During the last years, the wealth of prokaryotic genome sequencing data made it possible to study bacterial genome evolution from a new point of view and to demonstrate that the genome plasticity of some bacterial species is higher than expected. The model organism *E. coli*, for example, is known to exist as a harmless commensal in the gut, but several pathotypes are also able to cause severe disease. The phenotypic diversity between commensal and pathogenic strains is reflected by their genomic context and structure. The comparison of various *E. coli* genome sequences demonstrated that the *E. coli* pan-genome is an 'open' genome, i.e., this species is still evolving by gene acquisition and diversification, rendering the flexible genome a dynamic system (Rasko *et al.*, 2008).

MGEs, such as plasmids, bacteriophages, and genomic islands, and also conjugative transposons, integrative and conjugative elements (ICE) represent key elements for the exchange of genetic information by conjugation and transduction. They facilitate DNA exchange between the chromosome and MGEs and have the capacity to integrate into and excise from the bacterial chromosome by site-specific or simply by homologous recombination (Wozniak and Waldor, 2010). Accordingly, several identical or closely related determinants can often be found on the chromosome or on mobile DNA elements. If they do not provide a selective advantage to the host, these elements are frequently lost. They can also excise and translocate within the bacterial host genome by re-integration or they can be transferred to another recipient cell. Furthermore, insertion sequence (IS) elements and transposons contribute to genome plasticity due to transposition events and the fact that they can mediate DNA rearrangements by homologous recombination between multiple identical or similar copies within the genome. Furthermore, the transposition of IS elements and transposons can modulate the functionality of genes (Craig, 1996). (Super-) Integrons can be defined as a natural genetic engineering system: they capture and incorporate open reading frames by site-specific recombination and they express them (**Table 1**). They are frequently associated with transposons and conjugative plasmids that are required for their spread (Hall, 2012; Rowe-Magnus and Mazel, 2001). The high mobility and constant transfer, transposition, and recombination events can result in an ongoing generation of new MGEs with overlapping features (Darmon and Leach, 2014).

Plasmids are usually circular and self-replicating DNA elements. Although these autonomously replicating molecules exist as extrachromosomal genomes, some plasmids can be chromosomally inserted. Examples for the role of transferable elements as vectors and the constantly ongoing recombination between different mobilizable and transferable DNA elements are a large virulence plasmid of multi drug-resistant *Salmonella*

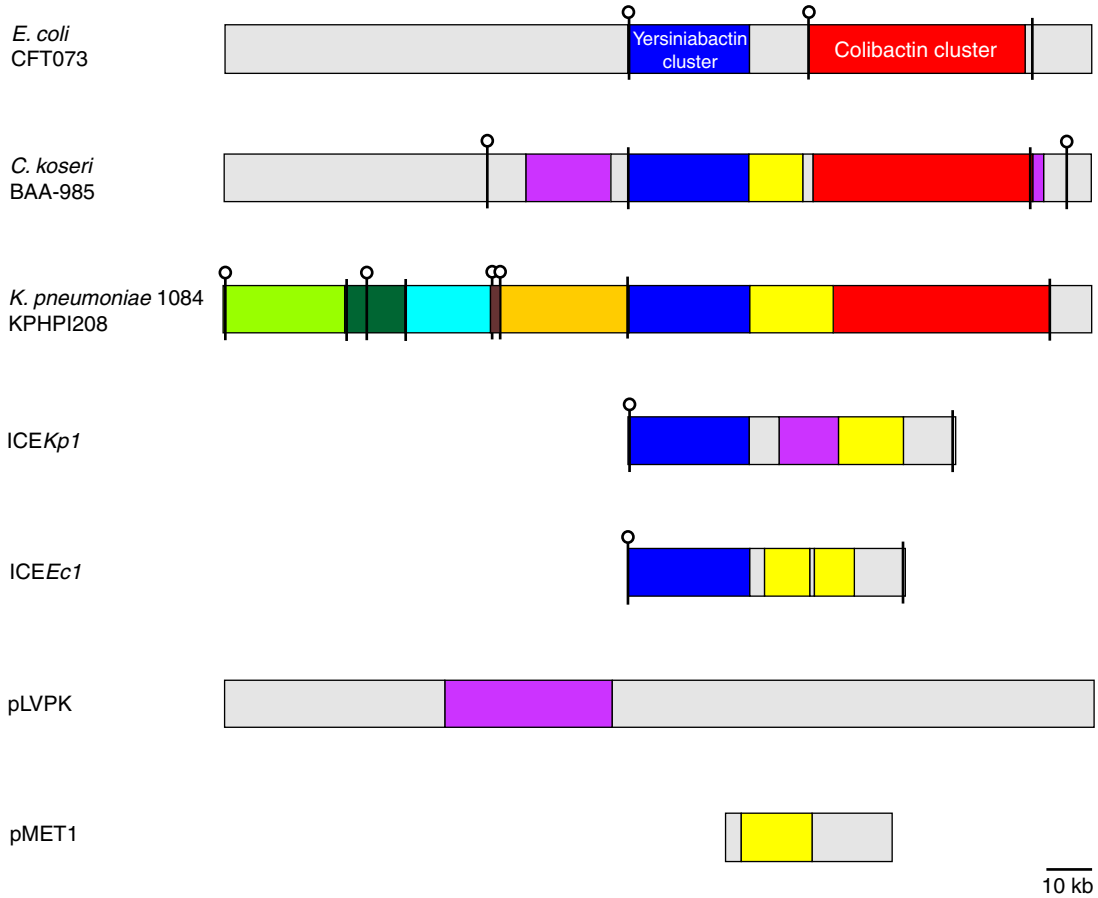

Figure 2 Genetic context of the *E. coli* yersiniabactin and colibactin determinants in comparison to other enterobacterial genomic regions. Modules with high homology to each other are shown in boxes of certain colors: the yersiniabactin cluster is represented in blue and the colibactin cluster in red, the DNA mobilization and transfer regions with high homology to DNA sequences of pMET-1 (GenBank accession number EU383016) are indicated in yellow, related sequences to parts of plasmid pLVPK (GenBank accession number AY378100) are shown in purple; orange and brown boxes represent regions of unknown function similar to *Eh*GM1 and *Eh*GM5 of ICE*Eh*1 (GenBank accession number FN297818), the light blue box represents a microcin module and with similarity to the microcin genomic island of strain *K. pneumoniae* RYC492 (GenBank Accession number AF063590).The green boxes are modules of unknown function. Gray boxes show regions that do not exhibit sequence similarities. Direct repeats are indicated by vertical black bars; tRNA genes are represented by vertical black bars with open circles (GenBank accession numbers for ICE*Kp*1 and ICE*Ec*1 are AB298504 and AY233333, respectively).

enterica serotype Typhimurium that carries several virulence genes and two class 1 integrons (Guerra *et al.*, 2002) as well as a multi-resistance plasmid of *Klebsiella pneumoniae* that resembles enterobacterial ICEs as well as plasmids found in *Yersinia pestis* (Soler Bistué *et al.*, 2008).

