particular host organism; the term has also been used to specifically refer to the collection of genes encoded by resident microbes.
Obligate symbiont A symbiont that is required by the host for survival and reproduction.

The term 'symbiosis' is derived from the Greek *σύν* 'together' and *βίωσις* 'living' and is generally defined as the persistent association of two or more dissimilar species. A large number of symbioses involve a single multicellular eukaryotic organism coupled with one or more microorganisms, including bacteria, viruses, eukaryotic microorganisms, or Archaea. By convention, the larger partner is usually called the 'host' and the smaller ones 'symbionts.'

'Symbiosis' has been notoriously difficult to define and hence there is often disagreement over which particular associations count as symbioses. In general, symbiotic interactions typically persist for most of the partners' lifespans, and many carry over to subsequent generations, exceeding tens of millions of years in age in the most ancient examples. This definition excludes transient interactions, such as most insect–plant pollination relationships, which are mutualisms but not symbioses. Further, many authors restrict the term symbiosis to refer only to persistent mutualisms, such as the interaction between diverse insect species and their obligate bacteriocyte-associated symbionts, which provide amino acids and other nutrients to their hosts. While this definition comports with the prevailing view of symbiosis outside of biology, it excludes many interactions that biologists typically consider symbioses, such as reproductive manipulators in arthropods, including the widespread bacterium *Wolbachia*. These maternally transferred bacteria can only survive and replicate in association with animal tissues, and they often provide no clear benefits to their hosts. Instead, they utilize a range of strategies that cause infected females to produce more female offspring than symbiont-free females, thereby favoring symbiont proliferation (Werren *et al.*, 2008; **Box 1**).

An additional complication with the 'narrow' definition of symbiosis is that particular symbionts, including rhizobia and mycorrhizal fungi (MF), confer net benefits to hosts under some conditions, but costs under others. Thus, a particular interaction could fluctuate temporally in 'symbiont' status. For this reason, symbiosis is more often defined (as above) to include interactions that span the continuum from mutualism to parasitism. While the broader definition resolves the aforementioned issues, new problems arise in its inclusion of interactions that are not generally considered symbioses by biologists, including persistent infections with specialized pathogens and parasites (e.g., malaria in humans). In accord with current practice, we take the broader definition, but exclude host–parasite/pathogen interactions.

Symbioses are Diverse and Ubiquitous in Nature

The first descriptions of symbioses in the nineteenth century provoked curiosity, but also a general perception that these interactions comprised interesting exceptions to the norm (Sapp, 2004). Today we recognize that virtually all multicellular eukaryotes are composites made up of multiple species and that microorganisms are often key players in the physiology, development, ecology, and evolution of eukaryotes (Douglas, 2014). Taking an even broader view, we also recognize that the success of eukaryotic life is itself largely due to the ancient acquisition of the symbiotic α-proteobacteria that evolved into today's mitochondria. This major symbiotic event brought to eukaryotes the capacity to execute aerobic respiration, enabling eukaryotic existence and expansion in an oxygen-rich world. Plants, algae, and a number of other unicellular eukaryotes similarly owe their success to ancient acquisitions of cyanobacteria, or more recent secondary or tertiary acquisitions of photosynthetic eukaryotes, enabling the conversion of sunlight, water, and carbon dioxide into sugars. While some groups appear to engage in symbiotic interactions more readily than others (e.g., Bacteria more than Archaea), symbioses are widespread in nature and occur within and among diverse groups. Here we focus on symbioses between plants or animals and their many microbial associates, using these to discuss patterns and processes common to nearly all life forms.

Box 1 Reproductive manipulation as a means of symbiont spread

While partner fidelity typically promotes the origin of beneficial symbionts, high fidelity of maternal transmission of symbionts in arthropods has opened the door to alternative symbiont transmission strategies collectively dubbed reproductive manipulation. Several bacterial lineages have evolved to employ one or more of these strategies. Most impressive among these are *Wolbachia* symbionts (α-Proteobacteria), which can execute all four types of manipulation (see below) (Werren *et al.*, 2008). *Wolbachia* are estimated to occur in 40% of terrestrial arthropods, thus possibly infecting millions of animal species (Zug and Hammerstein, 2012). While some *Wolbachia* strains benefit hosts, others manipulate reproduction, and both strategies are keys to success for one of the world's most prolific symbiont genus. Other common reproductive manipulators include, *Spiroplasma* (Mollicutes), *Rickettsia* (α-Proteobacteria), *Cardinium* (Bacteroidites), and *Arsenophonus* (γ-Proteobacteria). Bacterial invasion and maintenance in all four cases is achieved by increasing the number or fitness of infected females.

Male killing occurs when symbiont-infected males die during larval or embryonic development. Males are 'dead-ends' for maternally transmitted symbionts. If male deaths increase the fitness of infected females by increasing resource availability, then male killing symbionts may spread in the population.

Feminization occurs when maternally inherited symbionts block the production or action of masculinizing hormones. By causing genetic males to become female, symbionts create a transmitting host as opposed to a dead-end male.

Parthenogenesis induction takes place when a symbiont causes its host to reproduce asexually, such that females are produced from unfertilized eggs (thelytoky). This phenotype occurs primarily in hymenopteran insects, which have haplodiploid sex determination systems – the chromosomal complement of unfertilized, male-destined haploid eggs is doubled by activity of the symbiont.

Cytoplasmic incompatibility occurs when matings between infected males and uninfected females fail to produce viable offspring. As all other crosses are viable, infected females are favored over uninfected females as they can mate with any male. *Wolbachia* modify sperm to cause defects in early zygote development when a 'rescue' modification is not present in infected female mates carrying the same strain.

Plants and animals evolved, and still live today, in a microbial world. The result has been an astonishing diversity of eukaryote–microbe interactions. Microbial symbionts have evolved from many different lineages, playing key roles in eukaryote biology, as described in **Table 1**. In general, ectosymbionts colonize surfaces exposed to the environment, such as the root epidermis in plants, mammalian skin, insect exoskeletons, or animal guts. External surfaces are most often colonized by extracellular microbes that are acquired from the environment each generation. But social transmission also occurs, and the duration and specificity of the association varies greatly depending on the interaction. Ectosymbionts often have roles in defense, especially colonization resistance, and digestion. The other broad category of microbial associates, endosymbionts, tends to be much more specialized and typically restricted to internal tissues or cells. Many are vertically transmitted through seeds or eggs with high fidelity, and can persist within host lineages for timespans of thousands or even millions of years. Such parent-to-offspring transfer tightly links the fitness of interacting partners, allowing beneficial microbes to preferentially invade and persist in host populations. Benefits conferred by heritable symbionts include the provisioning of nutrients or secondary metabolites used in defense. An alternative strategy for the spread of heritable microbes, commonly employed by symbionts of arthropods, involves manipulation of host reproduction or development in ways that favor symbiont transmission (**Box 1**). Heritable endosymbionts occur in many plants and invertebrate animals, but not vertebrates, possibly due to differences in their immune systems.

Many symbioses involve the mutual exchange of benefits between host and symbiont. Microbes as a whole have a greater biosynthetic potential relative to plants and animals, and the microbial partner often provides a function or service that is lacking in the eukaryotic host. Through acquiring an entire organism, the eukaryotic host can expand its metabolic potential by obtaining not only complete functional pathways but also the accompanying regulatory machinery. In other cases, infection with microbial symbionts may modulate host regulatory pathways important for development and immunity, or those involved in resource acquisition (e.g., herbivores' symbionts may regulate plant defense pathways to better exploit plants as a food source). In general, resource acquisition and protection are the two most common services provided by microbial residents of plants and animals. These have had substantial impacts on hosts and, in some cases, on surrounding communities and ecosystems.

Symbiosis as a Source of Evolutionary Innovation

Mutation has long been seen as providing the raw material for evolution, yet studies in prokaryotes and viruses have revealed the importance of lateral gene transfer in microbial innovation (Ochman *et al.*, 2000). While the lateral acquisition of genes also affects the ecology and evolution of eukaryotes (Schoenknecht *et al.*, 2014), the acquisition of novel capabilities through symbiosis has played a larger innovative role in many eukaryotic lineages, including plants and animals (Moran, 2007). Like lateral gene transfer, the acquisition of a novel symbiont contrasts with the Fisherian model of gradual evolution through the accumulation of small changes. And while mutualistic symbionts may take some time to evolve fine-tuned relationships with novel hosts, symbiosis can be viewed as a type of macromutation that can rapidly alter host characteristics.

Symbioses Involved in Resource Acquisition

A diverse assemblage of organisms can photosynthetically fix atmospheric carbon into storable fuel supplies (Venn *et al.*, 2008). Interestingly, this incredibly important process, which underlies the bulk of primary production in both terrestrial habits (via plants) and oceans (via 'algae'), evolved only once in the ancestor to extant cyanobacteria, but has been shared

Table 1 Major animal and plant symbioses

Association	*Common eukaryotic hosts*	*Symbiont diversity*	*Major roles*	*References*
Plants – mycorrhizal fungi (MF)	a. Widespread: found in all major plant groups b. Angiosperms/ gymnosperms	a. Arbuscular MF (Glomeromycota) b. Ectomycorrhizal F (mostly Basidiomycota and Ascomycota)	Plants get phosphorus and other nutrients and pathogen protection; fungi get organic carbon; likely facilitated colonization of land by plants	Smith and Read (2008)
Plants – nitrogen-fixing bacteria	a. Legumes (Fabaceae) b. Various dicotyledon angiosperms c. Cycads and *Gunnera* (angiosperms)	a. Rhizobia (α and β-proteobacteria) b. *Frankia* (actinomycete) c. *Cyanobacteria*	Plants get usable nitrogen, bacteria carbon. Can expand host range to nitrogen-poor soils	van der Heijden *et al.* (2008)
Animals – photosynthetic bacteria or algae	a. Corals (Cnidaria) b. Sponges (Porifera) c. Mollusca d. Tunicates (Ascidia)	*Symbiodinium* (dinoflagellate) (a, b, and c) *Chlorella* (chlorophyta) (a, b, and c) *Cyanobacteria* (a and d)	Diverse animals derive photosynthetically fixed carbon from algae or bacteria. Corals symbioses support communities of marine life	Venn *et al.* (2008)
Animals – chemosynthetic bacteria	a. Annelid worms b. Bivalve mollusks c. Decapod crustaceans (arthropods)	Sulfur-oxidizing symbionts usually γ-proteobacteria (evolved many times), but some ε-proteobacteria Methane oxidizing γ-proteobacteria	Conversion of chemicals rather than sunlight into carbon-based energy. Allows for primary production and formation of ecosystems in deep sea where sunlight does not reach	Dubilier *et al.* (2008)
Nutrient-provisioning, heritable symbionts in insects	a. Sap-feeding Hemiptera b. Blood-feeding hemipterans, lice and flies c. Some ants, roaches, and beetles	Mostly Proteobacteria, but evolved many times independently; rarely fungi	Provides amino acids and cofactors for sap-feeders, B vitamins for blood feeders; symbionts get stable, nutritional environment. Allowed for niche specialization and subsequent diversification	Baumann (2005); Moran *et al.* (2008)
Gut symbionts in animals	Most bilaterian animals harbor gut microbiota	Mostly bacteria (diverse taxa), but also fungi and other eukaryotic microbes	Break down cellulose and other plant polymers, nutrient-provisioning, nitrogen recycling and fixation, detoxify plant defenses and pesticides, protect against ingested pathogens; can also affect development and immune function	Engel and Moran (2013); Ley *et al.* (2008b)
Facultative, heritable symbionts	Widespread in insects and other arthropods although infections are often sporadic within and among host lineages	Mostly bacteria	Protection against natural enemies, mediate plant–animal interactions, and reproductive manipulations; symbionts get stable, nutritional environment	Moran *et al.* (2008)
Plants – fungal endophytes	a. Grasses b. Most plant species	a. Clavicipitaceous fungal endophytes b. Diverse non-clavicipitaceous endophytes	Fungal produced alkaloids protect plants against herbivores and confer drought tolerance; fungi get carbon Pathogen protection, growth enhancement	Rodriguez *et al.* (2009)

(*Continued*)

Table 1 Continued

Association	*Common eukaryotic hosts*	*Symbiont diversity*	*Major roles*	*References*
Wasp – polydnarvirus symbioses	Ichneumonid and braconid parasitic wasps (Insecta: Hymenoptera)	Ichnoviruses and Bracoviruses	Protect wasps from insect host's immune system	Strand and Burke (2013)
Nematode – bacteria symbioses	Entomopathogenic nematodes (a) *Steinernema* and (b) *Heterorhabditis*	a. *Xenorhabdus* (γ-proteobacteria) b. *Photorhabdus* (γ-proteobacteria)	Help subdue and liquefy insect hosts to aid in resource acquisition	Stock and Goodrich-Blair (2008)
Animals – luminescent bacteria	Most common in marine animals, including fish, squid, and crustaceans	Mostly bacteria including *Vibrio* and *Photobacterium* (both γ-proteobacteria)	Used as a light source or lure in resource acquisition, defense, and interspecific communication	Widder (2010)
Agricultural symbioses	Leaf-cutter ants, some termites, and xylophagous beetles	Fungi	Special fungal cultivars gardened for consumption as a food source	Mueller *et al.* (2005)

among diverse eukaryotes through symbiosis. While plants photosynthesize through chloroplast organelles derived from cyanobacterial ancestors, many animals, including sponges and corals (**Table 1**), engage in photosynthetic symbioses with cyanobacteria or 'algae.' The latter is a polyphyletic group of unicellular eukaryotes that acquired this capability through an initial symbiosis with cyanobacteria. Of course, sunlight cannot reach deep-sea depths and drive primary production, yet life still thrives in locations such as hydrothermal vents through chemosynthesis – a process by which carbohydrates are derived from chemical energy via the oxidation of hydrogen sulfide or other inorganic molecules. Chemosynthesis has arisen numerous times throughout bacterial history, and bacteria from at least nine distinct chemosynthetic lineages are known to form symbioses with marine animals from at least seven phyla (Dubilier *et al.*, 2008; **Table 1**). Although first discovered near deep-sea hydrothermal vents, chemosynthetic symbioses are also found at deep-sea whale and wood falls, and even in shallow areas with ample sunlight. Symbiont-mediated fixation of inorganic carbon therefore fuels many of the world's ecosystems, with carbon-fixing plants and animals forming the base of many food chains. Thus, symbioses contribute greatly to primary productivity both locally and globally.

In addition to sugars, many macro- and micronutrients are essential for the growth, development, and reproduction of plants and animals. Due to the infrequent 'invention' of metabolic pathways required for nutrient biosynthesis, a more common solution has involved the acquisition of microbial symbionts that fulfill requisite nutritional needs. Animals, for example, ancestrally lack the ability to synthesize a subset of necessary amino acids (i.e., essential AAs) and many cofactors (e.g., vitamins) required for enzyme activity. While most animals acquire these by consuming a varied diet, others have acquired microbial partners that allow for niche specialization on previously unusable resources that are lacking in essential nutrients (Moran *et al.*, 2008). For example, some hemipteran insects have specialized on plant sap and harbor ancient, highly specialized bacteriocyte-associated symbionts that provision them with amino acids and other nutrients. As seen for some other eukaryotes, these nutritional symbionts are drivers of sap-feeding hemipteran diversity, having enabled novel niche occupation and subsequent species radiation. Nitrogen-fixing and nitrogen-recycling symbionts of plants and invertebrates also increase the availability of usable nitrogen to their hosts and facilitate exploitation of nitrogen-poor substrates, like wood by termites and shipworms, or the colonization of previously unusable habitats, such as desert soils by plants (van der Heijden *et al.*, 2008). In addition to nitrogen, phosphorus is also frequently a limiting macronutrient for plants, and most species engage in nutritional symbioses with phosphorus-providing MF (**Table 1**). Through their contributions to water and nutrient uptake, arbuscular MF likely facilitated the colonization of land by plants (Smith and Read, 2008).

In terrestrial habitats, plants comprise the bulk of biomass and thus represent an enormous, but challenging resource for heterotrophs (Hansen and Moran, 2014). In addition to low-nitrogen content, plants contain recalcitrant plant polymers and an array of chemical defenses that must be subverted for successful resource acquisition. Herbivorous and detritivorous animals can harbor digestive gut symbionts, which greatly aid in the breakdown of lignocellulose and other complex carbohydrates (**Table 1**). To counter the toxic and repellant secondary metabolites produced by their food plants, herbivores may also employ symbiotic microbes in addition to their own intrinsic mechanisms. For example, leaf-cutter ants, which are dominant herbivores in the tropics, engage in an agricultural symbiosis where they cultivate a fungus on plant material in the nest as a food source. In at least one interaction, the fungus produces enzymes that break down plant phenolics (Licht *et al.*, 2013). Leaf-cutter ants also harbor bacterial symbionts on their cuticles that produce antibiotics used to protect the cultivated fungus (Mueller *et al.*, 2005), demonstrating that symbioses often involve multiple parties. In addition to digestion, detoxification, and agricultural management, there is also emerging evidence that herbivores employ symbionts to modulate plant signaling pathways to

their benefit. Examples include orally secreted bacteria, which trigger plant responses to a microbial threat, constraining the abilities to defend against the herbivore (Chung *et al.*, 2013). Through these activities, animal–microbe symbioses can play important roles in terrestrial carbon and nitrogen cycling.

Symbiotic microbes are also known to aid parasitic animals in resource acquisition, including such hyper-diverse groups as insect parasitoids and entomopathogenic nematodes. For example, some hymenopteran parasitoids carry ancient, highly specialized polydnaviruses, which aid internally developing wasp larvae by compromising their host's immunity and creating an environment more suitable for development (Strand and Burke, 2013). Similarly, nematodes of the genera *Heterohabditis* and *Steinernema* harbor bacterial symbionts that help to subdue the insect host and break down tissues to increase resources to nematode juveniles (Stock and Goodrich-Blair, 2008).

Symbioses Involved in Host Protection

Virtually all plants and animals are attacked by natural enemies, and there is a growing appreciation that protective symbioses are widespread across eukaryotes (Clay, 2014). In some cases, the symbionts provide toxins, antimicrobials, or other bioactive compounds, defending hosts directly. For example, the larvae of the marine bryozoan, *Begula neritina*, are protected against predators by symbiont-produced bryostatins. Similarly, terrestrial beewolves (Hymenoptera) have bacterial symbionts that produce an antibiotic cocktail that protects brood cells from microbial pathogens. In other cases, symbionts can prime the host immune system, heightening vigilance against subsequent enemy attack. Defensive symbioses have been best studied in insects, grasses, and sessile marine invertebrates (**Table 1**).

In insects, facultative heritable endosymbionts are increasingly shown to protect hosts against natural enemies. Some are especially widespread and confer a wide range of phenotypes. For instance, in addition to executing all four types of reproductive manipulation (**Box 1**), *Wolbachia* symbionts confer protection against a wide range of natural enemies in dipteran insects and likely beyond (Hamilton and Perlman, 2013). In other cases, some insects harbor a diverse assemblage of more specialized heritable bacteria that mediate diverse ecological interactions. Pea aphids, for instance, are associated with seven common facultative endosymbionts that provide defense against high heat, parasites, and pathogens (**Figure 1**). Through defensive benefits, heritable symbionts may spread quickly through host populations, illustrating rapid adaptation through symbiosis (Jaenike *et al.*, 2010). Protective symbioses show much potential for coevolutionary interactions, with strain variation in the strength of protective phenotypes, symbiont strain specificity to particular enemy genotypes, and enemies that can evolve counter-responses to symbiont-based defenses (Clay, 2014). Protection against abiotic factors is an additional contribution of some symbioses, with microbes buffering hosts against the stressors of drought and heat (Gilbert *et al.*, 2010).

Origins of Symbiosis

Symbioses can originate from diverse interaction types, including antagonism, commensalism, or chance encounters. They can also be maintained and disrupted through a variety of

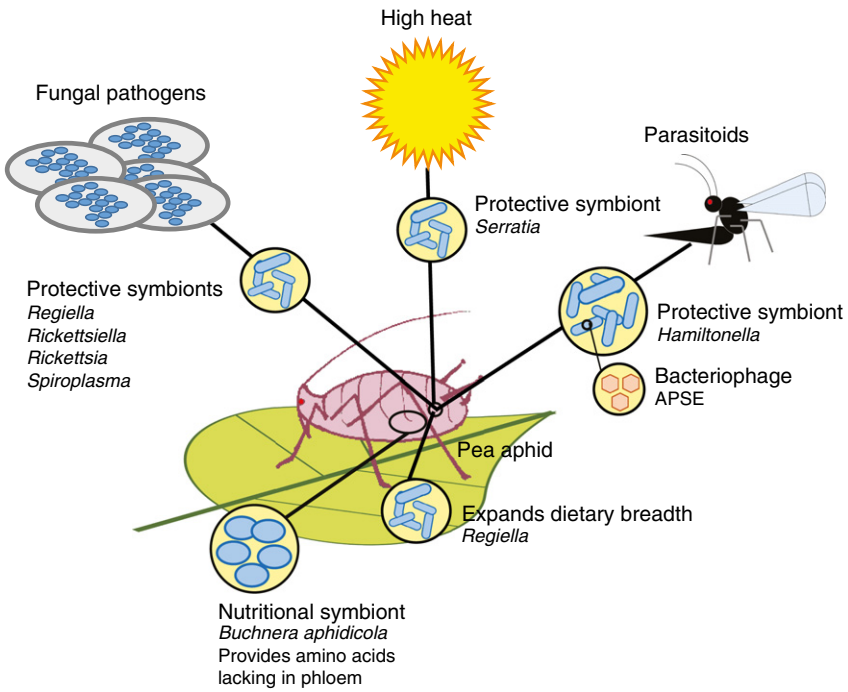

Figure 1 The pea aphid, *Acyrthosiphon pisum*, is a phloem-feeding insect that harbors at least eight heritable symbionts that have major effects on host ecology and evolution. All pea aphids carry an obligate nutritional symbiont allowing subsistence on a nitrogen-poor diet, and individual aphids may carry one or more facultative endosymbionts, with diverse roles in mediating important ecological interactions.

mechanisms. The result is substantial variation in the persistence and specialization of interactions. While germ theory was a major development for disease treatment it left the false impression that most microbes were pathogens. Given this, we expect that many symbioses, especially the microbial consortia inhabiting guts and external surfaces, originated from encounters with nonpathogenic organisms. Nevertheless, there is evidence that some symbiotic interactions are likely derived from antagonistic relationships. For example, phylogenetic evidence indicates that many plant and animal symbionts are closely related to pathogens, including the protective fungal endophytes of grasses, which likely evolved from entomopathogenic fungi (Sung *et al.*, 2007). In some extant symbioses, including *Photorhabdus* bacteria infecting entomopathogenic nematodes, a particular microbe can be a beneficial symbiont in one host and a pathogen or parasite in another (Stock and Goodrich-Blair, 2008). Transitions from pathogenicity to symbiosis can occur through several parallel processes including changes to the mode of transmission, the acquisition of symbiosis genes, and the amelioration of pathogenic effects of infection over time. In some cases, the eukaryotic host can even become dependent on a microbial partner, even when no novel benefit is conferred. The parasitic wasp *Asobara tabida*, for example, requires *Wolbachia* for oogenesis through its inhibitory effects on programmed cell death (Werren *et al.*, 2008). More broadly, although plants and animals can often develop and function in an aposymbiotic state, they often do so with impairments (Douglas, 2014). This highlights the integrated nature of symbiosis in eukaryotic biology that has come about through evolution in a microbial world.

Symbiont Maintenance and Stability

Symbiotic microbes must establish and persist in hosts with extensive means to recognize and remove microorganisms. Some symbionts borrow infective strategies employed by pathogens, such as evading recognition by the host, or if recognized as nonself, they may avoid elimination through the inhibition of mechanisms targeting their destruction. Conflict resolution allowing symbiont persistence can also be accomplished by restricting tissue tropism. Vertebrates, for example, tolerate high bacterial loads on external surfaces (including their gut lining), though their immune systems effectively eliminate internally circulating bacteria. In more specialized interactions, novel morphological structures have evolved to harbor specific symbionts, such as the light-emitting organs in some fish and squid, and the bacteriocytes of insects housing nutritional symbionts.

Many eukaryote–microbe symbioses have persisted for more than a hundred million years, including some obligate nutritional symbionts of insects. These ancient symbionts have undergone strict maternal transmission and show patterns of cospeciation between host and symbiont. Functional redundancy can lead to the loss of function in one or both partners. A striking feature of the obligate nutritional symbionts of insects is that their genomes are greatly reduced compared to free-living relatives, yet retain the specific metabolic pathways necessary for nutrient provisioning (Moran *et al.*, 2008). Genome reduction can lead to functional deterioration, potentially constraining suitable abiotic (temperature) or biotic (diet breadth) ranges. Potential solutions include the transfer of key symbiont genes to the host nucleus and symbiont replacement.

When symbionts are environmentally acquired there is considerable variation in the taxonomic specificity and persistence of the microbial partners, and the amount of specialization in the host. The gut microbiota of terrestrial animals, for example, are generally less specialized and partner specific, though there are exceptions (Engel and Moran, 2013). Mechanisms for partner recognition are also variable and can be sophisticated. Squid and their environmentally acquired *Vibrio* symbionts, for example, engage in a complex dialog that allows a 'winnowing' from thousands of bacterial species to one or two specific strains that occupy the light organ (McFall-Ngai, 2014). Policing of symbiont function leads to the removal of non-luminescing *Vibrio* strains. Mechanisms that ensure symbiont functionality appear critical for environmentally acquired symbioses to safeguard against cheaters. In contrast, policing in heritable symbioses occurs via host-level natural selection (**Figure 2**).

Correlations between particular environmentally acquired symbionts and host attributes have been hypothesized to reflect a role of microbes in host adaptation. For instance, most mammalian herbivores have specialized gut fermentation chambers to aid in the digestion of recalcitrant plant materials, and findings that unrelated herbivorous mammals harbor similar gut communities suggest symbiont roles in dietary evolution (Ley *et al.*, 2008a,b). Partner availability, host plasticity, and host or symbiont evolution, however, can all produce symbiotic variation in nature (**Figure 3**), and correlations between symbionts and host attributes should be carefully scrutinized when assessing symbiont roles in host adaptation. Common garden and microbial transplantation experiments can determine, for example, whether the host controls which symbionts colonize their bodies, and whether symbiont-correlated phenotypes are transported upon microbial transplantation.

Application of Symbiosis for Human Welfare

Understanding and manipulating symbioses may aid in solving many of the biological challenges facing our world today. Climate change is expected to affect symbioses more severely when partners have different environmental tolerances, a phenomenon exemplified by symbiont loss in bleached corals due to warming oceans and other anthropogenic impacts. Many symbionts, however, buffer environmental variability and these have the potential to confer tolerance to a rapidly changing climate. Thus, findings of such protective symbioses, including those that inhibit coral bleaching (Gilbert *et al.*, 2010), should be of growing interest in the coming years. Capacities of symbiotic microbes to degrade pesticides, influence the diet breadth of herbivores, affect host pest status, and to thwart biological control agents have important implications for the health and function of both natural and managed ecosystems. Alternatively, we may be able to leverage symbiont function to our own ends. For example, symbionts may represent an untapped source of antibiotics and other bioactive compounds with medical applications and provide a novel means to combat insect-vectored human pathogens either by changing vector characteristics or inhibiting pathogen

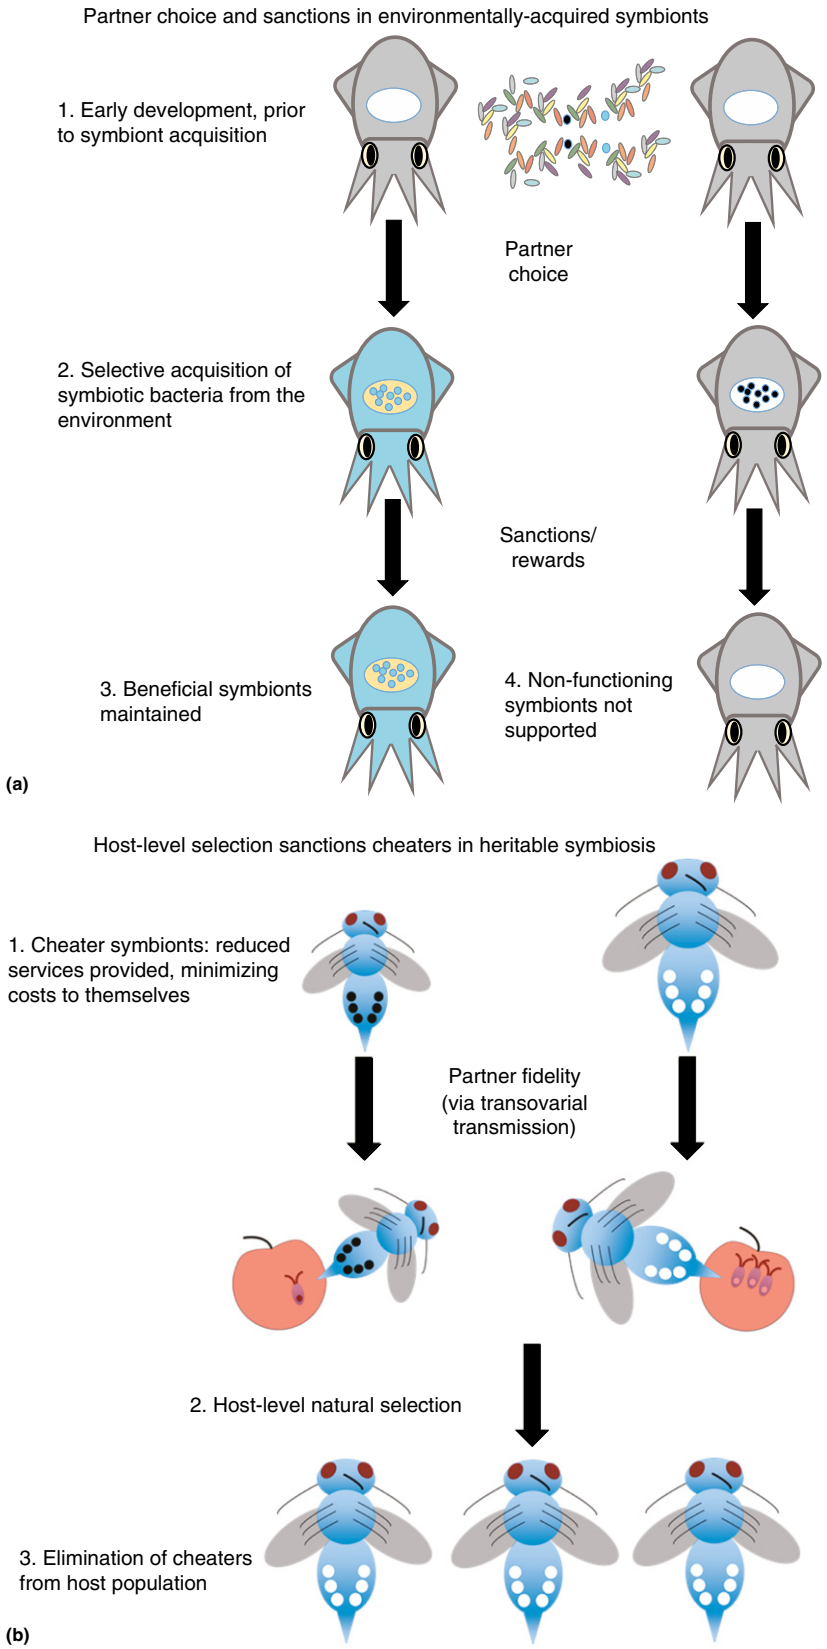

Figure 2 Forces stabilizing symbiotic mutualisms. For environmentally acquired associations, partner choice (i.e., selectivity/specificity of the hosts and microbes) and the capacity to sanction under-performing partners can stabilize beneficial symbioses (panel (a)). For associations with substantial vertical transfer (i.e., microbes move from parent to offspring), selection at the host level favors hosts with cooperative symbionts (panel (b)).

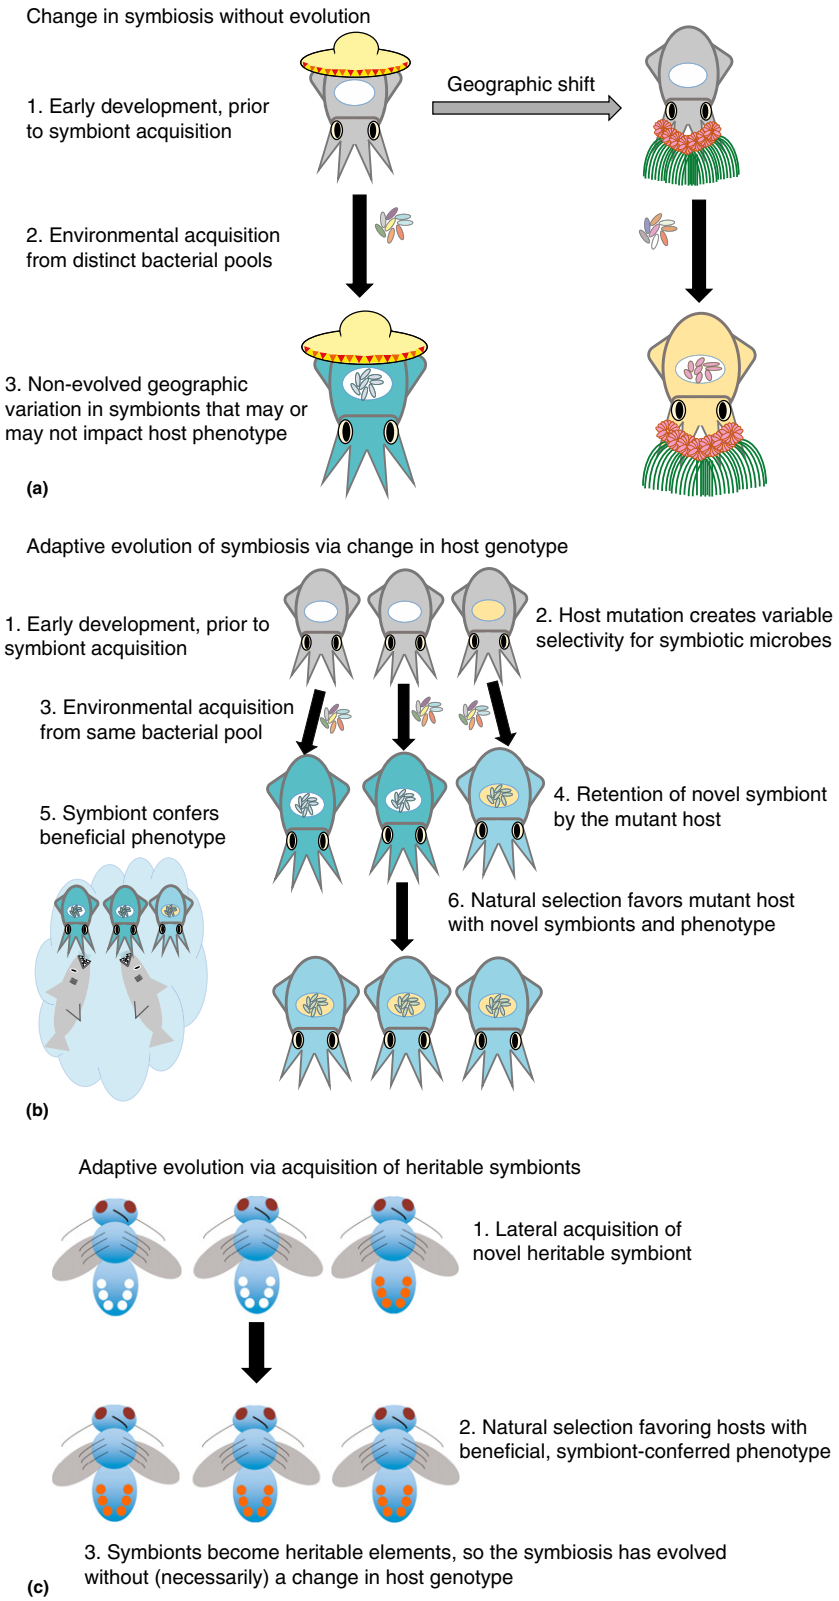

Figure 3 Change in symbiosis. Symbiotic associations vary over time and space and across ecological gradients. While this may be due to factors such as plasticity and shifting partner availability (panel (a)), it may alternatively reflect evolutionary change through symbiont-conferred adaptation (panels (b) and (c)). Panel (b) depicts this symbiotic evolution via host mutations that favor retention of beneficial microbes. Panel (c) depicts an acquisition of novel, beneficial symbionts; as the microbes are heritable elements of their hosts (like mitochondria), the hosts, and thus the symbiosis, have evolved without a change in host genotype.

Box 2 Symbiosis and human health

Discoveries on the diversity, abundance, and importance of microbes to human health have piqued public interest in symbiosis. Metagenomic research indicates that individual humans typically carry hundreds of bacterial species and trillions of cells and demonstrates that symbiont function varies across individuals with varying relatedness and diet. Moreover, our 'normal' microbiota may be altered in association with disease states. For example, obesity is associated with community-level microbiome shifts toward an increase in particular Firmicutes bacteria that drive an increased microbial capacity to extract calories from our diets (Ridaura *et al.*, 2013). The promise of probiotic therapies, fecal transplants, and other manipulations represent exciting possibilities for symbiosis research to improve human health (Spor *et al.*, 2011).

replication (Werren *et al.*, 2008). Manipulation of our natural gut microflora will also likely be important for the treatment of human diseases (see **Box 2**).

Conclusions

Modern molecular tools have led to an awareness that symbioses are widespread in nature and have contributed to major transitions in the evolution of life on Earth. Indeed, virtually all plants and animals, including humans, harbor microbial symbionts that can have large effects on host ecology and evolution. Symbionts can confer novel capabilities that influence ecological interactions, with effects that extend to other trophic levels. They may also impact the processes of speciation and diversification (Brucker and Bordenstein, 2012). Many particular symbioses are pertinent to medicine, agriculture, climate change, and frontiers in this field include exploiting symbiosis to improve the health of humans, our agricultural systems, and natural ecosystems. Among the many challenges include (1) understanding how genes and the environment interact to shape eukaryote–multipartite microbe associations, (2) how host immune systems regulate beneficial symbioses, and (3) how contributions from host and symbiont are coordinated between organisms from different domains.

Glossary

Adaptive landscape A heuristic tool to visualize the relationship between genotype and fitness.

Blending inheritance The notion that traits are inherited like different colors of paint blend. Under blending inheritance, the value an individual has for a trait would be a blend of the values that the individual's parents have for that trait. This notion was largely discredited by Mendel's findings.

Particulate inheritance The notion that inherited traits are transmitted from one generation to the next by specific particles. Mendel's findings and subsequent work by early geneticists confirmed the generality of particulate inheritance.

What is the Synthetic Theory of Evolution?

In essence, the synthetic theory is a unification of Mendelian genetics and Darwinian evolution. However, exactly what is included in the synthetic theory of evolution is hard to definitively determine, and different biologists and historians of biology differ regarding what should or should not be included.

Julian Huxley, grandson of 'Darwin's bulldog' Thomas Huxley, synthesized the views of many biologists in his 1942 book *Evolution – The Modern Synthesis*. Like his grandfather had in the 1860s and 1870s, Julian defended Darwinian evolution. Unlike the evolution of his grandfather's time, the version that Julian Huxley promoted had been synthesized with a clear theory of heredity, namely that associated with Gregor Mendel and Mendelian inheritance and was more firmly rooted in mathematical theory. Moreover, the younger Huxley was battling with biologists at the time, who had accepted evolution, but not one based on natural selection. Although the terms 'the modern synthesis' and 'the synthetic theory of evolution' often are used interchangeably, they are not the same. Huxley's (1942) modern synthesis encompassed views about society that are not in the synthetic theory of evolution (see Mather, 1943; Smocovitis, 1996). The modern synthesis, but not the synthetic theory, includes the institutional framework that supported the science. Ernst Mayr, in particular, established the Society for the Study of Evolution, serving as its first President, and the journal *Evolution* (Smocovitis, 1996; Haffer, 2008). The institution building is not part of the synthetic theory but does accompany its establishment. Finally, the synthetic theory of evolution spans a more expansive span of time than did Huxley's modern synthesis.

In this article the author traces the development of the synthetic theory, beginning with why such a synthesis was needed and why it took so long. Then he discusses the first step of the synthesis, the establishment of theoretical population genetics that occurred during the quarter century before Huxley (1942) and then discusses the solidification of the synthetic theory that occurred during Huxley's time as various disciplines latched onto a common framework. He concludes with a discussion of the challenges the synthetic theory has faced since the 1960s.

Before the Synthetic Theory

Although Darwin's insurmountable evidence and forceful argument quickly convinced biologists and naturalists of the reality of evolution, Darwin's preferred mechanism for evolution – natural selection – was still controversial up until well into the twentieth century (Provine, 1971, 2001; Mayr, 1982; Gould, 2002). Most biologists of this time acknowledged that natural selection could operate, but were skeptical of its potency and scope (Provine, 1971; Gould, 2002). These biologists had advanced several alternatives to natural selection. For instance, orthogenesis referred to several postulated theories of the time wherein organisms evolved along certain directions dictated more by 'channels of internal constraint, rather than external pathways of natural selection' (Gould, 2002, p. 66).

One of the main reasons for the skepticism regarding selection involved the lack of a clear mechanism of heredity. For instance, in a review of Darwin's *Origin of Species*, the engineer Fleeming Jenkin (1867) posed a puzzle to Darwin that seemed to challenge the importance of evolution by natural selection. Jenkin argued that if inheritance is blending, new variants quickly would be lost. For instance, suppose a new mutation changed the flower color from white to red. If the red individual outcrosses, it would have to breed with a white individual, as the entire population (aside from it) is white. The resulting offspring would be pink. Nearly all of the rest of the population would be white, so these pink individuals would have still lighter pink offspring. Soon, any trace of red would be lost. Because evolution via natural selection requires variation in the population, blending inheritance would seem to preclude evolution via natural selection.

Transmission genetics as a science developed quickly after the re-discovery of Mendel's laws of heredity at the turn of the twentieth century (Sturtevant, 1965; Mayr, 1982). Mendelian genetics follows particulate inheritance: that is, the hereditary materials (genes) come in different varieties (alleles) that are passed on from one generation to the next, and that while the action of one allele may be masked, these alleles are not lost during transmission. In Mendelian genetics, new alleles arise from mutations in genes. Yet, despite this development, Mendelian genetics and Darwinian selection still were not unified.

During the first quarter of the twentieth century, evolutionists coalesced into two opposing groups, the Mendelians and the biometricians (Provine, 1971). The Mendelians rejected Darwinian gradualism and viewed evolutionary change as being driven by mutations of large effect. In contrast, the biometricians dismissed the mutations the Mendelians were observing as being irrelevant to the evolutionary process, and were skeptical of the value of Mendelian genetics (Provine, 1971). Instead, they viewed slight differences in continuous traits as being most important for evolutionary change, and generally took a statistical or biometrical approach in their assessment of this variation.

Some authors at the turn of the twentieth century, such as William Castle and Udny Yule, quickly saw that the views of the Mendelians and the biometricians were compatible. In addition the British mathematician Godfrey Hardy (1908) and the German physician Wilhem Weinberg (1908) independently developed an early null model demonstrating that allele frequencies would not change unless evolutionary processes were operating in the population (Provine, 1971; Crow, 1999). Despite these developments, most of the biologists of the time did not appreciate the compatibility between Darwinism and Mendelism and the synthesis had to wait another generation (Provine, 1971, 1986).

Early Development of the Synthetic Theory: Theoretical Population Genetics

The first phase of the development of the synthetic theory came when mathematical population genetic theory united Mendelian genetics and Darwinian evolutionary processes, including natural selection. Predominant among these theoreticians were the British geneticists Sir Ronald Fisher and J. B. S. Haldane, and the American geneticist Sewall Wright.

Early in his career, Fisher (1918) showed that Jenkin's objection regarding selection was groundless given Mendelian particulate inheritance; genetic variation can persist in a population under Mendelian inheritance, in contrast to blending inheritance, because the alleles are not lost in the process (Grafen, 2003). More generally, Fisher (1918) also showed that Mendelian rules of inheritance could apply to continuous traits being studied by the biometricians, accounting for the correlations of traits seen across different relatives. In his subsequent book *The Genetical Theory of Natural Selection*, Fisher (1930) began by emphasizing the particulate nature of heredity and its consequences. In particular, Fisher emphasized the role of additive genetic variation, the proportion of the variation that is owing to the additive effects of genes. The more additive genetic variation for fitness, the faster alleles will change in frequency due to selection.

Starting in 1924, Haldane published a series of papers that presented a quantitative theory of how natural selection would operate in Mendelian populations. For instance, Haldane (1924, Figure 2) demonstrated that an autosomal dominant allele with a selective advantage of 0.001 could increase in frequency from 10% to 50% in about 2500 generations. With stronger selection, the time to change frequency would be correspondingly reduced. Quantification of the effects

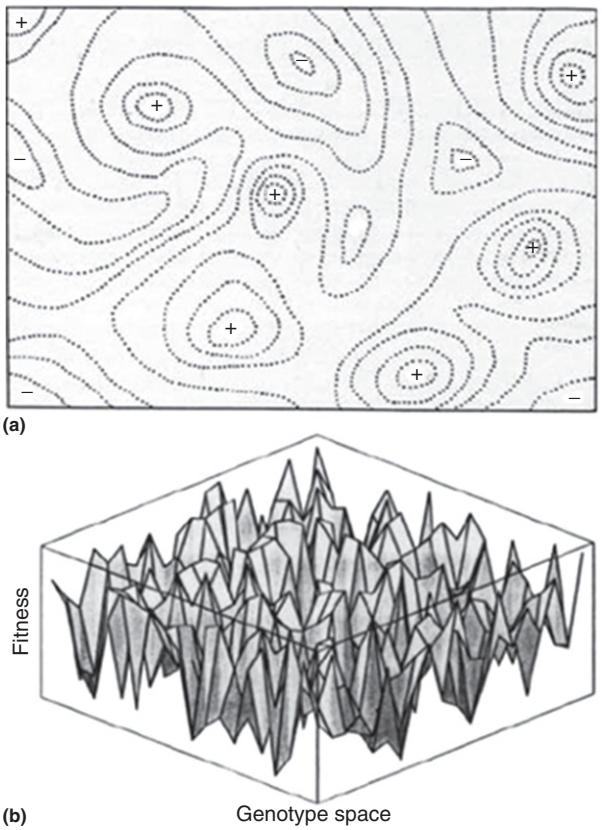

Figure 1 The adaptive landscape can be visualized in several ways. In (a), fitnesses are displayed in a contour map with the *x* and *y* axes representing different combinations of genotypes. In (b), high fitness is represented by peaks and low fitness is represented by valleys. Reproduced from Johnson, N., 2008. Sewall Wright and the development of the shifting balance theory. Nature Education 1(1), 52. Available at: http://www.nature.com/scitable/topicpage/sewall-wright-and-the-development-of-shifting-30508 (accessed 19.09.2015).

evolutionary processes had on changes in allele frequency, as done by Haldane (1924) and Wright (1931) among others, established theoretical population genetics as a science, and cemented the foundation for uniting Mendelian genetics and Darwinian evolution (Provine, 1971).

Wright (1931, 1932) emphasized that selection was not the only evolutionary process that could alter allele frequencies. Random sampling variation occurring every generation, which would become known as genetic drift, could also alter allele frequencies; the potency of this process is inversely related to population size (Hartl and Clark, 2007). Wright (1931, 1932, 1977) noted that drift could interact with selection even in large populations if those populations were subdivided.

Wright (1932) also introduced the metaphorical concept of the adaptive (or fitness) landscape, as a way to visualize the relationship between genotype and fitness (**Figure 1**). This heuristic enabled better understanding of how selection and other evolutionary processes could operate on populations and helped to open up theoretical population genetics to biologists with limited mathematical skill. Although Wright's own biographer, Will Provine (1986), criticized ambiguities in Wright's use of the adaptive landscape, it remains a key

concept in evolutionary biology (e.g., Arnold *et al.*, 2001; Gavrilets, 2004).

Population Genetics and the Synthesis

Although theoretical population genetics was established by the early 1930s, it did not actually reach most biologists interested in evolution for some time. The population genetics theory was largely in densely-written, equation-heavy papers that were inaccessible to many biologists. In addition, the theory needed to be applied to natural populations of organisms.

During the late 1930s and early 1940s, the publication of several books from a variety of authors advanced and solidified the synthesis (Mayr, 1982). These publications made the foundations of theoretical population genetics accessible to wider audiences of geneticists, zoologists, botanists, and paleontologists. Through these books and other works, these leading authors codified research agendas and influenced the next generation of evolutionary biologists (Smocovitis, 1996).

In his *Genetics and Origin of Species*, the Russian-born, American immigrant Theodosius Dobzhansky (1937) promoted and popularized the population genetic principles and theory established by Fisher, Haldane, and especially Wright. One key tenet emerging from this work was the promotion of selection as an evolutionary force: unless a population is very small, mutations will frequently appear in the population as a whole such that variation should be sufficiently abundant for natural selection to operate (Dobzhansky, 1937). To many, Dobzhansky's book functioned as the first textbook of evolution that integrated Darwinian theory with Mendelism. It also inspired other works, and influenced the German-born, American immigrant Ernst Mayr who had been studying the systematics of birds. Mayr (1942) folded systematics into the synthetic theory, viewing species through the lens of population thinking wherein the focus was on individual differences within a species and not an idealized type (see also Haffer, 2008).

Collaborations between the theoretical population biologists and empirical field researchers cemented the synthetic theory in empirical realism. The close collaboration with Sewall Wright helped Dobzhansky establish a research program to address the genetics of natural populations. Here, Dobzhansky's main organism of choice was *Drosophila pseudoobscura* (Dobzhansky, 1937; Lewontin *et al.*, 1981; Provine, 1986). In the United Kingdom, the Lepidopterist Edmund BriscoFord collaborated extensively with Fisher to develop what is now known as ecological genetics, the study of genetic variation and the evolutionary processes that influence it in natural populations (Connor and Hartl, 2004). Under Ford's supervision, Bernard Kettlewell (1955) tested and confirmed the hypothesis that bird predation was the selective agent behind changes in color morphs of the peppered moth, *Biston betularia*. This is one of the classic examples of evolution by natural selection taking place in a natural population (Grant, 1999).

The synthesis founders were not monolithic in their thinking, and indeed had frequent disagreements and debates. For instance, Wright (1931, 1932, 1977) emphasized the roles of population structure and gene interaction while Fisher was dismissive of these factors (Provine, 1986). This debate has persisted for several decades (cf Coyne *et al.*, 1997; Wade and Goodnight, 1998). Another major mid-century debate revolved around the nature of genetic variation within species and the processes that maintained such variation. As recounted by Lewontin (1974), the American geneticist Hermann Joseph Muller and the classical school thought that genetic variation was generally rare and was maintained mainly by a balance between mutation bringing in new variation and selection purging the variation, while Dobzhansky and the 'balance school' thought variation was much more common and was maintained by a balance between different forms of selection. Note that these disputes primarily revolved around model parameters and the relative frequencies of empirical biological phenomena, and were not about the types of questions to be addressed or the underlying mathematical theory.

Speciation and Macroevolution in the Synthetic Theory

In addition to examining evolutionary processes on variation within species, the modern synthesis also addressed speciation and evolution beyond the species level (macroevolution). In general, the proponents of the modern synthesis viewed evolution as a continuum with macroevolution as microevolution writ large (Dobzhansky, 1937; Huxley, 1942; Mayr, 1942; Simpson, 1944).

Both Dobzhansky (1937) and Mayr (1942) paid homage to Darwin in using 'the origin of species' in the titles of their books, and devoted much of those books to speciation. To Dobzhansky (1937), biological diversity came in more-or-less discrete entities (with species being the most basic level of biological diversity). He saw a central question being how can discrete packets of biodiversity emerge via evolutionary processes. Dobzhansky (1935, 1937) and Mayr (1940, 1942) argued for a biological species concept based on reproductive compatibility: species are entities of reproductively compatible populations that were reproductively isolated from other such groups. Influenced by Dobzhansky, Ledyard Stebbins (1950) applied the reproductive compatibility species concept to plants (Smocovitis, 2006). Although Haldane, among others, opposed this definition of species on the grounds that species were just human constructs, the Dobzhansky–Mayr species concept generally won out (Mayr, 1963; Coyne, 1994; Coyne and Orr, 2004).

Viewing species on the basis of reproductive compatibility enabled the founders of the synthesis to study speciation as the evolution of reproductive isolation.

Dobzhansky (1937) and Muller (1942) independently established a genetic framework for how the fitness of hybrids is reduced as nascent species diverge from one another. In the Dobzhansky–Muller framework, which is still commonly used today, hybrids have reduced viability and fertility due to changes at multiple interacting genes instead of single gene changes (Coyne and Orr, 2004; Johnson, 2002). Fisher (1930) and especially Dobzhansky (1940) also promoted the idea that reduction of hybrid fitness could lead to selection pressure against mating with other species. This idea, now known as

reinforcement, is generally accepted as a major factor in speciation (Coyne and Orr, 2004). Stebbins (1950) championed and provided evidence for the thesis that polyploidy – the acquisition of additional chromosome sets – could be an important mode of reproductive isolation, especially in plants (Smocovitis, 2006; Soltis *et al.*, 2014).

Beyond the species level, macroevolution was also brought into the synthetic theory. In his influential book *Tempo and Mode in Evolution*, the paleontologist George Gaylord Simpson (1944) argued that the paleontological patterns observed in the fossil record could be explained by the population genetics of the synthetic theory, and that no additional processes were needed to explain the patterns. Moreover, Simpson argued that the patterns observed (the tempo) could provide information about the types of evolutionary processes involved (the mode). Simpson (1944) adopted and expanded Wright's adaptive landscape to include phenotypes, with phenotypic measures represented locations on each of the axis and fitnesses depicted as contour intervals (see **Figure 1**). With this expanded adaptive landscape, Simpson could help unite population genetic and paleontological approaches to studying evolution (Arnold *et al.*, 2001).

The Synthesis as a Constriction

Provine (1989) contended that the synthesis was more of a constriction than a synthesis. Ideas that were dominant at the turn of the twentieth century, such as orthogenesis and Lamarckian inheritance of acquired characteristics, were removed from mainstream evolutionary biology thought during the synthesis of the 1930s and 1940s. It is true that many biologists working in the early part of the synthesis, including Ernst Mayr (Haffer, 2008; Mayr, 1982) started out accepting Lamarckian inheritance and later became convinced of the validity of evolutionary change occurring via Mendelian particulate inheritance as the synthetic theory developed. To describe the synthesis as strictly a constriction is unfounded given that it actually involved the fusion of Mendelian and Darwinian notions.

The views of the synthesis hardened and further constricted during the 1950s and 1960s (Gould, 2002). During this time, natural selection became the predominant explainer of biological phenomenon to the nearly complete exclusion of other evolutionary processes. For instance, successive editions of Dobzhansky's *Genetics and the Origin of Species* focused increasingly more on selection and de-emphasized the importance of genetic drift (Gould, 2002). In addition, approaches that attempted to link evolution with developmental processes such as those championed by Richard Goldschmidt and Conrad Waddington were de-emphasized during the evolution synthesis of the middle twentieth century (Gould, 1980, 2002; Jamniczky *et al.*, 2010).

Challenges to the Synthetic Theory

Beginning in the 1960s, new discoveries and ideas challenged the synthetic theory of evolution. Over the past half century, evolutionary biologists have debated whether the synthetic theory is still useful and whether we are in a new synthesis. There is no resolution to this debate (Laland *et al.*, 2014).

Advances in molecular biology led to new sources of data that ushered in the field of molecular evolution. Protein electrophoresis data revealed that natural populations of many organisms contain much more genetic variation than previously thought (Lewontin, 1974). Protein sequence data suggested that proteins evolve roughly linear to the time of divergence between species (a 'molecular clock') (Zuckerkandl and Pauling, 1965). Kimura (1968) noted that the observed rate of protein sequence evolution was higher than could be accounted for by selective deaths.

These and other observations led Motoo Kimura (1968, 1983) to argue against the primacy of selection as the driver of molecular evolution. Kimura's thesis, which became known as 'the neutral theory of molecular evolution,' posits that the vast majority of the variation at the protein and DNA level seen in natural populations is simply the result of mutational input, random genetic drift, and negative selection weeding out variants. Thus, most genetic variants in natural populations are effectively neutral. Deleterious mutations do occur but are weeded out.

Similarly, mutation and genetic drift– and not positive selection – drive divergence between species in molecular evolution (Kimura, 1983). Debates between advocates of the neutral theory (neutralists) and those who champion a larger role for selection driving molecular evolution continue to the twenty-first century (Lynch, 2007; Hahn, 2008). Even if the neutral theory is not a good representation of biological reality, evolutionary genetics of the twenty-first century generally think that mutation plays an important role in evolution, and especially molecular evolution (Stoltzfus and Cable, 2014).

Findings about the rates of phenotypic evolution also challenged the modern synthesis. Famously, Eldredge and Gould (1972) advanced the thesis that most phenotypic evolution involves long periods of relative stasis punctuated by rapid (on a geological scale) change. This observation, called punctuated equilibrium, is a pattern, but that pattern also generated much debate about the processes underlying evolution. For instance, Gould (1980) suggested that the observed pattern implied the need to examine additional mechanisms of evolution, including radical reorganizations of the genome. Population geneticists of the time strongly objected to this need, and proposed that stabilizing selection could be responsible for stasis (e.g., Charlesworth *et al.*, 1982). Why persistent stasis is commonplace remains the most enduring question from the punctuated equilibrium debate (Futuyma, 2010).

Although Darwin (1859) was well aware of correlated traits and had an intuitive grasp on how selection on one trait could constrain the evolution of other traits, the complications of correlated traits were generally not a focus in the mid-twentieth century synthesis. Starting in the early 1980s, quantitative evolutionary geneticists developed methods to deal with these complications (e.g., Lande and Arnold, 1983; Arnold, 2014). The expected evolutionary path of a population is dependent not just on patterns of selection, but also on internal genetic constraints (e.g., Futuyma, 2010). The extent to which internal genetic constraints channel evolutionary responses is still unresolved, but if such constraints are frequently strong, then

orthogenesis might bear a revisit as a cause of the observed stasis (Gould, 2002).

Developmental biology was generally not part of the synthetic theory of the middle twentieth century (Gould, 2002). Evolutionary developmental biology (evo-devo), the synthesis of evolutionary biology and developmental biology, came later. It posed challenges for the synthetic theory of evolution. One of these challenges is that of deep homology – very distantly related organisms (e.g., flies and mammals) share a common tool kit of important developmental genes (e.g., Palopoli and Patel, 1996). Deep homology was an unexpected surprise. In fact, Mayr (1963, p. 609) noted, "Much that has been learned about gene physiology makes it evident that the search for homologous genes is quite futile except in very close relatives" (see also Gould, 2002). While it was a challenge, the notion of deep homology is being weaved into the synthetic theory of evolution (Futuyma, 2013).

In recent years, the notion of inheritance has expanded beyond Mendelian genetics. Because the synthetic theory fuses Mendelism and Darwinism, epigenetics, defined in the broad sense as inheritance systems outside of DNA sequence, poses a challenge (Jablonka and Lamb, 1998; Goldberg *et al.*, 2007; Jamniczky *et al.*, 2010). At the time of writing this, the extent of the challenge remains unclear and a matter of contention (Laland *et al.*, 2014).

Systems in Evolutionary Systems Biology

L Loewe, Laboratory of Genetics and Wisconsin Institute for Discovery, University of Wisconsin–Madison, Madison, WI, USA

Glossary

EvoSysBio A transdisciplinary framework for constructing reliable, testable, interactive overviews of nestable, dynamic, multi-dimensional fitness landscapes, which mechanistically predict: (1) changes in fitness of individual organisms when their states and environments change; (2) how populations evolve when organisms traverse fitness landscapes.

Extra-Organism Biology (EOB) Biology focusing on actions, reactions, processes, parts, and patterns in ecosystems that alter states of individual organisms as they interact with biotic or abiotic environments.

Fitness Causality Network (FCNet) A network of nodes (defined by IFTs) and links (defined by LIFTs) that describes causal influences (e.g., genotypes, environments, and initial states such as maternal methylation patterns of DNA) on consequential IFTs (e.g., survival, reproduction) in a given time period.

Fitness landscape An abstract 'landscape' defined by *causal* 'positions in a plane' and their *consequential* 'heights,' as defined by a corresponding Fitness Causality Network.

Incomplete Fitness Trait (IFT) A phenotypic trait that impacts the fitness of an organism, its offspring, or its genetic relatives and that, at least occasionally, affects rates of survival, reproduction, merging, etc., or modifies evolutionary factors like mutation rates in one or more environments.

Intra-Organism Biology (IOB) Biology focusing on actions, reactions, processes, parts, and patterns within a single, individual organism that enable it to live (grow, survive, reproduce, move, etc.) by changing its state in a given environment.

Landscape of Incomplete Fitness Traits (LIFT) An abstract representation of a fitness landscape that maps causal IFTs to consequential IFTs, thus providing a causality statement about how input governs output, comparable to probabilistic mathematical functions.

Nest Organism A single, individual organism that is the environment for one or more populations of different types of nested organisms, which may themselves be nest organisms.

Nested Organism A single, individual organism that is contained by an encapsulating nest organism, which is the nested organism's environment and may itself be nested in a larger organism of a different type.

Organism A single, individual system that consists of different parts that builds a whole, which – in biology – must be able to replicate and may be nestable.

Population-Genetics Biology (PGB) Biology focusing on heritable information (genotypes, alleles, traits, methylation patterns, etc.) that can directly or indirectly affect IFTs (survival, reproduction, etc.) when passed on by individual organisms in evolving populations.

Trans-Organism Biology (TOB) Biology focusing on integrating Extra-Organism Biology (EOB), Population-Genetics Biology (PGB), and all direct or indirect actions, processes, and patterns that otherwise fall through the disciplinary cracks of EOB or PGB (excluding the inside of organisms).

Systems approaches to biology and genome evolution are becoming increasingly important. Since the 1920s, the New Evolutionary Synthesis has been constructing an increasingly coherent view of evolution by synthesizing ideas from different parts of biology. Further progress of this relentless synthesis will increasingly depend on crossing disciplinary boundaries, complex simulations of biological systems, and reliable reproducibility. Evolutionary Systems Biology (EvoSysBio) is defined here as working towards integrated interactive overviews of dynamic multi-dimensional fitness landscapes that are testable in the real world and enable the prediction of evolution. EvoSysBio further formalizes the New Synthesis as illustrated here for cancer and antibiotics resistance evolution.

Systems Approaches to Genome Evolution

Biology has a long history with numerous independent efforts to integrate diverse aspects of biological systems in order to understand the whole. For example, R.A. Fisher (1918) resolved a big controversy about inheritance by creating an integrative systems model with a mechanism for combining the varying effects by which different genes could impact a given phenotypic trait. The rise of population genetics has since inspired mechanistic modeling of how systems with populations of organisms evolve in response to the five fundamental factors of evolution, which may vary between these biological extremes over space and time:

1. *mutation* (perfect heritability ⇆ fast change);
2. *selection* (harmful ⇆ neutral ⇆ helpful);
3. *genetic drift* (last survivor ⇆ largest finite population);
4. *recombination* (complete linkage ⇆ free segregation); and
5. *migration* (homogeneity of space ⇆ movement maximizing impact of heterogeneity).

These factors are fundamental, since they affect *all* real-world populations of organisms with a phenotype capable of reproducing heritable variations; the complexity of evolutionary

outcomes (see this Encyclopedia) is fueled by variations of these factors over space and time at nested levels of replication. Simple interactions are well understood, but complex, dynamic patterns in heterogeneous, nested, multi-locus systems pose many questions that will keep defining the cutting-edge of population genetics for a long time to come (Loewe and Hill, 2010a,b). There is no better theory of evolution than population genetics, the 'auto-mechanics of evolution' (Singh and Krimbas, 2000, p.1); yet it has much room for growth by integrating expertise from biochemical reaction networks to ecological interactions. For example, biochemistry was instrumental for generally understanding dominance in heterozygous genes (Kacser and Burns, 1981); now more detailed, dynamic models could explain patterns observed in specific genes. Population genetics can be abstract, ignoring many details (Haldane, 1964), yet its core abstractions are powerful enough for mechanistically connecting intra-organism and trans-organism biology and their environments with the phylogenetic patterns they govern together (see **Table 1**). The power of these abstractions places population genetics in a remarkably central role in biology and makes it very difficult to ignore whenever populations of replicating organisms are involved.

This article points to various systems approaches in biology and how they connect to population genetics, starting with Current Systems Biology (CSysBio) and increasingly important aspects of formal and computational modeling. Section 'Defining EvoSysBio' uses abstractions from population genetics to define EvoSysBio without loss of generality. Section 'Fitness Landscapes' discusses **L**andscapes of **I**ncomplete **F**itness **T**raits (LIFTs), which help to define EvoSysBio and represent the best albeit fractured glimpses of true fitness landscapes that will be available for a long time. The last section presents examples of five important milestones for EvoSysBio.

Current Systems Biology

Systems approaches in biology emerged from a confluence of several broad trends:

(i) Researchers have always known that cellular molecules had a complex context, but this complexity came into focus only after enough details accumulated from studying isolated molecules.
(ii) Increases in computing power inspired developers of quantitative and computational methods in biology, ushering in the era of bioinformatics and genomics.
(iii) As genome sequencing matured, some perceived its data-driven discoveries to lack inspiring transformational hypotheses; this fueled a desire for more hypothesis-driven quantitative models and opened biology up to many physicists and engineers excited about modeling.
(iv) Medical interest in understanding how varied diseases work in humans motivated the Human Genome Project ('*read* the blueprint'), but locating candidate disease genes rarely satisfied curiosity ('*understand* the blueprint'). As differences between genomes were revealed, they stimulated interest in personalizing medicine ('understand *my* blueprint' (Hood *et al.*, 2004)). A theoretical framework could guide the long journey from wishing to actually understanding biology.

These trends supported the rise of CSysBio, which can employ data from genomics and other -omics to construct a more integrated view of molecular interactions, ideally by simulating them in dynamic mechanistic models that yield predictions to be tested by perturbations in high-throughput experiments (Ideker *et al.*, 2001b). It was initially contrasted to (1) a deep-but-narrow focus on functions of isolated molecules, and (2) a broad-but-shallow, data-driven genomic search for candidate genes with functional annotations, but without corresponding mechanistic models (Ideker *et al.*, 2001a). CSysBio started in molecular biology (Westerhoff and Palsson, 2004), and since it has been expanding its scope to include cells, physiology, and more, it still lacks a generally agreed-upon definition. Some see it as a cycle that could characterize *any* system (Kitano, 2002a,b; Ideker *et al.*, 2001a):

(i) collect all details possibly relevant for a given system and research question;
(ii) define a quantitative model with all parts and interactions relevant to the question;
(iii) predict from the model properties of observable real-world perturbations;
(iv) test the model by comparing its predictions to relevant real-world data;
(v) refine the model if the distance between predictions and real-world data is too large (as usual), or expand it by including new questions.

This definition reassuringly echoes the Scientific Method; absence of system types studied, methods applied or questions asked, it is also too general for any field, which risks defining CSysBio only in 'the eye of the beholder.' Despite difficulties of definition and adoption of more thorough systems perspectives (Cornish-Bowden, 2006), CSysBio has been producing some impressive mechanistic models of systems ranging from the molecular to the physiological, including: circadian clocks (Dodd *et al.*, 2005; Huang *et al.*, 2012), metabolic fluxes in microbes (Edwards *et al.*, 2001; King *et al.*, 2015), viral replication (Endy *et al.*, 2000; Lim and Yin, 2009), full intracellular dynamics over a simple cell cycle (Karr *et al.*, 2012), human heart (Noble, 2011), rat physiology (Virtual Rat, see Section Relevant Websites), and more, occasionally even venturing beyond Intra-Organism Biology (IOB) into topics such as evolution.

Current Systems Biology Meets Evolution

Most CSysBio works toward empirically supported models of processes that help genotypes and environments shape phenotypes. However, if CSysBio models include replicating entities with traits that are both heritable and mutable, then these need to be treated as organisms in their own right. Heritable variation of such traits inevitably activates the five factors with all their complicated dynamics. If evolutionary processes occur within multicellular organisms, they are easily overlooked even if they are highly relevant for medicine, such as the evolution of tumor cell populations in cancer (Stearns and Koella, 2008). Similarly, fast evolution of bacteria

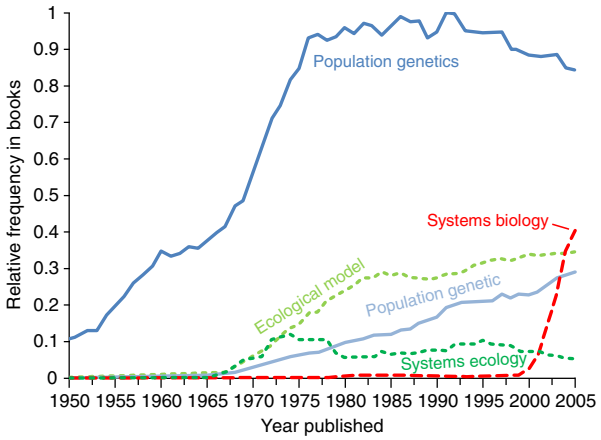

Figure 1 Rise of some terms related to systems approaches in biology as tracked by changes of frequency in books digitized by Google (terms are case insensitive; in relative units of $1 \approx 0.000\,037\%$; all big data cautions apply; Michel *et al.*, 2011). Data credit: https://books.google.com/ngrams.

(Edwards *et al.*, 2001) could be important to understand for industrial production plants.

Understanding population genetics mechanisms helps to recognize evolutionary processes and select the right types of tools and theorems for modeling them. Without some grasp of past population genetics work, researchers risk needlessly re-deriving past results instead of building on them. Trends in Figure 1 might provide rough indicators of this rich history (all caveats about 'big data' apply).

Ecological Systems Biology

CSysBio contrasts with an earlier era of 'systems theory in biology,' which inspired ecologists in the 1970s to build causal models of ecological systems (Wolkenhauer, 2001). As a discipline, ecology has learned important lessons about how to deal with extreme uncertainty and has accumulated statistical expertise in the art of developing knowledge by using empirical tests against real-world data to reduce uncertainty in models of complex systems. CSysBio can learn from Ecology's experience in quantifying uncertainty (Kirk *et al.*, 2015).

Advances in computing and the availability of 'big data' for *some specific* parts of systems provide opportunities for improving models from cells to ecosystems (e.g., high-resolution images inside cells and more (Editorial, 2015; Dietze *et al.*, 2013; Mackechnie *et al.*, 2011; Seksik and Landman, 2015; Sleeman, 2013; Xu and Rhee, 2014; Kuhlbrandt, 2014; Aronson and Rehm, 2015). However, this does not solve all modeling challenges. Integrating big data into mechanistic models can be difficult or infeasible; critical model details sometimes exist only as diffuse and diverse datasets in myriads of formats, and unknown parameters may only be amenable to 'guesstimating.' Such challenges for an integrated understanding can be substantial; appropriate advanced modeling techniques may help, but without special measures it can be surprisingly difficult to reproduce results from increasingly complex computations and statistics (James *et al.*, 2015; Stodden, 2015). These trends matter for complex models of evolution and their corresponding sub-models.

Systems Genetics

The new field of systems genetics builds on genetics, genomics, 'phenomics,' more -omics, CSysBio, and other fields to better integrate insights about how genotypes shape phenotypes in different environments (Hughes, 2010; Markowetz and Boutros, 2015) with huge medical implications (Aronson and Rehm, 2015). It combines into genome-wide association studies (GWAS) as many triplets as possible, each containing an individual genome, respective quantitative phenotypes (molecular and organismal), and a record of environmental conditions that shaped the genotype–phenotype map of these organisms. It aims to obtain integrated models that highlight which genes have probably been affected by selection on organisms with a specified phenotype in a given environment. Advanced statistical techniques used in GWAS provide empirical estimates about how much a given gene might have contributed to a particular trait of interest, thus identifying candidate genes that may cause important phenotypic functions. Systems genetics methods work because patterns of DNA sequence diversity contain information on the strength of the environment's selection of certain phenotypic traits, which affects the survival probabilities of organisms with corresponding mutations. Patterns in modern genomes echo a long history of selection. Examples include studies in the fruit fly *Drosophila melanogaster* (Anholt and Mackay, 2015; Huang *et al.*, 2014; Mackay *et al.*, 2009; Harbison *et al.*, 2009; Ayroles *et al.*, 2009).

Systems genetics provides a different perspective on the complex gene regulatory networks that govern phenotypes, which are also studied in CSysBio; thus in principle, both could combine their strength. For example, many unknowns often exist in detailed, mechanistic models of complex gene regulatory networks that could, in principle, predict phenotypes also amenable to systems genetics. Thus, GWAS may constrain overly large parameter spaces in mechanistic models, while CSysBio simulations may add mechanistic details about genetic architecture by highlighting genes with effects too small to detect in GWAS.

Integration

Better understanding evolution weakens boundaries between diverse systems approaches in biology, as evolution is its biggest system. Molecular systems biology can only study systems shaped by evolution (excludes extinct species), while systems ecology and evolution critically depend on biochemistry; systems genetics relies on all to shape the statistical patterns of genetic diversity in populations, and initiatives in 'personalized precision medicine' aiming to predict clinical consequences of genetic variants (Aronson and Rehm, 2015) will hardly be able to do so without computational models (Iyengar *et al.*, 2015), which will both inform and be informed by a profound understanding of evolution (Stearns and Koella, 2008). Continuing progress on this integrative trajectory increasingly depends on modeling skills and leads to the mechanistic view of EvoSysBio discussed in the next section.

Systems Science: The Whole is Different from the Sum of Its Parts

The realization that a system as a whole can be very different from a heap of its parts is at least as old as Aristotle (-344 ± 22). It also has long guided Gestalt theory, arguably an early form of systems science (Wagemans *et al.*, 2012b) used to study sensory perception (Wagemans *et al.*, 2012a), which undoubtedly affects the evolution of species reliant on learned mental models for navigating their world. Investigating how elements combine into a 'Gestalt' also inspired the thought that – at least in principle – the whole world could be understood with a single mathematical equation, albeit of extravagant composite complexity (von Ehrenfels, 1890, p. 292).

Computational models in systems science essentially provide such 'world-equations,' if only for the small, closed worlds described in the composite formal structures called 'programs.' Modeling investigates the whole by studying relevant parts, their interactions, and systemic properties. Good models usually start with a curiosity, informal questions, and a hunch. They grow as researchers integrate more observations and are eventually formalized as small, computable worlds that mimic relevant interactions of parts and the emergent properties of their whole. The main results of systems science are empirically tested models that become more valuable as they survive increasingly difficult challenges to mechanistically predict non-trivial phenomena. To develop such models, it is essential to actually look at the whole repeatedly and from different perspectives, which seems to be challenging even for systems biologists (Cornish-Bowden, 2006). It helps to know what types of systems others have already seen and which models were developed as a result.

Types of models can be classified in many broad categories using various criteria, such as their approach to randomness in the system, how they are computed, which values they allow, etc.; the myriad modeling approaches needed for understanding evolution could easily fill an encyclopedia the size of this one (and indeed fill many pages in this Encyclopedia too). Examples include approaches that are

- *deterministic*: assumes no chance exists, so recomputing always produces the same result;
- *stochastic*: chance exists, so recomputing always produces variable outcomes as computers use random number generators to choose between possible outcomes;
- *probabilistic*: effects of chance are modeled as probability distributions that can form complicated networks, which can be analyzed deterministically or stochastically;
- *equilibrium*: no effective changes over time can be observed, for example, in steady-state balance;
- *nonequilibrium*: the system is dynamic and changes over time.

Additional incomplete and overlapping classifications of modeling approaches may serve as search terms, illustrating model diversity and jumpstarting further investigations for readers: backwards in time (e.g., coalescent models) ⇆ forwards in time (e.g., individual-based simulations); analytic ⇆ numeric ⇆ computational; binary ⇆ integer ⇆ continuous; constrained by input ⇆ output ⇆ equations; mechanistic ⇆ descriptive; absence of submodels ⇆ multilevel nesting; linear ⇆ nonlinear; time-based ⇆ event-based ⇆ static; graph-based ⇆ matrix-based ⇆ agent-based ⇆ logic-based (see Zeigler, 2012; Thiele *et al.*, 2012; E, 2011; Grimm and Railsback, 2005; Zeigler *et al.*, 2000; Law and Kelton, 2000). There are many more computer programming paradigms that also expand the list. In fact, Gödel's incompleteness theorem of mathematical formalisms suggests that infinitely many modeling and programming approaches exist, each of which is extremely powerful. Many different such approaches need to come together to enable the modeling of nested multi-scale evolution of diverse organisms from a rigorous probability theory perspective. We are very far from this goal; to make progress, we need a better grasp of the limits of various modeling approaches and how they might complement each other.

After a eureka experience of realizing how many questions could be answered by just one approach, researchers can be tempted to ignore its limits. However, even if the approach is a great hammer, not every problem is a nail. Ignoring these limits is dangerous when software assuming one model is applied to data for which the assumed model does not hold. This is particularly true for the many tools that do not automatically check for such problems (contributing much to the current reproducibility crisis). Biologists familiar with a broader range of modeling approaches are in a better position to choose a more reasonable approach for their biological question.

Model-building for any particular biological system is more efficient when researchers (1) have clear questions for their model, (2) can choose from a broad range of approaches to construct models, and (3) are well supported by corresponding tools that help to quantify uncertainty, detect modeling errors, and document results. Most approaches worth learning mirror *certain* modeling problems in biology extremely well and reasonably approximate others; however, all fail for *some* real-world systems, either due to unreasonable assumptions or computational intractability.

For any complex real-world problem, even the best models will always differ from reality and easily become misleading if interpreted from perspectives that violate their simplifying assumptions. Hence, the conclusion of the famous statistician George Box: "*All models are wrong, but some are useful*" (see Box and Draper, 2007, p. 414). Such usefulness either increases our mechanistic understanding or translates into success at prediction challenges in the real-world, where models are tested against empirical data. Estimating parameters for many biological models is a substantial challenge: the sloppy parameter sensitivities make it impossible to predict the importance of a given parameter without simulation, even in small nonlinear CSysBio models (Gutenkunst *et al.*, 2007). Difficulties compound for whole-cell models (Karr *et al.*, 2015), which suffer from the curse of dimensionality as the number of parameters increases. Aiming for reasonable reliability, complex models in CSysBio and elsewhere *must* quantify their uncertainty (Kirk *et al.*, 2015) and may want to manage their error budget (Parysow *et al.*, 2000). It is important for the reproducibility at the heart of science to avoid illusionary precision (Stodden, 2015). A combination of reasonable models and efficient tools can vastly expand a biologist's thinking capabilities and will be essential for reliable EvoSysBio analyses discussed below.

Systems Approaches Are Young

Systems modeling, big data and computational science (e.g., HPC university, see Section Relevant Websites) are young and lack the centuries of aggregated experience in weeding out unreliable results – unlike mathematics, physics, chemistry, and biology. The beginning of the previous section illustrates many problems in computational science simply by attempting to referencing Aristotle in the usual style: missing data (surname), data beyond an unreasonably narrow range (BCE), and uncertainty (year ± 22); if this were input for a scientific simulation, chances are that nobody would realize the hidden bias it introduces unless the model 'misbehaves' and produces 'unreasonable' results (as judged by competent, but not infallible experts).

The biggest challenge of the field is to improve the quality of models so they (1) describe causality chains that connect real-world input and assumptions to real-world output and conclusions in a reasonable way, (2) are complete, clear, and contradiction-free, (3) are readable and well documented for semantic reproducibility, (4) accurately quantify uncertainty of all claims for statistical reproducibility and explicitly define limits of applicability, (5) continually integrate new evidence as it becomes available, (6) run reproducible tests to reject claims that are not compatible with increasingly accurate observations, and (7) automatically trigger updates of other models that build on its output.

Reasonable models satisfy (1)–(4) for the data and evidence available at construction, but need (5)–(7) to *activate* them. State-of-the-art modeling is advanced enough to inspire such noble goals, but current model reliability is often much less clear. Much time, effort and organization will be required before such high-quality models can become standard in biology (Macklin *et al.*, 2014). Progress might be accelerated by dropping the principally impossible aims to 'validate' or 'verify' models of the natural world, which is not a closed system (Oreskes *et al.*, 1994). 'Validation' could more likely stifle further testing than encourage curious critical exploration of the 'valid.' The reliability of a model can be measured by its ability to withstand diverse and difficult tests that contrast model claims with the real world.

Questions are keys, models are locks. The key to assessing the reliability of a model is in the questions that motivated building it and that defined its purpose. This insight is both simple and profound. It is easy to see that the street map of a city (a type of model) does not help determine geological strata (wrong question for this model). It usually takes much more experience to identify similar model-data mismatches in 'big data' collections, which can be analyzed using unreasonable models to generate irreproducible results (Stodden, 2015). Hence remembering the question and relevant transformations is essential for avoiding results like '42,' also known as the answer to everything (Adams, 1979).

Questions that drive models are also essential for determining the level of details to include, which can be increased (*fine-graining*) or decreased (*coarse-graining*) in almost all cases. These decisions determine required parameters to be measured, indirectly estimated, collected from the literature, or imported from appropriate databases (such as BrendaEnzymes for kinetic parameters or BioNumbers for cell biology, see Section Relevant Websites). Much of the value of the abstractions developed by the New Evolutionary Synthesis since the 1920s is in their ability to guide coarse-graining and fine-graining across vast parts of biology. The formal EvoSysBio framework discussed below further refines this process.

Optimistically, and with some organization and standardization, the transition toward reliable computational modeling in biology will require far less time than the centuries it took to move from alchemy to chemistry. EvoSysBio could help catalyze these efforts, and the definitions of IOB, EOB, PGB, and TOB given in **Table 1** could be a step on the way.

Defining EvoSysBio

EvoSysBio, in its fullest form requires a union of insights from three very broad areas of research: evolutionary research (studies replicators, sometimes beyond biology), systems science (studies dynamic things consisting of parts), and biology (studies all aspects of carbon based life). Without such a union of insights and matching computational tools, progress in EvoSysBio remains a distant dream or a daunting yet diffuse challenge. This integrative reading of EvoSysBio reflects its trans-disciplinary mission to build bridges between many diverse disciplines, making it both extraordinarily broad and deep.

However, English syntax interprets combined terms as intersections, so that 'EvoSysBio' is less general than 'SysBio,' which already specializes 'Bio,' just as in 'House Keys.' This reading might see EvoSysBio as a highly specialized add-on with narrow applicability, a view hardly appropriate on principal grounds: virtually every 'thing' studied in biology can also be studied with the tools of systems science and has also been evolving or playing a role in evolution. Thus, EvoSysBio represents a panoramic perspective that matters for quantifying change over time in systems with self-replication.

This astonishing breadth of EvoSysBio implies that its results can depend on preceding breakthroughs in far-flung fields of evolution, systems biology, computing, and other disciplines, often developed by researchers without interests in EvoSysBio, evolution, or related topics. Once fully grown, EvoSysBio will be more keystone than add-on, as it brings together various tall pillars of evidence quantified with enough precision to meet in one place, essentially stabilizing the enormously complex structure of biology as a discipline.

Thus, EvoSysBio is much more than the occasional application of evolutionary insights in CSysBio or the occasional inclusion of metabolic network analyses in evolutionary genetics (see, e.g., Klipp *et al.*, 2009; Voit, 2013; Caetano-Anolles, 2010; Walhout *et al.*, 2013). Different attempts have been made to define EvoSysBio (Loewe, 2009, 2012; O'Malley, 2012; O'Malley and Soyer, 2012; Soyer and O'Malley, 2013; O'Malley *et al.*, 2015). To help clarify its contributions, the definition of EvoSysBio below integrates previous definitions and provides formal abstractions that can facilitate quantitative connections to the diverse, descriptive, experimental, and theoretical contributions necessary for building the rational models essential to EvoSysBio. Since EvoSysBio's core goal is to explain how evolution works mechanistically, it inherits the astonishing integrative abilities of evolutionary theory.