Genomic islands (GEIs) and pathogenicity islands (PAIs) represent genomic elements in bacteria, that often result from repeated gene acquisition, insertion, and recombination events (for reviews, see Dobrindt *et al.*, 2004; Hacker and Kaper, 2000; Juhas *et al.*, 2009). Strikingly, they represent a major part of the flexible genome, thus playing a tremendous role in genome plasticity and rapid bacterial evolution. GEIs and PAIs are horizontally acquired DNA stretches. They are often chromosomally inserted at tRNA loci, which serve as chromosomal insertion hotspots for foreign DNA, and flanked by identical or almost identical direct repeats as a result of site-specific genome integration. These islands are considered to originate from the repeated chromosomal insertion and recombination of multiple inserted MGEs and accessory genetic elements. Consequently, they typically carry functional or cryptic genes of plasmid and/or bacteriophage origin, which may encode integrases and conjugation systems, that were or still can be involved in island mobilization and transfer (Dobrindt *et al.*, 2004; Hacker and Kaper, 2000; Juhas *et al.*, 2009). As traits encoded by islands increase bacterial fitness, many islands have already been stabilized in the bacterial chromosome and lost their mobile character due to inactivation or deletion of the required mobility and transfer genes. Self-mobilizable and self-transferable islands often exist as (part of) integrative or conjugative elements (ICEs) (Dobrindt *et al.*, 2004; Juhas *et al.*, 2009). ICEs represent a diverse group of MGEs found in both Gram-positive and Gram-negative bacteria, which primarily reside in the host chromosome, but they retained the ability to excise and to transfer by conjugation due to the presence of a self-encoded transposase and conjugation system (Burrus and Waldor, 2004; Wozniak and Waldor, 2010). There is evidence that many GEIs have originated from ICEs (Bellanger *et al.*, 2014; Boyd *et al.*, 2009).

The acquisition and the exchange of mobile and accessory genetic elements together with repeated transposition and recombination events within the genome result in the continuous generation of genomic variability, thus mainly affecting the content and organization of the flexible gene pool. A good example of a genetic element displaying strain- or species-dependent variability is the *pks* (colibactin) island of *E. coli* and closely related *Enterobacteriaceae*. This 54 kb gene cluster encodes multiple polyketide synthases, non-ribosomal peptide synthetases and accessory as well as tailoring enzymes involved in the biosynthesis of the hybrid non-ribosomal peptide-polyketide colibactin (Nougayrède *et al.*, 2006). Colibactin is considered a bacterial fitness and virulence factor. This polyketide acts as a genotoxin in eukaryotes as it causes DNA double strand breaks (Nougayrède *et al.*, 2006), induces genomic instability in mammalian cells (Cuevas-Ramos *et al.*, 2010) and promotes colorectal cancer (Cougnoux *et al.*, 2014; Raisch *et al.*, 2014). The colibactin island has only been detected in commensal and extraintestinal pathogenic *E. coli* (ExPEC) strains of phylogenetic lineage B2 and in a few lineage B1 isolates (Nougayrède *et al.*, 2006). Interestingly, it was also identified in other *Enterobacteriaceae* like *K. pneumoniae*, *Citrobacter koseri* and *Enterobacter aerogenes* (Putze *et al.*, 2009). The genes of the colibactin determinant are highly conserved and are located in close proximity to another enterobacterial hybrid non-ribosomal peptide-polyketide determinant, the so-called high pathogenicity island (HPI) (Putze *et al.*, 2009; Schubert *et al.*, 2004b). Despite these similarities, remarkable species- and strain-dependent differences with regard to the genomic localization and organization of the colibactin island exist. While in *E. coli* phylogroup B2 strains the colibactin island was found to be chromosomally inserted into the *asnW* tRNA gene, the *asnU* tRNA locus served as integration site in the *E. coli* strains of the phylogenetic lineage B1. Even different *asn* tRNA genes were identified as insertion site in the *K. pneumoniae* strains tested (Putze *et al.*, 2009). In *E. coli* strains of phylogroup B2, both the colibactin and yersiniabactin determinants represent individual islands, which harbor an integrase gene and are flanked by direct repeats (Nougayrède *et al.*, 2006; Putze *et al.*, 2009). In contrast, in phylogroup B1 *E. coli* strains as well as in the *K. pneumoniae*, *E. aerogenes*, and *C. koseri* isolates the colibactin determinant is part of an ICE-like element with similarity to ICE*Ec*1 and ICE*Kp*1 and to several enterobacterial plasmids. This organizational similarity between different chromosomally inserted genetic entities and plasmid-encoded sequences indicates how efficiently recombination and interaction between different MGEs can occur (Nougayrède *et al.*, 2006; Putze *et al.*, 2009; Schubert *et al.*, 2004a; Soler Bistué *et al.*, 2008). Just recently, a 208 kb genetic element, designated KPHPI208, was discovered in a newly sequenced *K. pneumoniae* isolate from a patient with pyogenic liver abscess. This element did not only carry the colibactin and yersiniabactin modules and showed further sequence similarities to ICE*Kp*1, but also contained a microcin module as well as a new module with unknown function (Lai *et al.*, 2014). The fact that this element comprises four *asn* tRNA genes, eight direct repeats, and four integrase genes (Lai *et al.*, 2014) nicely demonstrates how independent mobile elements can cluster together and form a new mobile genetic entity. The example of the colibactin and yersiniabactin determinants illustrates that mobile elements can cross species borders. In addition, it demonstrates that they also display variability regarding their composition, organization, and genomic context (Putze *et al.*, 2009). The genetic flexibility of GEIs points to the fact that they are unstable and often undergo repeated rearrangements, deletions, and insertions underlining their impact on bacterial genome plasticity and evolution.

Impact of Nucleoid-Associated Proteins on Genome Plasticity

Besides the availability of foreign DNA elements and their uptake by suitable recipients, the acquired genetic information has to be stably incorporated into the recipient`s genome and successfully integrated into the gene regulatory networks of the new host cell. In the natural habitat of a bacterial species, the expression of horizontally acquired genes is much more likely to result in a reduced than in an increased fitness when compared to an isogenic population that did not take up heterologous DNA. Especially under the environmental conditions to which a bacterial species is adapted, energetic costs for maintenance and expression of heterologous genes in individual bacteria within a population should result in selective pressure favoring the wild type bacteria. However, new sets of horizontally acquired genes could apparently also provide a 'test toolbox' for a bacterium trying, for example, to cope with stress. Therefore, a regulatory mechanism that results in repression of heterologous genes under normal growth conditions, but allows for the activation of these genes under survival conditions could apparently constitute an evolutionary advantage for a bacterial species. However, it is unlikely that the recipient bacterial species possesses the specific regulators that are required to directly activate or repress foreign genes. Moreover, even in the case of mobile plasmids that might contain the required transcription factors for the appropriate plasmid gene regulation in the donor organism, it appears unlikely that these factors would work in the same manner in combination with the enzymatic machinery of the new host. Therefore, it might not be surprising that a class of abundant bacterial host proteins that bind DNA in a rather unspecific manner, the so-called nucleoid-associated proteins (NAPs), was found to play an important role in transcriptional repression of horizontally acquired DNA. The first NAP that was identified to selectively silence DNA with low GC content was histone-like nucleoid structuring protein (H-NS) in *Salmonella enterica* serovar Typhimurium (*S.* Typhimurium) (Lucchini *et al.*, 2006; Navarre *et al.*, 2006). Subsequently, the MvaT-like and the Lsr2 proteins were shown to serve a similar function in *Pseudomonadaceae* and *Actinobacteria*, respectively (Ali *et al.*, 2012). As DNA architectural proteins, NAPs are also known to play important roles in other cellular functions that are essential for HGT, like replication, recombination, and transposition.