Table 1 Relationships among different focuses in biology

Focus of study	*Relationship to other focuses*
Intra-Organism Biology (IOB) *intra*, Latin for 'inside.' Relevant disciplines: *Biochemistry, molecular biology, gene regulation network biology, cell biology, cancer biology, developmental biology, physiology, neurobiology, and more.*	Focuses on actions, reactions, processes, parts, and patterns within a single, individual organism that enable it to live (grow, survive, reproduce, move, etc.) by changing its state in a given environment. IOB models simplify TOB models by assuming that genotypes and environmental interactions only matter where explicitly specified for a given individual organism and the nested organisms it may contain (e.g., gut bacteria, parasites, cancer cells). IOB details depend on environments; if the latter are known, then IOB allows in principle the prediction of all relevant fitness traits by constructing a complete Fitness Causality Network (see **Table 2**).
Extra-Organism Biology (EOB) *extra*, Latin for 'outside.' Relevant disciplines: *Ecology, biogeochemistry, climate science, population ecology, community ecology, ecosystem ecology, behavioral ecology, cognitive ecology, social ecology, and more.*	Focuses on actions, reactions, processes, parts, and patterns in ecosystems that alter states of individual organisms by interacting with biotic or abiotic environments. EOB models simplify PGB models by explicitly listing all relevant genotypic differences and assuming that no others matter. EOB models implicitly simplify IOB models by providing corresponding rates of interaction between individual organisms of the same or different types, even if these interactions are ultimately governed by biochemistry. Nested organisms have nested EOB ecosystems.
Population-Genetics Biology (PGB) *genetikos*, Classic Greek for 'generative' *γένεσις*, Classic Greek for 'origin.' Relevant disciplines: *Population genetics of single and multiple loci, quantitative genetics, breeding, coalescent theory, population genomics, population epigenetics, and more.*	Focuses on heritable information (genotypes, alleles, traits, methylation patterns, etc.) that can directly or indirectly affect fitness traits like survival and reproduction when passed on by individual organisms in evolving populations. PGB models simplify EOB models by using simple demographics (e.g., constant, exponential growth) to explicitly or implicitly summarize complex ecological mechanisms. PGB models also simplify IOB models to approximate genotype–phenotype-fitness maps for a given environment (e.g., multiplicative fitness models). An extreme focus on counting alleles in a population can turn PGB into efficient but abstract 'Bean-Bag Genetics' (Haldane, 1964). Nesting works as in EOB.
Trans-Organism Biology (TOB) *trans*, Latin for 'beyond' Relevant disciplines: *Evolutionary ecology, conservation biology, coevolution, sociobiology, metagenomics, phylogenetics, and more.*	Focuses on integrating EOB, PGB, and all direct or indirect actions, processes, and patterns that otherwise fall through the disciplinary cracks of EOB or PGB (excluding the inside of organisms). TOB models simplify IOB models. Examples range from the inclusive fitness of relatives (Gardner and West, 2014) to environmental DNA abundances in metagenomics (Wooley *et al.*, 2010) and phylogenetics at any nesting level (Felsenstein, 2004) or genotype by environment interactions (Pavlicev and Wagner, 2015). Nesting works as in EOB.
Evolutionary Systems Biology (EvoSysBio) Integrating 'keystone,' not 'add-on' Relevant disciplines: *All of above and more, including data science, computational modeling, network biology, information management, integrative biology or just 'biology'*	As a field, EvoSysBio has so far mostly used various informal definitions, which are not broader than the more formal definition given in the main text. *Formal EvoSysBio*: focuses on developing more reliable real-world 'flight-simulators for fitness landscapes' by integrating IOB and TOB using the five fundamental factors of evolution. Formal EvoSysBio drops the problematic aim to *directly* quantify the complex multi-dimensional dynamics of real-world fitness landscapes. Instead, it progresses by constructing **F**itness **C**ausality **Net**works (FCNets), which quantify and connect different types of **L**andscapes of **I**ncomplete **F**itness **T**raits (LIFTs; see **Tables 2** and **3**); formal EvoSysBio can then simulate evolving populations governed by dynamic, mechanistic IFT predictions from these FCNets. *Informal EvoSysBio:* builds bridges between IOB ('Current Systems Biology') and TOB ('Evolutionary Biology'). Even if using different terminology and not motivated by fitness landscapes, informal EvoSysBio results often contribute toward a better understanding of details that might directly or indirectly help to better quantify LIFTs.

Notes: The different interests of biologists often distinguish their focuses when studying organisms (see Table 2 for definitions). To create models relevant for their focus, researchers often simplify the models created by peers with other interests. EvoSysBio aims to integrate Intra-Organism and Trans-Organism Biology by using the five fundamental factors of evolution as shared abstractions to facilitate the construction of fitness landscapes. Other biological disciplines provide integration from different perspectives, for example, those of focal organisms (e.g., botany, virology, zoology), habitats (e.g., limnology), problems (e.g., cancer biology), organizational levels (e.g., cell biology), disciplines (e.g., biophysics), and more; but it is difficult to find biological theories more general than those evolutionary theories that enable, in principle, the construction of appropriately quantified fitness landscapes, thereby requiring the integration of vast amounts of biological results (Figure 2).

This integrative power can best be understood by reviewing how the definition of EvoSysBio developed in the past decade.

Partial Approaches

CSysBio has produced many analyses of molecular interaction networks; accordingly, 'evolutionary systems biology' has been used from the very beginning to denote the comparison of such molecular networks among different biological species (Stearns *et al.*, 2003; Medina, 2005). Such use might appear to contrast with more mechanistic frameworks (e.g., Loewe, 2009), which build on simulations that directly or indirectly include network interactions along with many other details affecting a system's dynamics. Network analyses often need only small subsets of the data required by corresponding mechanistic simulations. Therefore, collecting more data on the same system can, in principle, provide a common basis for using both approaches to ask the shared question of how life evolves. It seems unnecessarily confusing to fragment EvoSysBio into many different sub-definitions; one focusing on *network analysis*, another for *mechanistic simulations*, and many more for *different methodological approaches* (e.g., flux-balance-analysis (Ibarra *et al.*, 2002; Papp *et al.*, 2011), metabolic control theory (Kacser and Burns, 1981; Keightley, 1996), systems genetics (Markowetz and Boutros, 2015), etc.), others for *different biological levels of organization* (e.g., molecular functions (Dean and Thornton, 2007), cells (Lynch *et al.*, 2014), epigenetics (Hallgrimsson and Hall, 2011), development (Carroll, 2008), ecology (Pelletier *et al.*, 2009), etc.), and others for *different biological questions* (e.g., energetics (Watt, 1985), modularity (Wagner *et al.*, 2007), robustness (Payne and Wagner, 2014), game strategies (Pacheco *et al.*, 2014; Bohl *et al.*, 2014; Hummert *et al.*, 2014), etc.), or even focusing on *different perspectives provided by the five fundamental factors*, mutation (e.g., Loewe and Hill, 2010a,b), selection (e.g., Okasha, 2006), genetic drift (e.g., Lynch, 2007), recombination (e.g., Charlesworth *et al.*, 2009), and space (e.g., Westervelt and Cohen, 2012). All these contribute different important aspects to EvoSysBio, but where would the splintering stop?

Darwin and subsequent evolutionary geneticists have convincingly demonstrated the abstract elegance and unity of evolution based on the five fundamental factors. They demonstrated, in principle and with many examples, how these factors combined into a mechanism powerful enough to create the bewildering diversity of species and biological phenomena just by variations in the patterns of strengths of its fundamental factors. Ideally, the conceptual beauty of evolutionary genetics at the core of EvoSysBio will enable different important lines of EvoSysBio inquiry to sharpen evolutionary theory by extending a single consistent set of abstractions, which will make it easier for future researchers to build on its foundation. By comparison, defining different vital aspects of EvoSysBio in conflicting but partially overlapping terms seems less desirable if no clear conceptual integration can be provided.

Thus, the question of splintering EvoSysBio is related to the question of whether it is essential to extend evolutionary theory in any unusual way, for example, to integrate TOB interactions between genotypes and environments (Laland *et al.*, 2014). There is no doubt that evolutionary theory needs to be extended in many ways or else research would stop, but it seems unnecessary to extend it in any *unusual* way beyond its continued extension 'through relentless synthesis' (Wray *et al.*, 2014). EvoSysBio can add to this relentless New Synthesis in many ways, ideally by quantifying aspects that are necessary for mechanistically predicting evolution, one of the highest goals in evolutionary biology since Fisher, Wright, and Haldane laid the groundwork for the New Evolutionary Synthesis. The wish to avoid the splintering of disciplines has also inspired the wish to reintegrate all biological subdisciplines into a 'New Biology' (National Research Council USA, 2009).

Pragmatic Definitions

EvoSysBio has been defined as an effort to build bridges between CSysBio and evolutionary biology, integrating theoretical tools, experimental methods, and datasets from multiple disciplines into an evolutionary framework (see **Figure 2**; Soyer and O'Malley, 2013; Loewe, 2009). Comparable in breadth to CSysBio, this broad definition easily encompasses the diverse work associated with EvoSysBio (e.g. studies in the volume edited by Soyer (2012) and studies cited by Loewe (2009) and below). However, a more precise definition without loss of generality would be preferred, as it could facilitate creating powerful formal interfaces between EvoSysBio and other fields. These interfaces could help to interpret data collected elsewhere in its bigger evolutionary context. Conceptual advantages like these motivate a continued search for more precise definitions of EvoSysBio.

Formalizing EvoSysBio without Loss of Generality

Indeed, it turns out that EvoSysBio can be defined more precisely without loss of generality by building on the powers of abstraction offered by evolutionary theory. At the heart of this definition of EvoSysBio are evolving populations of *individual replicating organisms*, where evolution is governed by their *fitness landscapes*, a metaphor for mathematical causality statements about the traits of evolving populations in an abstract space with very many dimensions (see **Table 2** and Section Fitness Landscapes for more details).

To give EvoSysBio something to study, individual organisms have to exist and be near-perfect replicators of genotypic information, which affects phenotypic fitness traits like survival and reproduction in finite discrete populations. Hence, in these organisms all five fundamental factors of evolution can be active. This generic view includes viruses, microbes, and multicellular organisms (nested replicators), but also a fringe with exotic systems such as ribozymes (Martin *et al.*, 2015), prions (Li *et al.*, 2010), and data structures in computers (as exploited in biological individual-based simulations (Grimm and Railsback, 2005), evolutionary computation (De Jong, 2006), and artificial life studies (Adami, 1998)). Using the abstractions of evolutionary theory enables simulated populations with appropriately chosen parameters to closely mimic natural populations, facilitating their study. Organisms defined in this general way make it possible to see EvoSysBio as an integrating bridge between the great quantitative traditions of modern biology that complement each other through

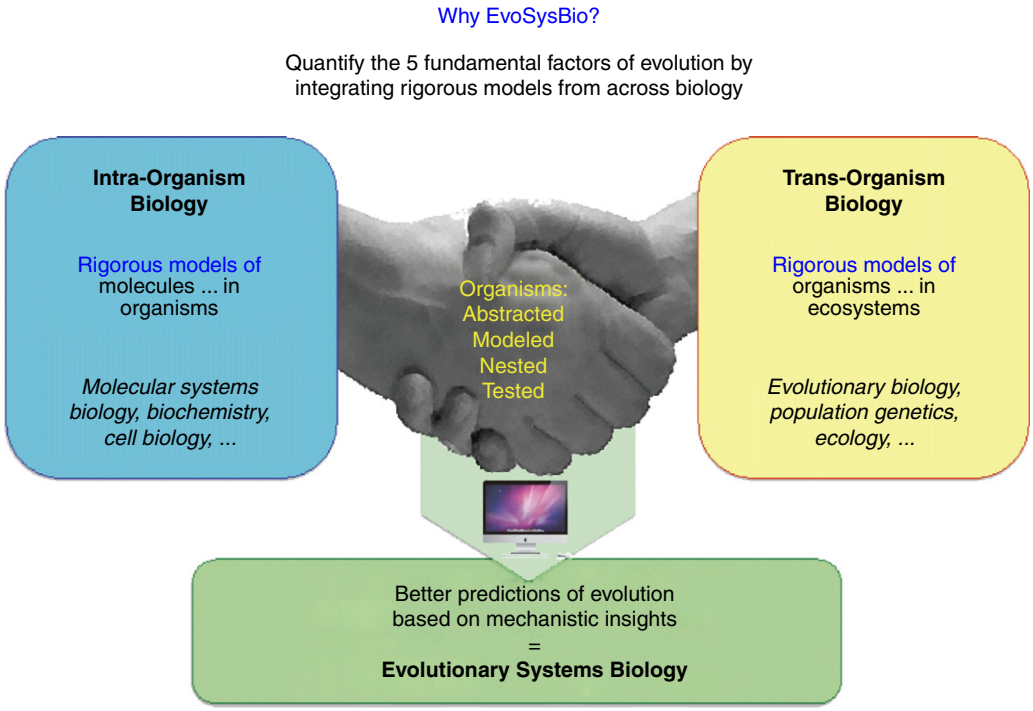

Figure 2 Overview of EvoSysBio integration. Traditionally, models from Intra-Organism Biology (IOB) and Trans-Organism Biology (TOB) have ignored each other to simplify rigorous modeling in their respective domains. This separation of concerns is facilitated by powerful abstractions such as the fitness of individual organisms and the five fundamental factors of evolution. When this separation fails at the cutting-edge of research, EvoSysBio offers a reversal that uses the same abstractions to bond branches of biology together. By measuring fitness traits of individual organisms and their contributions to the five factors, EvoSysBio enables asking new trans-disciplinary questions in addition to rigorously quantifying fitness landscapes. Fitness is either affected by – or itself affects – almost everything in biology, and 'nonquantitative' biology often breaks the conceptual ground for more precise studies; such observations have suggested: nothing in biology makes sense except *when properly quantified* in the light of evolution (Dobzhansky, 1973; Loewe, 2009). Picture credits: © Laurence Loewe (2015a), reuse under CC-BY 4.0, updated from previous versions (Loewe, 2009, 2012).

abstractions pioneered in population genetics (see **Table 1** and **Figure 2**):

(i) **I**ntra-**O**rganism **B**iology (IOB): biochemistry, molecular-, cell-, … -biology, … physiology; organisms may be nested (e.g., mitochondria in cells in humans; similarly gut bacteria, parasites, cancer cells, etc.). If nested, the IOB of the containing organism provides an environment for the smaller contained organisms, all of which come with their own IOB and TOB.

(ii) **T**rans-**O**rganism **B**iology (TOB): includes **E**xtra-**O**rganism **B**iology (EOB) disciplines such as ecology, **P**opulation **G**enetics **B**iology (PGB), the complementary genomics disciplines, and many diverse genotype-environment interactions (Pavlicev and Wagner, 2015). Nesting applies here too.

Over many decades, these traditions have produced outstanding empirical results and rigorous theory in their respective areas by using evolutionary fitness as a powerful abstraction for enabling an efficient separation of concerns. Both remain far from reaching their long-term goals: research in organisms ultimately aims to predict fitness and other phenotypic properties from genotypes (usually simplifying models of environmental changes), while population research ultimately aims to predict how populations evolve under a given set of environmental conditions (usually simplifying models of **IOB** to just a few numbers, such as fitness, epistasis, etc.). This mutual exclusion of broad areas of biology has enabled much progress, but the simplifications have started to break down for cutting-edge research. EvoSysBio can provide more detailed and explicit views of the relevant abstractions to facilitate more powerful evolutionary hypotheses that combine the strengths of both traditions. The elegance of these abstractions and the separation of concerns they enable between IOB and TOB are well illustrated by fitness landscapes, which provide a powerful intuition for explaining how evolution works (see Section Fitness Landscapes).

Based on these considerations and previous discussions (Loewe, 2009; National Research Council USA, 2009; Loewe, 2012; O'Malley and Soyer, 2012; Soyer, 2012; Calvert, 2012; Soyer and O'Malley, 2013; O'Malley, 2012; O'Malley *et al.*, 2015; Loewe *et al.*, 2015–2009), EvoSysBio can be defined in a way that leverages the integrative capabilities of fitness landscapes:

EvoSysBio is a trans-disciplinary **framework for constructing** reliable, testable, interactive **overviews of** nestable, dynamic, multi-dimensional **fitness landscapes**, **which mechanistically predict:** (i) **changes in fitness** of individual organisms when their states and environments change; (ii) **how populations evolve** when organisms traverse fitness landscapes.

This definition derives its formal power from IOB and TOB models of how individual organisms and populations change over time, respectively. These models can be efficient analytic summaries or approximations or computational models of much more complex underlying Continuous Time Markov Chains; they may require simulations to explore them. Reviewing relevant TOB theories (see e.g., Crow and Kimura, 1970, 2009; Charlesworth and Charlesworth, 2010; Kirkpatrick *et al.*, 2002; this Encyclopedia) and IOB theories (see e.g., Gillespie, 2007; Gillespie *et al.*, 2013; Klipp *et al.*, 2009; Gutenkunst *et al.*, 2007; Karr *et al.*, 2015; Kirk *et al.*, 2015; Section Systems Science: The Whole is Different from the Sum of Its Parts; **Table 3**) is beyond the scope of this article.

Informally, EvoSysBio and other work contributing to relevant computational models and appropriate visualizations might also be summarized as:

> EvoSysBio aims to improve the real-world reliability of 'flight-simulators for multidimensional fitness landscapes.'

This analogy is easily adapted to multi-dimensional data analyses, where researchers interactively explore interesting local features while relevant data is automatically selected, summarized, and presented by computers (as if 'flying' over the data; by comparison, manual coding for static snapshots feels 'pedestrian'). This requires a deep computational toolchain that integrates many diverse results extremely well; the approach thus enables EvoSysBio to leverage the full integrative power of *real-world* fitness landscapes, which are conceptually as powerful as evolution itself – known as the only theory general enough to unify biology.

In practice, this elegance comes at the steep price of requiring a deep mechanistic understanding of *real-world* fitness landscapes, an extraordinary challenge as relevant modeling expertise is often lacking in biology, statistics, formal modeling research, and more (see end of Section Systems Approaches to Genome Evolution).

This definition of EvoSysBio encourages developing more precise ways of defining fitness landscapes (see **Tables 2** and **3** and Loewe, 2009, 2012) to reduce the confusion surrounding the exact nature of these landscapes.

Fitness Landscapes

Sewall Wright (1932) introduced the now well-known concept of fitness landscapes to provide an intuitive understanding of how evolution works. These landscapes have been defined in various ways and labeled by different names, including adaptive landscapes, surfaces of selective value, and seascapes (Svensson and Calsbeek, 2012; Gavrilets, 2004; Loewe, 2009; Mustonen and Lassig, 2009). In statistics, similar landscapes have been described as response surfaces (Box and Draper, 2007).

Intuition behind Fitness Landscapes

Fitness landscapes provide a strong intuitive analogy for how evolution works. They are based on the familiar experience of walking in a hilly landscape. By representing potential genotypic states as points in a **plane** with fitness as the **height**, it becomes easy to see how evolution works:

> In a fitness landscape, *populations* evolve by moving toward higher (fitter) points whenever such points can be reached by the stochastic movement of *organisms* between positions in the plane (e.g., by mutation to other genotypic states); organisms tend to accumulate at these positions (genotypes) because there they are more likely to survive or reproduce (selection).

The strength of selection (selection coefficients) is governed by an organism's life history of survival and reproduction in comparison to other organisms in the same population. Selection and population size together govern the probabilities that the genotypes existing in one generation make it into the next, but these factors do not change genotypes (which is done by mutation and recombination). Thus, parents at higher points in the landscape have higher probabilities of generating offspring that also live at these higher points: the population evolves (see movie in **Figure 3**, Movie 1).

At a very high level, this intuition correctly captures the essence of what the complicated evolutionary mechanisms are all about: explaining why organisms are likely to exist in states of higher fitness. This intuitive nature of fitness landscapes has captured the imagination of many interested in evolution, from popular science writers to professional evolutionary biologists (Svensson and Calsbeek, 2012; Gavrilets, 2004; Loewe, 2009). Taken to one extreme, it leads to adaptationist interpretations of evolution that view populations *always* at the top of some adaptive peak and ignore the exceptions to the rule (e.g., quasi-species populations of RNA-viruses mutate at such high rates that they form 'bands around peaks' (Biebricher and Eigen, 2006); see **Figure 3**). Taken to another extreme, fitness landscapes become neutral networks, where all genotypes share the same fitness (Kimura, 1983).

Criticisms and Limitations

Critics of fitness landscapes as a concept highlight (1) the frequent lack of precise definitions, (2) its abstract nature, which does not easily lend itself to directly proposing new experiments, and (3) general human difficulties with navigating multi-dimensional spaces (Kaplan, 2008).

Little can be done about the limits of human imagination, which often fails when attempting to translate the multi-dimensional planes and heights of fitness landscapes into more familiar spatial dimensions. Different useful visualizations have been developed for highlighting various aspects of fitness landscapes (McCandlish, 2011), yet it is difficult to convey an undistorted picture. Visualizing landscapes from larger EvoSysBio projects may require interactivity, but appropriate 'flight simulators' are missing. These problems have not prevented numerous speculative drawings, which are prone to misinterpretation. It might be beneficial for the field to label them accordingly to contrast them with *attempts* that precisely define and measure the much less comprehensive real-world LIFTs (see below and **Figure 4**).

Table 2 Concepts related to fitness landscapes

Concept	*Description*
Fitness Landscape Ultimate EvoSysBio goal	An abstract 'landscape' defined by causal 'positions in a plane' and their consequential 'heights' as defined by a corresponding FCNet, mapping genotypic traits to IFTs (see below). Each position in a plane describes a potential causal state of an individual organism and its given environment; both govern its height(s). Fitness landscapes are near-impossible to measure, compute, or visualize, since both planes and heights often have very many dimensions and their 'points' often turn into fuzzy distributions due to stochasticity. Nevertheless, Evolutionary biology studies them due to their importance (even if resorting to MOCA-LIFTs, see below), and EvoSysBio formalizes these studies to make them more efficient.
Fitness Causality Network FCNets define fitness Landscapes	A network of nodes (data) and links (functions), together describing causal influences on consequential IFTs over a given time period. Causal influences include genotypes, environments, and initial states (e.g., maternal methylation patterns of DNA). Nodes in FCNets are defined by IFTs and links between nodes by LIFTs. A complete FCNet of a single organism links all LIFTs (see **Table 3**) relevant for predicting the fitness consequences of mutations and environmental changes.
Landscape of Incomplete Fitness Traits LIFT, LIFTs are always context specific	An abstract representation of a fitness landscape that maps causal IFTs to consequential IFTs, thus providing a causality statement about how input governs output, comparable to probabilistic mathematical functions. Inputs are distributions of causal states of organisms ('positions in a plane,' e.g., mutations), and outputs are distributions of consequential IFTs ('local heights,' e.g., survival, reproduction); both only apply to a given context and time duration. IFT designations 'causal' and 'consequential' are relative to a LIFT, sometimes indicated by adding 'more' to distinguish 'more causal IFTs' from the 'most causal IFTs' (e.g., DNA). If complete and rigorous, these representations of fitness landscapes can be viewed as existence probability theorems that facilitate predictions of the probability that a given number of organisms will exist in a given set of locations of the plane. Such results are mathematically related to the analysis of Continuous Time Markov-Chains, which is extremely useful for defining and analyzing such fitness landscapes. This technical aspect makes LIFTs markedly different from the MOCA-LIFTs often used for illustration (see below). The strength of LIFTs is in their simplicity, which enables precise measurements and simulations. See **Figures 7** and **8** for examples.
Incomplete Fitness Trait IFTs never quantify fitness in full	A phenotypic trait that impacts aspects of the fitness of an organism, its offspring, or its genetic relatives. Traits are IFTs when they, at least occasionally, affect rates of survival, reproduction, merging, etc., or when they modify evolutionary factors (mutation, migration, etc.) in one or more environments, at least to a small degree.
Organism Single individual replicating system	A single, individual system that consists of different parts that builds a whole, which – in biology – must be able to replicate and may be nestable. Intra-Organism Biology (IOB) investigates how these parts work together. Extra-Organism Biology (EOB) studies how each individual organism interacts with its environment and other organisms of any type. If organisms (i) use hereditary information to grow on environmental resources and (ii) can produce identical or similar descendants, then their populations necessarily evolve as modeled in Population-Genetics Biology (PGB). Remaining indirect interactions are captured by Trans-Organism Biology (TOB), which also integrates EOB and PGB at its level of replication (but not IOB). Note the simplification when a huge nested stack of replicators is denoted as a 'single multi-cellular organism.'
Nesting (in Organisms) Organisms in organisms	A nest organism is a single, individual organism that contains one or more populations of different types of nested organisms, which replicate(d) by themselves. A nested organism is a single, individual organism encapsulated by a larger nest organism, which is the smaller nested organism's environment. Organisms can be both nest and nested organisms at the same time. Examples of nesting include mitochondria in cells in multi-cellular organisms, microbes in the gut, viruses in cells, parasites in hosts, cancer in patients, and more. In each case, the smaller contained ('nested') organism is nested in the larger containing ('nest') organism. The Trans-Organism Biology (TOB) of evolving populations of nested organisms and the Intra-Organism Biology (IOB) of the nest organism affect each other, but the IOB of a nest organism has to describe the TOB of its nested organisms well enough to exclude relevant surprises (e.g., evolution of tumors). Each population of nested organisms needs its own EvoSysBio analysis, where the IOB of the nest organism plays the role of the ecological environment in the TOB of the nested organism. The complex TOB of nested organisms can sometimes be simplified by assuming nested populations are homogeneous and incapable of mutation.
MOCA-LIFT 'Instant' LIFT cartoons	**M**assively **O**versimplified **C**artoonish **A**bstract **LIFT**s are essentially like LIFTs, but without much clarity on how their various dimensions map to reality. Their cartoon-like distortions can be caused by complex transformations, lack of data, imprecise definitions and other problems that are often difficult to resolve. The value of a MOCA-LIFT can range from useless speculation to useful stop-gap (capturing some aspects of reality) to ground-breaking 'Gedankenexperient.' While researchers put in the enormous effort to measure more rigorous LIFTs, they will likely construct increasingly realistic MOCA-LIFTs, since their cartoonish nature facilitates smooth transitions from fact-free figures to high-precision result repositories with varying degrees of usefulness. As a rule of thumb: LIFTs that are (i) not fully defined by measurements or simulations, (ii) are not quantified in defined units, and (iii) do not specify their real-world uncertainty are MOCA-LIFTs (see **Figures 3**, **4**, and **6** for examples).

Notes: A fitness landscape provides an intuitive understanding of how complicated evolutionary mechanisms impact the fitness of an organism. To comprehend the complexities of fitness landscapes and use them to predict the fitness consequences of mutational and environmental change, it is important to understand (i) the concept of an organism as it relates to biology, (ii) how researchers use Incomplete Fitness Traits (IFTs) to construct Landscapes of IFTs (LIFTs) that represent different aspects of the fitness landscape of an organism, and (iii) how IFTs and LIFTs form FCNets, which mediate finely tuned trade-offs in response to the environment. Only when complete FCNets are fully quantified is it possible to compute a complete fitness landscape, which can predict the distributions of phenotypes and fitness from an organism's distributions of genotypes and environments. See Table 3 for the types of LIFTs that can collectively bridge the whole gap from DNA to fitness.

Table 3 **Fitness predictions from genotypes** are, in principle, enabled by the types of **L**andscapes of **I**ncomplete **F**itness **T**raits (LIFTs) shown here

PT: Plane Type	→	***LT: Landscape Type***	→	***HT: Height Type***
Compute: Input type	→	Compute: Function type	→	Compute: Output type
FCNet: causal Node type	→	FCNet: Link type	→	FCNet: consequential Node
More causal IFT type	→	*LIFT: Landscape of IFT type*	→	*More consequential IFT type*
Type of multidimensional point in the causal plane of a FCNet node is given by its input data type that governs height as calculated by its LIFT type.	→	*Type of LIFT that represents a mapping function type that accepts a point in its causal plane as input and computes a consequential height as output. LIFTs define types of links between FCNet nodes in a larger FCNet.*	→	*Type of multidimensional point of consequential height that integrates all effects from replication (with all existing nested levels). It is computed as output type by its LIFT from a given input point in its plane type.*
PT7: Organism life history of fitness traits: survival, reproduction, etc.	→	LT7: **Summarizing** statistics of survival, reproduction, etc. for relevant groups of organisms over a given duration of time in a specified environment	→	HT7: Fitness summary statistics for organism genotypes in specified environments per time interval
PT6: Real-world Incomplete Fitness Traits (RIFTs)	→	LT6: **Balancing** trade-offs in IFT networks of organism life-history and physiology	→	HT6: Organism life history: survival, reproduction, etc.
PT5: Simulated Incomplete Fitness Traits (SIFTs)	→	LT5: **Mapping** simulations (*in silico* IFTs) to observed real-world IFTs	→	HT5: Real-world Incomplete Fitness Traits (RIFTs)
PT4: Time-series of phenotypic traits	→	LT4: **Extracting** fitness relevant traits (IFTs) from time-series analyses	→	HT4: Simulated Incomplete Fitness Traits (SIFTs)
PT3: Molecular functions network	→	LT3: **Simulating** dynamic time-series predictions (over multiple scales) for a given initial state in a given environment	→	HT3: Time-series of phenotypic traits
PT2: Molecular structures	→	LT2: **Abstracting** the structural biology of structure–function relationships	→	HT2: Molecular functions network
PT1: Hereditary information	→	LT1: **Folding** of expressed hereditary information	→	HT1: Molecular structures

Note: All LIFTs contribute some aspect to constructing the full **F**itness **C**ausality **Net**work (FCNet) that governs the dynamic distributions of various incomplete fitness traits of an organism. Each FCNet node connects at least two LIFTs (In → Out; see header row for terminology illustrative for different contexts). The fitness of an individual organism depends on the structure of its FCNet and on its genotype (broadly defined as any hereditary material), its environment (abiotic and biotic), its initial state (immediately after being 'produced'), and the time period over which the expected change in organism numbers is to be measured. Real-world examples exist for all LIFT types in this table, albeit spread across different organisms (see Loewe, 2009). Defining a full FCNet for any *single* organism will be a major milestone for EvoSysBio and requires the computational integration of all LIFT types in this table that are required for representing the organism. These LIFTs require many independent studies of Simulated IFTs (SIFTs) and Real-world IFTs measurements (RIFTs). The huge costs and high risks of pursuing this integrative vision are matched by the high rewards of enabling rational, *in silico* analyses of arbitrary mutations. Hence, such EvoSysBio work is at the core of personalizing medicine and reliably predicting evolution.

Fitness Landscapes Map to Real-World Concepts

Criticism of the notorious lack of quantitative and semantic precision in depictions of fitness landscapes does not imply that they are not real or cannot be defined rigorously.

(i) As introduced above, real-world fitness landscapes *are by definition* all possible states of real-world populations of replicating organisms, which *by definition* are subject to the five fundamental factors of evolution that describe how organisms traverse fitness landscapes.

(ii) *Models* of fitness landscapes *aim to approximate* real-world fitness landscapes by choosing features deemed relevant by modelers; thus, human reconstructions of fitness landscapes are *by definition not perfect*.

(iii) The quality of these approximations is determined by *testing* how useful their predictions and/or insights are for navigating their real-world counterparts.

(iv) Neither existence nor quality of these approximations influences real-world fitness landscapes, as long as they do not affect how humans shape their world.

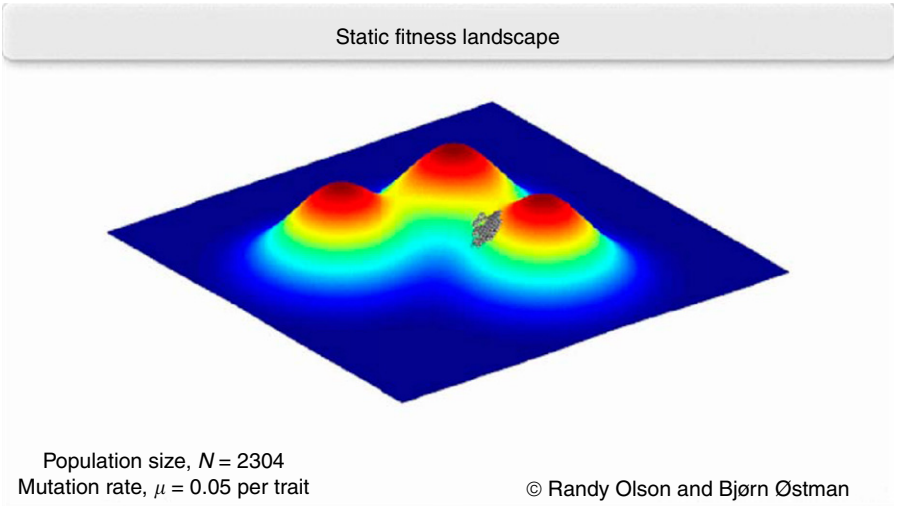

Figure 3 Future EvoSysBio 'flight simulators for fitness landscapes' might provide dynamic overviews of how populations evolve on measured data-rich Landscapes of Incomplete Fitness Traits. This MOCA-LIFT (see **Figure 4**) shows a snapshot from a cartoonish movie of a population that evolves on a static MOCA-LIFT (for more details, see also links in Section Relevant Websites). Picture credits: © Østman and Olson (2014a), reusable under CC-BY-SA 3.0.

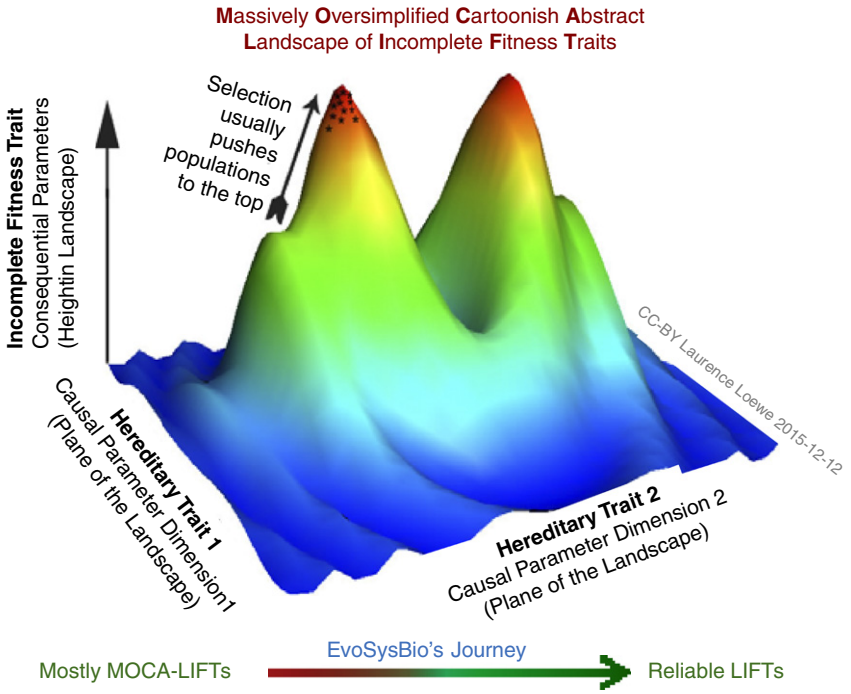

Figure 4 **M**assively **O**versimplified **C**artoonish **A**bstract **L**andscape of **I**ncomplete **F**itness **T**raits. Such a MOCA-LIFT captures the central causality statement of a fitness landscape: each position in the causal plane determines its consequential height. Its value usually ends here, as real-world LIFTs tend to differ substantially. Picture credits: © Laurence Loewe (2015a), reuse under CC-BY 4.0, updated from previous versions (Loewe, 2009, 2012).

(v) Human measuring or managing can severely limit the ability of EvoSysBio to improve model quality if these actions substantially perturb real-world fitness landscapes.

Fitness landscapes play a central role in the EvoSysBio definition because they integrate all fundamental factors of evolution. Quantifying fitness landscapes accurately is a key long-term goal for EvoSysBio (and other systems approaches to genome evolution, even if they have other priorities).

Though compelling, the mechanistic goals of EvoSysBio can be extraordinarily difficult to achieve. In such cases, less-than-ideal fitness landscape definitions can enable important progress. These may (1) *only describe* observed phenomena without requiring explicit rational hypotheses on real-world

causal mechanisms, or (2) are *only system-specific* and so enmeshed with their particular context that abstraction obscures their meaning, or (3) are so *highly abstracted* from the real world that they are essentially void of interpretable biological facts.

How to Avoid Misreading Fitness Landscapes

The following simple principles might help to keep the useful aspects of **fitness** landscapes while reducing the confusion:

1. **Fitness landscapes exist** for all organisms that produce offspring at all nested levels of replication, even if the landscapes are impossibly difficult to define.
2. **Pictures mislead.** A single picture of a fitness landscape is usually misleading, as it can rarely be created without distorting vital views of the underlying model when distilling the potentially many dimensions of a plane and height down to the three dimensions humans are used to.
3. **Uncertainty quantifies accuracy.** As elsewhere, quantifications of fitness landscapes are at most as reliable as the uncertainty quantifications performed for them from diverse perspectives to obtain reliable error bounds. Hence, the qualities of uncertainty measures of a landscape indicate the accuracy with which it was measured.
4. **Fitness has many measures**. The definition of fitness landscapes is intricately linked to the definition of fitness, which has its own challenges. While it first appears easy enough to measure (survival, reproduction), crucial complications appear when the subtle timing and indirect effects of real life are accounted for as well. Life history theory has compiled a substantial body of theory on how multiple traits combine in order to contribute to fitness (Stearns, 1992, 2000; Brommer, 2000; Houle *et al.*, 2011; Gardner, 2015; Gardner and West, 2014).
5. ***Incomplete F*itness *T*raits (IFTs) are easily defined**. The current inability to define or compute *complete* fitness measures does not prevent the definition and measurement of IFTs, which are defined as having at least some probability to impact survival and/or reproduction in at least one known environment (irrespective of whether the traits are continuous or not). Defining such IFTs is comparatively easy, and predicting them computationally, as well as observing them in the lab, is already possible for some IFTs. Thus, researchers can accumulate now the observations and prediction capabilities required for later EvoSysBio analyses.

From MOCA-LIFTs to Reasonable LIFTs

Intuitive appeal with difficulties of measurement and visualization have generated many speculative depictions of 'fitness landscapes'; most are probably misleading and deserve a name that distinguishes them from real-world measurements. Figure 4 shows such an entirely fact-free ***M*assively *O*versimplified *C*artoonish *A*bstract *L*andscape of *I*ncomplete *F*itness *T*raits**, or in short, a **MOCA-LIFT**:

- *Massively Oversimplified*: the *many* dimensions of plane and height are arbitrarily distilled to one or two dimensions, often without defined mapping or appropriate justification;
- *Cartoonish*: the landscape only captures a causality statement; a lack of real-world data precludes any further statements;
- *Abstract*: plane and height do not represent any biological systems in the real world.

Unless spoiled by 'MOCA properties,' LIFTs represent real-world progress in EvoSysBio, as LIFTs measure, model, simulate, and/or summarize real-world biology in a reproducible way:

- *Landscape*: a function that maps a multi-dimensional point in a plane of *more causal* IFTs (input) to its computable multidimensional height, which is a *more consequential* IFT (output);
- *Incomplete*: the recognition that IFTs are not complete and do not even attempt to be; IFTs may or may not affect other traits or be affected by other traits; all LIFT statements are conditional on 'all else being equal';
- *Fitness*: the statement that some aspect of this trait affects survival, replication, or some other evolutionary factor directly or indirectly at least with a small probability in some environments;
- *Trait*: a type of property of an organism; if traits do not affect fitness, they may be only phenotypic (e.g., gene expression without impact on fitness is irrelevant), or neutral (e.g., DNA sequences never expressed and without any impact on fitness).

It often makes more biological sense to investigate LIFTs than to attempt direct predictions of fitness (which often require abstracting too many complex processes at once, increasing the likelihood of failure). At their core, LIFTs can be thought of as the basic building blocks of fitness landscapes; they provide the most direct link between real-world biology and EvoSysBio simulations, either by interpolating real-world measurements or by simulating known processes. Deliberately ignoring the bigger picture of fitness in favor of simplicity makes basic LIFTs much easier to use and provides two additional conceptual advantages, one experimental and one conceptual.

Experimentally, the artificial nature of many LIFTs can remove them far enough from the finely tuned fitness trade-offs that dominate in the wild; it might thus be easier to find IFT mutants that are measurably different from wild-types, enabling tests of *in silico* prediction quality (see Loewe, 2009; Figure 3 there, read IFT for Candidate Fitness Correlate).

Conceptually, large collections of basic building-block LIFTs may facilitate the construction of **F**itness **C**ausality **Net**works (FCNets, see Table 2), which capture all causal influences that govern the expected distribution of fitness values for an individual organism over a given time interval in a given environment. Table 3 gives an overview of the diverse LIFT types and fitness causality node types that enable, in principle, the construction of a full causality chain, which ranges from DNA to fitness. Biological examples for each particular LIFT type have been given elsewhere (see discussion of Table 2 in Loewe, 2009) and details of linking them into full FCNets are beyond the scope of this article.

An alternative to mechanistic predictions of LIFT networks is to observe evolution by empirically measuring the speed at which different genotypes grow in a given environment. Such direct IFT measurements can be conducted for each individual genotype, as has been done for bacterial genotypes with respect to their ability to survive antibiotics (see below, EvoSysBio Milestone 5: Antibiotics Resistance Evolution). Several empirically observed LIFTs (Weinreich *et al.*, 2013) have been compiled for visualization with the MAGELLAN tool (Brouillet *et al.*, 2015). These measurements can provide important high-resolution views of very small local LIFT areas, assuming the context of otherwise constant fitness landscapes.

It is also possible to mix empirical observations of IFTs with statistical modeling in order to predict fitness landscapes with very many points from measurements of much fewer genotypes. As more big data sets become available, this approach becomes increasingly powerful, fueling a revival of the fitness landscape paradigm (Schuster, 2012). It has been used to computationally explore the complexity of HIV for *in vitro* LIFTs (Kouyos *et al.*, 2012). Statistical methods and quasi-species theory have also been employed to infer fitness landscapes *in vivo* using sequenced HIV samples from patients (Seifert *et al.*, 2015).

As evolutionary geneticists have struggled with the question of how to best capture relevant glimpses of fitness landscapes, they have developed a number of useful abstractions. Some of these quantify particular aspects of fitness landscapes and build on formalisms, which produce general complex landscapes of different types (Orr, 2005; Gravner *et al.*, 2007). Others analyze fitness landscapes from particular angles, including speciation (Gavrilets, 1997, 2004), game theory (Nowak and Sigmund, 2004), and more (e.g., Svensson and Calsbeek, 2012; Richter and Engelbrecht, 2014). Also, evolutionary geneticists have defined evolutionary parameters that, in principle, could be measured in the real world or be computed from fully known fitness landscapes. These provide excellent summaries of particular aspects of fitness landscapes.

Abstractions for Aspects of Fitness Landscapes

The complexity of multi-dimensional fitness landscapes and the notorious difficulties of exploring them have long been motivating evolutionary biologists to develop concepts that quantify more limited aspects of fitness landscapes, sometimes empirically or without requiring a full understanding. Such incomplete empirical summary statistics of fitness landscapes include:

- *distributions of mutational effects on fitness*: pick a point on the landscape as wildtype starting point, jump into all directions that represent genotype changes from naturally occurring mutations, then compare fitness to observe selection coefficients (e.g., Schenk *et al.*, 2012; Eyre-Walker and Keightley, 2007; Loewe and Charlesworth, 2006; Loewe and Hillston, 2008);
- *epistasis*: interactions between mutations that increase or decrease the effects of additional mutations play a major role in evolution, but nomenclature can be confusing (Wolf *et al.*, 2000; Phillips, 2008; Loewe and Hill, 2010a); epistasis captures the gene-regulatory and biochemical reaction network complexity of IOB (Phillips, 2008), so it is no surprise that higher-order epistasis can result in surprising changes of fitness (Weinreich *et al.*, 2013); it can sometimes be measured (Schenk *et al.*, 2012; Schenk and de Visser, 2013); it can determine the accessibility of certain evolutionary paths (Poelwijk *et al.*, 2007; Weinreich *et al.*, 2006) and affect robustness, even within a protein (Bershtein *et al.*, 2006); epistasis is also important for understanding the evolution of antibiotic resistance (e.g., MacLean *et al.*, 2010; Hall and MacLean, 2011; Schenk *et al.*, 2012; Schenk and de Visser, 2013);
- *robustness*: helps developmental or simpler processes produce patterns that reduce observable changes in phenotypes (e.g., Wagner, 2014, 2012; Payne and Wagner, 2014);
- *fragility* or *capacitance*: is the opposite of *robustness*; increases variability beyond usual amounts (e.g., Bergman and Siegal, 2003).

These measures can be used for investigating the evolvability of a system (e.g., Wagner, 2005) or its mechanisms of adaptation (e.g., Wagner, 2011). More on summary statistics of fitness landscapes can be found elsewhere (see Loewe, 2009 and in this Encyclopedia).

Practical Relevance of EvoSysBio

Ideas for applying EvoSysBio to solve practical problems are easy to conceive. From agriculture to medicine to zoos, replicating organisms are everywhere. For some, replication is desirable (e.g., rare species in zoos), for others not (e.g., cancer cells, agricultural pests, superbugs). Humans can sometimes shape the impact of these organisms as planned by increasing growth of desired organisms and blocking growth of undesired ones. Success usually requires the ability to predict growth with some reliability, which in turn often requires a deeper understanding of evolution, as also needed for computationally exploring potential management decisions and their side effects. EvoSysBio models can help by providing a rich framework that facilitates the integration of all important aspects of IOB, EOB, PGB, and TOB (see Table 1). If not overwhelmed by statistical prediction errors or numerical rounding errors, such mechanistic models might reliably predict important practical aspects of very rare, high-impact events, such as the extinction of endangered species, catastrophic virus epidemics, the evolution of superbugs resistant to all known antibiotics, or the origin of tumors.

The next milestones on the long journey to formal EvoSysBio analyses mirror many models in mixing mechanistic and descriptive aspects. Using their motivating questions and chosen levels of abstractions, most models combine known cause and effect mechanisms with a coarse-grained phenomenological basis that merely describes statistical estimates of empirical data. For example, modeling metabolic regulation neither requires a simulation of the full quantum mechanics of ribosomes (too fine-grained) nor empirically observed cell-division rates (too coarse-grained). Summarizing individuals as fitness values is the ultimate coarse-graining in IOB; however, to merge IOB and TOB requires the inclusion of substantially more details than currently possible. The following milestones mark important points in building the capabilities for such broad integration.

EvoSysBio Milestone 1: Observed LIFTs

This marks the definition and observation of a new consequential IFT for a set of diverse causal traits that mechanistically specify how consequential IFTs are computed from causal traits, irrespective of how many LIFT types from **Table 3** are implicitly integrated. For example, consider the low probability that light-colored **mice** will be caught by birds of prey on sandy hills (Linnen *et al.*, 2009). It is easy to map genotypes to phenotypes if coat color is controlled by few known genes and mutations of coat color can be recognized in DNA sequences. Thus, a LIFT for survival in such an environment can be trivial to predict if good measurements of predation risks are available for different coat colors. Full measurements of fitness are much more complicated, as mice can die from many causes and reproductive success requires essentially a prediction of everything a mouse can do in that environment. The complexities of such measurements are beyond what most researchers would be willing to contemplate, let alone adding similarly complex models for the corresponding birds of prey, whose survival may depend on their ability to learn how to detect the mice (adding complex neuronal and evolutionary feedback loops). This example illustrates key reasons behind the 'Incomplete' in IFTs: measurements of mouse survival are clearly fitness relevant; yet they are also clearly incomplete and need to be complemented by additional studies that might never be conducted if 'fitness has been measured in this mouse.'

A simpler example uses flux-balance analysis to predict *in silico* how *Escherichia coli* evolves by adapting to a certain environment (Edwards *et al.*, 2001). It only needs a network of relevant metabolic reaction stoichiometries and the assumption of flux-balance equilibrium (influx = efflux everywhere). Such models are easily coupled with genomic datasets that indicate the presence of genes for particular enzymes that catalyze certain metabolic reactions; thus, inferring relevant metabolic networks becomes much easier. Additional empirically observed LIFTs are listed elsewhere (Brouillet *et al.*, 2015).

EvoSysBio Milestone 2: Fragmented LIFTs

Biology has now conceptually mapped much of the most causal LIFTs in the FCNet of model organisms (DNA sequences available). It has also followed diverse LIFTs in the network, spanning all the way to direct fitness contributions. At least since 2009, it has become possible to provide specific realistic examples for *all* LIFT types specified in **Table 3** (see discussion of **Table 2** in Loewe, 2009). Thus, each critical step on the full path from DNA to fitness can, in principle, be modeled; such LIFT-type models have been developed independently in different model-organisms, greatly complicating a potential integration. As biological research continues, the addition of increasing numbers of LIFTs will simply connect different types of LIFTs in the same organism.

EvoSysBio Milestone 3: Simulate a Whole Cell

While the first two milestones were passed some time ago, somewhere on the EvoSysBio journey toward integrating IOB and TOB it must become possible to mechanistically simulate a whole cell in a simple lab environment. This milestone is well aligned with the goal of Evolutionary Cell Biology (Lynch *et al.*, 2014), which requires the quantitative integration of a very large number of diverse quantitative models of cellular subsystems. It has recently been demonstrated that a very simple (but complete) single cell in a simple growth medium can be simulated at the level of biochemical interaction over a whole cell cycle (Karr *et al.*, 2012), though much work remains before such simulations become robust enough and available for more complicated cells. While organizing and curating the thousands of parameters required for simulating the complete biochemical reaction network of a single cell remains challenging (Macklin *et al.*, 2014), obtaining reasonable values for them can be even harder (Karr *et al.*, 2015). New experimental methods provide a wealth of diverse information about cellular processes that was previously difficult to conceive: genomic ontologies are being constructed to list all genes, types of RNAs and proteins (many with functional annotations); advances in microscopy are approaching imaging at atomic resolution in cells (Kuhlbrandt, 2014); fluorescent proteins allow the recording of live single-cell time series of intracellular amounts or tracking the movement of individual molecules. In fact, for some types of cells, it is no longer clear if EvoSysBio is more limited by the need to observe relevant data or the need to organize, interpret, and integrate data that has already been collected (Macklin *et al.*, 2014). This growing need for more efficient data analysis can also be seen in sequencing, where the cost of analysis can substantially exceed the cost of obtaining raw data.

EvoSysBio Milestone 4: Predict Mouse Cancer

Successfully predicting the growth of diverse, complex cells on controlled growth media might encourage addressing the challenges posed by more complex ecologies. The need to understand the full-scale ecology of an animal or plant can be postponed by focusing on the small-scale 'internal ecology' of the body of a mouse from the perspective of cancer cells. In cancer cell biology, cells cannot grow outside their 'mouse-body-ecosystem'; from an experimentalist perspective, mice with known cancer mutations are about as well-controlled and well-studied as ecosystems can be. While predicting the full IOB of a mouse will remain very unlikely for some time, it is easily replicated with high accuracy by growing more mice, all of which can be analyzed with the tools of modern biology. Thus, in comparison to the full-scale EOB of wild mice, it is relatively easy to quantify the IOB of mice for the purposes of describing the environment that controls much of the possibilities of mouse cancer cells. Such mice facilitate addressing a number of interesting challenges in EvoSysBio and cancer research, simply because they can be so extraordinarily well characterized. Given the big interest in mouse cancer research, important breakthroughs are more likely to occur here first.

Cancer therapy resistance remains the most difficult challenge in the diagnosis and treatment of cancer. It is enabled by diverse populations of cancer cells, some of which keep surviving therapy to grow back. Populations of cancer cells are, in principle, governed by the same complex TOB processes studied in ecology and evolutionary biology. Measurements of survival and reproduction rates of cells enable

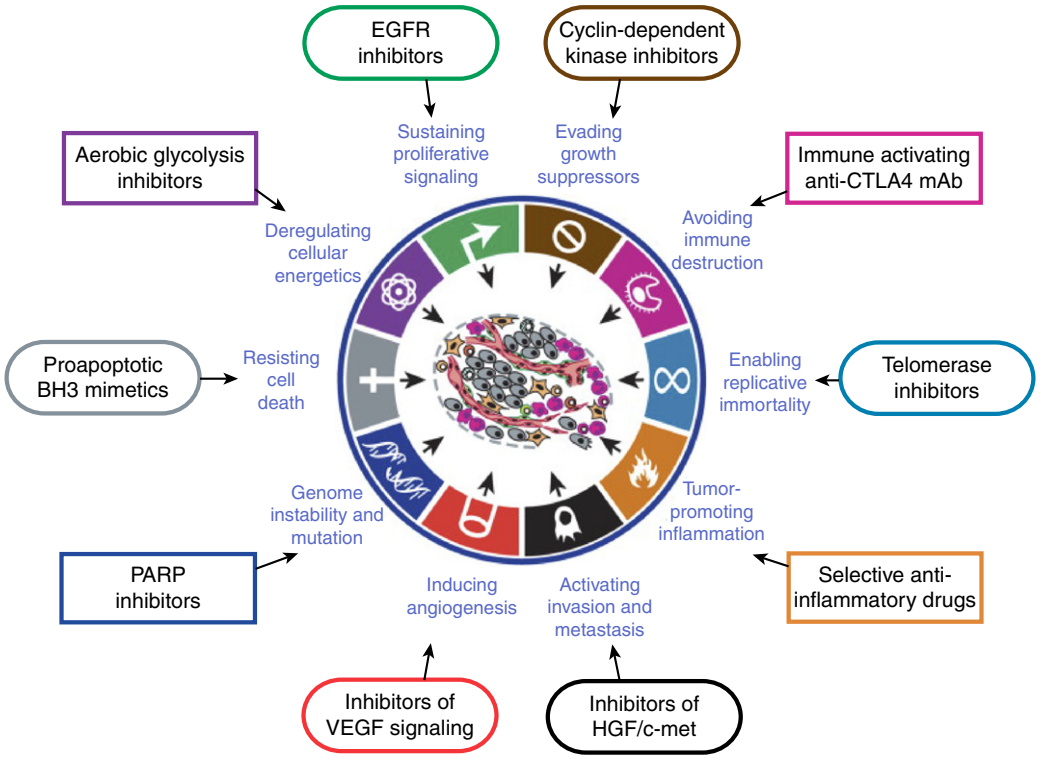

Figure 5 The hallmarks of cancer have strong links to either survival incomplete fitness traits (IFTs) or reproductive IFTs, hence the evolutionary processes triggered by cancer cell biology are interesting test cases for EvoSysBio. Picture credits: Hanahan and Weinberg (2011) © Elsevier, reuse now allowed under CC-BY-SA 4.0 (http://creativecommons.org/licenses/by-sa/4.0/).

predicting evolutionary outcomes of a population in a given environment. Survival of cancer cells in therapy depends on the dynamics of intracellular reaction networks, which can, in principle, be studied with the modeling tools of CSysBio. EvoSysBio aims to combine the theoretical modeling with the real-world observations needed to simulate evolutionary outcomes for cancer populations with increasing precision.

Cancer is an evolutionary process of a population of cells that replicate too much and can grow outside of their normal boundaries. A substantial number of survival and reproductive traits in cancer cells provide a target for natural selection among them (see **Figure 5**): Evolutionary factors like surviving attacks from the immune system, mutating, migrating to new tissues, and other such traits have vexed cancer biologists for a long time (Hanahan and Weinberg, 2011). It is not difficult to define corresponding IFTs for cancer cells and all fundamental factors of evolution are active (Gerlinger *et al.*, 2014).

Mouse cancer as a milestone for EvoSysBio is reasonable due to high independent interest, a wealth of existing information, and readily applicable methodologies. Once it becomes routinely possible to simulate the biochemistry of whole cells with reasonable accuracy, these techniques could be used to quantify relevant mouse IOB and define the TOB for a type of mouse cancer that is comparatively well understood. It is relatively easy to compare predicted numbers and sizes of a given tumor type with actual observations. This could even be done in many replicate mice to explore the impact of chance and necessity in cancer evolution at a very fine-grained level. Such analyses are impossible in large-scale ecology, since 're-running' the world is impossible. Mouse cancer provides unique opportunities for learning about the dynamic aspects of LIFTs in a context where real-world checks are conceivable, as cancer cells are affected by dynamics in their environment (rhythms of mouse life; attempts to cure cancer, etc.) and in return affect their environment (eventually killing the mouse). This might eventually allow turning the dynamic MOCA-LIFT in **Figure 6** into a LIFT (Movie 2).

Ongoing discussions between evolutionary biology and cancer biology (Horne *et al.*, 2015) include work in evolutionary modeling (Nagy, 2005), ecology (Korolev *et al.*, 2014), investigations of life-history trade-offs (Aktipis *et al.*, 2013), evidence for positive selection (Crespi and Summers, 2006), evidence for the role of mutations during development (Frank, 2010), interactions between cancer and viruses (Brandon Ogbunugafor *et al.*, 2013), and epigenetics (Swanton and Beck, 2014).

EvoSysBio Milestone 5: Antibiotics Resistance Evolution

The first part of this milestone predicts how fast bacterial model-organism cultures evolve resistance to well-understood antibiotics under defined laboratory conditions without nested organisms, a challenge comparable to Milestone 3. Adding nested organisms increases difficulties to **the level of** Milestone 4 by requiring the specification of a TOB for the bacteria. However, in simple applied real-world contexts, it is no longer possible to repeat the 'world history' for improving the model

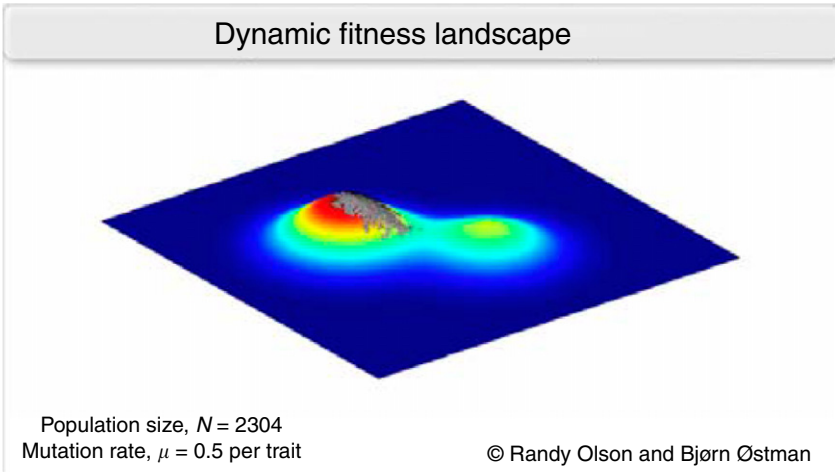

Figure 6 Fitness always depends on the environment. Frequent environmental changes can trigger perpetual changes in fitness, resulting in a constant need for adaptation. Dynamically changing Landscapes of Incomplete Fitness Traits pose additional challenges to EvoSysBio 'flight simulators,' which now also have to predict environmental properties and how they might be affected by populations of organisms over time. Here a snapshot is shown from a cartoonish movie of a population that evolves on a dynamic MOCA-LIFT (for more details, see also links in Section Relevant Websites). Picture credits: © Østman and Olson (2014c), reuse under CC-BY-SA 3.0.

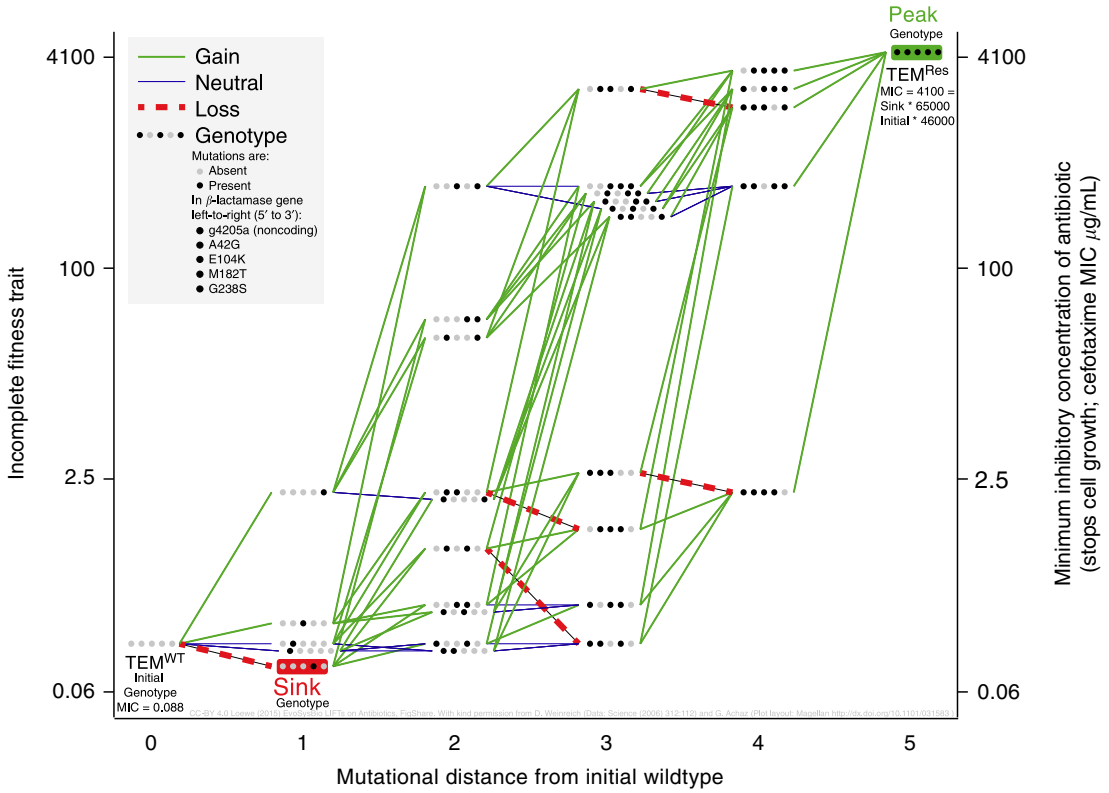

Figure 7 Evolution can take different paths to increase an IFT, such as in this experimentally observed LIFT snapshot of antibiotics resistance from five point mutations in a bacterial gene, where they can accumulate from the original TEM^{WT} genotype to the TEM^{Res} with different trajectories of fitness increases, which are followed with different probabilities as shown elsewhere (Weinreich *et al.*, 2006; DePristo *et al.*, 2007). This LIFT uses MIC, a cellular IFT that depends on a corresponding protein based LIFT where IFTs are determined by molecular features, which can be measured independently (Meini *et al.*, 2015). Picture credits: © Laurence Loewe (2015b), reusable under CC-BY 4.0. Data (Weinreich *et al.*, 2006) was plotted by the MAGELLAN fitness landscape mapping tool (Brouillet *et al.*, 2015), both shared with kind permission of Daniel Weinreich and the MAGELLAN authors.

(tumor evolution is repeatable by using new mice; but hospitals are difficult to sterilize, turning their resistance evolution into a historic process). Nested organisms, reservoirs, and very complex ecologies further complicate the picture by introducing many unknowns of potential importance. Unfortunately, these difficulties are matched by the urgency of the problem.

Prescribed doses of antibiotics have been climbing and now some bacterial strains are resistant to all known antibiotics. The evolution of antibiotic resistant bacteria has been discussed since antibiotics were first used (Neu, 1992; Normark and Normark, 2002; Choffnes *et al.*, 2010; Perros, 2015; Baker, 2015): How can we use these antimicrobial 'super-drugs' in a way that reduces the ability of 'superbugs' to evolve complete resistance? If we do not succeed, bacterial infections will become more deadly until one of the biggest medical advances of the twentieth century will have lost practical relevance. Predicting antibiotic resistance evolution (Martinez *et al.*, 2007) might allow us to find ways to use antibiotics that minimize the evolution of resistance.

Challenges of dynamic, multi-level simulations of evolution need to be mastered for truly understanding antibiotics resistance evolution. At the molecular level, questions include how many mutations a bacterial protein needs to accumulate to confer a higher level of resistance to the cell that produced it. The molecular features of such a protein can be interpreted as IFTs that define a protein-based LIFT (Meini *et al.*, 2015). The interplay of new mutations with the other content in crowded cells leads to an IFT at the cellular level: the Minimum Inhibitory Concentration (MIC) of an antibiotic above which a given bacterial cell is not longer able to grow. **Figure 7** shows the results of experimentally measuring a small, but combinatorially complete LIFT for an antibiotic-based IFT defined by a corresponding MIC (Weinreich *et al.*, 2006). At intermediate levels, events in organisms need to be modeled, since bacteria evolve during an infection. On geographic scales, the diverse use of antibiotics contributes to resistance evolution in many unexpected places (e.g., soil in agriculture, biofilms in hospitals). Despite progress, it is not clear how to optimize the use of antibiotics overall in hospitals and agriculture (where infected humans can carry resistant super-bugs between both, unwittingly exposing others). International travel adds further complications by moving infections over large distances. The challenges of both dynamic and static fitness landscapes (**Figures 6** and **3**) apply to antibiotics resistance evolution, as changes in antibiotics usage policies can easily generate either.

Complex evolutionary phenomena, such as epistasis, mutation rates in the stationary phase of bacteria and many other effects are important for understanding the evolution of antibiotics resistance (Loewe *et al.*, 2003; MacLean *et al.*, 2010; Hall and MacLean, 2011; Schenk and de Visser, 2013; DePristo *et al.*, 2007; Poelwijk *et al.*, 2007; Weinreich and Knies, 2013). For example, resistant bacteria often pay a fitness cost unless it is mitigated by compensatory mutations (Andersson, 2006). Unfortunately, antibiotics are often used in a way that facilitates the evolution of antibiotics resistance by creating environments where sublethal concentrations of antibiotics can select for resistant bacteria over longer periods of time (e.g., in sewers or agriculture; see **Figure 8**, (Gullberg *et al.*, 2011)). To preserve one of the biggest medical success stories of the twentieth century requires continually solving the riddles that bacteria pose by evolving antibiotics resistance (Choffnes *et al.*, 2010; Perros, 2015; Baker, 2015). Given that prokaryotes rule the world (by numbers and by speed of growth), it will require the best, most precise, and most integrated understanding of evolution to outsmart them – with the help of many computers.

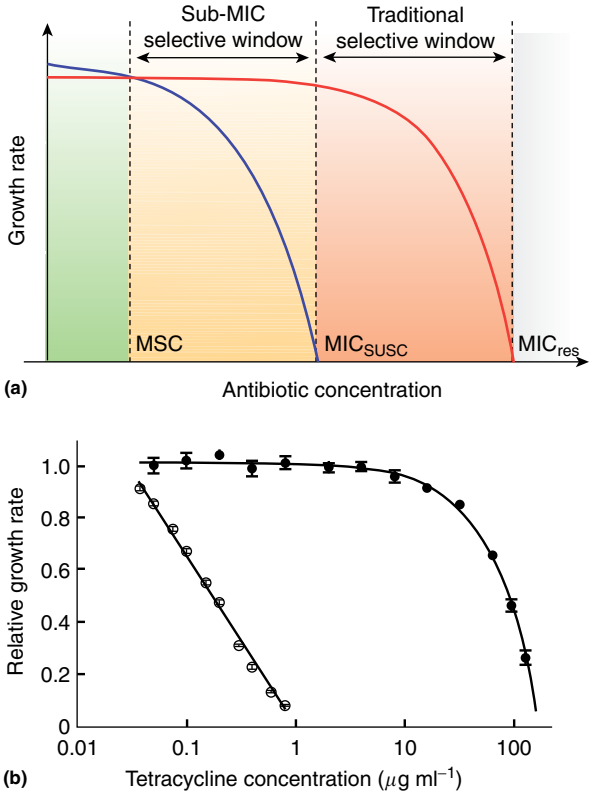

Figure 8 Small selective advantages can combine over a longer period of time to substantially accelerate antibiotics resistance evolution (Gullberg *et al.*, 2011). (a) Schematic overview, *MIC*: Minimal Inhibitory Concentration for susceptible (*susc*) and resistant (*res*) bacteria, *MSC*: Minimal Selective Concentration. (b) Experimental measurements for the antibiotic tetracycline. Picture credits: © Gullberg *et al.* (2011), reusable under CC-BY.

Conclusions

Even though the New Evolutionary Synthesis started in the 1920s and biological progress has continued at a phenomenal pace, much biology remains to be discovered and integrated. The New Synthesis is being renewed each day when researchers integrate new results into its framework through relentless synthesis (Wray *et al.*, 2014). The explosion of expertise on evolution and the complexity of systems science require reliable computational tools to give researchers a chance to keep up with the pace of the New Synthesis. Success critically depends on the strength of underpinning abstractions, which may be measured by intangibles such as conceptual clarity, completeness, simplicity, and elegance. The power of good abstractions is the best defense against the swamp of

complexity that otherwise mires researchers in endlessly redundant repeats of researching, reinventing, and rediscovering. There is nothing more practical than a good theory.

The ambitious aims of EvoSysBio for understanding and reliably predicting evolution depend on accelerating the pace of the relentless New Evolutionary Synthesis to which EvoSysBio is ultimately contributing. This can be done by making it easier to connect the five fundamental factors of evolution to results from models of complex Intra-Organism and Trans-Organism Biology. Toward this end, this article provides a high-level overview of FCNets and LIFTs, but many details remain to be worked out.

The relentless New Synthesis can benefit from lessons learned by programmers in their struggles in the swamp of complexity: aim for 'as simple as possible, but not simpler' (Raymond, 2003). To make EvoSysBio efficient, this view of Occam's Razor needs to inspire new computational approaches for knowledge organization, provenance, modeling, reliability, precise uncertainty quantification, ease of automation, abstraction management, automatic testing, efficient debugging, and reproducibility. Without such innovations, EvoSysBio researchers will either get stuck in the complexity swamp of constructing FCNets (and debugging their dependencies) or get lost in the fog of finding signals drowned by noise (due to missing uncertainty quantification).

Biology's complexity is so pervasive that efficient approaches for solving these problems often require semantic architectures with the strength of general programming languages that can integrate most biological research, if not all. Developing such general semantics is usually slow and challenging, but enables great leaps forward once the right concepts are ready for automation. Given the slow pace of developing semantics and the complexity of evolution, it may take ≥ 30 years until integrated computational pipelines can enable the use of all state-of-the-art expertise to mechanistically predict the effects of unknown mutations in well-studied model organisms. Analyzing resulting fitness landscapes with interactive 'multidimensional flight simulators' may sound like science fiction today – perhaps like 'population genomics' would have sounded in the 1970s. Yet it took only about 30 years to go from a method of DNA sequencing to population genomics. Maybe it is possible to start transitioning from a formal definition of EvoSysBio to usable flight simulators for fitness landscapes as the New Evolutionary Synthesis approaches its 100th year of relentless integration service. A bit of strategic long-term thinking might help to avoid swamps and fogs to make evolutionary research more efficient in the long run.

Transposable Elements, Population Genetics of

J Blumenstiel, University of Kansas, Lawrence, KS, USA

Glossary

Beta distribution A continuous probability distribution, between 0 and 1, whose shape is determined by two parameters, α and β.

Gamma function A generalization of the factorial function, allowing for non-integer numbers.

Hill–Robertson effect The phenomenon in which the efficacy of selection acting on an allele is reduced by genetic linkage to a locus that is also the target of selection.

Muller's ratchet The accumulation of deleterious mutations that occurs in a finite population in the absence of recombination. In a finite, asexual population, fitness will decline due to stochastic loss of the most fit genotype that cannot be recovered by recombination.

Rolling circle amplification A mechanism of TE amplification in which a circularized DNA molecule is used as a repeated template for the generation of multiple DNA copies.

Synergistic epistasis A form of fitness function in which the fitness effects of additional mutations are stronger than the prior ones.

Introduction

Transposable elements (TEs) are selfish elements, typically the size of a gene, that reside in genomes and encode the machinery of their own proliferation. There are two dominant classes of TEs: Retrotransposons and DNA transposons (Figure 1). Autonomous retrotransposons are commonly designated 'copy-and-paste' elements. They encode reverse transcriptase and generate new DNA insertions off an RNA template either in the cytoplasm, in the case of long terminal repeat (LTR) elements, or in the nucleus, in the case of non-LTR elements. Because they replicate via an RNA intermediate, retrotransposons are capable of making many copies of a single insertion. DNA transposons replicate via DNA intermediates and the most well-understood class of DNA transposons are the 'cut-and-paste' transposons. Autonomous cut-and-paste'

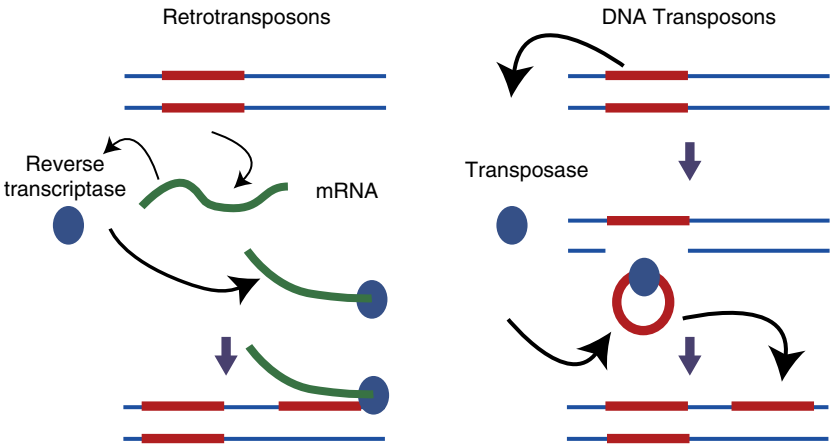

Figure 1 Most transposable elements can be classified as either retrotransposons or DNA transposons. 'Copy-and-paste' retrotransposons encode reverse transcriptase and can copy themselves via cDNA. 'Cut-and-paste' DNA transposons encode transposase and can increase in copy number when transposon excisions are repaired by the host repair machinery using retained copies as a template.

transposons code for transposase proteins that excise and reinsert DNA elements elsewhere in the genome. Such elements are able to proliferate in genomes when the gaps left by excised copies are refilled by the host DNA repair machinery using sequences that correspond to retained insertions. A second poorly understood class of DNA transposon known as a *Helitron* does not proliferate through a 'cut-and-paste' mechanism. Rather, such elements proliferate through rolling circle amplification (Kapitonov and Jurka, 2007).

Across species, TEs play a significant role in determining differences in genome size. For example, salamanders are known for some of the largest genome sizes and much of this can be attributed to significantly greater numbers of retrotransposons compared to other vertebrates (Metcalfe and Casane, 2013; Sun *et al.*, 2012). TE insertions also contribute significantly to variation between individuals within species because TE insertions are frequently polymorphic within populations. These polymorphic insertions may disrupt gene function and be harmful, but occasionally they may be beneficial. It also appears that TEs play an important function in shaping the evolution of gene function and gene networks. For example, the V(D)J recombination mechanism in the immune system evolved by taking advantage of transposase encoded by a DNA transposon (Hencken *et al.*, 2012).

Genetic analysis in maize by Barbara McClintock was the first work to identify TEs. After their molecular characterization in the late 1960s and through the 1970s, the dynamics of TE proliferation in species became of significant interest because it was clear that the genome could no longer be viewed as static. Rather, genomes were shaped by dynamic processes of TE mobilization within and across generations. Moreover, TEs provided an explanation for the C-value paradox, the observation that genome size does not correlate with organismal complexity. The population dynamics and genetics of transposable elements became a topic of significant interest in the early 1980s and continues to this day as genome sequencing has revealed significant complexity in TE dynamics within species.

Critical Parameters and the Role of Sex and Recombination

A central question driving population genetics research in transposable elements is: What determines variation in TE proliferation in populations? Answering this question may allow us to understand why TE profiles differ greatly among species. There are several critical parameters to consider: the rate that TEs enter genomes, the rate of movement (transposition), host mechanisms that modulate the rate of transposition, the strength and form of selection acting on TEs, the population size of the host, and the amount of recombination in the genome. The latter parameter – the amount of recombination – is critical. This is because in species with effectively no recombination – either due to asexuality or complete selfing – TEs are unlikely to spread because a lack of genetic exchange means that TEs cannot escape the genome in which they reside (Hickey, 1982; Charlesworth and Charlesworth, 1983). In species with no sex at all, the fate of TEs is completely determined by the success of the clonal host lineage. Clonal lineages lacking harmful TEs will outcompete clonal lineages that carry TEs, thus jointly driving TE lineages residing within asexual lineages to extinction. In contrast, sex and sexual reproduction allow TEs to proliferate within species even if they are harmful. This fact was first pointed out by Donal Hickey in 1982 (Hickey, 1982). A selfish element may proliferate within a species, even if detrimental, if the rate of movement to new genomes through sexual reproduction is greater than the rate of removal due to selection. More generally, the rate of recombination plays a key role in determining the fate of TEs because linkage leads to an association between original insertions and potentially harmful descendant copies (Charlesworth and Charlesworth, 1983). When the rate of recombination is low, selection can limit the spread of an original insertion because it will become linked to the harmful mutations that it causes. When the rate of recombination is high, harmful descendant insertions are uncoupled from progenitor copies, allowing progenitor copies greater opportunity to make new copies.

While recombination and sex are critical for the spread of TEs from genome to genome, recombination can jointly play an important role in limiting the increase of individual insertion alleles in populations that already carry a burden of elements. This is because asexual lineages in finite populations are susceptible to Muller's ratchet. When a sexual population undergoes a transition to asexuality, all individuals may carry proliferating elements that have high transposition rates. However, in the absence of sex, recombination cannot reestablish insertion free chromosomes. Since TE lineages will continue to proliferate, newly asexual species are likely to experience a great increase in copy number. In fact, simulations have shown that this proliferation can become unbounded, likely driving asexual species to extinction when populations are small (Dolgin and Charlesworth, 2006).

This effect can also be seen in regions of the genome with low recombination rates. Since Hill–Robertson effects can limit the efficacy of selection where recombination is low, regions of the genome with little exchange are also expected to accumulate TE insertions. This has been born out by simulation (Dolgin and Charlesworth, 2008) and is also clearly seen in empirical analysis of genomes. For example, in *Drosophila*, there is no recombination in males and neo-Y chromosomes that never recombine quickly accumulate TE insertions (Bachtrog and Charlesworth, 2002).

The Equilibrium Model of TE Population Genetics

Assuming an infinite population size, one may ask what allows TEs to proliferate and what limits their spread. Without constraint on copy number, we might expect TEs to amplify exponentially and entirely fill the genomes they reside in. This is not plausible, so we may consider two forms of constraint that limit unbounded TE proliferation – a diminishing transposition rate and natural selection against TE insertions.

Does a Diminishing Transposition Rate Constrain TE Proliferation?

Evidence suggests that the per copy transposition rate is not independent of copy number. With increasing numbers of TEs,

the per insertion transposition rate may decrease. Mechanistically, this form of regulated transposition may be due to saturation of the transposition machinery, host defense mechanisms that limit TE spread or encoded TE self-regulation. If we consider a transposition rate that decreases with copy number, is an equilibrium possible without selection?

Considering the average number of elements in each individual (Charlesworth and Charlesworth, 1983; Charlesworth and Langley, 1989) equal to $\overline{n}$, the per generation change in copy number is given by:

$$\Delta\overline{n} \approx \overline{n}(u_{\overline{n}} - v_{\overline{n}})$$

where u_n and v_n are the respective per copy transposition rates and excision rates of insertions in an individual with n copies. An equilibrium will be achieved when the transposition rate equals the excision rate since the rate of increase will be equal to the rate of loss. However, there is little evidence that the rate of excision (which is mostly relevant to DNA transposons that encode transposase) would ever equal the rate of transposition. Most evidence shows that the rate of excision is likely quite low. For this reason, it is unlikely that a diminishing transposition rate with increasing copy number would be sufficient to entirely constrain TE proliferation. Instead, another force is required to limit unbound TE proliferation. This force is most likely natural selection.

How Can Selection Prevent Runaway TE Proliferation?

In 1983 Brian Charlesworth and Deborah Charlesworth developed the standard model for TE dynamics with selection that allows us to determine how an equilibrium may be established when the rate of transposition is greater than the rate of excision (Charlesworth and Charlesworth, 1983). To do so, they used the theory of selection on a quantitative trait (see Charlesworth and Charlesworth, 2010, p. 579) to show that the selective change in the mean number of elements per individual $\overline{n}$ is given by:

$$\Delta\overline{n} \approx V_n \frac{\partial \ln \overline{w}}{\partial \overline{n}}$$

where V_n is the variance in copy number and $\frac{\partial \ln \overline{w}}{\partial \overline{n}}$ is the derivative of log fitness w with respect to $\overline{n}$. The interpretation here is that the mean number of elements per individual is a quantitative trait and the rate of removal is equal to the variance in copy number multiplied by the slope of the log-fitness function, which indicates how strongly selection is acting against insertions in individuals with n copies. If we assume that the rate of recombination is sufficient such that linkage disequilibrium between elements can be ignored and that the frequency of each insertion is low enough, it can be shown that copy number is Poisson distributed, with variance simply equal to the mean. Thus, also including the addition of new elements arising from the excess of transposition over excision, the change of copy number is given by (Charlesworth and Charlesworth, 1983):

$$\Delta\overline{n} \approx \overline{n} \frac{\partial \ln \overline{w}}{\partial \overline{n}} + \overline{n}(u_{\overline{n}} - v_{\overline{n}})$$

and an equilibrium is established when

$$-\frac{\partial \ln \overline{w}}{\partial \overline{n}} = u_{\overline{n}} - v_{\overline{n}}$$

Stability in this equilibrium, in which TEs are maintained in the population, will be obtained when

$$\frac{-1}{\hat{n}} < \frac{\partial^2 \ln \hat{w}}{\partial \hat{n}^2} < 0$$

Here one can see that the second derivative of the log-fitness function at equilibrium must be less than zero. In other words, there must be synergistic epistasis, where the log-fitness function is concave, or decreasing more sharply than linearly, at the equilibrium point for copy number. Additional copies are required to decrease fitness by an increasing magnitude at equilibrium. This balance can be understood given the fact that with even a modest transposition rate, the rate of increase of insertions is exponential when there is no selection. An increasing strength of selection acting against increasing TE copy number is required to limit TEs that are exponentially proliferating.

Behavior of Insertions in a Finite Population

The analysis given above establishes the equilibrium copy number in an infinite population, but it does not describe the dynamics of insertions that might be expected to drift to moderate frequency in finite populations. Here, Charlesworth and Charlesworth (Charlesworth and Charlesworth, 1983) also described the steady-state distribution for TE insertions that are selected against, but for which drift may allow an increase to modest frequency. This steady-state distribution $\phi(x)$ is approximated by a beta distribution for which the two shape parameters correspond to the joint effects of transposition and drift (α) and excision and selection coupled with drift (β):

$$\alpha = \frac{4N_e u\hat{n}}{T - \hat{n}}$$

$$\beta = 4N_e(s + v)$$

where T is the number of possible sites in the genome for inserts, u and v are transposition and excision rates respectively, and s is the selection parameter equal to:

$$-\frac{\partial \ln \hat{w}}{\partial \hat{n}}$$

when the equilibrium copy number, $\hat{n}$, is obtained.

This gives

$$\phi(x) \approx \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha - 1}(1 - x)^{\beta - 1}$$

where Γ is the gamma function.

The influence of the coupled parameter β – through either the effects of drift in smaller population sizes or stronger selection – can be seen in **Figure 2**. When β is high, selection is stronger and elements only segregate at low frequencies. As β decreases, the stationary distribution shifts and some elements can fix. One may fit observed TE insertions frequencies from natural populations to obtain estimates of β. This has been fruitful in *Drosophila* where the site frequencies of TE insertions

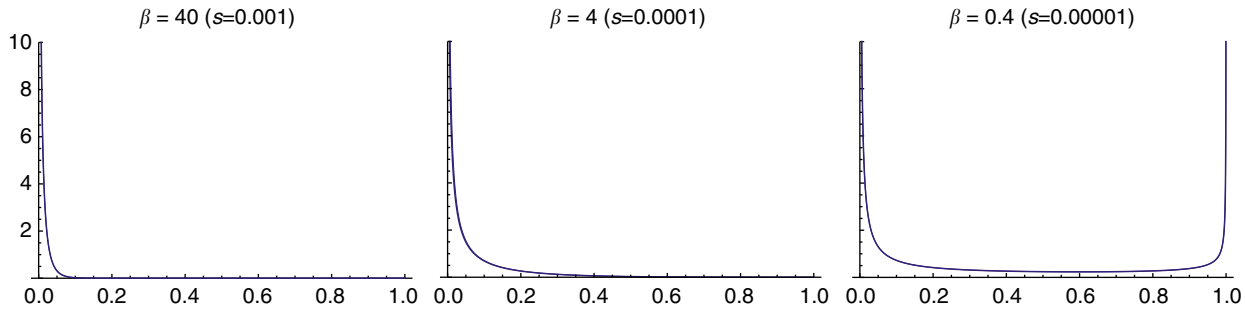

Figure 2 The equilibrium frequency distribution for deleterious TE insertions in a finite population. The β term captures the selection coefficient of insertions. With higher values of β, insertions remain at low frequency. With lower values of β, selection is weaker and some are allowed to fix.

are typically very low and estimates of β can be above 1 (Charlesworth and Langley, 1989). However, in other species, insertion frequencies can be high. In these cases, some of the assumptions outlined above – such as copy number being Poisson distributed – may be violated. In addition, studies have shown that TEs may proliferate in bursts and be recent introductions to genomes. In this case, the assumptions of equilibrium are violated. For these scenarios, simulation has been a critical tool for describing TE dynamics.