Nucleoid-Associated Proteins and Their Importance for Genome Architecture

Due to their molecular size, biochemical properties, and abundance the NAPs were initially termed bacterial 'histone-like'

proteins (Drlica and Rouviere-Yaniv, 1987). NAPs are conserved to various degrees in Bacteria and Archaea and are the most abundant DNA-binding proteins in bacteria (Dillon and Dorman, 2010). *E. coli* K-12, for example, possesses at least 12 NAPs with varying intracellular composition, dependent on growth condition and growth phase (Talukder, 1999). During growth of *E. coli* in batch culture, the most abundant NAPs in exponential growth phase are DnaA (DNA-binding protein A), CbpB (Rob) Fis (Factor for inversion stimulation), H-NS, HU, and StpA (suppressor of *td* mutant phenotype A), whereas CbpA (curved DNA-binding protein A), Dps (DNA-binding protein from starved cells), and IHF (integration host factor) are most abundant in stationary phase (Ishihama *et al.*, 2014; Talukder, 1999). NAPs are important for the structural organization of the bacterial nucleoid and differ in their localization within the nucleoid. Dps, HU, IHF, and StpA are evenly distributed, whereas CbpA and CbpB are found at specific loci in the chromosome. Fis has been localized to specific chromosomal regions and H-NS was reported to be evenly scattered throughout the chromosome, whereas a recent study using super-resolution imaging suggested the opposite (Talukder *et al.*, 2000; Wang *et al.*, 2011). As they affect DNA topology and flexibility, NAPs play pleiotropic roles in very basic cellular functions like replication and recombination that are also essential for genome plasticity and the stable integration of foreign DNA into the recipient's chromosome. NAP binding alters the local structural genome organization, thereby affecting the accessibility of the chromosomal DNA to recombination processes and, thus, the recombination frequency. HU, for example, plays an important role in replication of both the chromosomal origin and plasmids (Bahloul *et al.*, 2001; Dixon and Kornberg, 1984; Yasukawa *et al.*, 1997). Fis was first identified as a factor stimulating G inversion in bacteriophage Mu (Kahmann *et al.*, 1985), but plays also a role in replication (Wold *et al.*, 1996). Similarly, IHF is required for site-specific recombination of bacteriophage λ (Friedman, 1988; Kikuchi *et al.*, 1985), but is also important for replication at OriC and at plasmid origins of replication (Fekete *et al.*, 2006; Skarstad *et al.*, 1990).

Nucleoid-Associated Proteins and Gene Regulation

In addition to their often redundant functions in replication and recombination, NAPs regulate the expression of substantial gene sets. Fis is an important regulator of virulence-associated genes and was shown to bind and regulate hundreds of operons in *E. coli* and *S.* Typhimurium (Kahramanoglou *et al.*, 2011; Wang *et al.*, 2013). *In vitro*, Fis binds with affinities that vary by several orders of magnitude to sites with a degenerated 15-bp core sequence, and introduces bends ranging from 50° to 90° (Pan *et al.*, 1996; Schneider *et al.*, 2001). This property in combination with the strong fluctuations in intracellular Fis concentrations and binding site competition with NAPs and other DNA-binding proteins is resulting in a highly dynamic *in vivo* situation that can be utilized to fine-tune gene expression. In the exponential growth phase, the NAP gene *dps* was shown to be repressed by Fis-dependent trapping of RNA polymerase (RNAP) containing the housekeeping sigma factor σ^{70} at the *dps* promoter and by H-NS preventing binding of RNAP σ^{70}. With decreasing Fis levels toward stationary phase, RNAP σ^{70} is no longer trapped at the *dps* promoter and can be bound and transcribed by RNAP containing the stationary phase sigma factor σ^{38}, which is not blocked by H-NS (Grainger *et al.*, 2008). In addition to gene regulation by such rather classical mechanisms based on local protein–DNA interactions at gene promoters, NAPs like Fis, HU, and H-NS also regulate transcription by modulating DNA topology. Fis binding to upstream activating sequences of stable RNA promoters, for example, constrains writhe that can then be either used to facilitate wrapping of DNA around RNAP, or for untwisting of the promoter for transcription initiation (Travers and Muskhelishvili, 2005). Moreover, the absence of Fis and H-NS is resulting in alterations of the supercoiling sensitivity of genomic transcription in *E. coli*. Therefore, these proteins are coordinating growth phase-dependent transcription, at least in part, by locally constraining the torsional energy of negatively supercoiled DNA, thereby directing the stored energy to gene promoters (Blot *et al.*, 2006). Changes in DNA supercoiling and NAP expression do not only occur during regular growth transitions, for example, from logarithmic to stationary phase of growth, but also during intracellular growth of *S.* Typhimurium in a murine macrophage, suggesting that such mechanisms play also an important role in the regulation of horizontally acquired virulence genes (Mangan *et al.*, 2006).

NAPs in Transcriptional Silencing of Horizontally Acquired DNA

Silencing of horizontally acquired DNA by H-NS was first described in *S.* Typhimurium (Lucchini *et al.*, 2006; Navarre *et al.*, 2006). By analyzing the transcriptional profiles of wild type and *hns* mutants of *S.* Typhimurium, the authors could show that most genes repressed by H-NS were likely to be acquired by HGT, including the *Salmonella* pathogenicity islands (SPI) SPI-2, SPI-3, and SPI-5 (Navarre *et al.*, 2006). The genes that were found to be repressed by H-NS in this study displayed a lower G + C content than the average genome, which led to the hypothesis that H-NS would preferentially bind to AT-rich DNA sequences and thereby repress transcription. This suggested that the mechanism by which H-NS is repressing the transcription of horizontally acquired genes is different from mechanisms that are based on repressor interactions with promoter proximal binding sites. To distinguish the mechanistically distinct transcriptional repression of AT-rich sequences by H-NS from classical H-NS-dependent gene promoter regulation, the term 'xenogenic silencing,' i.e., silencing of DNA that originated from a distinct species was introduced (Navarre *et al.*, 2007). As H-NS-mediated xenogenic silencing affects chromosomal regions rather than individual operons, a higher order nucleoprotein structure formed by H-NS and silenced DNA was proposed to result in transcriptional repression. According to this model, H-NS dimers are binding to AT-rich DNA with C-terminal DNA-binding domains and polymerizing by N-terminal H-NS–H-NS interactions. Depending on the binding mode, two different types of H-NS–DNA complexes were proposed (**Figure 3**), even though the exact molecular mechanism of binding and bridging by H-NS is yet to determined (Navarre *et al.*, 2007) (for review see Ali *et al.* (2012)). Specificity of transcriptional silencing can be achieved by high-affinity binding sites, which serve as nucleation site for H-NS polymerization.