Regulation of Transposition Rates: Host and TE Lineage Selection

As indicated previously, unless the transposition rate becomes equal to the excision rate, selection is required to constrain TE proliferation in genomes. This is true if the transposition rate decreases with increasing copy number, as long as it is always higher than the excision rate. However, when regulated transposition and selection act together, the requirement for a concave log-fitness function becomes relaxed (Le Rouzic and Capy, 2009). Thus, regulated transposition can be critical when selection is insufficient for constraining runaway TE proliferation. How might we expect natural selection to act on regulation of the transposition rate? We must consider two forms of selection.

In the first case, we can consider selection acting on the TE lineage to modify the transposition rate of all members of the TE family. As previously mentioned, the amount of recombination is a critical parameter. If recombination rates are low, or zero in the case of asexuals, selection will favor low transposition rates if insertions are harmful. This is because TE lineages become burdened by their own harmful effects without recombination. In contrast, with high levels of recombination, high transposition rates will be favored because progenitor copies can become unlinked from the harmful consequences of descendant copies. Generally, when recombination rates are high, selection for lower transposition rates is weak, but this depends on how harmful insertions are. When insertions cause dominant lethal or sterile alleles, there is no opportunity for recombination to disassociate the source element from these effects. In this case, selection will favor variants in the TE family with lower transposition rates (Charlesworth and Langley, 1986). Early invasion of TEs may also place significant constraints on transposition rates. If the transposition rate is too low, element loss by drift during early invasion will occur nearly all the time. However, if the transposition rate is too high, rapid amplification within the genomes of infected individuals will cause significant loss of host fitness, and loss of the TE lineage. Overall, invasion appears favored by elements that have a high transposition rate during the initial phase of invasion, but soon have a reduced transposition rate that does not result in TE loss due to excessive TE load imposed on the host (Le Rouzic and Capy, 2005).

In addition to selection on TE lineages, we may also consider selection on host alleles that limit transposition rates. As before, the amount of recombination is an important parameter, but the conditions that lead to selection for a reduced transposition rate are not as restrictive. The selection coefficient for a host allele that reduces the transposition rate u by δu is given by (Charlesworth and Langley, 1986; Nuzhdin, 1999):

$$s \approx \delta u \frac{\overline{n}u}{2\tilde{H}}$$

Here, H is a summary statistic for the amount of recombination genome wide and is defined as the harmonic mean of $(r+u)$ for all pairs of loci, r being the recombination rate between any two loci. With standard transposition rates greater than 10^{-7}, u has only a modest influence on $\tilde{H}$ and $\frac{1}{2\tilde{H}}$ is at most as high as 10 to 20 when recombination rates are low. With completely free recombination the recombination frequency between any two random loci is 0.5 and $\frac{1}{2\tilde{H}} = 1$. If we consider transposition rates of 10^{-4} (a typical estimate for *Drosophila* (Nuzhdin *et al.*, 1997)), 20 copies in the genome, and $\frac{1}{2\tilde{H}} = 5$, an allele that completely represses transposition ($u = \delta u$) will have a selection coefficient of 1×10^{-6}. Since selection is limited with coefficients less than the reciprocal of the population size, in this scenario selection on host repressor alleles would be restricted to population sizes on the order of one million or more. However, a transposition rate of 10^{-3} and 100 copies yields a selection coefficient of $s = 5 \times 10^{-4}$. In *Drosophila* transposition rates of 10^{-4} may underestimate the transposition rates of early invasion because they may have been measured in backgrounds in which host repressor alleles may have already been selected for. Thus, it appears that selection for host repression may evolve under reasonable conditions.

Deviations from Equilibrium Assumptions

To consider non-equilibrium dynamics, simulation approaches have been critical. Such approaches allow relaxation

of many of the assumptions of the standard model. For example, non-equilibrium dynamics may occur in the early stages of invasion when copy number is below the equilibrium value. In addition, over the long term, there may be heterogeneity among TE copies. Le Rouzic and Capy have paid special attention to these long non-equilibrium TE dynamics through simulation (Le Rouzic *et al.*, 2007). In particular, they considered a TE lineage that could periodically cause mutations beneficial to the host but was also itself susceptible to mutations that reduced the activity of the insertion. Depending on a balance between beneficial effects and disabling mutations that occur within the lineage, several different outcomes were observed over the long term.

As suggested by previous work, when there are few beneficial insertions and a very low rate of disabling mutations on the TE lineage, a long-term steady-state equilibrium is observed. Copy number remains fairly stable and TEs impose a continuous fitness burden. In contrast, when the rate of disabling mutations is increased significantly, non-autonomous copies lacking the ability to catalyze their own movement begin to accumulate and these non-autonomous copies lead to lower levels of activity. Beneficial insertions, however, act as a reserve. As non-autonomous elements drive activity levels down, elements begin to disappear, but then autonomous beneficial insertions can drive a new wave of activity, leading to cycling. Depending on the rate of disabling mutation and the proportion of insertions that are beneficial, heterogeneity among TE copies can also result in persistence through beneficial insertions or complete loss. Interestingly, when there is heterogeneity in the selective effects of TE insertions, larger populations may maintain more active TEs than smaller populations. This contradicts the standard expectation that smaller populations, most influenced by drift, should harbor a greater TE burden. This is because slightly beneficial insertions, that act as a reserve for maintaining an active lineage across generations, are more likely to be lost to drift in smaller populations. In contrast, such reserve insertions may persist in larger populations and maintain a higher TE burden.

Forms of Selection

These analytical and simulation-based studies all agree that natural selection is critical for constraining TE proliferation in genomes. However, it is not clear what form of harm is most likely to limit TE copy number. Three standard forms have been proposed: (1) disruptive effects of insertion into genes, (2) the cost of expressing the transposition machinery, and (3) the chromosome damage caused by ectopic recombination events between insertions at non-homologous positions. Under the standard model, equilibrium is only achieved when the log-fitness function is curved downward. However, it is not apparent that gene disruption can yield this form of synergistic epistasis. In addition, there does not seem to be significant selection against expression of the transposition machinery because TEs carrying promoter sequences achieve similar frequencies compared to TE insertions lacking a promoter (Yang and Nuzhdin, 2003). Thus, the cost of expression is also unlikely to constrain copy number. In contrast to these two forms of selection, the damage caused by ectopic recombination may be the most plausible selective force that constrains TE proliferation (Lee and Langley, 2010). This is because the probability of ectopic recombination between elements will increase quadratically with copy number. This meets the equilibrium requirement that the log-fitness function must be concave and decreasing at a rate that is more than linear.

Empirical Studies of TEs

Genetic studies show clear evidence that TEs are harmful. About half of all visible mutations arise from TE insertions in *Drosophila* (Tenhave *et al.*, 1995). While TEs are not very active in humans and transposition events are rare, cases of hemophilia and cancer caused by TE insertions have been found (Belancio *et al.*, 2009). To further characterize TE dynamics in species and populations one may measure the genomic distribution and abundance of different TE classes and families. In addition, a population genetic approach can be used to measure the frequency of TE insertion alleles in natural populations. Empirical studies have confirmed many of the theoretical predictions outlined above.

Evidence for Selection

Theory suggests that TEs can spread in populations even if they are harmful. Therefore, many studies, especially in *Drosophila*, have employed population approaches to estimate the strength of selection acting on TE insertions to test this hypothesis. *Drosophila* has a large population size and studies have consistently shown that single TE insertion alleles segregate at low frequency (Charlesworth and Langley, 1989). This is consistent with selection acting to limit TEs. Interestingly, in species with smaller populations, the evidence for selection is weaker. For example, pufferfish (Neafsey *et al.*, 2004) and *Anolis* lizards (Tollis and Boissinot, 2013) both carry TE insertion alleles that segregate at higher frequency than in flies. Nonetheless, *Anolis* lizards from larger populations display lower insertion frequencies for harmful full-length elements. The overall trend of an inverse population size effect on TE abundance and frequency strongly supports a model in which natural selection against their harmful effects is a limit on TE proliferation. Studies have also shown that TEs with promoters tend to segregate at similar frequencies compared to TEs without promoters (Yang and Nuzhdin, 2003). This suggests that the expression costs of TEs are not significant. In contrast, smaller TE insertions segregate at higher frequencies than larger TE insertions (Petrov *et al.*, 2003). Since the likelihood of ectopic recombination will be higher among larger copies, this supports the premise that ectopic recombination is a key form of selection that limits TE copy number. In addition to comparing patterns of polymorphism across species, studies that examine the distribution of elements across the genome within a species also find that TEs can accumulate in regions of low recombination. Because of Hill–Robertson effects, natural selection is less effective in regions of low recombination. This further supports the idea that TEs are harmful, though a reduced rate of harm mediated by lower rates of ectopic

recombination in these regions of the genome can also contribute to this observation.

The Role of Mating System

Because harmful TEs can proliferate only to the extent that they can escape their harmful effects, theory suggests that mating system can have a significant effect on TE dynamics. Over the long term, selfing is predicted to select for TEs with reduced transposition rates. Plants provide a test of this model because there are multiple transitions to selfing. So far, however, results suggest that there is a complicated relationship between mating system and TE proliferation (Agren *et al.*, 2014). This is because the earliest stages of selfing can lead to a reduced effective population size. Thus, a transition to selfing can be associated with an *increased* TE burden due the reduced efficacy of selection limiting TEs (Nuzhdin and Petrov, 2003). Only in the long term might we expect evolution or extinction of TE lineages to lead to a decline of TE movement in selfing species. Studies suggest that this time effect must be more thoroughly investigated (Agren *et al.*, 2014).

Host Mechanisms of TE Repression

Until recently, natural selection was considered the dominant force limiting TE proliferation. However, recent studies have shown that host encoded mechanisms of genome defense by DNA methylation and small RNAs also contribute (Aravin *et al.*, 2007). Theory has shown that when transposition rates are sufficiently high, mechanisms of host control can evolve, but little is known about the population dynamics of TE control by genome defense in actual populations. Studies of the P-element in *Drosophila melanogaster* demonstrate that alleles that repress transposition can accumulate rapidly in populations soon after genome invasion (Ajioka and Eanes, 1989; Ronsseray *et al.*, 1991). Since small RNA mechanisms of genome defense rely on TE insertions to generate the repressor molecules, the strength of TE repression may increase with increasing copy number. If so, genome defense mechanisms may play a crucial role in limiting runaway transposition in the genomes of sexually reproducing species (Lee and Langley, 2010; Blumenstiel, 2011). Further studies are required to determine the significance of genome defense mechanisms in limiting TE proliferation over the long term.

Glossary

Amoeba A cell of a eukaryote that does not have a set shape. Rather, it varies dynamically in outline as it produces temporary extensions called pseudopodia. *Amoeba* is a formal name for a genus of organisms that have amoeboid cells, but not all amoebae belong to that genus.

Amoebozoa One of the two major monophyletic lineages of the unikonts. It contains many of the classical amoebae, including the genus *Amoeba*, and many of the slime molds. Note: Not all amoeboid eukaryotes are members of Amoebozoa.

Bikont A flagellated cell where the flagellar apparatus contains two basal bodies, from each of which extends a flagellum. Thus, a bikont cell is one with two flagella that arise from the same point on the cell.

Dikaryon A kind of cell found in certain members of the Fungi that contains two genetically different haploid nuclei (di – two, karyo – nucleus). A dikaryon originates when gamete nuclei enter into a cell but do not undergo nuclear fusion, karyogamy. Karyogamy is delayed for several cell generations during which each of the two nuclei undergo synchronized divisions. A dikaryon is genetically equivalent to diploidy except that the homologous chromosomes are housed in separate haploid nuclei rather than in one diploid nucleus.

Karyogamy The final event of the fertilization stage of a sexual life cycle. Two haploid gametic nuclei fuse to form a single diploid nucleus, the zygote nucleus.

Lysotrophy A form of heterotrophic nutrition in which the cells of an organism secrete digestive enzymes to the outside environment. These enzymes break down biological macromolecules into their component subunits, and these subunits are absorbed back into the organism's cells to be used as sources of energy or as building blocks for the organism's own macromolecules.

Mycelium The vegetative body of many of the groups of fungi and fungus-like protists. It consists of a system of branching filaments that grow longer from their tips. The cells of a mycelium are surrounded by a cell wall. Each individual filament of a mycelium is called a hypha.

Obazoa The second major monophyletic lineage of the unikonts. It consist primarily of the Opisthokonta and two protist lineages that do not branch within the opisthokonts.

Opisthokonta The most species-rich monophyletic lineage in Obazoa. It has two major monophyletic subgroups. One subgroup (Nucletmycea) includes the true Fungi plus some groups of protists, including the parasitic Microsporidia. The other subgroup (Holozoa) includes the animals (Metazoa) and several groups of protists.

Phagocytosis The process by which individual cells engulf particles of dead or living organisms to use them as food. A food particle is ingested by the cell such that it becomes contained in a food vacuole surrounded by cytoplasm. The cell secretes digestive enzymes into the food vacuole, and the digestion products are absorbed by the cytoplasm through the food vacuole's membrane. Parts of a food particle that are not digested are released to the outside environment by exocytosis.

Phagotrophic, s.s. Where phagotrophy (see below) relies solely on the ingestion, phagocytosis, of food particles by single cells.

Phagotrophy Any form of heterotrophic nutrition where a eukaryotic organism takes food into its body to be digested. When an organism is unicellular, phagotrophy is essentially synonymous with phagocytosis. When an organism is multicellular, food is taken in by a mouth and enters the digestive system. Together, the mouth and the space within the digestive system form a pocket or tube of the outside environment that is surrounded by the organism. Food may get from the digestive system to the individual cells either by the cells using phagocytosis, as in sponges, or by lysotrophy, as in all other Metazoa.

Protist Any eukaryote that is not a member of the following monophyletic groups: Metazoa (animals), Embryophyta (land plants), or Fungi.

Pseudopodium A transitory extension from a cell that may be extended or retracted either to effect motility or to engulf food particles. Sometimes both activities occur at the same time. A few protists have fixed body shapes from which a pseudopodium can arise only from a particular

point. Most pseudopodial eukaryotes are amoeboid and can, therefore, extend pseudopodia from any place on the cell surface.

Slime mold An informal term used to designate organisms who spend their active life as some kind of amoeba. At some point in a slime mold's life cycle, it will develop into a spore-bearing dispersal structure, often called a fruiting body. There are two kinds of fruiting bodies (that unfortunately have very similar names), sporocarp and sorocarp.

Sorocarp Cellular slime molds produce spore-bearing structures following the aggregation of lots of amoebae into a multicellular mass. The spore-bearing structures built by multicellular masses are called sorocarps. Sorocarpic development is found in both major lineages of unikonts and in all but one of the major lineages of bikonts.

Sporocarp Sporocarps are spore-bearing structures that develop from a single amoeboid cell. This kind of differentiation is found only among several lineages of Amoebozoa.

Unikont A flagellated cell from which a single flagellum is associated with each flagellar apparatus. In strict unikonty, the flagellar apparatus contains only the basal body from which the flagellum arises. Note: There are a number of kinds of flagellate cells in eukaryotes where there is only one flagellum per flagellar apparatus and there is a second, flagellum-less basal body present. Whether to consider such cells bikont or unikont is subject to various intepretations. However, it is generally agreed upon that such flagellar apparatuses are derived by reduction from ancestors that had bikont flagellar apparatus.

Introduction

At some point in time, probably between 1 and 2 gigayears ago (see Eme *et al.*, 2014; Sharpe *et al.*, 2014), a population of eukaryotes became the foundation, the Last Common Ancestor, of a major lineage of eukaryotes that is often informally designated as unikonts (following Cavalier-Smith, 2002, 2003), although the formal names Amorphea (Adl *et al.*, 2012) and Opimoda (Derelle *et al.*, 2015) have recently been proposed, as well as the informal designation, podiates (Cavalier Smith, 2003). For the sake of brevity, this ancestral population will be referred as LunCA (Last unikont Common Ancestor) from here forward.

The surviving descendants of LunCA include two major eukaryote lineages, or 'supergroups,' Amoebozoa and Opisthokonta (see Adl *et al.*, 2012). In addition, it has recently been suggested that the descendants of LunCA also include some groups of protists that are not members of either of these 'supergroups' (**Figure 1**; **Table 1**). Amoebozoa (**Figure 2**) (see Adl *et al.*, 2012) contains many of the classic 'naked' amoebae, including the namesake genus *Amoeba*, the amoebae that are partially enclosed in a shell (arcellinid amoebae), and several groups of slime molds (mycetozoans). Slime molds are amoeboid organisms that produce 'fungus-like' spore dispersal structures as part of their life cycles (see Spiegel *et al.*, 2004; Olive, 1975).

Opisthokonta (**Figure 3**) (see Adl *et al.*, 2012) has two major lineages: (1) Holozoa (Lang *et al.*, 2002) which includes animals (Metazoa), unicellular and colonial eukaryotes considered the closest relatives of Metazoa (choanoflagellates), and several protist groups, and (2) Nucletmycea (Brown *et al.*, 2009), which includes Fungi, a small group of ameoboid protists called nuclearids, and a varied but monophyletic group of intracellular parasites (see James *et al.*, 2013; Karpov *et al.*, 2014). This latter group is sister to Fungi. It has recently been proposed that the clade that includes the opisthokonts also includes two groups of flagellate protists (breviates and apusomonads) that are in separate lineages from

Opisthokonta. The name applied to this more inclusive group is Obazoa (Brown *et al.*, 2013). Therefore, Obazoa (**Table 1**; **Figure 3**) is sister to Amoebozoa.

Finally, Derelle *et al.* (2015), among others, present evidence that two flagellated protist groups (collodictyonids plus the genus *Malawimonas*) form either a monophyletic sister group to Amoebozoa or a monophyletic sister group to Amoebozoa + Obazoa. In either case, they are considered to be among the extant descendants of LunCA. **Table 1** and **Figure 1** summarize the most recent suggestions of relationships among the descendants of LunCA. The groups of unikonts on which this article focuses are highlighted.

Depending on which eukaryotic Tree of Life one accepts, the sister group to the unikonts is either all the other eukaryotes (**Figure 1**) – a group informally referred to as bikonts (Cavalier-Smith 2002, 2003) or more formally, as Diphoda (Derelle *et al.*, 2015) – or, alternatively, unikonts are sister to all other eukaryotes except the Excavata, a group of unicellular protists that often lack typical mitochondria (He *et al.*, 2014). This latter unikont sister group, called Diaphoretickes (Adl *et al.*, 2012) or, informally, corticates (Cavalier-Smith, 2003), along with unikonts, forms a monophyletic sister group to excavates (He *et al.*, 2014). It should also be noted that Katz *et al.* (2012) have argued that opisthokonts are sister to all other eukaryotes, in which case unikonts would be a paraphyletic assemblage, and LunCA would also be LECA (Last Eukaryote Common Ancestor). However, even if that were to be true, the following discussion would still be sound.

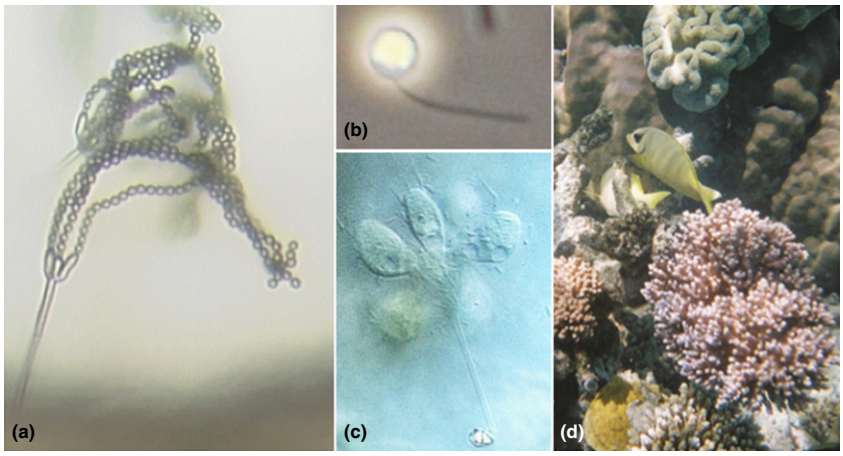

Figure 3 Examples of Opisthokonta. (a) A sporulating member of Fungi, *Penicillium* sp. (b) A typical flagellated cell of opisthokonts, a zoospore of a species of Fungi in the Chytridiomycota. (c) A colonial choanoflagellate. (d) A Metazoa-rich community on the Great Barrier Reef.

When LunCA was alive, it represented the entire unikont lineage that is now represented by its highly diversified descendants. That is a point that should go without saying, but it is often ignored. It is likely that LunCA was not terribly different from many of the other eukaryotes that were extant when it was, but it would have carried some unique traits it could potentially pass on to its descendants that it did not share with any of its contemporaries. Thus, the basic unikont 'toolkit' that LunCA could have passed on to its descendants would have consisted both of the traits that it shared with other eukaryotes, i.e., the symplesiomorphies of the unikonts, and traits that were unique to it, i.e., the synapomorphies of the unikonts. In part, how the elements of that 'toolkit' were passed on, or not, to its descendants is a very important aspect of understanding the subsequent diversification of unikonts. This will be the focus of the rest of this article.

Because there are myriad approaches to discussing the diversification of unikonts from LunCA to the present, and because that would require more space than is available for this article, discussion is limited to the spread of certain sets of characters that were potentially passed from LunCA to its descendants. In particular, the examples focus on unikonts that have traditionally been considered as fungi, s.l. These include the taxon Fungi and the various slime molds found throughout the Amoebozoa and Opisthokonta.

What Traits Could LunCA Have Transmitted to Its Descendants?

By comparing contemporary unikonts with each other, and also by comparing them with other eukaryotes, it is possible to reconstruct some of the traits that had to have been present in LunCA. The following list gives several examples.

1. It had a flagellated stage in its life cycle that consisted of flagellar apparatus that supported two flagella, one extending from each basal body. Because of the complexity of the flagellum, the basal bodies, and the flagellar apparatus (see Yabuki and Leander, 2013), it is extremely unlikely that these structures evolved more than once. Because flagellated cells are found in all lineages of eukaryotes, it must be the case that LECA was flagellated during at least part of its life cycle. Eukaryotes, including many unikonts, that lack any flagellated stage in their life cycle, are non-flagellate because of the loss of flagella.

The term unikont, which means 'single pole (flagellum)' was coined (Cavalier-Smith, 2002) because phylogenetic evidence available at that time suggested that opisthokonts and amoebozoans formed a monophyletic group, and these groups were thought ancestrally to have a single flagellum. Essentially all flagellated cells of opisthokonts have a single flagellum arising from one of a pair of basal bodies, and that flagellum pushes the cell through water, a trait unique to opisthokonts. The opisthokont flagellar apparatus, i.e., the cytoskeletal apparatus associated with the basal bodies, is very reduced compared to the rest of the eukaryotes (Cavalier-Smith 2002; Adl *et al.*, 2012; Yabuki and Leander, 2013). Many amoebozoans have a flagellar apparatus with only a single flagellum (see Adl *et al.*, 2012; Spiegel 1990, 1991) that arises from a single basal body (true unikonty). In amoebozoans that swim, the beating of the flagellum pulls the cell through the water, in contrast to opisthokonts. The flagellar apparatus in amoebozoans is structurally complex, unlike the reduced structure in opisthokonts, and it is relatively easy to recognize homologies shared with other eukaryotes outside the unikonts (Adl *et al.*, 2012; Spiegel, 1990, 1991; Yabuki and Leander, 2013).

However, the assumption that unikonts were ancestrally unikont (Cavalier-Smith, 2002) was based on a number of misconceptions, including observations that had been published prior to 2002 (Spiegel, 1990, 1991). Subsequently, the flagellated protists in Obazoa that are sister to the opisthokonts (apusmonads and breviates, **Figure 3**; **Table 1**) (Brown *et al.*, 2013; Cavalier-Smith, 2013) were shown to have a pair of flagella that arise from a pair of basal bodies, as do several amoebozoans (see Adl *et al.*, 2012; Spiegel, 1990, 1991), and aspects of the flagellar

apparatus of these bikont unikonts have been proposed to be homologous with those found throughout the non-unikont eukaryotes (Spiegel, 1991; Yabuki and Leander, 2013; Spiegel, 2012). Thus, it seems likely that LunCA was bikont and that the unikont condition has arisen separately several times among descendants of LunCA. Because the complexity of the homologies proposed among the flagellar apparatuses of bikonts and unikonts are so structurally intricate, convergence is highly unlikely.

An important point to consider, however, is that the presence of a flagellated cell in its life cycle does not provide evidence to conclude that LunCA was an organism with its sole cell type being a flagellate (i.e., a monad). Whether LunCA had other states, somatic or reproductive, that were not flagellated is presently unclear. There are extant unikonts that are monads, and there are unikonts whose flagellated stages are limited to propagules and/or gametes. Until there exists much more comparative genomic data on a broad range of unikonts, it will be difficult to be certain how LunCA used flagellated states in its life cycle.

2. It was able to feed by phagocytosis. Zuck (1953) coined the term 'phagotroph' to describe organisms that ingest their food, but he did not distinguish carefully between organisms whose cells acquire their own food by phagocytosis and multicellular organisms that bring food into their digestive systems to be digested extracellularly as is the case with most Metazoans. The term phagotrophy here is limited to only those organisms whose cells acquire a significant portion of their nutrition by phagocytizing other organisms. A strong case can be made that LECA was phagotrophic, s.s. (see Cavalier-Smith, 2013) and the presence of phagotrophic members in all major lineages of unikonts is entirely consistent with LunCA being phagotrophic.
3. LunCA was able to produce pseudopodia. All members of all major lineages of unikonts contain species that produce pseudopodia, at least in association with phagocytosis (see Derelle *et al.*, 2015; Adl *et al.*, 2012). Whether LunCA had cells that regularly moved using pseudopodia, i.e., ameoboid cells, as a part of its life cycle is not clear. Ameoboid cells are present in most major lineages of eukaryotes (see Adl *et al.*, 2012), but the work has not yet been done to evaluate whether the underlying genetics of being ameoboid is a result of a single origin or multiple origins. Therefore, more work is necessary to determine whether all pseudopodial cells in unikonts share homologies.
4. LunCA had stages in its life cycle in which cells were surrounded by cell walls. Walled cells as cysts, spores, or somatic cells are found in all groups of unikonts (see Adl *et al.*, 2012). About the only group of unikonts lacking a walled-cell stage is the Metazoa. Walled-cell stages are also present in almost all groups of non-unikont eukaryotes as well. So, being able to produce a cell wall might be a universally present trait of all eukaryotes that has been retained by unikonts. However, sufficient work has not been done to determine whether the ability to produce cell walls in eukaryotes, in general, and unikonts, in particular, is homologous or if it has arisen multiple times.
5. It was sexual. Almost all eukaryotes, including the major lineages of unikonts, that have been examined carefully enough, have a life cycle in which haploid nuclei produced by meiosis eventually give rise to diploid nuclei via karyogamy (see Spiegel, 2011; Lahr *et al.*, 2011a; Adl *et al.*, 2012; Cavalier-Smith, 2013). Meiosis is so complex and stereotypical that it is extremely unlikely that it had multiple origins (Spiegel, 2011). However, evidence is still lacking to determine whether the somatic stages of LunCA (here defined as those stages in which mitosis occurs) were haploid, diploid, dikaryotic, or a combination of these. Thus LunCA's life cycle is open to speculation.

There are other aspects of LunCA that could be hypothesized, but these examples provide a framework to develop hypotheses concerning how the unikonts have diversified from their start as LunCA. It should be noted that no characters of LunCA yet mentioned are proposed to be synapomorphies of unikonts. At this point, that would be premature since not enough evidence exists on which to base such hypotheses.

There follow some examples of how certain, but not all, aspects of diversification could have been manifested in some of the mycological descendants of LunCA.

Diversification of the Mycological Descendants of LunCA

Cellular slime molds, a.k.a. sorocarpic amoebae (Brown *et al.*, 2011; Brown and Silberman, 2012; Spiegel *et al.*, 2004; Olive, 1975), are amoeboid organisms in which individual amoebae, upon starvation or some other signal, aggregate to form a multicellular fruiting body, or sorocarp, containing walled, dormant spores. Sorocarpic amoebae are found in all supergroups of eukaryotes (Amoebozoa, Opisthokonta) except Archaeplastida (red algae, green algae, and land plants) (see Brown and Silberman, 2012) and thus sorocarpy represent the most phylogenetically diverse kind of multicellularity found in eukaryotes. It is found in three major sublineages of the unikonts, two within Amoebozoa (dictyostelids in the Conosa lineage, **Figure 4**; and copromyxids in the Lobosa lineage, **Figure 5**), and one within Opisthokonta (the nucleariids in the Nucletmycea lineage, **Figure 6**) (see Adl *et al.*, 2012). It seems unlikely that either LunCA or, more distantly, LECA were sorocarpic amoebae. However, as pointed out above, LunCA could well have had an amoeboid stage in its life cycle, and since amoebae are found in almost all of the major lineages of eukaryotes, LECA may also have had an ameoboid stage in its life cycle.

In examining the diversification of unikonts, two questions, at least, seem obvious. (1) To what extent are the amoebae of unikonts homologous to each other? (2) To what extent are cell signaling and sorocarp development homologous among the diverse groups of cellular slime molds? In other words, how many times did these traits arise?

We know that amoebae are widespread among eukaryotes, but the genetic underpinnings of amoeba development and physiology have not yet been well studied to determine if the ameoboid condition has a single or multiple origins in eukaryotes. Unikonts offer an ideal system from which to begin to address the possible homology of amoebae. Briefly, if there exists some subset of genes that are expressed in the amoeboid stages of all unikonts, then that would suggest that LunCA had

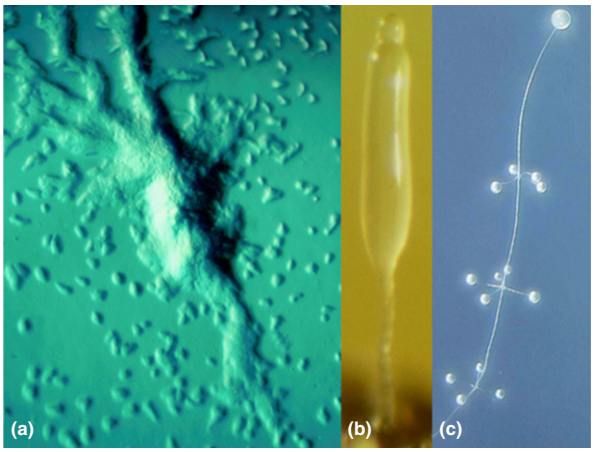

Figure 4 The stages in sorocarpic development in the amoebozoan dictyostelid sorocarpic amoebae. (a) Aggregation of individual amoebae into a central, multicellular mass. (b) Differentiation of the multicellular mass such that it has some cells that become stalk and some that will become spores. (c) A mature sorocarp in which masses of spores, propagules, are suspended in the air by multicellular stalks.

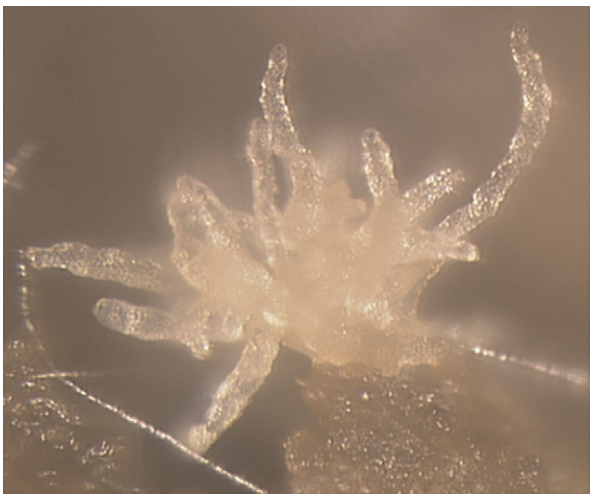

Figure 5 The mature sorocarp of the amoebozoan sorocarpic amoeba, *Copromyxa*. In this case spores develop as amoebae aggregate and pile on top of one another. Photo by Matthew W. Brown.

an ancestral amoeboid state. If those same genes, or a subset of those genes is found in amoeboid stages of non-unikont eukaryotes, that potentially provides support for an ancestral ameoboid state of LECA.

While it seems unlikely that sorocarpy, the aggregation of amoebae into a fruiting body containing walled dormant spores, had a single origin in unikonts (see Brown and Silberman, 2012), it is quite possible that some aspects of cell signaling necessary for both aggregation and triggering cell dormancy and cell wall development could have been present in LunCA or, more broadly, in LECA. Studies in comparative genomics and gene expression during development may possibly be able to reconstruct the evolution of developmental

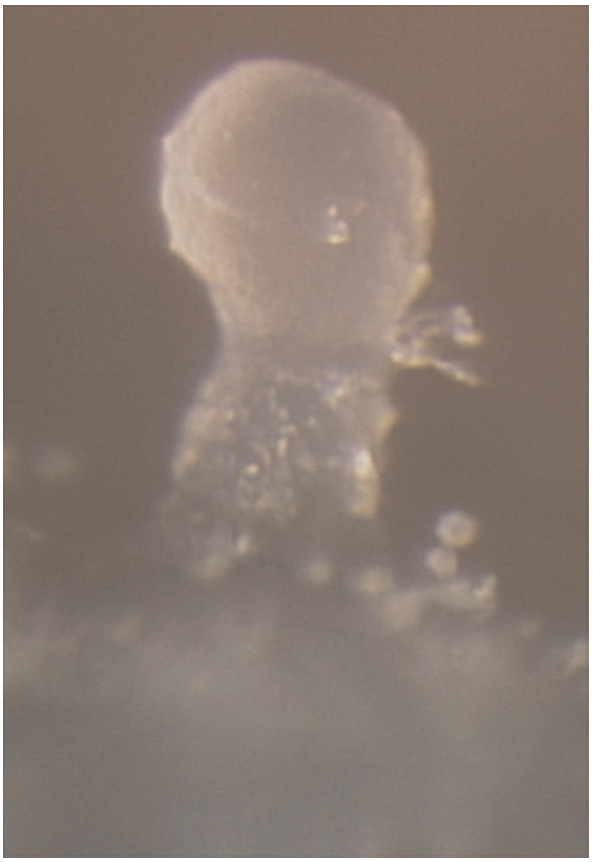

Figure 6 The mature sorocarp of the opisthokont sorocarpic amoeba, *Fonticula*. In this case the aggregate secretes an extracellular stalk through which the cells move to form a ball of spores at the apex. Photo by Matthew W. Brown.

events that are universal or phylogenetically limited in aggregation and spore development, shedding light on the number of origins of this complex trait. Also, as mentioned in Brown *et al.* (2009), the aggregation of cells in opisthokonts can be found in Fungi and in Metazoa even though the result of aggregation is not a sorocarp. The evolution of aggregation-related mechanisms could possibly be more widespread than just for cellular slime molds.

Sporocarpy, in which a single amoeba differentiates into a spore-bearing fruiting body, called a sporocarp (see Adl *et al.*, 2012; Spiegel *et al.*, 2016; Shadwick *et al.*, 2009, Spiegel *et al.*, 2004) is found solely in Amoebozoa among two groups: The plasmodial slime molds (Myxogastria), which have a life cycle in which a large, multinucleate amoeba, the plasmodium, eventually differentiates into a sporocarp containing many spores (**Figure 7**), and various groups of microscopic protosteloid amoebae, which individually round up, secrete a stalk, and then differentiate into one to a few spores (**Figure 8**).

Until recently, sporocarpy, because of its similarities, was considered to be a synapomorphy of a monophyletic subset of Amoebozoa (called Eumycetozoa) (see Olive, 1975; Spiegel *et al.*, 1995). However, Shadwick *et al.* (2009) and subsequent molecular phylogenetic studies, for example, Lahr *et al.* (2011b), clearly show that protosteloid amoebozoans form a para/polyphyletic assemblage in Amoebozoa. Sporocarpy may

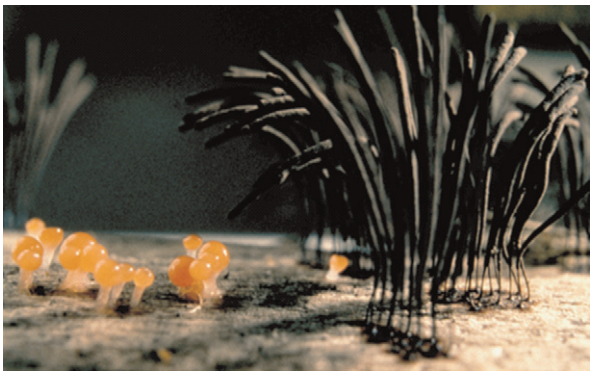

Figure 7 Sporocarpy in two different macroscopic amoebae in the myxogastrid amoebozoans. The species of *Hemitichia* on the left still consists of multinucleated, single cells that are secreting an extracellular stalk. The species of *Stemonitis* on the right has matured fully such that the multinucleate cell has divided up into uninucleate spores that are suspended above the substrate by the stalk. Each *Stemonitis* sporocarp is about 2–2.5 cm tall.

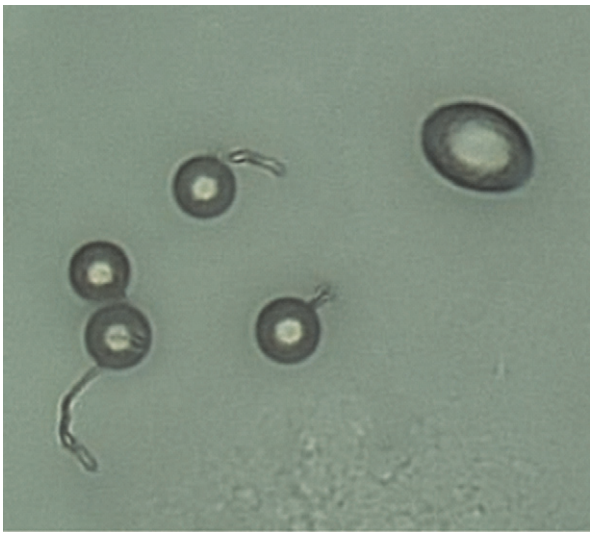

Figure 8 Microscopic, stalked, single spored sporocarps of the protosteloid amoebozoan, *Protostelium mycophaga*. The cell at the upper right is an amoeba that has rounded up prior to synthesizing a stalk. The cell will become a spore once stalk synthesis is completed.

prove to have one origin or it may have evolved independently several times. More work is needed to demonstrate if the genetic underpinnings of sporocarpy are homologous or not. Should they prove to be, that would suggest that the Last Common Ancestor of Amoebozoa was sporocarpic. Since nothing similar to sporocarpy is found in Obazoa, it would appear to be unlikely that LunCA was sporocarpic.

The taxon Fungi is the best-known group in the Nucletmycea lineage of Opisthokonta. It is sister to a group of protists that are intracellular parasites (see James *et al.*, 2013; Corsaro *et al.*, 2013). Two related characteristics of Fungi that will be discussed here in relation to their place in the unikonts are the fungal mode of nutrition and the presence in many

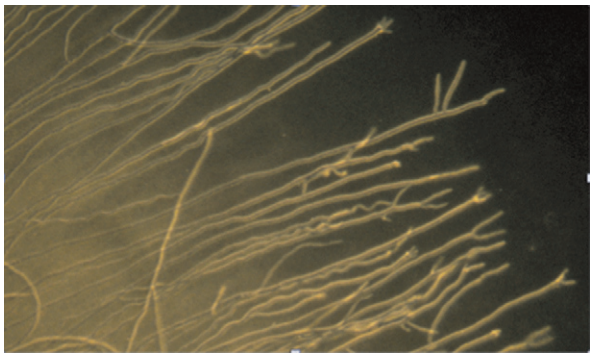

Figure 9 A portion of a mycelium of a member of Fungi in the genus *Penicillium*. Notice that it consists of many branching, filamentous hyphae.

lineages of Fungi of a somatic stage that is filamentous, the state called the mycelium (see Dee *et al.*, 2015).

Fungi are lysotrophic, a term also coined by Zuck (1953). This means that they release digestive enzymes into the extracellular medium, and absorb the digestion products. This is a form of absorptive nutrition. All organisms may be able to use lysotrophy to some extent, but few rely on it entirely. Two major groups of opisthokonts are lysotrophic, Fungi and Metazoa except the sponges. Also within the Holozoa, the fungus-like Eccrinales may be lysotrophic. While most people would call animals phagotrophs, they excrete extracellular enzymes into the topologically external space in the digestive tract and absorb the digestion products. Some fungus-like members of the bikont lineage Stramenopila, for example, water molds (oomycetes), are also lysotrophic (see Adl *et al.*, 2012).

By carrying out comparative studies of the physiology and genetic basis of lysotrophy in Fungi, Metazoa, and Stramenopila, it should be possible to determine whether the kind of lysotrophy found in Fungi is homologous with that in Metazoa or stramenopiles. If only the former, that would be the evidence that this process is not something that occurred in LunCA. If it is homologous in all exclusively lysotrophic eukaryotes, then it must have been present in LECA and, therefore, also in LunCA. Obviously, it is possible that some elements of lysotrophy could be more universal than others.

Fungi are the only group of unikonts, with the exception of the Eccrinales, whose cells are walled during the part of the life cycle during which they take in nutrients. Because of that, they cannot use phagotrophy, nor can they move around actively when in this state. That puts constraints on how they can successfully acquire nutrients. Many fungi are mycelial (**Figure 9**). That is, they have filaments, hyphae, that grow from their tips and penetrate and surround the substrates they are digesting (see Dee *et al.*, 2015). A mycelium has a high surface-to-volume ratio that makes absorption of digestion products efficient. In Fungi, the phylogenetic distribution of mycelial morphology suggests that mycelial growth arose at least three independent times (Dee *et al.*, 2015).

Among unikonts, mycelium-like growth is found only in Fungi and the Eccrinales, both opisthokonts (see Adl *et al.*, 2012). It is not present in Amoebozoa. The only other place it is found among the eukaryotes is in the oomycetes, the

stramenopile analogues of Fungi. In order to test the hypothesis of Dee *et al.* (2015), comparative studies of gene expression during hyphal growth initiation and growth of established hyphae in the mycelial lineages of Fungi, Eccrinales, and oomycetes should be carried out in addition to microscopic and ultrastructural examination. These would establish the levels of homology among the underlying mechanisms of mycelial growth. Only then will it be safe to conclude if any mycelium-specific traits are limited exclusively to certain groups, and only then will it be possible to conclude that there were multiple independent origins of mycelial growth. In essence, then, it will be possible to determine whether the last common ancestor of Fungi, the last common ancestor of opisthokonts, or LECA, and of necessity LunCA, had the potential to grow as a mycelium as part of its life cycle.

V

Vertebrates, the Origin of

DA McLennan, University of Toronto, Toronto, ON, Canada

You are a member of the group 'Vertebrata,' as is every creature with a backbone: cats, eagles, poison dart frogs, salmon, great white sharks, lamprey, etc. (Figure 1). If you look at the base of the phylogenetic tree shown in Figure 1, you will see the species highlighted as 'the ancestor of the vertebrates'. About 530 million years ago, this species was flourishing in early Cambrian seas. What did the world of the vertebrate ancestor look like? The supercontinent of Rodinia had begun to fragment (Figure 2), leaving the massive continent of Gondwana (South America, Africa, Australia, Antarctica, India) to the

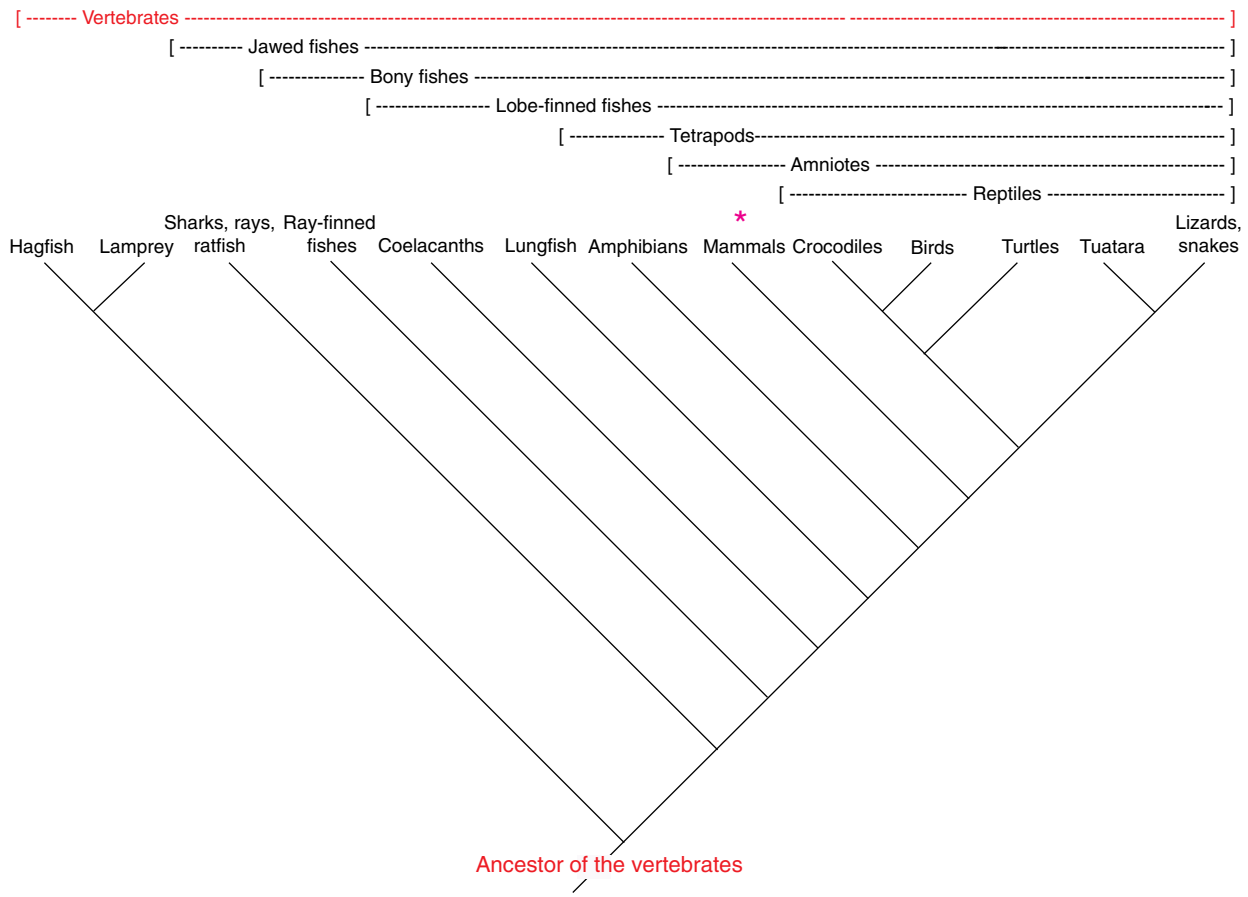

Figure 1 'Wave your fins in the air'. Family (phylogenetic) tree for major extant (=living, fossil groups not included) groups of animals with backbones (Vertebrata). *=you! If you trace your ancestry back from the small group to which you belong (mammals) you can see that you are a jawed, bony, lobe-finned fish with a backbone, four legs and an amniotic egg. To understand this diagram better, listen to *The Devonian Blues* by Ray Troll (www.youtube.com/watch?v=g9j0Mq0knDo). In the song, the following terms refer to the common names on this figure: Sarcopterygian=lobe-finned fish; Dipnoi=lungfish.

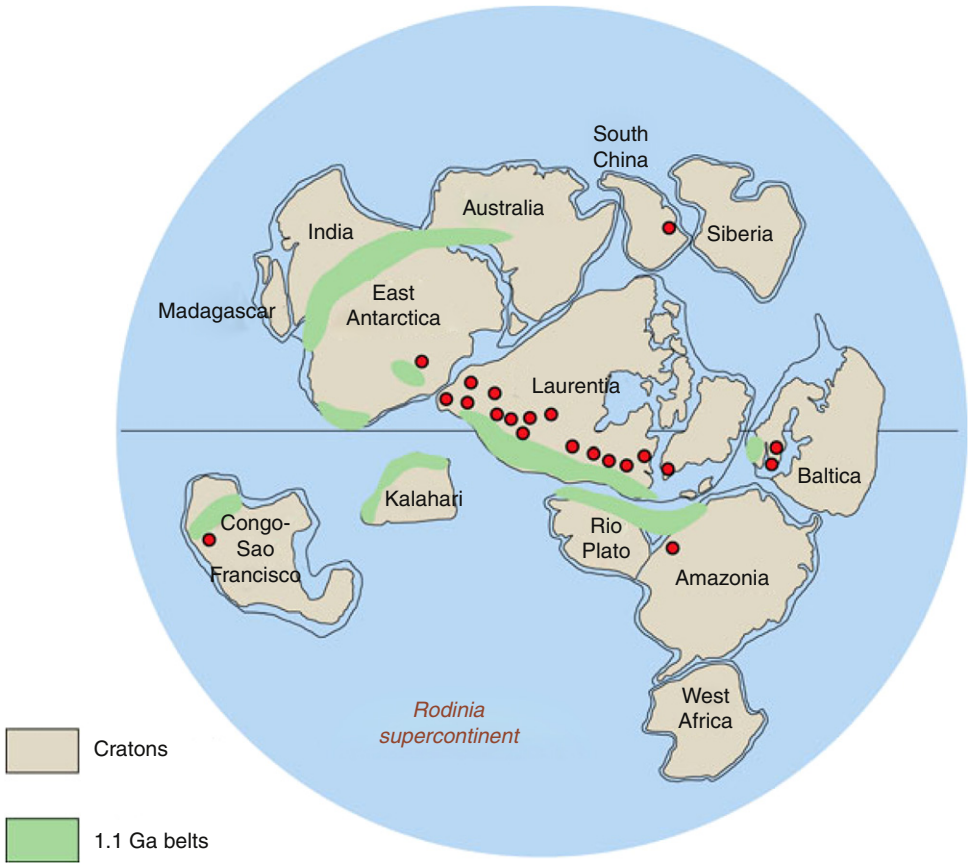

Figure 2 The supercontinent of Rodinia beginning to break apart about 750 million years ago. Author: John Goodge (commons.wikimedia.org/wiki/File:Rodinia_reconstruction.jpg).

south. Laurentia (North America) was drifting northwards to the Equator; Baltica (northern Europe), Siberia and South China were drifting northeastwards away from Laurentia and each other (for an image see www.ucmp.berkeley.edu/cambrian/cambrian.php). Much of the smaller, northerly landmasses were covered by shallow seas, formed as glaciers from the late Proterozoic ice age melted and sea levels rose. These seas were undergoing a transformation as the levels of oxygen (allows more efficient metabolism), calcium (along with phosphorus, necessary to produce hard tissues such as bone and teeth), and phosphorus (necessary for metabolic processes, building cell membranes and DNA/RNA) began to increase, while the sea itself became less saline (Zhang *et al.*, 2014 and references therein). It was a time of great biological exuberance; the majority of invertebrate phyla became established during the Cambrian explosion (540–520 Ma). By 530 million years ago, the shallow, warm seas were teeming with life, with complex ecosystems comprising single celled bacteria, phytoplankton and zooplankton, and multicellular burrowers, filter feeders, detritivores and predators. Part of this complexity was the ancestor of the vertebrates.

What exactly did this ancestor look like? To answer this question we must first establish what exactly a vertebrate is. Oddly, this is not as easy as it seems.

Who Are the Vertebrates, Really?

Historically, there have been three extant (living) groups involved in this discussion, hagfish, lamprey, and gnathostomes (jawed fishes; **Figure 1**), along with a bevy of fossil 'fishes,' both jawed and jawless. Their relationships one to another have been the basis of heated debate for nearly three centuries.

Linnaeus (1958) is widely credited for recognizing that creatures with backbones formed a group distinct from other animals. But where exactly did the hagfish (**Figure 3(a)**) and lamprey (**Figure 3(b)**) fit in this scheme? Artedi (1738) grouped lamprey in the Chondropterygii with sturgeon, dogfish, and rays. Linnaeus (1758) agreed but added the chimera and renamed the group Nantes. He placed hagfish, which Artedi had not discussed, in Vermes (along with leeches, earthworms, and some parasitic flatworms). Duméril (1806) was the first biologist to classify lamprey and hagfish together, in the family Cyclostomes, still related to sharks and rays. Cope (1889) dramatically restructured the whole picture, oddly characterizing the Vertebrata as containing the invertebrate groups Hemichorda (acorn worms), Cephalochorda (lancelets) and Urochorda (tunicates) plus the Craniata. The Craniata, in turn, was subdivided into the Agnatha (jawless fishes: Ostracodermi (extinct) + Marsipobranchii (=Duméril's

Figure 3 (a) Hagfish are unusual looking creatures, to say the least. Reproduced with permission of the photographer, Juanjo Alonso (freefins.com).

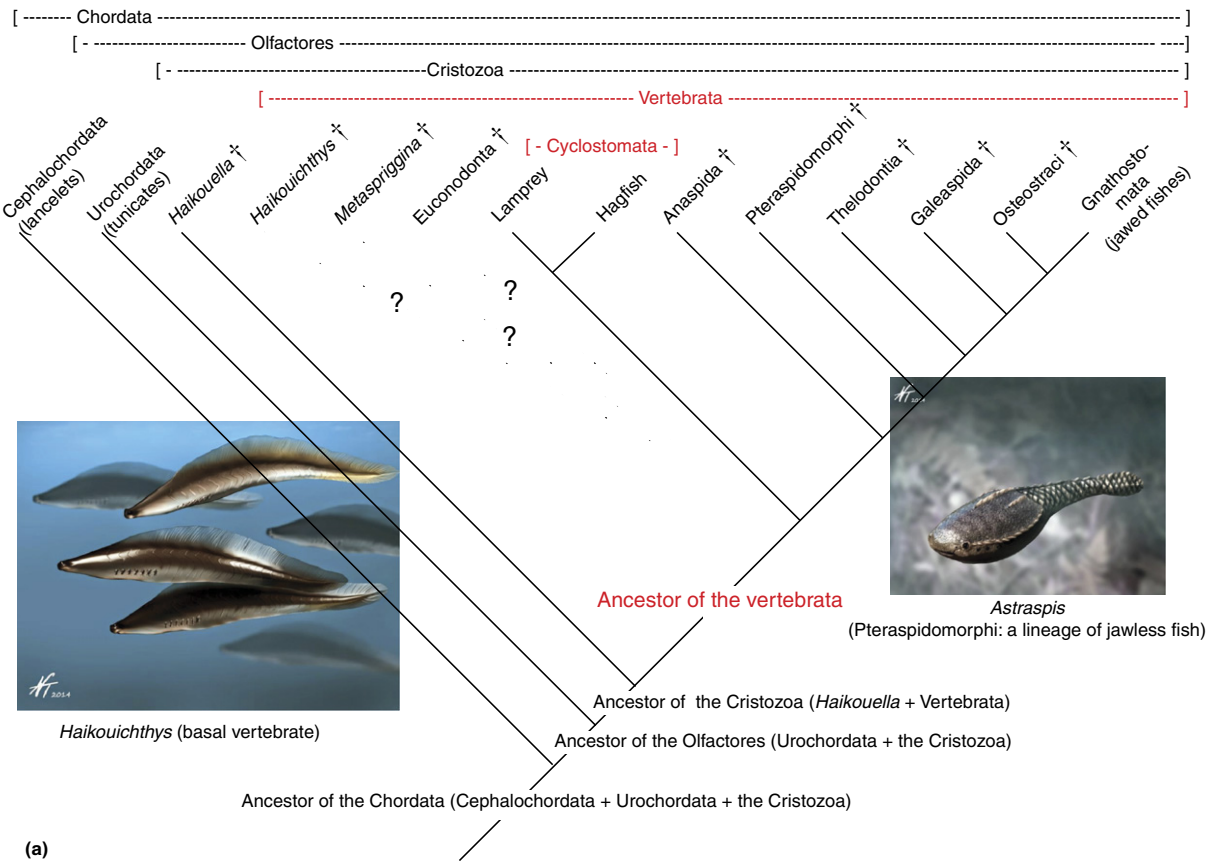
Cyclostomes)) and 4 classes of jawed animals (In 1898, Hans Gadow wrote a book (Gadow, 1898) that seems to have been largely ignored. In it he proposed that the vertebrates consisted of the Acrania (lancelets) and the Craniota, which was subdivided into three superclasses, Cyclostomata (name attributed to Richards; hagfish + lamprey), Hypostomata (various extinct groups) and the Gnathostomata (name attributed to Haeckel).). Cope's Ostracodermi was a grab bag of fossil fishes placed together solely because they had no jaws. As more fossil taxa were added to (and removed from) the agnathans, disputes over the relationships among these taxa escalated, but most authors still supported a monophyletic Cyclostoma. In 1927, this view was shaken when Stensiö (1927) concluded that lamprey and hagfish were more closely related to different extinct jawless fishes than to each other (see discussion in White, 1935).

Debates concerning the relationships of the jawless fishes to one another and to jawed fishes continued among the paleontologists, but most neontologists continued to support the sister-group relationship between lamprey and hagfish. This consensus vanished when Løvtrup (1977) published a phylogenetic tree based on morphological and physiological traits indicating that lamprey were more closely related to jawed fishes (Gnathostomata) than to hagfish, leading Janvier (1981) to propose that systematic terminology should be changed to reflect the new hypotheses of relationships: Vertebrata, diagnosed by the presence of vertebral elements, included gnathostomes, lamprey and some jawless fossil fishes, while the term Craniata would be applied to the larger group characterized by a skull and otic, optic and olfactory capsules (hagfish, other jawless fishes, vertebrates). Subsequent morphologically based studies overwhelmingly supported the Vertebrata–Craniata distinction (Maisey, 1986 and references therein) and for a time, relative peace reigned again.

Fifteen years later, however, the newly emerging field of molecular systematics began to cause uneasiness once more, when the first phylogenetic systematics-based tree resurrected a monophyletic Cyclostomata (Stock and Whitt, 1992). This uneasiness was amplified as subsequent studies provided evidence both for, and against, the phylogenetic hypothesis. But with the dawn of the new millennium, molecular analyses began to show overwhelming support for monophyly (reviewed in Near, 2009), although many morphologists remained, paradoxically, unconvinced. A study by Heimberg *et al.* (2010) based on microRNAs (highly conserved, noncoding genes) seems to have tipped the balance as Janvier (2010), echoing the sentiments of many biologists, wrote "I am impressed by the evidence … and prepared to admit that cyclostomes are, in fact, monophyletic". After four years and no further data sets emerging to challenge the hypothesis of monophyly, it appears that molecular data have finally returned us to the initial intuitions of morphologists: lamprey and hagfish are united in a group (Cyclostomata) that forms the sister-group to the remaining jawless and jawed fishes (**Figure 4**).

Why does all this matter? There are two ways to answer this question. First, science is based on the search for the hypothesis that is best supported by the data, so there will always be periods of intense debate as new data are discovered. So the preceding discussion is a textbook example of why the scientific process 'works'. Second, and more importantly for this article, hypotheses of evolutionary relationships form the framework upon which questions of character evolution and speciation are investigated (Brooks and McLennan, 1991, 2002 and references therein). If we want to understand more about the ancestor of the vertebrates, we need to know where that ancestor fits on a larger phylogenetic tree. Any conclusions we draw from those genealogical patterns are only as strong as the phylogenetic hypothesis – so this is why the decades of debate, which have gradually begun to converge on a consensus, are important.

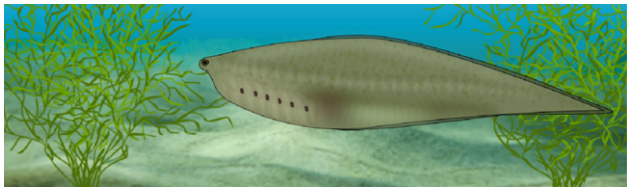
Why was it so difficult to reach consensus in the first place? Aside from the obvious problems with character description and data analysis, the answer to this question is simple – hagfish (~29 species with at least four awaiting description); creatures that appear at once as extremely simplified (for a 'vertebrate') and extremely odd (**Figure 3(a)**). The idea that hagfish were very simplified arose because they evidently had poorly developed eyes with no lens, only one semicircular canal in their inner ears, no vertebral elements and no lateral line (Contrary to the common wisdom, recent studies have shown that some species of hagfish do develop rudimentary vertebral elements (Ota *et al.*, 2014) and an embryonic lateral



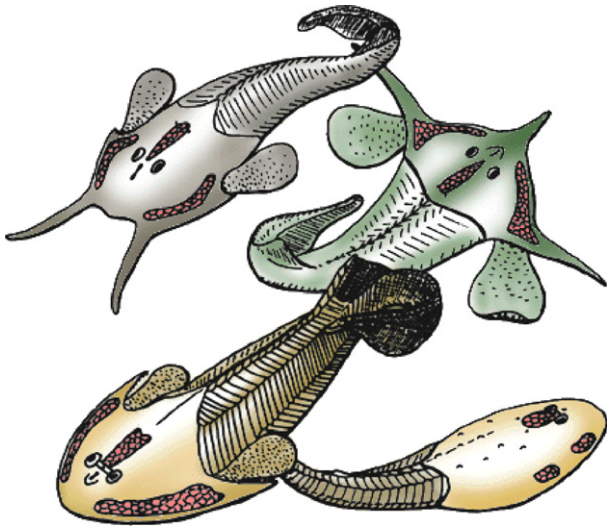
Haikouichthys (basal vertebrate)

Astraspis
(Pteraspidomorphi: a lineage of jawless fish)

(a)



(b)



(c)

line (Wicht and Northcutt, 1995).). Their oddness came from their ability to eject streams of mucins that coagulate into a wall of slime upon contact with seawater (hence one of their less complimentary names of 'snot eels') and their skill at tying themselves in a knot during feeding or when grabbed by a predator (or biologist). The unusual traits are unique to hagfish. It is the 'simple' traits that are problematic because they can be interpreted in two ways. Either (1) hagfish represented an early stage in vertebrate evolution, in which case the evolutionary scenarios for many characters would appear to be a straightforward linear progression from 'simple-complex' or (2) hagfish were secondarily simplified, in which case the evolutionary scenarios for character evolution might be more complicated. The current configuration of the phylogenetic tree, coupled with recent studies on the genetics and development of hagfish, support the latter scenario.

All of this is very interesting in terms of investigating hagfish biology. But what does it mean in terms of reconstructing the vertebrate ancestor?

Meet Your Ancestors (Some of Them)

All organisms are a mosaic of conserved (plesiomorphic) and novel (apomorphic) traits, there is no such thing as an 'all plesiomorphic' species, although many people often mistakenly equate the term 'ancestor' to mean 'all plesiomorphic'. So, in order to reconstruct what the vertebrate ancestor (=VA) might have looked like, we have to go further back in time to disentangle the conserved old traits from the unique new ones.

The following discussion is based on the origin and diversification of morphological traits depicted in **Figure 5** (see **Figure 4** to identify the various ancestors discussed in the following paragraphs). Phylogenetic trees are hypotheses of the genealogical (evolutionary) relationships among taxa. You read them like you would any genealogical diagram – the characters are mapped onto the ancestor in which they are hypothesized to originate. So, for example, say all your ancestors were blue-eyed until your great grandfather married a brown-eyed woman, thus introducing a change in the trait 'eye color' into your family. From that point onwards your family tree will include both blue-eyed and brown-eyed descendants, brown being traced back to that one ancestral event.

Based upon characteristics of the oldest chordates (Cephalochordata (lancelets) and Urochordata (tunicates)), we hypothesize that the following traits evolved before the origin of the vertebrates: caudal, dorsal, and ventral fins; numerous slits in the pharynx; a dorsal, hollow nerve cord expanded anteriorly into a rudimentary two part brain; a collagenous notochord providing support for somatic muscles (myomeres); a rudimentary light sensing eye (ancestor of the Chordata); a one-chambered heart; and type 1 mechanosensory cells (whether these cells functioned as a precursor to the lateral line, or as hydrostatic balance is currently unknown; ancestor of the Olfactores). In the ancestor of the Cristozoa, the pharyngeal slits, which had functioned solely in filter feeding up to this point in time, were modified to serve more of a respiratory role (possibly true gills: Chen, 2008 and references therein). Importantly, this is also the point at which large, paired eyes appear. These small, fish-like creatures are thought to have prowled the shallow seas, sucking up small soft-bodied invertebrates from the substrate by means of a more powerful muscular pumping system that drew water into their mouths and out over their gills. (Interestingly, there is evidence that some of that musculature is present in lancelet larvae, disappearing when the larva goes through a complicated metamorphosis to become a filter-feeding adult (Yasui *et al.*, 2014). If so, then the precursor to vertebrate muscular ventilation was already established in the ancestor of the chordates). Prior to this, water had been moved by the beating of small, hair-like structures called cilia lining the pharynx. The change in pharyngeal slit morphology and the way in which water was moved from the environment across those openings was thus associated with two major ecological shifts – from a predominantly low activity, filter feeder, to a much more active, free-swimming benthic feeder; something that would have been promoted by the development of a larger two-part brain and paired eyes.

When you look at **Figure 5** it is obvious that the 'vertebrate ancestor' is characterized by numerous morphological innovations. These traits, however, are only depicted in this way because as of yet there is no consensus about the relationships among the putative basal-most vertebrate species (e.g., *Haikouichthys* and *Metaspriggina*) and, even when that gets resolved, the level of detail described (so far) from the fossils is not sufficient to resolve the state of many characters (Donoghue and Keating, 2014). Ignoring the perplexing euconodonts, for which very little soft tissue characters have been preserved, it appears that the common ancestor of *Haikouichthys* + *Metaspriggina* + everyone else possessed, minimally, rudimentary vertebrae (which, as shown on **Figure 5**, may be even older), paired eyes with a lens, a nostril (possibly), nasal sacs (possibly), rudimentary fin-rays and, in *Metaspriggina* at least, a rudimentary skull (Shu *et al.*, 2003; Zhang and Hou, 2004; Conway and Caron, 2014, references therein and, at the end of the article, an artistic depiction of *Metaspriggina* by M. Collins). The exact point in time in which the remaining characters evolved will be difficult to determine – molecular studies place the potential for trait development in the vertebrate ancestor based on data from extant species – but that reconstruction does not contain molecular information from the basal extinct animals. Still, it is obvious

Figure 4 (a) Simplified phylogenetic tree for the Chordata (see e.g., Near, 2009; Goudemand *et al.*, 2011; Conway and Caron, 2014 and references therein), identifying ancestors of various groups discussed in the text. ?=There is no consensus on the exact relationships among these extinct groups. Researchers do agree that *Haikouichthys* and *Metaspriggina* are basal vertebrates, but exactly where the Euconodonts fit is still a mystery. The Anaspida, Pteraspidomorphi, Thelodontia, Galeaspida, and Osteostraci are an assemblage of extinct (indicated by †) jawless fishes (they are not a monophyletic group). The *Haikouichthys* and *Astraspis* illustrations are reproduced with the permission of the artist, Nobu Tamura (paleoexhibit.blogspot.ca/2014/04/early-vertebrates-myllokunmingiidae.html and paleoexhibit.blogspot.ca/2014/04/jawless-armored-fish-from-ordovician_20.html). that a great deal of morphological innovation was happening in a very brief (evolutionarily) period of time. How is that possible?

Generating Novelty: How Did the Vertebrate Ancestor Get To be So Different?

In 1970, Susumu Ohno proposed that duplication of the entire genome provided an important source of raw material upon which evolutionary processes could act. Based upon comparing genome sizes across various groups, Ohno (1970) suggested that two such widespread duplication events had occurred before and during vertebrate diversification. Subsequent research, primarily on Hox gene clusters (**Figure 6**), moved the timing of these events somewhat; two rounds of whole genome duplication (WGD) were hypothesized to have occurred in vertebrates, the first in an early ancestor of the group (**Figure 7**), followed by a second round sometime after the split between the cyclostomes and origin of the jawed vertebrates (Holland, 1992; Holland *et al.*, 1994). Although the 2R (two rounds) hypothesis was initially the subject of intense debate, support has since come from a wide variety of gene families (see, e.g., Panopoulou and Poustka, 2005; Steinke *et al.*, 2006; Huang *et al.*, 2010; Huminiecki and Heldin, 2010; Tostivint *et al.*, 2013; Hartmann *et al.*, 2014).

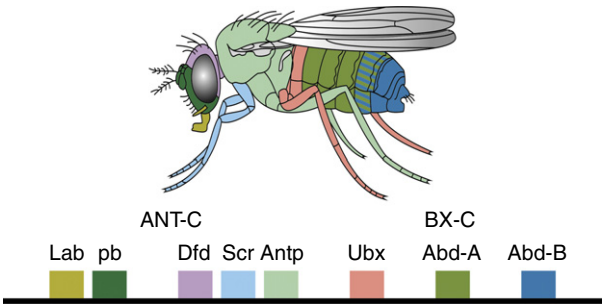

Figure 6 Diagram showing the areas whose development is influenced by eight Hox genes in the fruitfly, *Drosophila melanogaster*. For a discussion of Hox gene functions, see https://en.wikipedia.org/wiki/Hox_gene. Author: PhiLiP (https://commons.wikimedia.org/wiki/File:Hoxgenesoffruitfly.svg).

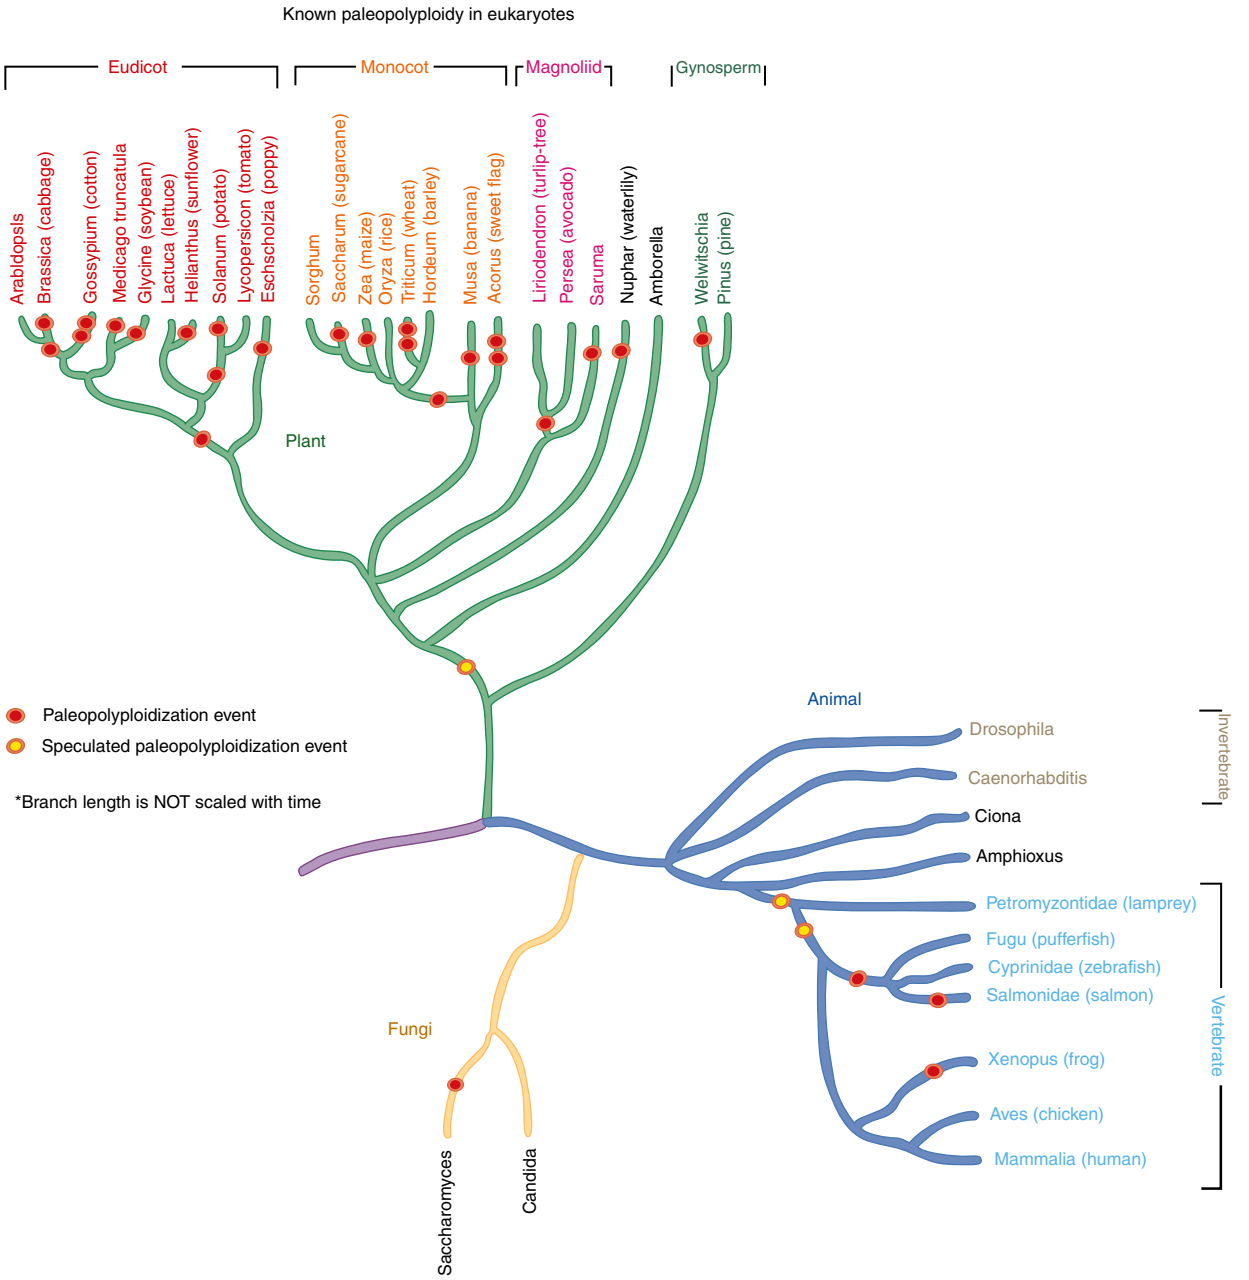

Figure 7 Summary of genome duplication events within the eukaryotes (organisms whose cells contain a nucleus and various organelles bounded by membranes). The event we are interested is occurred in the ancestor of the vertebrates (on this tree, the ancestor of the group comprising the lamprey + fishes + frog + chicken + human). Author: 5dPZ (https://commons.wikimedia.org/wiki/File:PaleopolyploidyTree.jpg).

At the moment, it is impossible to tell whether both of those events occurred rapidly in the vertebrate ancestor near the timing of the split between the Cyclostomata and its sister group, or whether the events were separated in time, the second possibly happening, as originally suggested, after the Cyclostomata diverged from its sister-group (but before the origin of the gnathostomes: Putnam *et al.*, 2008 and references therein; Decatur *et al.*, 2013).

Why are such duplication events important? The most obvious answer is that increasing the number of copies of a particular gene increases the scope for evolutionary change because you can get a novel function (neofunctionalization) appearing in one copy while retaining the original function of the gene in the other copy (**Figure 8**; for beautifully written reviews of this topic see Hurles, 2004; Cañestro *et al.*, 2013). So, for example, globins are oxygen-binding proteins, widespread throughout the animal kingdom, that fulfill a variety of roles from O_2 sensing to the detoxification of harmful reactive oxygen species (Ebner *et al.*, 2010). Hemoglobin and myoglobin, vertebrate specific molecules that evolved from duplicates produced during the WGD events (albeit through a very complicated pathway), took their oxygen-binding capacities to

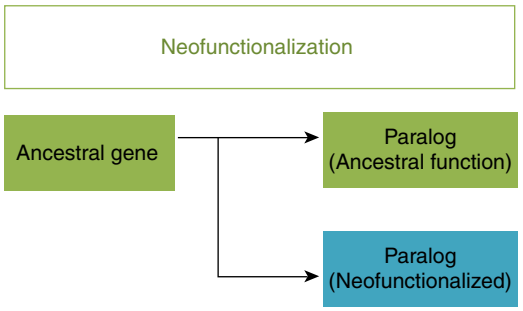

Figure 8 Neofunctionalization following a gene duplication event. Author: Jennonita (https://commons.wikimedia.org/wiki/File:Neofunctionalization_after_a_gene_duplication_event.png).

new areas in the body – oxygen transportation within red blood cells (hemoglobin) and oxygen storage in the muscles (myoglobin). These two novel functions allow oxygen to be delivered more efficiently to tissues.

Why was this important? Cephalochordates are capable swimmers, so clearly neither myoglobin nor hemoglobin are necessary for an animal to be active. Cephalochordates, however, are very small and thin and are active only in short bursts. They possess a closed circulatory system in which the colorless blood (no globins) is moved throughout the body by the pulsing of contractile blood vessels. Gas exchange is accomplished by the passive diffusion of oxygen across the skin or coelomic cavity (Schmitz *et al.*, 2000), a very slow process that can only occur over short distances. The ability to more effectively deliver and store oxygen was thus a critical prerequisite to the evolution of larger, more active animals (Storz *et al.*, 2013 and references therein). Overall then, gene duplications resolve the seeming paradox of novelty – the purported requirement for a gene to undergo a series of gradual changes that maintain functionality while, at the same time, promoting change – because 'conservation' of function and 'evolution' of function are partitioned into two separate (but initially identical) gene copies.

The Critical Vertebrate Developmental Innovations

If you look at a photograph of a lancelet and compare it to any vertebrate, even hagfish, one thing is immediately obvious – vertebrates have a very complex head. Northcutt and Gans (1983) postulated that this 'new head' was formed by two uniquely vertebrate embryological tissues, the neural crest and the cranial placodes. Both of these tissues arise in the developing neural plate, as it folds to form the dorsal hollow nerve cord (recall this character itself appeared in the ancestor of the chordates: **Figure 5**).

The neural crest consists of a population of multipotent neuroepithelial cells that originate in the inner walls of the folding neural plate, transform into mesenchymal cells and then begin to migrate outwards (green cells in **Figure 9**). Streams of these cells move to various places in the body, forming, among other things, the mineralized facial skeleton (cellular cartilage, bone, teeth), pigment cells, cranial ganglia, valves and walls of the heart, sensory and autonomic ganglia of the peripheral nervous system, and the enteric nervous

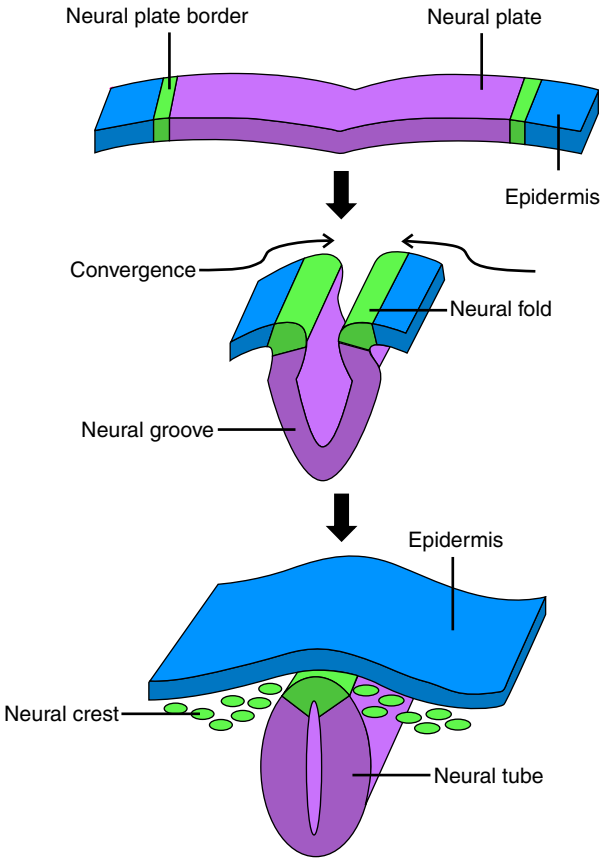

Figure 9 Diagram showing the formation of neural crest cells during neural plate folding. Author: NikNaks (https://commons.wikimedia.org/wiki/File:Neural_crest.svg).

system that innervates the gut (Simões-Costa and Bronner, 2013). It is no wonder the neural crest has been hailed as one of the most important vertebrate developmental innovations. But, what exactly was the innovation? All of the genes involved in neural crest formation were present in the ancestor of the chordates. Some of those genes (e.g., *Zic1*, *Pax3/7*, *Dlx3/5*, *Msx*) still play the same role today, specifying the development of the neural plate border, while others (e.g., *slug/snail*, *Foxd3*, *AP-2*, *Sox9/10*, *Twist*) are expressed in different tissues. Early in vertebrate evolution the latter group of genes became active in the preexisting neural plate border (changes in the timing and location of gene expression), changing the properties of their new target cells; this was the vertebrate innovation. Molecular studies indicate that these genes were not co-opted simultaneously, but rather that some were integrated into the developing neural crest before the genome duplications, while others were recruited afterwards (Green and Bronner, 2013; Ono *et al.*, 2014 and references therein). These studies may explain why some of the purported neural crest functions (e.g., the formation of bone) are not found in the basal-most vertebrates.

Cranial placodes, like the neural crest, develop from the folding neural plate. These placodes, which participate in the formation of various sensory systems in the vertebrate head (e.g., lens of the eye, olfactory receptors, inner ear sensory hair cells (otic), lateral line sensory hair cells, cranial nerve V

(sense of touch, pain, temperature in the face), neurons innervating the taste buds) have also traditionally been hailed as another major 'vertebrate innovation'. Recent studies, however, indicate that some of these placodes (olfactory, otic, lateral line) may have originated in the common ancestor of the Olfactores. Indeed the adenohypophysis placode may be even older (Graham and Shimeld, 2013). Interestingly, these stepwise patterns are largely congruent with a study of 5592 zebrafish genes (2222 of which are expressed in the neural crest or placodes) that uncovered three pulses of dominant adaptive evolution in sensory structures within the chordates. The third of these pulses occurred in VA (Šestak *et al.*, 2013).

So, did the neural crest and cranial placodes originate in VA? The answer to that question is 'No'. Genetic precursors to these structures were already in place by the time that ancestor appeared. This does not mean that the neural crest and cranial placodes are not important vertebrate innovations because all of them were highly modified in VA. What we are converging upon, then, is a more realistic picture of vertebrate origin based upon the stepwise assembly of genetic/developmental toolkits rather than the sudden appearance of complexity (for a detailed discussion of how complicated this assembly was, see Schlosser *et al.*, 2014). Indeed, this stepwise pattern is a recurring theme throughout the evolution of life (see e.g., de Mendoza *et al.*, 2013). The take-home message here is simple: the genomic/developmental architecture underlying the morphological exuberance displayed in the ancestral vertebrate species did not appear *de novo* in that species. It is not so much that new genetic material evolved in that ancestor (although this may have played a minor role; Khalturin *et al.*, 2009; Smith *et al.*, 2013), but that new developmental patterns emerged involving changes in timing and interactions among preexisting genes.

Putting It All Together

More than half a billion years ago, the vertebrate ancestor was flourishing in warm, shallow Cambrian seas. Current evidence suggests that VA was a small, jawless fish-like creature, with (1) moderately well-developed tail, dorsal and ventral fins (no paired fins yet), gills supplied with water by muscular ventilation and a two-chambered, endothelial lined heart, all of which contributed to increased swimming performance. In other words, VA was an active animal; (2) well-developed sensory capabilities: image forming eyes and the ability to detect chemosensory cues (smell and taste), the movement of water particles (lateral line) and sound/body position (inner ear); (3) a well-developed brain, including the vertebrate novelty – the telencephalon. The telencephalon contains the basal ganglia, which is responsible for the control of motor patterns that underlie so many physiological and behavioral traits (Grillner *et al.*, 2013 and references therein). In conjunction with the changes to sensory and aerobic capabilities, this implies that VA was capable of sophisticated swimming maneuvers and responses. In other words, VA had the toolkit to change from being a benthic feeder to a free-swimming pursuit predator.