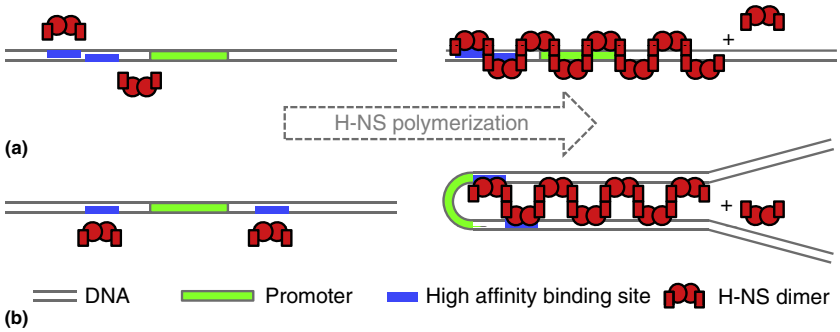

Figure 3 Different polymerization modes of H-NS affect the nucleoid architecture and thus recombination as well as gene expression. (a) High-affinity binding sites on opposite sides of the DNA double helix. Initial binding of H-NS dimers to opposite sides of the DNA double helix results in H-NS polymerization on the same DNA double helix. (b) High-affinity binding sites on the same side of the DNA double helix. Initial binding of H-NS dimers to the same side of the DNA double helix results in polymerization by bridge formation between two DNA helices. The nucleoprotein complex formed by H-NS may depend on the exact positions of high-affinity binding sites that serve as starting point for H-NS polymerization.

High-affinity binding sites for H-NS were shown to be clustered within operons of horizontally acquired virulence related GEIs in pathogenic *E. coli*, which further corroborated the idea that initial binding to high-affinity binding sites and subsequent cooperative binding of H-NS from these sites – eventually in combination with H-NS-dependent bridging of two bound DNA helices – is the mechanistic basis for H-NS-dependent repression of AT-rich DNA regions (Lang *et al.*, 2007). The finding that H-NS homologues are often encoded on large and especially AT-rich plasmids, for example, Sfh and others (Doyle *et al.*, 2007; Takeda *et al.*, 2011), further confirms the importance of this transcriptional repression mechanism for HGT.

The Role of NAPs in Anti-Silencing of Horizontally Acquired DNA

There is, however, no doubt that the silenced regions, for example, the PAIs of *S.* Typhimurium or the 'locus of enterocyte effacement' (LEE) of enteropathogenic or enterhemorrhagic *E. coli* are expressed under specific environmental conditions. Therefore, mechanisms that counteract transcriptional silencing by H-NS and its homologues have to exist. As described above, H-NS-mediated silencing is believed to be rather dependent on the formation of higher order nucleoprotein structures than on local interactions with binding sites on individual promoters. This implies that the activation of H-NS silenced genes is mechanistically distinct from the activation of genes that are repressed by classical H-NS promoter interactions. A recent study showed that the activation kinetics of genes, which are activated by the PhoP master regulator in *S.* Typhimurium depends on gene ancestry (Zwir *et al.*, 2014). Ancestral genes of *S.* Typhimurium are activated by PhoP first, whereas genes that were acquired by HGT are activated later. This expression pattern was not due to differences in PhoP binding site affinities, but dependent on H-NS. Therefore, the delay in activation of silenced genes most likely reflects the more time-consuming requirement for the disintegration of the higher order H-NS-dependent nucleoprotein structure at horizontally acquired genes (Zwir *et al.*, 2014). The additional observation that some of these late genes are also expressed to higher levels than early genes may be explained by individual promoter strength in the absence of H-NS-mediated silencing (Zwir *et al.*, 2014), or the prolonged time requirement for reestablishing the silencing nucleoprotein complex. The molecular anti-silencing mechanisms are diverse and encompass topological changes in DNA structure or the formation of heteromeric protein complexes of H-NS with other H-NS-like proteins (for review see Stoebel *et al.* (2008)). However, recent insights in the activation of the *S.* Typhimurium SPI-1 and SPI-2 by DNA topology changes, mediated by changing DNA supercoiling levels during the infection process and NAPs, suggests a general and in evolutionary terms old mechanism for the initial steps in the activation of horizontally acquired chromosomal regions (Cameron and Dorman, 2012). The regulatory genes *ssrA* of SPI-2 and *hilC* of SPI-1 are induced by DNA relaxation and OmpR, whereas *hilD* of SPI-1 is repressed by DNA relaxation and OmpR. DNA relaxation results in increased OmpR binding and decreased binding of the NAP Fis. Fis interaction with the same DNA sequence was reduced with DNA relaxation, whereas OmpR binding increased with reductions in superhelical density (Cameron and Dorman, 2012; Dorman, 2013a,b). Further evidence for the hypothesis that changes in DNA topology mediated by NAPs are a general mechanism for anti-silencing of horizontally acquired DNA regions comes from the recent finding that Ler, the activator of the H-NS repressed LEE PAI, forms toroidal DNA complexes at LEE promoters (Mellies *et al.*, 2011). This HU-dependent nucleoprotein complex is similar to the complexes known to be required for osmotic induction of the supercoiling sensitive *proU* operon in *E. coli* and S. Typhimurium as well as the complex involved in activation of the virulence gene regulatory gene *hilA* in *S. Typhimurium* (Higgins *et al.*, 1988; Manna and Gowrishankar, 1994; Maurer *et al.*, 2009; Schechter *et al.*, 2003). The facts that Ler expression in turn is dependent on the NAP Fis and that *fis* mutants of *E. coli* and *S.* Typhimurium are attenuated in their virulence, whereas an *hns* mutant of *S.* Typhimurium is not viable, underscore the importance of NAPs for the functional integration of horizontally acquired DNA into bacterial systems (Goldberg *et al.*, 2001; Navarre *et al.*, 2006; Wilson *et al.*, 2001).

Taken together, bacterial evolution depends on the ability to adapt to different environments. Bacterial genome plasticity is a prerequisite for adaptability and results from the

generation of genetic variability without impairing genome fidelity. Various often interrelated processes are involved, which act on genome architecture, genome content and genome organization as well as on gene expression regulation and gene function. These processes enable the constantly ongoing generation of new bacterial variants, some of which will be able to conquer and stably colonize new ecological niches.

Genome Size and Structure, Bacterial

H Ochman and A Caro-Quintero, University of Texas, Austin, TX, USA

Glossary

Effective population size The size of the population that makes a genetic contribution to the subsequent generation – usually much smaller than the actual population size.
Genetic drift The change in gene frequencies in a population due to random sampling.
Okazaki fragments Short DNA fragments synthesized on the lagging strand during DNA replication.
Paralogs Genes whose shared ancestry can be traced to a duplication event.
Plasmids Small, circular, autonomously replicating, double-stranded DNA molecules that are distinct from the cell's chromosome.
Pseudogenes Previously functional regions that have been inactivated by mutation.
Xenologs Genes whose shared ancestry can be traced to a horizontal transfer event.

Abbreviations

bp basepair
kb kilobase
Mb megabase
sRNA Small RNA

The Architecture of Bacterial Genomes

Early work on diverse model systems, such as *Escherichia coli* and *Bacillus subtilis*, led to the view that all bacteria possessed a single circular chromosome. However, physical mapping techniques revealed that species from divergent bacterial phyla have linear chromosomes, including *Borrelia burgdorferi* (a spirochete), *Agrobacterium tumefaciens* (a proteobacterium), and *Streptomyces coelicolor* (an actinomycete), indicating that this chromosome structure arose multiple times independently (Casjens, 1998; Ochman, 2002). The prevalence of circular chromosomes seems to reside in the fact that linear chromosomes must solve the problem of fully replicating their chromosome ends. Otherwise, the advantage of one configuration over the other is unknown (Marri *et al.*, 2008): in experiments in which the normally circular chromosome of *E. coli* was linearized synthetically, showed no obvious changes in growth rate, gene expression, or cell morphology (Cui *et al.*, 2007).

Several bacterial species have genomes that are partitioned into multiple chromosomes, including at least one instance, that of *A. tumefaciens*, where the genome contains one linear and one circular chromosome. The presence of multiple chromosomes of different genetic content within a cell – as opposed to those bacteria that maintain multiple copies of their single chromosome – is not surprising given that bacteria often harbor additional replicons in the form of plasmids. Distinguishing between chromosomes and plasmids is not always straightforward, and differentiation between the two has been based on size, contents, copy number, dispensability, transmissibility, and mode of replication (Ochman, 2002). In the majority of cases, the origins of a second chromosome in a bacterial genome – and indeed, it appears that a single circular chromosome is the ancestral state – can be traced to an extrachromosomal accessory element that enlarged and acquired essential genes as opposed to the duplication or dissolution of the single ancestral chromosome.

Bacteria Have Compact Genomes

Bacterial genomes are notable in that they are tightly packed with protein-coding genes (Figure 1), which average about 1 kb in length and do not contain introns. Typically, 80–90% of a bacterial chromosome encodes proteins, and a large fraction of intergenic DNA is devoted to regulatory sequences and large numbers of other functional noncoding elements, such as sRNAs (as well as the structural RNAs required for protein assembly). This greatly contrasts the situation in the human genome, in which protein-coding regions are nearly a hundred times longer (owing mostly to the presence of introns) and noncoding regions constituted nearly 98% of the genome (Ahnert *et al.*, 2008). The paucity of nonfunctional DNA is one of the hallmarks of bacterial genomes, and their high-coding densities means that there is a strong association between genome size and gene number (Mira *et al.*, 2001).

Insights into the basis for the high density of functional sequences within bacterial genomes came from several sources, but particularly from those genomes that were anomalous in that they contained large numbers of pseudogenes. The first sequenced genomes shown to have substantial numbers of inactivated genes was *Mycobacterium leprae* (the etiological agent of leprosy), in which over half of its encoded sequences were pseudogenes, which had intact counterparts in its congener *Mycobacterium tuberculosis* (Cole *et al.*, 2001). When comparing nonfunctional regions, such as pseudogenes, to their functional counterparts across a wide array of bacterial lineages, the nonfunctional regions display an excess of deletional events, implying that the mutational process in bacteria

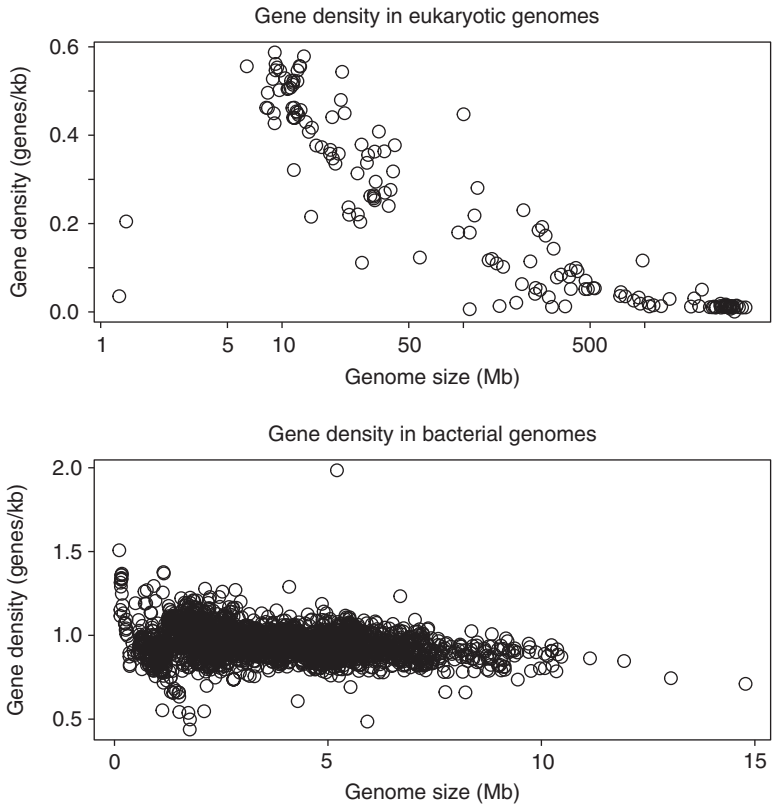

Figure 1 Relationship between gene density and genome size. Gene densities are calculated as the number of genes (in a genome of a given size) per kilobase. Note that gene densities in bacteria are similar regardless of genome size (such that gene numbers increase with genome size), whereas in eukaryotes, there is an inverse relationship between genome size and gene density (such that larger genomes do not necessarily encode additional genes).

is biased toward deletions over insertions. This mutational bias has also been observed in experimental populations, in which evolved strains can harbor individual deletions up to 200 kb in length (Nilsson *et al.*, 2005).

The deletional bias maintains the high density of functional genes observed in bacterial genomes: when inactivating mutations occur in genes that are no longer required, the nonfunctional regions gradually erode through deletions and are eventually eliminated (Andersson and Andersson, 2001; Mira *et al.*, 2001). The presence of a deletional process that removes nonfunctional sequences implies that virtually all genes in a bacterial genome are functional and maintained in the genome by natural selection (Kuo and Ochman, 2009).

Determinants of Genome Size in Bacteria

Among bacteria, genome sizes varies over two orders of magnitude, which, due to the relationship between genome size and gene contents in bacteria means that lineages can differ by as much as a 100-fold in their gene numbers. (In contrast, humans and the budding yeast, *Saccharomyces cerevisiae*, differ by only fourfold in gene number.) Even after the sequencing of only a dozen bacterial genomes, there was a notable association between genome size and bacterial lifestyle: those bacteria possessing small genomes were host-associated pathogens and symbionts, whereas those bacteria with large genomes were either free-living or environmental isolates. Currently, the bacteria with the smallest genomes are obligate symbionts of insects (Moran and Bennett, 2014), with the tiniest genome yet sequenced – only 112 kb – belonging to *Nasuia deltocephalinicola*, a symbiont of leafhoppers (Bennett and Moran, 2013). At the other end of spectrum are free-living bacteria, and a soil-associated species, *Ktedonobacter racimifer*, which at 15.6 Mb has the largest sequenced genome to date (Chang *et al.*, 2011).