The sensory systems thus appear to have evolved out of step in chordates, beginning with vision, followed by otic and olfactory input, and finally taste. Intriguingly, Feinberg and Mallatt (2013) proposed that the ability to integrate sensory information from multiple sensory sources may have represented a major step forward in the evolution of consciousness – and that such an ability may in fact have arisen and been amplified in the basal vertebrates (beginning with *Haikouichthys*). So it is possible that VA was conscious of, at least, its sensory experiences. Studies on mice and people have shown that a family of four genes ('*Dlg*') responsible for shaping neurotransmitter receptors and enzyme complexes in the brain are intimately involved in learning, cognitive flexibility, and attention. Only one *Dlg* gene is found in lancelets, but four copies are present in vertebrates (another example of the importance of whole genome duplication early in vertebrate evolution) (Nithianantharajah *et al.*, 2013). So, not only was VA possibly conscious of its sensory experiences, but it might have been capable of flexible and sophisticated cognitive tasks (studies on basal chordates and vertebrates are needed to test this suggestion). Finally, based on the life histories of basal extant vertebrates and cephalochordates (tunicates are highly derived and strange creatures), VA probably had separate sexes. Given the further WGD-associated evolution of the pituitary gland (Dong *et al.*, 2013 and references therein), which is the master controller of hormone-mediated behaviors, coupled with the origin of the telencephalon, we can speculate that VA individuals engaged in courtship behavior – but based on which cues and what did courtship look like? To answer these questions, we must begin to unravel the genetic developmental pathways underlying such behaviors. Once we can do this, then VA will truly come alive in our minds.

We have had a complicated interaction with vertebrate species over the millennia. We have hunted, feared, worshiped, domesticated, tried to obliterate, and bonded with some of them. We began painting their images on cave walls more than 40 000 years ago, and ever since we have watched and studied them because they teach us about ourselves. Data are accumulating at an ever-increasing rate as technological advances give us the ability to uncover smaller and smaller pieces of this complicated evolutionary story. As of 2015 we know so much about some aspects of our vertebrate ancestor, and so little about others. That is what makes science so exciting!

Vicariance Biogeography

G Giribet, Harvard University, Cambridge, MA, USA

Glossary

Area cladograms A representation of a relationship of areas resulting from substituting taxa for the areas where they occur.
Center of origin The supposed geographical area where a clade originated and from where it dispersed to subsequent areas.
Cladistics Phylogenetic systematics; the science that studies clades and their inference.
Cladogram A phylogenetic tree derived using cladistic techniques.
Model-based approaches In a biogeographical context, different events (vicariance and dispersal) receive different probabilities, but these values are difficult to estimate.
Molecular dating The methodology that infers the dates of cladogenesis or origins of taxonomic groups.
Node calibration The act of assigning an age to a node to calibrate other nodes in the tree.
Node dating A molecular dating technique that assigns ages to nodes without the need of prior analysis.
Panbiogeography An inference of a biogeographical relationship based on repeated occurrences in different areas, but without explicit methodologies.
Paraphyly/paraphyletic Terms applied to non-monophyletic groups including the common ancestor and some but not all the descendants of such ancestor, for example, dinosaurs are paraphyletic with respect to birds.
Parsimony-based approaches In a biogeographical context, parsimony-based approaches assume that vicariance often requires no cost, and dispersal has a cost associated (the methods favor vicariance over dispersal).
Phylogenetics The science that infers genealogies of higher taxa, or the so-called phylogenetic trees.
Taxon A group of organisms in the hierarchy of life; for example, a species, family, order, class, etc.
Total evidence dating A molecular dating technique that includes fossils (and their ages) into a phylogenetic analysis containing data on morphology and molecules for the extant taxa.
Vagility The degree to which a taxon moves.

After the introduction of the idea of continental drift (Wegener, 1912) and later its acceptance subsequent to the understanding of plate tectonics as the mechanism underlying the concept of continental drift, vicariance biogeography emerged as the favorite mechanism to explain disjunct distributions of ancient organisms. Vicariance has, for instance, been used to explain the modern distributions of ancestral Pangean animal and plant lineages (e.g., San Mauro *et al.*, 2005; Giribet *et al.*, 2012; Mao *et al.*, 2012; Murienne *et al.*, 2014). Perhaps one of the most paradigmatic case studies of vicariance is that of the breakup of Gondwana, with many studies focusing on a diversity of lineages (e.g., Sanmartín and Ronquist, 2004). Whether trying to explain the global distribution of ancient biotas through the reconfiguration of entire continental landmasses, or more local and recent events (e.g., the detachment of the Corso-Sardinian microplate from the Iberian Peninsula before the Miocene), vicariance biogeography assumes that the biotic distributions are due to drifting with landmasses and not due to subsequent dispersal, hypotheses that can be difficult to distinguish. For instance, a *trans*-Tasman distribution – of organisms found both in Eastern Australia and New Zealand – could be easily explained by vicariance, but also by dispersal as postulated by the West Wind Drift hypothesis (Sanmartín *et al.*, 2007), and an accurate estimate of the age of cladogenesis is a prerequisite to distinguish between hypotheses, as cladogenesis must predate the geological event supposedly causing vicariance in order to be considered more likely than dispersal. Only in well-sampled studies of diverse groups, the tree topology can help to infer the timing and directionality of dispersal (e.g., Sharma and Giribet, 2012). Vicariance, however, remains the paradigm against which one tests alternative hypotheses of dispersal, whether using parsimony-based approaches (where vicariance often requires no cost) (Ronquist, 1997) or model-based approaches (Ree and Sanmartin, 2009; Yu *et al.*, 2010).

A Brief History of 'Vicariance Biogeography'

The discipline of vicariance biogeography was a development of the 1980s, and a paradigm shift from previous biogeographic ideas that focused on dispersal from centers of origin, or other disciplines such as panbiogeography, which had been mostly 'story telling.' Vicariance biogeography really allowed the field of biogeography to move into the scientific domain, as it was hypothesis driven. According to Wiley (1988), vicariance biogeography developed from three key events: the emergence of plate tectonics as a major geological paradigm, the emergence of biological systematics, and the discovery of Croizat's works by Nelson (e.g., Nelson, 1974). Methodological developments followed (e.g., Nelson and Platnick, 1980, 1981). The implications of the new discipline were that current higher taxa were once species that diverged as a result of a vicariant event and that cladograms are able to reflect such events by transforming taxa into area cladograms (**Figure 1**). It is beyond this article to discuss the many specific methods for conducting analyses of area cladograms. A thorough discussion of the methods historically used to analyze vicariance biogeography can be found in Crisci *et al.* (2003). For the purpose of this article, it suffices to say that repeated

 doi:10.1016/B978-0-12-800049-6.00107-4

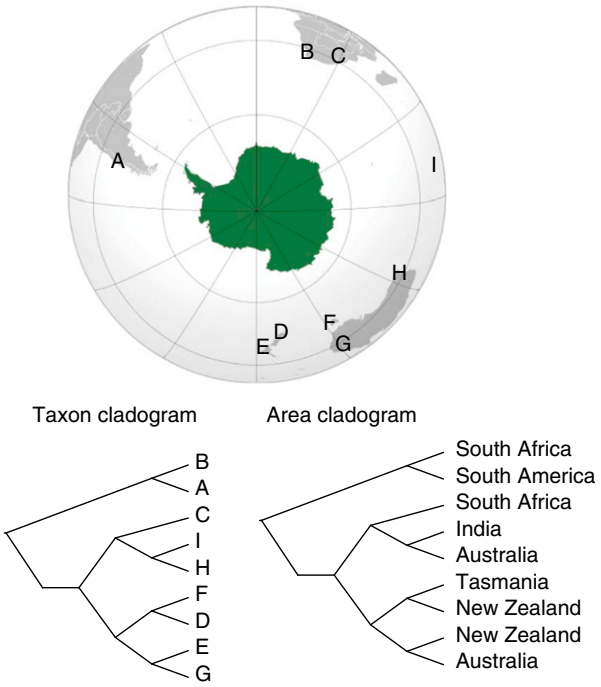

Figure 1 Example of the distribution of a temperate Gondwanan lineage found in modern circum-Antarctic terrains and their taxon cladogram and area cladogram derived from it.

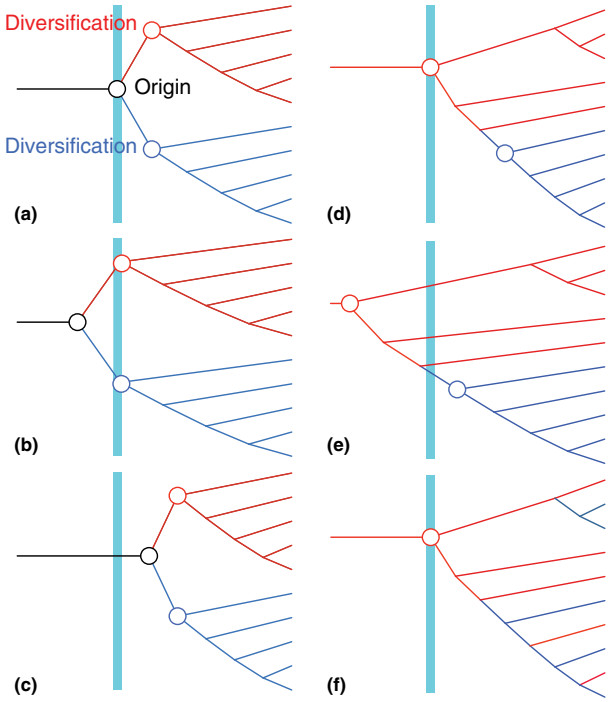

Figure 2 Alternative scenarios assuming a tectonic event (vertical cyan blue line) and accurately dated phylogenies. The different colors (red and blue) indicate modern distribution in two currently noncontiguous landmasses. (a) A scenario with the tectonic event coinciding with the cladogenetic event, and thus compatible with vicariance, with each descendant lineage diversifying in a different landmass. (b) Scenario with ancient cladogenesis preceding the tectonic event but compatible with vicariance. (c) Scenario where cladogenesis occurs after the tectonic event and thus incompatible with vicariance; this scenario assumes that one of the lineages (or both) achieved their current distributions through a mechanism of dispersal. (d) Scenario implying dispersal of the blue lineage, rendering paraphyly in the landmass of origin. (e) Scenario compatible with vicariance but with a deep cladogenetic history prior to the tectonic event. (f) Phylogenetic scenario with landmass paralogy, requiring multiple instances of dispersal.

(congruent) patterns – those found across taxa – may reflect common historical vicariance events, in the same sense that congruence among characters is used to derive phylogenetic hypotheses of taxa. Major problems with this approach are the assumptions that incongruent patterns are due to dispersal – they could also be explained by differences in the timing of the cladogenetic events – and that areas can be defined a priori. As an example, South Africa, Australia, and New Zealand are each non-monophyletic in **Figure 1** – because their inhabitant taxa do not form clades. Non-monophyly of these landmasses is, however, common in studies of groups that do not disperse well, if cladogenesis predated the rifting of Gondwana (e.g., Giribet *et al.*, 2012; Murienne *et al.*, 2014) (a scenario as in **Figure 2(e)**). In addition, assuming that South Africa or Australia are each an area of endemism for all types of organisms, it has been refuted by many studies based on short-range endemisms (e.g., Harvey, 2002; Giribet and Edgecombe, 2006). Interestingly, new methods for estimating areas without predefining them prior to biogeographical analysis – the so-called 'spatial analysis of vicariance' – are now being developed (Arias *et al.*, 2011). The method uses observed distributions as data, thus requiring neither predefined areas nor assumptions of hierarchical relations between areas.

Modern Approaches to Understanding Vicariance in Biogeography

Vicariance has played a key role in our understanding of the evolutionary process through large timescales, but in its original formulation, pattern alone, and not time (as it was difficult to obtain at the time), was used. Unfortunately, the timing of the cladogenetic events is key in biogeographical studies, as landmass or ocean configurations change drastically through time. This change of landmasses, emerging and disappearing through Earth's history, is beautifully illustrated in a recent biogeographic study of Sulawesi (Stelbrink *et al.*, 2012). However, few studies like this are available for other regions of the world. Examples of identical patterns with different timings, and thus different biogeographical explanations, are found in **Figure 2**. For example, **Figures 2(a)–2(c)** show the same pattern for three scenarios: In one case (a), the time of origin of two clades coincides exactly with the time of the 'event,' thus indicating vicariance; in another case (b), cladogenesis takes place earlier and diversification coincides with the timing of the 'event,' not necessarily constituting a case of vicariance; and in the third case (c), both the origin of the two groups and their diversification postdate the event – a clear case of dispersal between landmasses.

Problems with Assumptions of Vicariance Biogeography

A common assumption of supposing a strict correlation between a cladogenetic event and a vicariant event is that both more or less coincide in time (**Figure 2(a)**), and thus one is informative of the other. This is typically done by calibrating one or more nodes of a phylogeny with the geological time of separation of two landmasses, as was done, for example, by Boyer *et al.* (2007) for a group of arachnids and has been applied to many groups without a known fossil record – the so-called tectonic calibrations or vicariance-based calibrations (see a list of papers using tectonic-based calibrations in Kodandaramaiah, 2011). This practice has been legitimately criticized by Kodandaramaiah (2011), as this assumption does not allow for cladogenesis preceding the tectonic event (**Figure 2(b)**), while molecular evidence has shown in several cases that cladogenesis can indeed precede the geological event by vast amounts of time (e.g., Giribet *et al.*, 2012; Murienne *et al.*, 2014). Tectonic calibrations thus have the dual problem of not testing for vicariance (since it is assumed) and resulting in a push-toward-the-present effect (Giribet, 2015), as the approach equates time of cladogenesis with the tectonic event. Therefore, only those studies using independent calibration methods are now considered proper tests for vicariance.

While vicariance was originally invoked by observing organisms distributions (e.g., Brundin, 1965, 1966), dispersal could generate similar patterns, especially in the southern hemisphere with the circum-Antarctic current or the West Wind Drift hypothesis (Sanmartín *et al.*, 2007). The tempo of evolution is thus crucial for claiming vicariance. Dating phylogenies has progressed a great deal since the introduction of molecular data, especially recently, as researchers often use the fossil record to calibrate nodes in phylogenies instead of molecular clock approaches (Laurin, 2012). Fossil calibration is not without controversy, and two approaches currently exist: the so-called 'node calibration,' where a fossil is assigned to a particular node to constrain such node or a split, or the more recent 'total evidence dating' (Murienne *et al.*, 2010; Pyron, 2011; O'Leary *et al.*, 2013; Wood *et al.*, 2013), where fossils are positioned more precisely in a phylogeny using morphology in combination with molecular data (see a recent revision of the topic in Sharma and Giribet, 2014). But even when the same fossils are used for calibrating trees, dating methods are inherently different and few studies explore alternative outcomes (e.g., Mao *et al.*, 2012; Murienne *et al.*, 2014) and even fewer have studied the impact of the calibrations per se (Sauquet *et al.*, 2012). This latter study shows that estimates for the crown group age of *Nothofagus* – an emblematic tree for the study of Gondwanan vicariance biogeography which has more recently been found to show rampant dispersal – varied from 13 to 113 Ma across a full range of calibration scenarios (Sauquet *et al.*, 2012), in part due to inaccurate dating of the fossils and to the phylogenetic uncertainty of the fossils. Another recent example refers to the use of a Devonian harvestman fossil (Dunlop *et al.*, 2003), which has been interpreted as a member of the extant Phalangioidea and used as a node calibration in Opiliones trees (Giribet *et al.*, 2010; Hedin *et al.*, 2012). However, recent phylogenetic investigation of the fossil has shown it to be a member of a stem group Opiliones (Garwood *et al.*, 2014), contradicting prior node-based calibrations, and now used for total evidence dating (Sharma and Giribet, 2014).

To summarize, vicariance biogeography provides a powerful explanation for many biotic distributions, but these require proper dating to distinguish whether cladogenesis occurred prior to, during, or subsequent to a given tectonic event. Other ecological aspects, including range expansions and contractions, niche conservatism, secondary contacts with other biotas (e.g., the case of the Indian subcontinent; Ali and Aitchison, 2008), and competition, often play a role in preserving the vicariant biotas on both sides of a tectonic event. It is well known that this is not the case for many groups of organisms, once broadly distributed across Pangea, but now restricted to remote continental islands, such as monotremes of the Austro-Papuan region, or the tuatara and rheobatrachid frogs in New Zealand – all of them subjected to large continental extinctions.

Three premises are thus required to distinguish vicariance from dispersal:

1. The organism distribution requires a pattern consistent with continental rifting, and that the landmasses it inhabits are of continental origin, not islands of oceanic origin or Darwinian islands (*sensu* Gillespie and Roderick, 2002).
2. If continental in origin, the landmasses should not have undergone total submersion, as supposedly happened in New Caledonia (Grandcolas *et al.*, 2008; Murienne, 2009), or, less likely, in New Zealand (Waters and Craw, 2006; Giribet and Boyer, 2010; Sharma and Wheeler, 2013; Mildenhall *et al.*, 2014).
3. Although less commonly used, a phylogenetic pattern must also be concordant with the vicariant hypothesis, often represented by reciprocal monophyly of clades at opposite sides of the tectonic event (**Figures 2(a)** and **2(b)**), or paraphyly, in the case that the lineage has an old history in the contiguous landmass prior to the split (**Figure 2(d)**). However, multiple instances of paraphyly are difficult to reconcile with vicariance, even for lineages older than the tectonic event.

Recognizing vicariance is becoming more feasible, but this does not mean that biogeographic analyses should be restricted to this mode of cladogenesis. In fact, most biogeographic research focuses on island processes in Darwinian islands, based on the premise that the first colonizers of those islands must have been able to disperse, and that many were subject to different types of radiations, perhaps most prominent adaptive ones in places like Galapagos, Hawaii, the Canaries, or Cape Verde archipelagos (e.g., Arnedo *et al.*, 2001; Carranza *et al.*, 2001; Hormiga *et al.*, 2003; Gillespie, 2004; Parent and Crespi, 2006; Lerner *et al.*, 2011). Nonetheless, vicariance is still a much more parsimonious explanation for ancient distributions of organisms with low vagility and narrow ecological requirements – the latter condition often overlooked, but often tightly linked to low vagility – and is able to explain the distributions of disparate groups including amphibians (San Mauro *et al.*, 2005), velvet worms (Murienne *et al.*, 2014), arachnids (Giribet and Kury, 2007; Murienne *et al.*, 2013), myriapods (Giribet and Edgecombe, 2006;

Wesener and VandenSpiegel, 2009), insects (Krosch *et al.*, 2011), and plants (Mao *et al.*, 2012; Beaulieu *et al.*, 2013), to mention just a few of the most charismatic groups.

Waddington's Epigenetic Landscape, History of

S Borish, California State University East Bay, Hayward, CA, USA
S Gilbert, Swarthmore College, Swarthmore, PA, USA

Glossary

Spineless-aristapedia (ssa) Regulatory gene in Drosophila melanogaster, encoding a basic-helix-loop-helix-PAS transcription factor that is required for the proper specification of distal antennal (arista) tissue. Loss-of-function mutations transform the arista cells into distal leg (tarsus) tissue ('aristopedia') and the reduction of bristle size ('spinelessness').

Introduction: Conrad H. Waddington as Systems Integrator

Conrad Hal Waddington (1905–75) began to follow the unusual developmental pathway of integrating embryology, evolution, and genetics early in his professional career. Although his epigenetic landscape model was first presented more than 50 years ago, its brilliance and elegant originality have enabled it to add useful explanatory and aesthetic dimensions to important current discoveries in the emerging fields of epigenetics and developmental biology. New research on Waddington's epigenetic landscapes (Gilbert, 1991a,b; Bard, 2008; Fagan, 2012; Baedke, 2013; Fusco *et al.*, 2014) has shown their heuristic value for several fields, some of them outside biology. The significance of Waddington's "epigenetic landscape" diagrams becomes clearest when placed in the detailed context of his life and work.

Although Waddington designed the "epigenetic landscape" to show the individuation of a pluripotent population of cells into distinct and different pathways of differentiation, Waddington's own life shows a quite different pattern of individuation. What is remarkable about Waddington's individuation is the way in which multiple options, talents and interests evident in his early university years are not foreclosed, but kept open throughout his life. Followed passionately over many decades, these talents and interests cross-fertilize, leading to the creative synergy seen in his epigenetic landscape model. He spent his early years in India where his father was a tea planter. Returning to England at the age of four, and following preparatory school, he won a scholarship to Cambridge University. After taking a First Class Honors degree in geology in 1926, Waddington pursued graduate work in paleontology with a focus on the systematics of ammonites, an extinct group of cephalopods. Reflecting his diverse interests, he held at the same time an 1851 studentship in paleontology and an Arnold Gerstenberg studentship in philosophy (1927).

Whether speaking of Waddington's early work in paleontology or his subsequent work in fields as diverse as embryology, genetics, ethics, and interconnections in the fields of science and art history, a common theme is that all reflect the process philosophy of Alfred North Whitehead (Robertson, 1977). For Whitehead, no thing exists except in relation to other things, and the relationships thus created are always in a process of becoming. As Waddington would later write of his early work in paleontology, it "forces on one's attention the Whiteheadian point that the organisms undergoing the process of evolution are themselves processes … The whole developmental process is preserved so that one cannot avoid examining it" (Waddington, 1975). In this early work, one can see him already viewing the fossil record with the developmental eye of an embryologist.

While pursuing his graduate work in paleontology, Waddington's interest began to move from paleontology toward genetics. Yet, he had also been reading the work of Hans Spemann, the German embryologist, who discovered the organizer. After a meeting with Dame Honor Fell, director of the Strangeways Research Laboratory, Cambridge, he was encouraged to begin work there in the field of embryology. Using techniques he himself developed for growing chick embryos *in vitro*, he successfully manipulated and transplanted different embryonic regions from one early chick embryo to another. Among his discoveries he could show that the elongation of the primitive streak was directed by the underlying hypoblast. His photographs of twin chick embryos resulting from the transplanting of an exogenous node beneath the ectoderm constituted an important demonstration of primary embryonic induction in a warm-blooded animal: the earlier discovery of the organizer by Spemann and Mangold (1924) had been with amphibians.

Waddington was able to present his first results on culturing chick embryos in 1930 at the International Congress of Experimental Cytology in Amsterdam. His presentations were extremely well received; he soon received several invitations to come to work in Germany. From 1932 to 1938, Waddington studied amphibian neural induction, attempting to learn and transfer the techniques of amphibian experimental embryology to the study of chick development. Approximately 14 single-authored papers would appear between 1932 and 1938; an additional four were the product of joint authorship with distinguished colleagues in the field. The budding paleontologist who saw the world at least in part through the eyes of Whiteheadian process philosophy had undergone his own metamorphosis. By the last years of the 1930s he had become a skilled research scientist, a respected contributor to embryology whose careful work was widely viewed as having made important contributions to the field.

The Split between Embryology and Genetics: A Brief Review

A disciplinary split between genetics and embryology was fundamental and formative to all working in those fields at this time. Waddington's lifelong commitment to reconciling this split provides an essential key for understanding the work that led him to formulate the epigenetic landscape model. We must take a brief look at the history of those disciplines as they unfolded during this period.

A central question for the experimental embryology that had emerged in the early years of the twentieth century was this: Which compartment of the zygote – the nucleus or the cytoplasm – directs heredity and development? (Gilbert, 1988, pp. 312–314). A critical finding emerged from *Drosophila* studies of Thomas Hunt Morgan and coworkers at Columbia University: factors for eye color, body color, wing shape, and sex determination, all segregated with the X chromosome within the nucleus. In the years following 1910, Morgan's work – which had become a primary driving force in American biological science – drove a wedge into embryology, splitting it into two divisions, the embryologists and the new geneticists. Soon after 1911, genetics began to arise as a separate discipline, complete with its own techniques, favored organisms, rules of evidence, journals, and vocabulary (Gilbert, 1991a, pp. 182–183).

In the 1920s and 1930s, the remarkable success of genetics in applied breeding techniques in both animal husbandry and plant breeding led it to be seen by many as the preeminent biological science in America (Gilbert, 1996a, pp. 101–106). Geneticists began to encroach upon what had been the traditional territories of embryology. If cytoplasmic development was little more than an epiphenomenon of genetic control (as many geneticists argued), then perhaps it was the research methods of genetics that could best obtain the answers to the developmental questions that embryologists had been asking (Gilbert *et al.*, 1996b).

Many embryologists reacted strongly to this territorial push by geneticists. Prominent figures such as Lillie, Spemann, and Just argued that there could be no 'genetic theory of development' until geneticists could meet at least two major challenges:

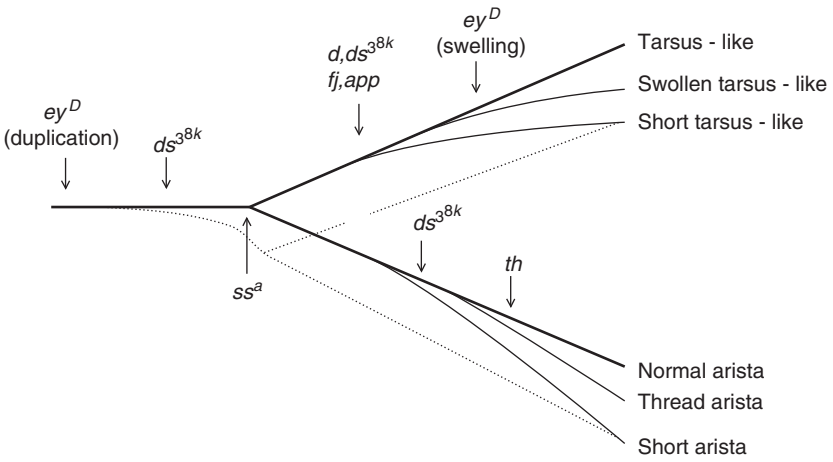
1. they needed to explain how chromosomes – thought to be identical in every cell of the organism – could produce different and changing types of cell cytoplasms; and
2. they had to provide evidence that genes control the early stages of embryogenesis (almost all the genes known at the time affected the final steps in development, such as eye color, bristle shape, and wing venation in *Drosophila*).

As E.E. Just summed it up, embryologists were interested not so much in the number of bristles a fly has on its back, but in understanding how a fly forms its back in the first place.

This brief sketch gives something of the general climate at the time. Geneticists and embryologists were for the most part professionalizing their respective disciplines, focusing on either genes or organizers. From the beginning, Waddington was a consistent and conspicuous exception to this pattern of disciplinary exceptionalism, and the words in the title of his book, *Organisers and Genes*, should be recognized as being metonymous for embryology and genetics, respectively. He would argue consistently in a large body of work over four decades that the phenomena investigated by genetics and embryology were not separate. They represented two sides of the same coin. What was desperately needed was a form of synthesis and integration that would demonstrate this underlying unity. The synthesis as envisioned by Waddington would involve not only these two disciplines but the broader study of evolutionary change revealed through paleontology. Waddington firmly believed that epigenetics, or 'the science concerned with the causal analysis of development' would provide the key for the needed synthesis. The preceding definition appears on the title page of *The Epigenetics of Birds* (Waddington, 1952), but it is only a variation on a theme that appears much earlier and is consistently reintroduced in all of his subsequent work.

'Development as an Epigenetic Process': Steps Toward the Epigenetic Landscape

After an initial decade of research in embryology, the topic of Waddington's first book was, surprisingly, not embryology but genetics. Moreover, when *An Introduction to Modern Genetics* (Waddington, 1939) appeared, he was only 33 years old, and had not published a single academic paper in genetics. He states in the Preface "a word of explanation, and perhaps of apology, for having written a text-book of genetics although the field of my own research is usually classified as the separate science of embryology." He explains that the need to do so has arisen "primarily because the different kinds of biological cobblers have in the past stuck to their own lasts." He then suggests that "the connection between genetics and the other branches of biology, such as cytology, embryology, the study of evolution and of the biochemical nature of cell constituents, is much closer than is often admitted, and that the boundaries between these subjects deserve less attention than is usually paid to them." It is, in typical Waddington fashion, an apology that does not sound much like an apology.



The aristapedia developmental track system. The developmental process runs from left to right, either into the tarsus track above or the arista track below. Both these tracks are affected by various genes. The dotted lines represented one interpretation of the actions of ds38k, which affect both normal and tarsus-like antennae. Only the mutant genes have been inserted; their normal allelomorphs would act in the opposite sense.

Figure 1 The aristapedia mutation. Reproduced from Waddington, C.H., 1940. Organisers and Genes. Cambridge: Cambridge University Press.

In this book, Waddington introduces an area of theoretical focus in which he will make major contributions for the rest of his professional life. The section "Development as an Epigenetic Process" (Waddington, 1939, pp. 154–155) begins by reviewing the classical controversy in embryology "between the preformationists and the epigenisists." Perhaps playing the role of Devil's advocate, the author, although an embryologist, sees light on both sides. He finds on the one hand that the modern view of development necessitates an admission that "development proceeds on the basis of the 'preformed' qualities of the fertilized egg." Nevertheless, this must be balanced by the understanding that "the interactions of these [the egg's] constituents gives rise to new types of tissue and organ which were not present originally, and in so far development must be considered as 'epigenetic.'" Waddington, who is generally given credit for coining the term 'epigenetics' (Goldberg *et al.*, 2007), was not only the first to use the term 'epigenetic' at this systems level, but in a short paper published almost at the same time (Waddington, 1942) he introduced the term "epigenotype" to capture the interactions between genes, their products, and the environment. It has been suggested that in today's language "we might think of the epigenotype as the networks of transcription factors, paracrine factors, and environmental influences that allow the genotype to realize the phenotype" (Gilbert, 2000, 2011). What a gene does or does not do, then, can depend upon its context.

Pursuing the theme of integration, in *Organizers and Genes* Waddington calls himself a student of 'diachronic biology,' a science, in his own words, of "embryology-genetics-evolution which again form a group whose interconnections are obvious and unavoidable" (Waddington, 1940, p. 1). Its conclusion (1940, p. 148) seems to go one step further: "the developmental side of biology – embryology, genetics and evolution – seems to be reaching a point where radically new types of thinking are called for."

Waddington became a contributor to this effort to find new types of thinking over the following decades. Yet the first steps toward this can be seen even in this early work. First, he presents (1940, pp. 77, 83) an important thought predecessor of the epigenetic landscape diagram, 'the branching-track system.' Its purpose is to represent a sequence of reactions constituting the developmental pathway leading from the gene for a particular trait to the adult morphogenetic structure of that trait. Choosing the example of the genetic control of the development of the antenna in *Drosophila melanogaster*, he compares the development of this organ in the wild type fly with that caused by the recessive mutation aristapedia ssa, in which 'the arista is transformed into a more or less leg-like organ.' After showing the different end stages, the developmental process that gives rise to these allelomorphs is represented in this 'branching-track diagram' shown in **Figure 1**.

The 'branching-track' model is already a significant departure from the customary forms of presentation in the field, in which successive compounds would be listed in a linear array and referred to as "substances in a chain reaction" (e.g., Beadle and Ephrussi, cited in Gilbert, 1991b, p. 142). With only a little imagination, one can see the same developmental patterns represented by a true epigenetic landscape diagram. And in fact, the first schematic representation of an epigenetic landscape appears as the frontispiece of this 1940 volume (an actual landscape, drawn by an artist friend John Piper). A brief note below guides the reader to a later section: 'The Epigenetic Landscape.' Here the following (1940, pp. 91–92) appears:

> In embryonic development we are confronted with alternative modes of development … The system of developmental paths has been symbolized in two dimensions as a set of branching lines. Perhaps a fuller picture would be given by a system of valleys diverging down an inclined plane.

As this suggests, the frontispiece illustration is only a preliminary version. The 'fuller picture' representing the

epigenetic landscape model appeared in subsequent major publications (1954, 1956, 1957).

The Evolution of the Epigenetic Landscape

In order to extend, illustrate, and clarify his concept of the epigenetic system, Waddington began to experiment with a new form of symbolic representation of the entire developmental process. A key chapter in *Principles of Embryology* (1956, pp. 329–347) is entitled 'The role of genes in the epigenetic system.' This chapter begins with a discussion of developmental pathways and their genetic control. Citing Waddington in close paraphrase to best follow both his thinking and terminology, the pathways are analyzed as follows:

1. The development of an organ or complex tissue takes place in a series of steps, each of which is affected by genes.
2. At each step, there are several genes acting and actual development is the result of a balance between opposing gene programs.
3. An organ or tissue is formed by a sequence of changes which can be called 'the epigenetic path' leading to it.
4. In a normal or 'wild type' egg these paths are usually quite distinct, so that a specific embryonic tissue can turn either into a leg or into a wing, but only with great difficulty into something else.
5. Development produces not merely 'substances' or 'tissues,' but organs showing altered pattern and three dimensional shape. For example, a neural plate rolls up into a neural tube through morphogenesis (1956, p. 415).
6. Once a piece of tissue has entered on a path of development, its final condition can be affected by all the genes which are concerned in that path (1956, p. 340).
7. Finally, each path is 'canalized,' or buffered, protected by threshold reactions, so that even if it is mildly disturbed it will be effectively regulated back to the normal end result, which is the cell fate.

The synergistic action of many genes "whose operations interact in such a way to define a pathway of change in a multidimensional phase space" has a stability to which the developing system tends to return after disturbance (Waddington, 1973, p. 502). Such stabilized pathways are to be called "chreods" (Waddington, 1957).

The influence of Whitehead's philosophy is clear. In Waddington's autobiographical sketch, he writes that the lessons scientists can learn from Whitehead are "his replacement of 'things' by processes which have an individual character which depends upon the 'concrescence' into a unity of very many relations with other processes" (Waddington, 1975, p. 3). Waddington wrote that he used the term chreods as a substitute for Whitehead's 'concrescence' to indicate a stabilized or buffered pathway of change.

The term "chreods" (Waddington 1957) received much theoretical attention when the idea first appeared. The following citation from Piaget (1971, p. 47), quoted here at length, is illustrative. It not only explains Waddington's distinction between 'homeostasis' and 'homeorhesis,' but clarifies how this distinction contributes to Waddington's proposed synthesis of genetics and embryology (see also the discussion of Piaget and Waddington in Gilbert and Borish (1997)):

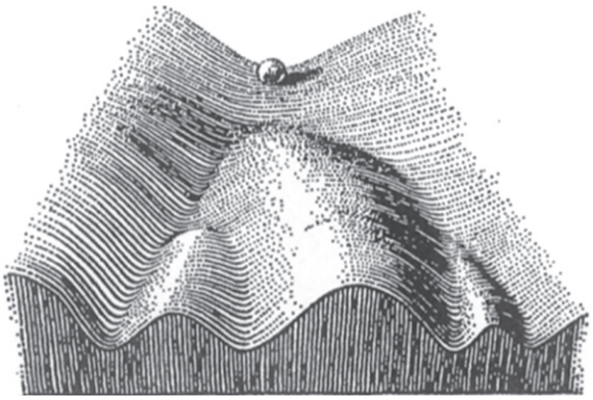
> Waddington has suggested the name 'chreods' (necessary routes) to describe developments particular to an organ or part of an embryo, and he applies the term 'epigenetic system' … to the sum of the chreods, taken as being – to a greater or lesser degree – channeled. But the main interest of this idea is not just in the names he gives things (or in the symbolic patterns thereby presented to us, of channels, some wide, some narrow, that the processes must follow). It is, rather, in a new kind of equilibrium as something which is, as it were, kinematic and which, in determining such processes, is nevertheless quite different from homeostasis: there is a kind of 'homeorhesis' when the formatory process, deviating from its course under outside influence, is brought back on course by the interplay of coercive compensations. In Waddington's opinion, such a mechanism is dependent upon a network of interactions rather than upon the action of individual genes …

Piaget recognizes that in 'homeorhesis', Waddington has invented a whole new term for discussing homeostasis in movement, as when embryonic precursors follow along the canalyzed tracks. It is important to see that behind this new terminology is Waddington's attempt to integrate the competing perspectives of genetics and embryology. It enables him to develop his view that the system of tracks and their genetic control, rather than the simple action of genes, is fundamental in embryonic development.

Waddington also believed that natural selection could work on aspects of development. If such a developmentally controlled pathway is advantageous to the survival and functioning of an organism, the path that leads from one state to another (e.g., from ectoderm to neural tube) becomes canalyzed by natural selection. His synthesis would therefore include both micro- and macroevolutionary changes, thus addressing the 'diachronic' perspective that he had pointed to in his early work.

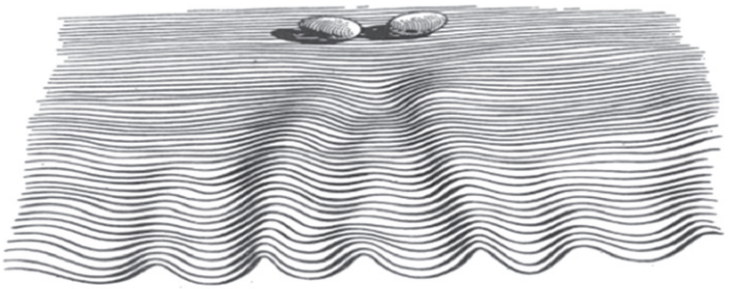
Ever interested in art and the visual representation of scientific ideas and data (he would later try using Japanese sumi-e-techniques to data splay rather than error bars), Waddington saw that aspects of the organismic developmental process could lend themselves to visual, pictorial representation. Going beyond the simpler branching-track diagram, which was itself a departure from the convention of strict linear representation of change, he began to experiment with what he called "a symbolic representation of the developmental potentialities of a genotype in terms of surface" (Waddington, 1956).

The establishment of cell fate can be visually represented by a ball rolling down the valleys of the epigenetic landscape. The resulting image of the epigenetic landscape is "a set of valleys or channels separated from one another by hills. The inclined plane of the landscape represents the tendency of the cells to pass from an immature to adult condition" (Gilbert, 1991b, p. 148). At certain times two downhill paths are possible, and the cell or tissue can be deflected into one or the other path. Regulation normally takes place only at specific branch points, where development has led the embryo into a valley with 'gently sloping sides.' As development proceeds, the original wide and gently sloping valley branches into subdivisions having far steeper sides. Once pushed down one path, it would be difficult to get to another. The further the ball rolls, the steeper the sides get. Three alternative, but complementary, representations of the Epigenetic Landscape – all proposed by Waddington – are shown in **Figures 2(a)–2(c)**.



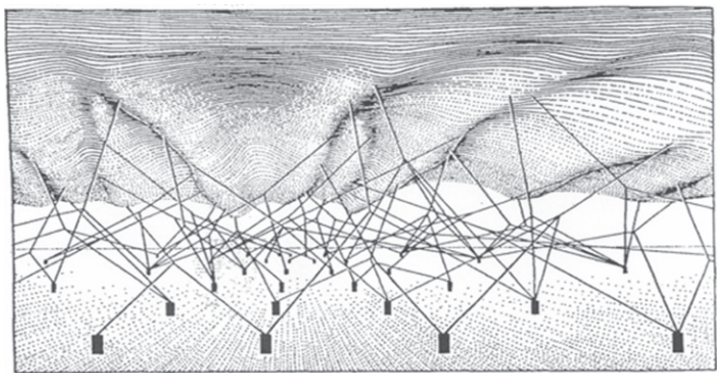
Waddington's image of the epigenetic landscape. The path of the ball represents cell fate. Depending on what happens at the different bifurcating branch points, each valley leads to the specific fates the embryonic cell might become if it rolls down that path. At the beginning of its journey, development is plastic, and a cell has many potential fates. However, as development proceeds, certain decisions cannot be reversed. (For more details on the use of these epigenetic landscapes to synthesize genetics, embryology and evolution - see Gilbert 1991b)

(a)



The 'epigenetic landscape." A symbolic representation of the developmental potentialities of a genotype in terms of a surface, sloping towards the observer, down which there run balls each of which has a bias corresponding to the particular initial conditions in some part of the newly fertilized egg. The sloping surface is grooved, and the balls will run into one or other of these channels, finishing at a point corresponding to some typical organ

(b)



Waddington's representation of how genes interact with the epigenetic landscape. The pegs in the ground represent genes or complexes of genes; the valleys are formed by tension acting on the guy ropes. The action of genes thus shapes the different pathways that canalize development toward specific cell fates.

(c)

The integration of gene-controlled processes and its bearing on evolution. In: Proceedings of the 9th International Congress of Genetics (Caryologia, Suppl. Vol.), p. 132; Waddington, C.H., 1956. Principles of Embryology. London: George Allen & Unwin. (c) Interactions underlying the epigenetic landscape. Reproduced from Waddington, C.H., 1956. Principles of Embryology. London: George Allen & Unwin.

The steepness of the valley walls indicates the changing equilibrium state of the track. It is a depiction of how canalyzed the reaction is. If the walls are steep, it would be difficult to escape from that valley once inside it. However, if the hills representing the two valleys are small, it would be possible for the cell fate to change from one cell type to another. The long road of discovery and exploration that lay behind Waddington's epigenetic landscape diagrams can recall these lines by the poet Robert Frost:

> Two roads diverged in a wood, and I—
> I took the one less traveled by,
> And that has made all the difference.

The Hidden Potential of the Epigenetic Landscape Diagrams

How were Waddington's epigenetic landscape diagrams received at the time they were first proposed? Although there were notable exceptions such as Piaget and the French mathematician Thom (1970), the concept of the epigenetic landscape did not receive an enthusiastic reception from either the geneticists or the embryologists for whom they were primarily meant. Whatever he may have thought about these developments, Waddington did not actively defend, or attempt to make converts for the epigenetic landscape diagrams he had spent so much time working toward. In fact, he was even instrumental in promoting their disuse.