Phylogenetic analyses indicate that host-associated bacterial lineages are derived from ancestors with larger genomes, which is not surprising considering that bacteria as a group are much more ancient than their potential eukaryotic hosts. Pathogen and symbiont genomes can possess fewer functional genes because many nutrients and biochemical pathways are supplied by their hosts. Considering all of these factors together, it is possible to trace the evolutionary progression toward highly reduced genomes and to account for the variation in the gene repertoires observed among contemporary species. Initially, (ancestral) free-living bacteria become associated with a (nutrient-rich) eukaryotic host. This association renders many bacterial genes superfluous in the host environment, and these unnecessary genes accumulate mutations, becoming pseudogenes. The inactivated genes are eventually removed by the pervasive mutational bias toward deletions, resulting in a compact genome harboring only functional genes. Note that this scenario accounts not only for the high gene densities

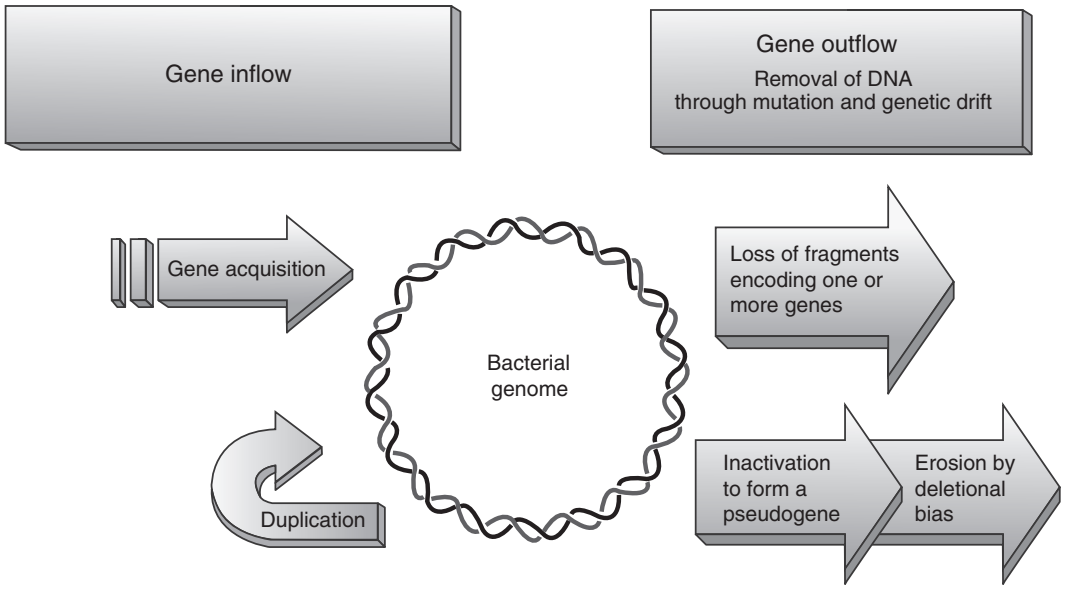

Figure 2 Interplay of factors impacting bacterial genome size. New sequences are acquired by gene transfer and gene duplication, whereas DNA loss occurs by large deletions that remove multiple genes in a single event and by the erosion of pseudogenes and other nonfunctional sequences. Modified from Mira, A., Ochman, H., Moran, N.A., 2001. Deletional bias and the evolution of bacterial genomes. Trends in Genetics 10, 589–596.

observed in the largest and smallest genomes but also for the presence of large numbers of pseudogenes observed in recent pathogens and other host-associated lineages.

The compactness of bacterial genomes has traditionally been thought to result from 'streamlining' and considered to be an adaptation to increase replication speed and growth rates. For the most part, this view is incorrect. When looking across bacteria, there is no clear association between generation time and genome size (Mira *et al.*, 2001). In tests within species, natural strains of *E. coli* that differed by 15% in genome size did not differ in growth rates (Bergthorsson and Ochman, 1998), and isogenic strains of *Salmonella* engineered to harbor duplications up to 700 bp in length did not replicate significantly slower than the parental strain in either minimal or nutrient-rich media (Matthews and Maloy, 2010). Although bacterial genome size is not generally driven by selection for replication efficiency, a few species in nutritionally poor environments have reduced genomes in order to decrease the metabolic burden associated with replicating extra DNA. The marine planktonic bacteria, *Prochlorococcus* (Dufresne *et al.*, 2005) and *Pelagibacter ubique* (Giovannoni *et al.*, 2005) occupy environments where nitrogen and phosphorous concentration are limited, and both possess the smallest and most gene-dense genomes among free-living bacteria.

The contrasting view is that bacterial genome size is governed by a nonadaptive process (Kuo *et al.*, 2009). Due to the association between genome size and gene number in bacteria, the evolutionary forces that act on individual genes will have profound effects on overall genome size. As a result, those species with small effective population sizes, such as those whose populations are severely restricted during transmission between hosts, are subject to genetic drift, which reduces the efficacy of selection and allows the accumulation of deleterious mutations, even in useful genes. Thus, bacteria with small effective population sizes, such as symbionts and pathogens, will have the smallest genomes because they are more susceptible to gene decay and loss, even for genes that are usually considered beneficial.

The view that small genome size in bacteria is largely a consequence of a nonadaptive process, i.e., genetic drift, runs counter to the situation in eukaryotes. Lynch (2007) has posited that reductions in the efficacy of selection in eukaryotic species with small effective population sizes have allowed the proliferation of deleterious sequences in the form of introns and transposable elements, both of which serve to increase genome size. Therefore, increased genetic drift has caused the size of eukaryotic genomes to increase but bacterial genomes to decrease.

Offsetting the deletional processes that serve to reduce genome size, bacterial genomes can grow by gene duplication and gene acquisition (*a.k.a.* lateral/horizontal gene transfer) (**Figure 2**). To determine the relative contributions of these two processes to the emergence of new bacterial genes, the numbers of paralogs (genes arising by duplication) and xenologs (genes acquired by transfer) were compared in bacterial groups across a wide range of genome sizes (Treangen and Rocha, 2011). In general, gene transfer played a larger role in the expansion of protein families and provided bacteria with genes of new function, whereas gene duplication usually led to an increase in gene dosage.

Genome Size Variation within Species

DNA content was considered to be invariant within a species, hence the application of the term 'C(onstant)-value' to denote the amount of DNA contained in a gamete or genome. Whereas the sexual system of eukaryotes has a homogenizing effect on chromosome size, no such constraints are imposed on organisms that reproduce by binary fission. But because the

Figure 3 Genome size variation within bacterial species. Size ranges are shown for species for which complete genome sequences are available for at least 10 strains.

members of a bacterial species are metabolically and phenotypically similar – in fact, species assignment and differentiation were based largely on metabolic capabilities before DNA typing became routine – the genomes of bacteria typed to the same species were thought to be alike in their sizes and contents, with variation, if any, attributable to the sporadic distribution of extrachromosomal elements among genomes.

There is early evidence, based on DNA reassociation experiments, that there was substantial variation in the genome sizes among clinical isolates of *E. coli* – variation could not be attributed to extrachromosomal sequences since many strains had smaller genomes than a control strain known to lack plasmids (Brenner *et al.*, 1972). However, it was not until the broad-scale application of pulsed-field gel electrophoresis – a method that allows resolution of very large DNA fragments – that the true extent of genome size diversity within bacterial species was fully appreciated (Cole and Saint Girons, 1994).

The sequencing and assembly of complete bacterial genomes has led to comparisons of the contents of genomes among closely related bacteria, and scrutiny of the extent of variation and the specific changes that contributed to variation in genome size (**Figure 3**). The first in-depth analysis of multiple sequenced members of bacterial species was of strains of *E. coli* that differed in their pathogenic potential (Welch *et al.*, 2002). The most pronounced source of the differences among these strains of *E. coli* was the integration of large DNA segments, mostly by phage-mediated events, forming islands of genes that were unique to a particular strain. This seems to be a common theme among bacteria: although changes in the numbers of repetitive and translocatable elements can inflate and deflate genomes, the acquisition of large regions by horizontal gene transfer is the major contributor to the genome size variation among members of a bacterial species. The within-species variation in genome size and contents has led

to the concept of the 'core-genome,' which comprises those genes that are present in (virtually) all members of a species, and the 'pan-genome,' which is the entire set of genes encoded by the species (Tettelin *et al.*, 2005).

Genome Organization

Genes encoded are not positioned at random along the bacterial chromosome. It has long been known that certain sets of genes are situated in proximity because they constitute a single functional unit (i.e., an operon); however, the location, arrangement, and distribution of genes in bacterial genome are influenced by several gene- and genome-level factors, many of which result from the manner in which replication occurs. Recall that in bacteria, there is a single replication origin, and that replication of the circular chromosome proceeds bidirectionally to a terminus that is situated transversely, at approximately 180°, from the origin. This replication process is asymmetric, generating leading strands, which are synthesized continuously from the origin to the terminus, and lagging strands, which are replicated discontinuously through the synthesis and joining of short Okazaki fragments.

Maintenance of Chromosome Balance

Early comparisons of the genetic maps of *E. coli* and *Salmonella typhimurium*, related enteric species thought to have diverged about hundred million years ago, displayed a high degree of concordance but differ with respect to a large inversion that spanned the replication terminus (Krawiec and Riley, 1990). Additionally, other *Salmonella* strains possess different inversions that were similarly symmetric with respect to the replication terminus, suggesting that inversions that offset the positions of the origin and terminus relative to one another are deleterious (Liu *et al.*, 1993). Although experimentally disrupting the positions of the origin and terminus through the introduction of large duplications on one side of the chromosome showed no appreciable effect on growth rates (Matthews and Maloy, 2010), there is evidence that selection acts to maintain chromosome balance over evolutionary timescales. Using physical maps to reconstruct the history of the *Salmonella paratyphi* genome exposed that an insertion that disrupted the balance between origin and the terminus was succeeded by an inversion that restored their positions (Liu and Sanderson, 1995).

Gene Location and Orientation

Inversions that maintain chromosome balance, i.e., those that are symmetric with respect to replication origin and terminus, preserve not only the positions of the origin and terminus but also the distances of all genes relative to the origin and terminus. All other inversions alter the positions of some genes relative to the origin. Moreover, those inversions that do not include the replication origin or terminus reverse gene orientation, such that genes that were originally encoded on the leading become lagging-strand genes and vice versa. Comparing the relative positions of genes in pairs of related genomes revealed a remarkable pattern: most genes retain the same orientation and the same relative distance to the replication origin despite the occurrence of numerous rearrangement events, yielding whole-genome alignment plots that display a characteristic X-shaped pattern (Eisen *et al.*, 2000; Tillier and Collins, 2000; Suyama and Bork, 2001; **Figure 4**).

How can proximity to the replication origin exert a selective effect on genes and chromosome organization? This can occur in two ways: Firstly, both mutation rates (Mira and Ochman, 2002) and recombination events (Louarn *et al.*, 1994) increase with distance from the replication origin, so it is possible that selection might favor the positioning of highly conserved, essential genes nearer to the replication origin as is observed in *B. subtilis* and *E. coli* (Rocha and Danchin, 2003). Secondly, because new rounds of replication can be initiated before the previous round is complete, genes closer to the replication origin exist in higher dosage and are more highly expressed than those near the replication terminus (Segall *et al.*, 1988; Liu and Sanderson, 1996). Therefore, the relocation of genes or operons by inversions or transpositions can alter their expression patterns and have a detrimental effect on the cell.

How can strand orientation exert a selective effect on gene and chromosome organization? The difference in the processes

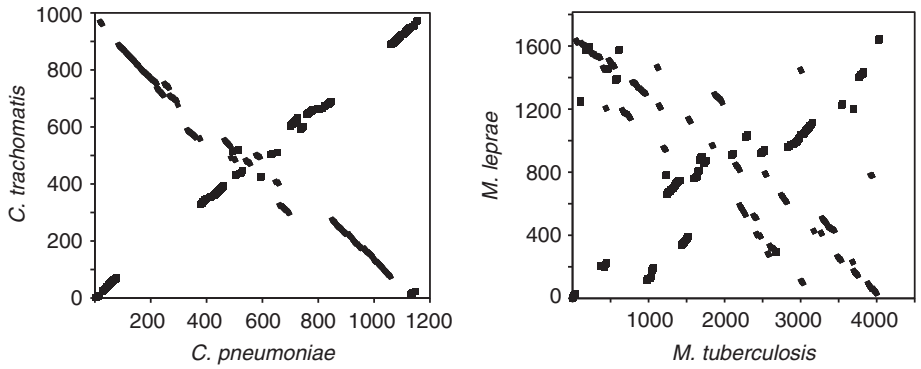

Figure 4 Correspondence of positions of homologous genes in pairs of sequenced genomes in *Chlamydia* (*C. pneumonia*e and *C. trachomatis*) and *Mycobacterium* (*M. tuberculosis* and *M. leprae*). Genomes are represented linearly beginning at the replication origin (position 0) with gene positions, indicated in kb from the replication origin, proceeding clockwise around the chromosome. Scatterplots redrawn from Tillier, E.R., Collins, R.A., 2000. Genome rearrangement by replication-directed translocation. Nature Genetics 26, 195–197 and Eisen, J.A., Heidelberg, J.F., White, O., Salzberg, S.L., 2000. Evidence for symmetric chromosomal inversions around the replication origin in bacteria. Genome Biology 1, research0011.1–0011.9.

used to replicate the leading and lagging strands causes asymmetries in the rates and patterns of mutations, and hence, the nucleotide contents of each strand (Francino and Ochman, 1997; Frank and Lobry, 1999). In general, there is an excess of guanine residues on the leading strand – termed 'GC skew,' which calculated as degree of the difference in the number of guanines and cytosines on a given strand relative to the total number of these guanines and cytosine residues (i.e., G − C/G + C) – and many genome sequences show an abrupt change in the direction of skew at the replication origin and terminus (Lobry, 1996).

Because the same DNA strands are used as templates for replication and transcription, both processes will occur simultaneously; however, DNA polymerase proceeds at over 10 times the speed of RNA polymerase causing collisions between the two polymerization machineries. On the leading strand, replication and transcription proceed in the same direction, such that collisions between DNA polymerase and RNA polymerase are co-oriented and produce fully formed transcripts. On the lagging strand, however, DNA polymerase and RNA polymerase have head-on collisions that abort transcription (Rocha and Danchin, 2003; Merrikh *et al.*, 2012). Owing to the deleterious nature of head-on collisions, there is an asymmetric distribution of genes between the two strands. In most genomes, the majority of genes are preferentially encoded on the leading strand (Mao *et al.*, 2012; Chen and Zhang, 2013), indicating that there is selection against inversions and translocations that alter the orientation of genes or operons.