When Jacob and Monod proposed the bacterial lac operon, in 1961, Waddington almost immediately introduced it into developmental biology as a useful model for embryonic induction. He devoted most of the first chapter of his *New Patterns in Genetics and Development* (Waddington, 1962) to a detailed and favorable explication of Jacob and Monod's work. Nowhere in this book is the epigenetic landscape even mentioned. Indeed, as developmental genetics supplanted Waddington's 'epigenetics,' the 'wiring diagrams,' pioneered by Jacob and Monod and extended to eukaryotes (see, for instance, Britten and Davidson, 1969), supplanted the more physical epigenetic landscape. Bacteria could be used to explain differential protein synthesis, but they were not envisioned to generate multiple cell types in a multicellular organism. The epigenetic landscape was eclipsed for nearly 50 years, until the study of stem cells in regeneration refocused attention on the alternative paths that multipotential cells could travel (see below). The potential of the epigenetic landscape diagrams can be described as follows:

1. They present a view of development as a four-dimensional dynamic process, a movement, an unfolding, a becoming.
2. They illustrate that this process of becoming involves movement along alternate and competing developmental pathways, each of which leads to a specific outcome. They impel recognition of the critical fact that the choice among pathways is not made at all points along the pathway, but at a succession of critical branch points.
3. They encourage a critical focus on the challenging task of locating, among a complex series of developmental events, those critical branch points along developmental pathways where the fate of a cell (or perhaps an individual, an institution, a society or ecosystem) is potentially in one or more directions up to the branch point, but where choice is made, development after the branch point is constrained to go in only one direction. They strongly imply that factors relating to the branch points, once located, should become serious targets of study.
4. They demand giving serious attention to identifying the nature of the underlying competence, or in Waddington's terms, the "period of competence," which is required to allow or "attract" development to proceed along the canalized pathways in the valleys below the contoured hillsides.
5. Once the decision has been made to move down one of the pathways beyond a branch point, leading toward a specific outcome, the representation of the terrain or contour lines between diverging pathways provides a useful representation of the difficulty of undoing an earlier decision, of moving over a higher contour line to get back to another pathway not chosen at the earlier branch point.
6. They thus suggest a framework for dealing with different possibilities of intervention in whatever developmental system is under discussion: how can we most effectively modify the height of the hills, providing the impetus to enter a different and perhaps more positive path than would otherwise have been accessible?

Waddington (1957, p. 167) would use these landscape models in his discussions of genetic assimilation, wherein some of the ridges between the valleys would be lowered by mutation or environmental perturbation.

The many new associated developments in contemporary biology in the last 20 years have brought about a marked resurgence of interest in the concept of the epigenetic landscape, thus fulfilling Slack's (2002, p. 894) prediction that Waddington's ideas would doubtless resurface to help meet new challenges facing theoretical biology. Indeed, the epigenetic landscape is still used to represent mechanisms for genetic assimilation (see Landecker, 2011; Paaby and Rockman, 2014), and the alteration of one cell type into another, as in cell fate specification (Bhattacharya *et al.*, 2011), in reprogramming (Wang *et al.*, 2011) or cancer (Huang *et al.*, 2009; Pujadas and Feinberg (2012). But its major comeback has been in studies of regeneration and embryonic stem cells (ES).

One of the most exciting developments in contemporary epigenetics was made by Japanese biologists Takahashi and Yamanaka (2006), who were able to demonstrate that when mouse embryonic fibroblasts were made to carry viruses carrying four specific active genes (Oct4, Sox2, Klf4, and c-Myc), the cells could be caused to return to their earlier state of ES. The newly reprogrammed 'induced pluripotential stem cells' (iPSC) could both change shape and become transformed into the three different tissue types of ectoderm, mesoderm, and endoderm. From here, the stem cells would follow Waddington's epigenetic landscape to their various cell fates. The important program for science, then, was to determine what chemical and physical factors would direct a stem cell to a particular fate. What factors would cause the pluripotent cell to travel down the pathway to make cardiac myocytes (that might cure heart disease), while what other factors could direct the pluripotent cell into the pathway of

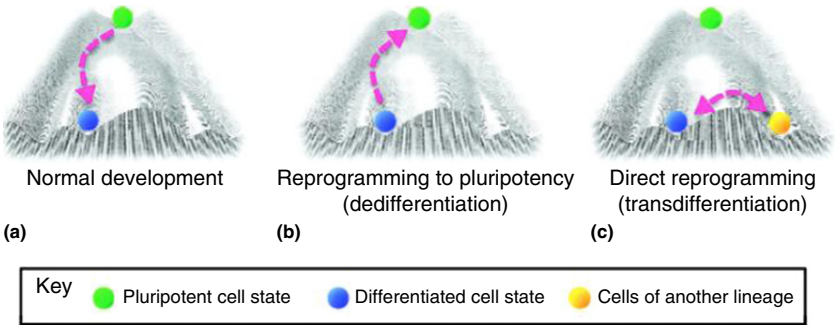


Figure 3 Changing cell fates on Waddington's epigenetic landscape (Takahashi, 2012).

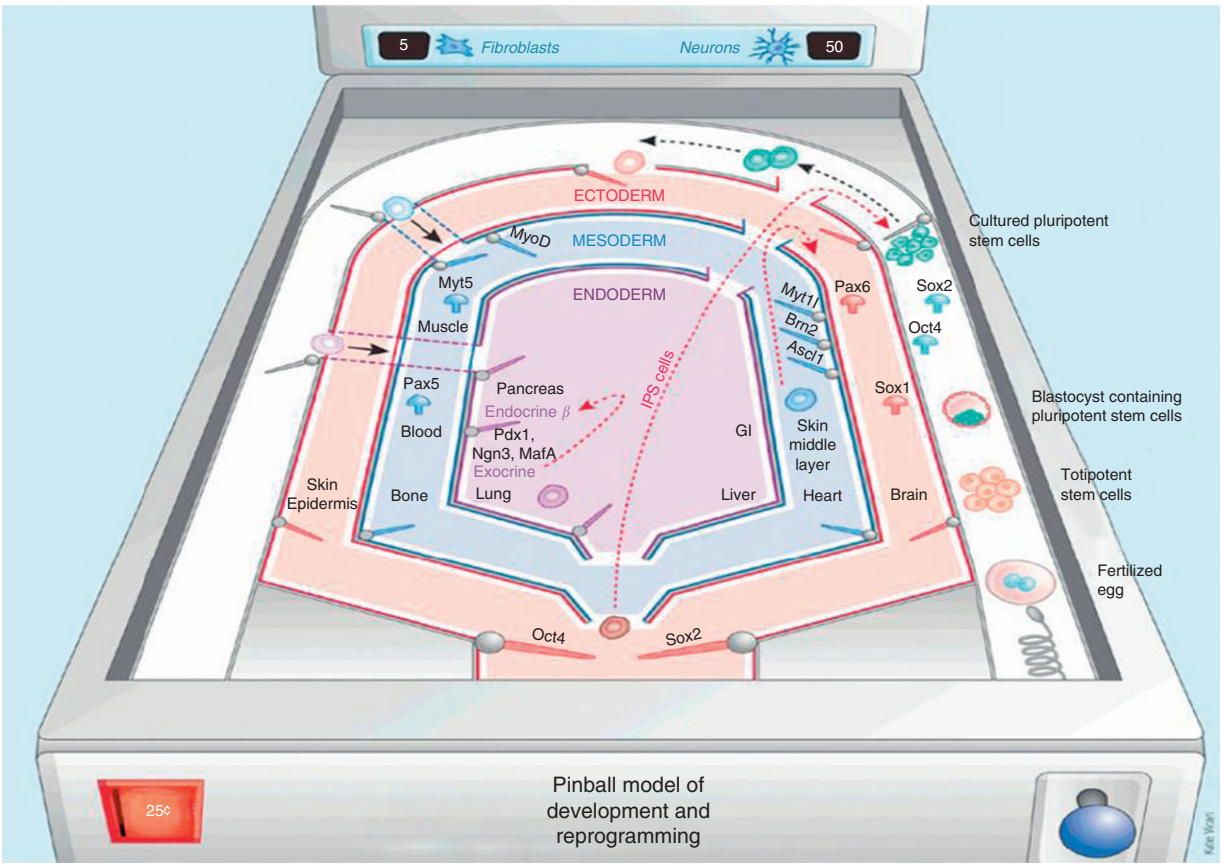

Figure 4 Pinball model of development and reprogramming. Reproduced from Sareen, D., Svendsen, C.N., 2010. Stem cell biologists sure play a mean pinball. Nature Biotechnology 28 (4), 333–335.

neuroblasts (to regenerate lost brain cells due to neurodegenerative diseases)?

More than a half-century after they were first proposed, stem cell pioneer Kazutoshi Takahashi (2012) chose to use Waddington's epigenetic landscape diagrams to represent not only his own team's path-breaking discoveries (See Figure 3(b)), but all of the newer work on cellular reprogramming (See Figure 3(c)).

With the ability to choose from all previous work in genetics and embryology or any desired image from art of science outside of biology, why did Takahashi choose to represent his team's work in this form? The answer may be that the epigenetic landscape diagrams have a dynamic quality which makes it possible to represent a complex four-dimensional process involving development over time on a two-dimensional surface. This must be recognized as an unusual achievement in and of itself. It also starkly represented the new 'explananda' for the field of regenerative medicine: What controlled each of these branch points on the epigenetic landscape?

Initially formulated by Waddington to represent possible cell fates in embryonic development over time, could the epigenetic landscape diagrams have a usefulness beyond that originally envisioned by Waddington? Many in the field are pursuing this. Altered versions of Waddington's original

landscapes using other images have been proposed, such as a saddle-node bifurcation (Ferrell, 2012), a nonhierarchical 'epigenetic disc' model (Ladewig *et al.*, 2013), or 'cusp catastrophes,' attractor surfaces in a multidimensional space (Thom, 1970). Building on Takahashi's creative use above, Waddington's landscapes have even been transformed into 'Epigenetic Pinball' games (Sareen and Svendsen, 2010) wherein the balls rolling down the hill could be shot back up the hill again by the transcription factors encoded by the genes encoded by the Takahashi virus mix (See **Figure 4**).

Waddington saw science and art as changing together. The biology of the 1960s, as well as the art of the 1960s, were entering a new era, eschewing representation for mechanism. The title of Waddington's book of art criticism, *Beyond Appearance* (Waddington, 1970), expresses this well. His quotation of Dryden to begin this book shows his views that the old world is changing and that he is impatient to get into the new one.

> All, all of a piece without.
> Thy chase had a beast in view,
> Thy wars brought nothing about,
> Thy lovers were all untrue:
> T'is well an old age is out
> And time to begin a new.

Waddington's concerns embraced biological science but also went beyond them in his multiple explorations of so many different areas of human knowledge and experience. Nevertheless, both in art and in science he always came back from the search for details to the search for pattern, and then one step further for, in the language of his friend and colleague Gregory Bateson (1979, p. 12) "the pattern that connects." Perhaps one of his major contributions, the epigenetic landscape, draws some of its strength and cogency from Waddington's persistent and lifelong inquiry into this seminal question. It is the pattern of processes that mattered. Waddington's epigenetic landscape added no new pieces of data. Rather, these diagrams provided a Gestalt, a framework into which one could place one's new data and give that data meaning. Thus, on the last page of *Principles of Embryology* (1956), he quotes T.S. Eliot:

> And to make an end is to make a beginning.
> The end is where we start from…
> We shall not cease from exploration
> And the end of all our exploring
> Will be to arrive where we started
> And know the place for the first time
> –From 'Little Gidding' by T.S. Eliot

These seem all the more apt for the new uses of epigenetic landscape diagrams in regenerative medicine.

Water Transport, the Role in Plant Diversification of

J Pittermann, University of California, Santa Cruz, CA, USA
JP Wilson, Haverford College, Haverford, PA, USA
TJ Brodribb, University of Tasmania, Hobart, TAS, Australia

Glossary

Cavitation (xylem) The breaking of the xylem water column under tension, most often by the entry of air through pit membranes.
Embolism (xylem) The consequence of a cavitation event that leads to the formation of an air – vapor void, which fills the conduit such that it is unable to transport water.
Euphyllophytes Plants with true leaves.
Hydroids Present in some mosses, hydroids are functional analogues of xylem, but with little to no lignin in the conduit walls.
Lagerstätten A deposit of sedimentary rock that preserves fossils in exceptional detail. Examples include the Burgess Shale in Canada, which preserves early animals from the Cambrian Period, the Solnhofen Limestone in Germany, which contains exceptionally preserved fossils of the early flying dinosaur Archaeopteryx, and the Rhynie Chert from Scotland, among many others.
Mesophyll Photosynthetic parenchyma tissue that lies between the upper and lower leaf epidermal layers.
Microphylls Small plant leaves with a single, unbranched vascular trace.
Parenchyma The most common soft tissue in plants, parenchyma cells are characterized by their large size and thin walls. They may be specialized for mechanical support, storage, and photosynthesis.
Perforation plates Digested cell wall openings on one or both ends of a vessel element. Water moves through perforation plates as it flows through multiple vessel elements within a vessel. Perforation plates may be foraminate (comprising several round openings), scalariform (comprising several elongated, ladder-like openings), and simple (a single unobstructed opening).
Phloem Adjacent to xylem, phloem is metabolically active vascular tissue specialized for the transport of sugars, small proteins, and signaling molecules.
Pit membranes Partially digested and non-lignified regions in the radial walls of tracheids and vessels that allow water to move from one conduit to another. Pit membranes may be homogeneous, as in angiosperms or they may have variably thickened regions as in the torus-margo type found in conifers.
Scalariform pit membranes Homogeneous pit membranes arranged in a ladder-like manner.
Secondary xylem Originating from the vascular cambium, secondary xylem comprises at least one growth ring and imparts woodiness to stems and roots.
Specific conductivity The volume flow rate of water through a segment such as a stem, standardized for the pressure driving the flow, the length of the segment, and the functional xylem area.
Stomata Small apertures most commonly found on the underside of leaves comprising a pore surrounded by two elongated guard cells, which open and close to regulate the size of the pore. Open stomata allow CO_2 entry for photosynthesis but at the cost of water escaping from the leaf.
Thallus In ancestral taxa such as liverworts, a thallus is a flat, weakly differentiated vegetative structure only a few millimeters thick, that combines photosynthetic parenchyma on the top side with root-like cells on the bottom.
Torus-margo pit membranes Found primarily in tracheids of extant conifers, these membranes are composed of a thickened, central torus structure surrounded by a highly porous margo region, through which water moves from conduit to conduit. Should some tracheids become embolized, the torus acts as a seal, protecting the neighboring water-filled conduits from air entry.
Tracheids Single, elongated xylem cells. Conifer tracheids rarely exceed 80 μm in diameter and a few millimeters in length, whereas in ferns and some extinct taxa, tracheid size can greatly exceed these dimensions. Conifer tracheids have torus-margo pit membranes, whereas homogeneous pitting occurs in the tracheids of seed-free vascular plants.
Tracheophytes Plants with well-developed and lignified xylem tissue.
Vessels Found primarily in angiosperm xylem, vessels are composed of vessel elements (single cells with digested end-walls) stacked to form conduits that in some lineages may be up to 500 μm in diameter and several meters in length.

Introduction

The evolution of xylem tissue transformed plant life on land. Without efficient water transport, plant hydration was a function of habitat water availability, first relegating plants to simple photosynthetic thalli appressed to wet substrates, with more derived taxa reaching heights of only a few centimeters, much like modern bryophytes. The appearance of vascular tissue, and the subsequent evolution of hydraulically adaptive traits changed all this (Figure 1). Equipped with the ability to move water from roots to shoots through dedicated conduits, plants decoupled leaf hydration from their environment, growing progressively taller, and better at competing for light and effective spore dispersal. The simultaneous evolution of stomata ensured that plants were able to balance CO_2 uptake for

 doi:10.1016/B978-0-12-800049-6.00259-6

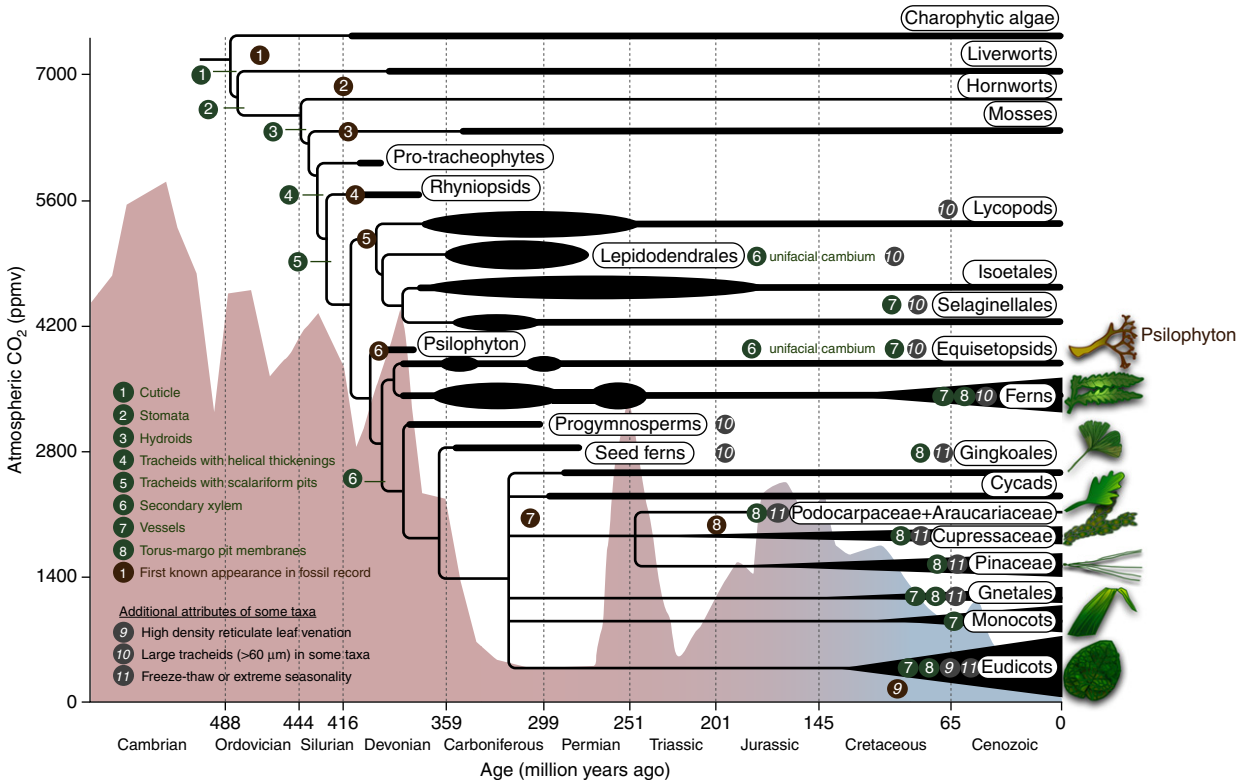

Figure 1 A simplified phylogeny of extinct and extant groups of land plants versus geologic age (modified from Sperry, 2003 and Pittermann, 2010), plotted against a backdrop of estimated atmospheric CO_2 levels (Berner, 2006). Heavy lines indicate presence in fossil record, with branch thickenings informally indicating estimated abundance and/or taxon diversity. Green labels indicate synapomorphies or independently evolved xylem traits, while gray labels mark relevant environmental or vascular attributes. Brown labels show first appearance in the fossil record; vessels (7) and torus-margo pit membranes (8) first appeared in lineages that have closest affiliation with conifers. Cartoon leaves represent the characteristic leaf type of select euphyllophytes (taxa with true leaves), of which *Psilophyton* is the ancestral euphyllophyte. Basal taxa vary with respect to the presence of microphylls. See Kenrick and Crane (1997), Sperry (2003), Feild *et al.* (2011) and Wilson (2013), and references therein for more detailed information.

photosynthesis in the leaves against the inevitable cost of water loss through the stomatal pore.

Despite the evolutionary leaps made possible by transport tissue, life on land presents considerable challenges for plants. Of these, hydraulic failure by drought-induced air embolism in the xylem is perhaps the most pressing, so plants evolved means to either cope with this problem, or avoid it altogether. This of course involves functional trade-offs, which drive fitness, shape the evolutionary direction of plant morphospace, and influence plant diversity and abundance. This review examines the general principles by which the structure and function of xylem tissue propelled plant evolution, borrowing examples from ancient, extinct flora as well as modern-day angiosperms and conifers. The xylem is but one of many drivers of plant diversity, but it is central to the physiological shifts that occur during large-scale radiation events, and it bears on past, present, and future patterns in plant biogeography.

Plant Water Transport

Xylem tissue comprises a network of dead, hollow elongated conduits such as tracheids or vessels, which may be contact with living phloem or parenchyma tissue. Extending from the roots to the leaves, the xylem is the central component of the soil – plant – atmosphere continuum (SPAC), and is responsible for moving water throughout the plant body from regions of high water availability (roots) to areas of low water availability (leaves). In a transpiring plant, water evaporates from the leaf mesophyll tissue to the atmosphere through open stomata, with drier atmospheres driving higher rates of water loss. As water evaporates from cell wall pores, the menisci within those pores curve, and their high surface tension places hydrogen bonds in an energetically unfavorable state, as compared to those that are flat during full hydration. Effective water transport ensures that the curvature of the menisci is reduced by continual replacement of lost water, which ultimately arrives through cell wall contact with xylem conduits. Hydrogen bonds sustain this dynamic wicking process by cohesion, allowing maintenance of hydraulic continuity over long distances. However, water movement along the SPAC generates tension (negative pressure) because opposite to the transpiring leaves, water is bound to soil particles and is subject to frictional forces as it moves into the root and through the xylem. Plant water transport has thus come to be known as the Cohesion – Tension theory (Tyree and Zimmermann, 2002; Pickard, 1981). It is an energetically free process that is powered primarily by the sun, with efficiency

being mostly a function of conduit diameter raised to the fourth power, a basic physical law of fluid flow through tubes. To optimize water transport, selection favors conduits that are much longer than they are wide (Sperry *et al.*, 2006). Reliable xylem function is critical to canopy performance: without sufficient replacement of lost water, stomata close, the leaves lose turgor, wilt and possibly die.

If the demand for water by the leaves exceeds that which can be supplied by the roots, such as during a drought, the negative pressure of the xylem sap can exceed a species' specific threshold, which allows air to enter water-filled conduits and can cause the water column to rupture. This phenomenon, known as cavitation, occurs when surrounding air is pulled into the conduit through the largest pores in the interconduit pit membranes. The resulting air embolism blocks the flow of water and increases the friction of the xylem network, impeding flow (Tyree and Zimmermann, 2002). Experimental and comparative work suggests that conduit dimensions, which influence the extent of pitting per conduit, along with adjustments to pit membrane porosity, and conduit arrangement, play a role in the entry and spread of air such that species with conduits that are smaller, spatially separated from one another or have less permeable pit membranes, are most resistant to cavitation (Brodersen *et al.*, 2012, 2014; Christman *et al.*, 2009; Lens *et al.*, 2011; Wheeler *et al.*, 2005). Arising from this is the axiom that embolism resistance comes at the cost of hydraulic efficiency because resistant xylem has higher frictional resistance. Such trade-offs are variable, but they are apparent in north-temperate plants at the level of the pit membrane, the conduit, and the xylem tissue (Jacobsen *et al.*, 2007; Pittermann *et al.*, 2006a,b, 2010, 2012), and may be related to the overall size, architecture, and phenology of woody plants (Domec *et al.*, 2008; Hacke *et al.*, 2015; Pittermann *et al.*, 2012).

The Early Evolution of Plant Water Transport

The evolution of water transport tissue and hydraulic capability in early land plants facilitated a diverse suite of anatomical and morphological features at the beginning of land colonization. The best-known early vascular plants are found in association with a number of nonvascular plants in an Early Devonian Period lagerstätten from Scotland, known as the Rhynie Chert. This locality preserved a diverse ~405 million year old hot spring ecosystem, and includes nonvascular plants like the protracheophyte *Aglaophyton major* (**Figure 2(a)**), once thought to be a vascular plant for many decades because of its close resemblance to another Rhynie Chert vascular plant, *Rhynia major*. Additional rhyniophytes include partially vascularized stem group bryophytes (*Horneophyton*), and a completely vascularized stem group lycophyte, *Asteroxylon mackiei* (**Figures 1** and **2(b)**; Taylor *et al.*, 2009). Of these, only the xylem-bearing *A. mackiei* could support

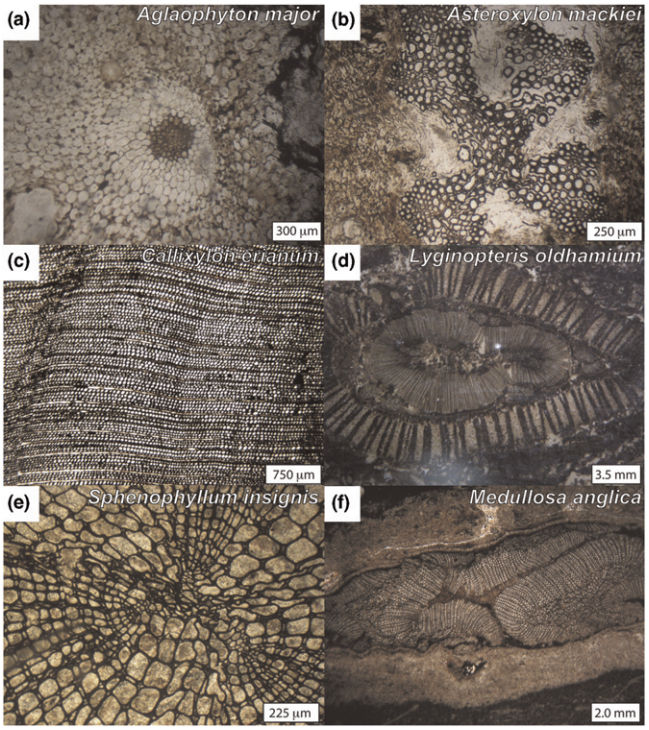

Figure 2 Cross-sections of fossil plant xylem. (a) Cross-section of the nonvascular plant *Aglaophyton major* from the Rhynie Chert. Note the dark central strand: these cells contain proto-tracheids. (b) Cross-section of the stem group lycophyte *Asteroxylon mackiei* from the Rhynie Chert with xylem cells arranged in the shape of an X. (c) Cross-section of secondary xylem (wood) from *Archaeopteris*, assigned the specific name *Callixylon erianum*. (d) A stem of the stem group seed plant *Lyginopteris oldhamium* showing xylem and its diagnostic cortical tissue. (e) Transverse view of xylem from the extinct sphenopsid *Sphenophyllum insignis*, showing its large tracheids. (f) Transverse view of the stem group seed plant *Medullosa anglica*, notable for its large secondary xylem tracheids.

microphylls. Although early land plants had much in common, including relatively simple reproductive systems and photosynthetic stems, their differential water transport capability, among other adaptations, facilitated the partitioning of the Rhynie Chert ecosystem into a series of distinct ecological niches, in which *A. mackiei* may have occupied a drier, upslope habitat, and regrown aerial stems from a subterranean rhizome in favorable conditions.

Rhynie Chert plants possessed xylem with a number of curious anatomical features, including conduits with complex ornamentation, isolated conduits, or alternatively, conduits connected by large holes. A likely explanation for the diversity of xylem cell features found in these Early and Middle Devonian taxa is that some plants contained xylem adapted for drought resistance and diversified into infrequently wet ecosystems, whereas other plants evolved xylem adapted for efficient water transport and specialized in disposable aboveground structures in everwet environments.

The major constituents of the Middle Devonian flora are plants with small stems that produced secondary (woody) xylem such as *Psilophyton* (**Figure 1**); given the limits of current data, it appears that wood first evolved within small-stemmed plants (<1 cm diameter) with low cavitation resistance (Gerrienne *et al.*, 2011). The ability to produce woody xylem has evolved at least four times, and appears to have enabled and driven a series of biomechanical and functional innovations that led to an explosion of ecological and taxonomic diversity of seed-free vascular plants, as well as seed ferns during the Devonian, Carboniferous, and Permian Periods (**Figure 1**). By the end of the Devonian Period, forests were dominated by large, spore-bearing *Archaeopteris* progymnosperms, which contained xylem that functionally and morphologically resembles the wood found within living conifers (e.g., *Callixylon erianum*, **Figure 2(c)**; Meyer-Berthaud *et al.*, 2000). Early seed plants, in particular, evolved a series of experiments in xylem structure and architecture that facilitated ecological and evolutionary expansion into new niches (Wilson and Knoll, 2010). A Carboniferous seed fern from Western Europe and North America, *Lyginopteris oldhamium*, evolved one of the earliest scrambling and climbing morphologies by coupling highly conductive woody xylem with a distinctive striped cortex that acted as a mechanical collar (**Figure 2(d)**), allowing its stems to bend and flex under mechanical stress (Masselter *et al.*, 2007). Two other plants with diverse biomechanical strategies, *Sphenophyllum* (Equisetopsida) and the seed plant *Medullosa* (**Figure 2(f)**) independently evolved quasi-vessels, individual cells more than 200 microns in diameter and more than 2.0 cm long, which functionally served as vessels in their stems. These giant conduits supported large leaf areas per individual stem in *Sphenophyllum* and *Medullosa* and expanded the niches that both spore-bearing and early seed plants, respectively, could occupy (Wilson, 2013).

Many of these anatomical experiments in high-conductivity xylem tied Paleozoic Era plants to nearby water sources. During the assembly of the supercontinent Pangaea in the Permian, the broad, tropical, everwet swamps that had been the loci of plant diversification were uplifted and dried, causing the extinction of many of the unusual Paleozoic plant taxa and their xylem experiments. The radiations of conifers, most ferns, and angiosperms later in the Mesozoic Era opened new functional niches that had previously been occupied by some of these physiological and biomechanical novelties, and facilitated a diversification of new anatomical forms, including highly productive leaves.

The Evolution of Xylem in Leaves

Research into the evolution in vascular water transport in plants has traditionally focused on improvements in root-to-shoot flow derived from the production of larger and longer conduits such as those found in wood, but the most significant gains may have occurred in leaves. The earliest angiosperms occupied understory habitats (Feild *et al.*, 2004), lacked vessels, had relatively low leaf vein density, and were neither hydraulically efficient nor cavitation resistant (Feild and Arens, 2007; Hacke *et al.*, 2007). Whilst large tracheids occurred in many extinct seed-free vascular plants, the combination of long, multi-cellular conduits coupled with a morphologically adaptive body plan eventually transformed the physiological capacity of angiosperms, with profound implications for downstream leaf hydraulic function and gas-exchange. Two key factors make leaf vein networks highly informative about the broader physiology of an individual or plant species:

1. The leaf is a major resistor in the hydraulic continuum, comprising over >30% of whole plant resistance (Sack and Holbrook, 2006), so adaptive improvements in leaf water transport will likely increase photosynthesis.
2. The efficiency of leaf water transport is highly dependent upon the spacing of the leaf venation (the vein density), a feature that is easily measured and frequently well preserved during fossilization.

Leaf vein density in living plants is a reliable indicator of photosynthetic performance, with higher densities of veins found to deliver water more efficiently to mesophyll tissues (Sack and Frole, 2006). More effective delivery of water by veins to sites of evaporation in leaves allows greater densities of stomata to be produced on the leaf surface (Fiorin *et al.*, 2015), and higher photosynthetic rates to be achieved (Brodribb *et al.*, 2007). Leaf venation thus provides a sensitive proxy for both transpiration and CO_2 uptake in leaves that can be used to reconstruct the performance of fossil species.

Following the emergence of single-veined, microphyllous vascular plants onto land, the early evolution of leaf venation in euphyllophytes was associated with changes in architecture to distribute water across the 2D surface of the leaf blade. Branched networks, such as in ferns, evolved soon after colonization of the land by vascular plants, followed about 100 million years later by multiple origins of internally reticulate vein systems (**Figures 1** and **3**; Boyce, 2005). These looped networks are believed to better accommodate damage (Katifori *et al.*, 2010) than branched vein architectures, and also yield a more optimal distribution of water under variable evaporative loads on the lamina (Corson, 2010). During this period of architectural evolution in leaf venation, the density of venation in the blade (measured as the length of veins per area of leaf tissue: mm/mm^2) of fossil species appears to have remained in a low and stable range, a feature that still characterizes the living relatives

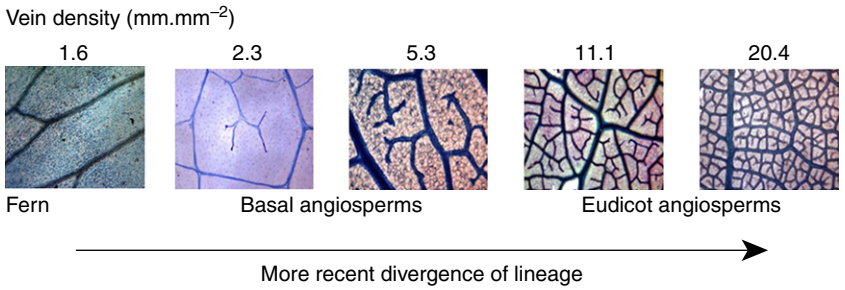

Figure 3 A clear trajectory in the density of veins in the leaves of vascular plants can be seen over time. Early-diverging lineages such as ferns (far left) all have low densities typically <4 mm mm^{-2}. Maximum vein densities climbed rapidly as angiosperms radiated, but the early clades remained at low density (such as *Amborella trichopoda*, second panel). Modern Eudicots (right) have maximum vein densities >10 mm mm^{-2} giving them the ability to photosynthesize and transpire rapidly.

of early-diverging lineages such as lycophyte, fern, and gymnosperm species (Boyce *et al.*, 2009).

In one of the most remarkable functional shifts in plant evolution, an abrupt end to the extended period of stasis in leaf vein density appears to coincide with the diversification of angiosperms, whereby vein density in this group rose sharply (Boyce *et al.*, 2009; Brodribb and Feild, 2010; **Figure 3**). Although this jump in vein density is unique to angiosperms, it is not synonymous with angiospermy, because vein density did not rise immediately after the appearance of angiosperms, but rather appears to have remained in the same range as ferns and lycophytes (2–4 mm/mm^2) throughout the earliest branches of angiosperm evolution (up to $\sim$100 million years) (Brodribb and Feild, 2010). This delayed evolution of high vein density in angiosperms is evident from fossil assemblages (Feild *et al.*, 2011) and when examining living representatives of early angiosperm branches, with all living relatives from the first five extant branches of the angiosperm phylogeny found to possess fern-like vein densities and corresponding low rates of photosynthesis (Feild *et al.*, 2011). The impact of high vein density evolution in angiosperms must have been dramatic, with suggestions that the accompanying rise in species productivity may explain the rise to dominance of angiosperms during the late Cretaceous. Models of rainfall patterns also imply that the increase in evaporation made possible by high vein density leaves may have led to the expansion of lowland rainforest in the equatorial zone (Boyce *et al.*, 2010).

The trigger for high vein density evolution in angiosperms is debatable. Extrinsic forcing by falling CO_2 concentration has been proposed, but more recent analysis suggested that intrinsic factors unique to angiosperm development are also required (Zwieniecki and Boyce, 2014). The most plausible explanation is that increased efficiency of primary xylem allowed leaf veins to become much narrower and more densely packed in the leaves of the more derived angiosperm clades (Feild and Brodribb, 2013). There is a clear trend toward increasing porosity of xylem perforation plates in the angiosperm phylogeny, with the most porous (simple) perforation plates found only in the relatively derived Magnoliid, Monocot, and Eudicot clades. This adaptation, providing greater efficiency in leaf vein water transport, would have preadapted angiosperms to benefit from the declining atmospheric CO_2 concentrations that occurred during the Cenozoic Era (Berner, 2006; Zachos *et al.*, 2008).

The radiation of broad-leaved angiosperms had a profound effect on the diversity of low-latitude forests, with the extinction of some gymnosperm clades and the contraction of other groups to higher latitudes (Crane and Lidgard, 1989; Millar, 1998). One family of conifers that has been successful in the shadow of angiosperms is the Podocarpaceae, which appears to have radiated in the tropics during the Cenozoic period producing multiple origins of shoot flattening. Like the Polypod ferns (Schuettpelz and Pryer, 2009), the Podocarpaceae appear to have radiated in the sub-canopy of angiosperm forests where competition for light is paramount. As a result, many podocarp species exhibit leaf flattening associated with reduced self-shading (Brodribb and Hill, 1997) and lower leaf mass per unit area. This is an unusual evolutionary trajectory for a conifer group, particularly considering that most conifers are characterized by needle leaves. At least nine independent origins of leaf flattening can be seen in Podocarpaceae (Biffin *et al.*, 2012). The most successful of these is the genus *Podocarpus*, the most speciose of all conifer genera after *Pinus*, with species distributed mostly in wet tropical regions. *Podocarpus* leaves can reach 300 mm in length and 50 mm in diameter despite the fact that they are supplied by water from a single midrib – a feat achieved by tracheid-like tubes that distribute water radially from the xylem into the mesophyll (Brodribb and Holbrook, 2005). Taken together, the post-Cretaceous dominance of angiosperms created physiological challenges for competing plants such as conifers, but as the next section will show, new niches and Cenozoic climate change also created opportunities for the radiation and diversification of several important clades.

Cenozoic Climate Change, Hydraulic Efficiency and the Evolution of Cavitation Resistance

The deep-time evolution of xylem shows trends toward increased axial and leaf hydraulic capacity, but there is reason to suspect that drops in atmospheric CO_2 levels ($[CO_{2atm}]$) coupled with both cooler and drier climates in the Cenozoic challenged xylem function and plant physiology as a whole (**Figure 1**; Berner, 2006; Pittermann, 2010; Ward *et al.*, 2005; Zachos *et al.*, 2008). Recent experiments have shown that plants grown at sub-ambient $[CO_{2atm}]$ levels that are representative of the Pleistocene have higher xylem conductivities than plants grown at ambient and elevated $[CO_{2atm}]$ (Rico *et al.*, 2013;

Medeiros and Ward, 2013). This shift toward increased water transport was mirrored in higher leaf stomatal densities, and by extension, higher stomatal conductance, both interpreted to compensate for reduced mesophyll CO_2 levels (Rico *et al.*, 2013 and references therein). Interestingly, stems of *Helianthus annuus* were more vulnerable to cavitation when grown at low [CO_{2atm}] due to inherently weaker xylem; it may be that wider vessels with thinner walls were predisposed to increased occurrence of air seeding (Rico *et al.*, 2013, but see Medeiros and Ward, 2013). How large-scale shifts in xylem traits bear out in the Cenozoic fossil record has not been studied.

Carbon stress may have altered xylem physiology, but increasing aridity in some parts of the globe almost certainly selected for improved water-use efficiency, as seen in the low-latitude Oligocene expansion of C4 plants and succulent lineages (Arakaki *et al.*, 2011; Edwards *et al.*, 2010). However, along with Cenozoic climate change, the expansion of tropical angiosperm forests may have also left its mark on xylem in lineages such as ferns. Competition for light pushed terrestrial ferns into the canopy (Schuettpelz and Pryer, 2009), but vascular adaptations to the increased evapo-transpirative demands this habitat entails, including cavitation resistance, greater water-use efficiency, and desiccation tolerance must have kept them there (Watkins *et al.*, 2010; Pittermann *et al.*, 2013; Schuettpelz and Pryer, 2009; gametophytes are discussed in Watkins *et al.*, 2007 and Watkins and Cardelús, 2012). Extant ferns have only primary xylem, so adaptations to water deficit include spatially separated vascular bundles to reduce the spread of embolism, along with smaller tracheids and less permeable pit membranes (Brodersen *et al.*, 2012, 2014; Pittermann *et al.*, 2015). Passive, leaf turgor-mediated stomatal closure supports a rapid response to water stress that is consistent with the humid habitats to which most ferns are constrained (McAdam and Brodribb, 2013). Further studies on the directionality and tempo of xylem evolution in ferns are currently under way (Pittermann *et al.*, 2015).

In climates with high water availability, angiosperms, ferns, and a small number of conifers benefit from the hydraulic gains that large conduits afford, but in habitats where drought and freezing are common, wide conduits can pose some problems. Temperate angiosperms such as deciduous oaks have large vessels, but their growing season is abruptly abbreviated following the first hard freeze. The problem is that freeze – thaw cycles can impede water transport if coalesced gas bubbles that are pushed out of the ice front in the conduit sap expand during a thaw, and nucleate cavitation (Sperry and Robson, 2001). Cavitation risk scales largely with conduit width: the wider the conduit, the larger the bubble, and the greater the probability that the bubble will expand under tension (Pittermann and Sperry, 2003, 2006). Safe, narrow tracheids are an ancestral character, so the conifers' conserved xylem structure (and that of the vesselless angiosperms, Feild *et al.*, 2002) may have preadapted them to the challenging climates of the Cenozoic; this idea is consistent with the high-latitude Mesozoic origins of *Pinus*, and pine expansion during the Oligocene (Millar, 1998). Similar safety versus efficiency trade-offs played out within the Cupressaceae conifers, in which narrower conduits and smaller pit membrane apertures supported the radiation of *Juniperus*, *Cupressus*, and *Callitris* lineages into drier, cooler habitats, relegating ancestral taxa such as *Cryptomeria*, *Taxodium*, *Sequoia*, and *Metasequoia* to refugia with higher water availability (Pittermann *et al.*, 2010, 2012). In the north-temperate Cupressaceae, drought resistance came at a cost however: narrower conduits with thicker walls lead to denser wood and thus a substantial carbon investment in xylem tissue (Hacke *et al.*, 2001; Pittermann *et al.*, 2012; see also Jacobsen *et al.*, 2005 who find similar trends in angiosperm fibers). Parallel costs included reduced hydraulic efficiency, which compromised photosynthetic capacity and growth (Pittermann *et al.*, 2012). Unable to produce very wide tracheids, conifers have traditionally been viewed as physiologically inferior to angiosperms, but the evolution of low-resistance torus-margo pit membranes has compensated for their narrow tracheids (Pittermann *et al.*, 2005; Brodribb *et al.*, 2012), and allowed them to remain competitive even in the suboptimal habitats of Cenozoic climates.

Conclusion

A variety of xylem adaptations at scales ranging from pit membranes to conduits, and from stems to leaves have facilitated the diversification and radiation of numerous plant groups over evolutionary time. As plants competed for light, increased stem and leaf efficiency supported the transformation of the planet's surface as plants came to occupy nearly every continent, adapting to climate change and competition. This review has focused exclusively on how reliable and efficient water transport shaped the evolution of plants, omitting other critical and equally important functions such as mechanical support (Rowe and Speck, 2005; Couvreur *et al.*, 2014), and general plant architecture, both of which contribute to clade diversification and resistance to drought stress (Schenk *et al.*, 2008). In these and other respects, natural selection demands compromise because the appearance of one physiologically adaptive trait may arrive at the cost of another. It is this complex interplay of anatomy, physiology, biochemistry, and biomechanics that supports plant diversification, and places the structure and function of xylem right at the center of this history.

Acknowledgments

The authors thank Amy Litt for constructive comments on the manuscript. We are grateful for the support of the National Science Foundation (IOS-1258186, JP), the Australian Research Council (TJB), and Haverford College (JPW; junior leave support), during the preparation of this chapter. JPW thanks Brigitte Meyer-Berthaud for access to fossil material.

Index

Note
This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of three levels of heading.

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space).

Location references refer to the volume number, in bold, followed by the page number.

Major discussion of a subject is indicated by bold page numbers; page numbers suffixed by '*F*' and '*T*' refer to Figures and Tables, respectively.