Genomic Base Composition

One of the most highly variable features of bacterial genomes is overall base composition, which among sequenced genomes ranges from 13% to 75% G + C. The fact base composition is relatively homogeneous within a genome but varies greatly among genomes led to the view, developed in the 1960s, that the variation was caused by differences in the underlying patterns of mutations, such that high G + C and low G + C organisms differed in their spectra of replication errors (Freese, 1962; Sueoka, 1962). (It is interesting to note that this attribution of molecular variation to a strictly mutational process preceded Kimura's neutral theory of molecular evolution by several years.) An alternative explanation is that the variation in genomic base compositions is adaptive, such that the differences are due to a selective force that favors certain base compositions under some particular environment conditions (McEwan *et al.*, 1998; Naya *et al.*, 2002; Rocha and Danchin, 2002; Romero *et al.*, 2009). In that G/C basepairing is more thermally stable than A/T basepairing, it has been suggested repeatedly that genome base compositions reflect growth conditions; however, there is no association between growth temperature and genomic base composition when analyzed across diverse taxa (and in fact, many thermophiles have genomic G + C contents that are substantially lower than those of mesophiles) (Galtier and Lobry, 1997; Hurst and Merchant, 2001; Wang *et al.*, 2006).

To date, no fewer than a dozen factors have been proposed as the source of the base-compositional variation in bacteria (Rocha and Feil, 2010); however, the lack of a single unifying explanation has led many to adopt the decades-old view that the variation is neutral and caused by differences in the mutational process. Recent analyses performed on multiple taxa suggest that, even in bacterial groups with intermediate and high genomic G + C contents, the mutations are biased toward A + T (Hershberg and Petrov, 2010; Hildebrand *et al.*, 2010). These results, based on sequence comparisons, are most readily explained by the action of natural selection favoring individual base substitutions that increase the G + C composition of the genome; however, the manner in which selection is operating is still unknown.

Genotype-by-Environment Interaction

K Donohue, Duke University, Durham, NC, USA

Glossary

Across-environment genetic correlations Genetic correlations (see below in glossary) between traits expressed in different environments. Most typically, this refers to the same trait expressed in two or more environments, but it also encompasses correlations among different traits expressed in different environments.

Co-gradient variation A geographic pattern of phenotypic variation in which the direction of trait plasticity elicited by an environment is in the same direction as genetic differentiation in the trait caused by local adaptation to that environment (as opposed to 'counter-gradient variation' in which the direction of plasticity is opposite to that of genetic differentiation).

Cost of plasticity The decrease in fitness caused by the ability to be plastic, independent of fitness consequences of the expressed phenotypes. This can theoretically be caused by costs of maintaining the behavioral or biochemical capacity (environmental sensors, signal transduction pathways) to respond to environmental variation. A cost of plasticity can be detected by comparing the fitness of plastic versus nonplastic genotypes that exhibit the same phenotype in a given environment: if two genotypes have identical phenotypes in a given environment, but one of them exhibits plasticity (changes its phenotype in a different environment) and the other does not, the nonplastic genotype would have the higher fitness if there is a cost to being plastic.

Discontinuous trait A trait that exhibits distinct phenotypes, instead of continuously varying phenotypes, in response to continuous environmental factors.

Function-valued trait A trait that exhibits incremental plasticity in response to a continuous environment (contrasted to a discontinuous trait, see glossary). Its reaction norm is depicted as a continuous function of the phenotype in response to the continuous environmental factor.

Genetic accommodation A type of reaction-norm evolution whereby a phenotype that was originally induced by the environment contributes to adaptive evolution in that new environment and can cause the phenotype to be expressed even without the environmental cue. Genetic accommodation includes several types of reaction-norm evolution, including 'genetic assimilation' (see glossary below), as well as an increase in the mean trait value across all environments when the function of response to the environment (e.g., the slope of the reaction norm) remains the same.

Genetic assimilation A type of reaction-norm evolution whereby a phenotype that was originally induced by the environment becomes expressed even when the environmental cue is absent. Genetic assimilation entails the reaction-norm evolving from that of a plastic trait to a nonplastic trait; that is, the trait becomes 'canalized.'

Genetic correlation The degree to which two traits are correlated because of a shared genetic basis or linkage disequilibrium. Genetic correlations cause direct selection on one trait to result in indirect selection on correlated traits. As a consequence, a trait can evolve in response to selection even if it is not the target of selection.

Heritability (narrow-sense) Denoted h^2, heritability is the proportion of total phenotypic variation (Vp) that is additive genetic variation (Va): $h^2 = Va/Vp$. Heritability is proportional to the expected response to selection, with larger heritability leading to greater response to selection.

Maternal effect More narrowly specified, a 'maternal environmental effect' is phenotypic plasticity across generations, such that the environment experienced by the maternal parent influences the phenotype expressed by progeny. Parental environmental effects occur when the environment experienced (or provided) by either parent – maternal or paternal – influences the phenotype expressed by progeny.

Phenology The timing of biological events, such as the timing of developmental transitions, including germination, flowering, leaf-out, senescence in plants, or hatching, metamorphosis, and reproduction in animals.

Phenotypic plasticity The ability of a genotype to alter its phenotype in response to the environment.

Polyphenism Discrete phenotypic states expressed by an organism in response to environmental conditions. Examples include different color morphs of insects that eat different host plants and different color morphs of insects that develop at different times of year.

QTL analysis Quantitative trait locus (QTL) analysis is a form of genetic analysis of quantitative traits, or traits that are controlled by many genes. The analysis uses lineages that have been genotyped at many markers throughout the genome, and tests for associations between the alleles at each marker and the phenotype that is expressed by individuals with those alleles. An association between a phenotype and a marker allele is evidence that a locus near the marker contributes to genetic variation in the phenotype.

Reaction norm The graphical depiction of phenotypic plasticity, with the phenotype on the y axis and the environmental factor on the x axis. A line connects the phenotypes expressed by one genotype in each environment.

 doi:10.1016/B978-0-12-800049-6.00049-4

General Concepts

The ability of a genotype to alter its phenotype in response to the environment is called 'phenotypic plasticity.' Examples of phenotypic plasticity include the elongation of plants growing in shade (Smith, 1982; Ballaré *et al.*, 1990), the increase in a snail's shell thickness when grown in the presence of predators (DeWitt, 1998), or the polyphenism of coloration or form of some insects depending on the season of their development or the host plants they consume (e.g., Kingsolver, 1995). Phenotypic plasticity can occur not only in morphology, but also in behavior, life-history expression, and phenology (the timing of biological/developmental events). Phenotypic plasticity can also occur across generations, such that the environment experienced by parents influences the phenotype expressed by progeny, resulting in 'parental effects' (or commonly 'maternal effects'; Mousseau and Fox, 1998).

When different genotypes exhibit different responses to an environmental factor, there is a 'genotype-by-environment interaction.' Phenotypic plasticity of a given genotype can be represented graphically as a 'norm of reaction' or 'reaction norm.' A reaction norm represents the mean phenotype expressed by a genotype in two or more environments. The environments can be discrete, such as distinct host plants; or continuous, such as temperature. Genotype-by-environment interaction is manifest when genotypes differ in their reaction norms (**Figure 1**).

Genotype-by-environment interaction has consequences for trait evolution because it influences the expression of genetic variation and covariation for traits and because it enables the evolution of phenotypic plasticity, as reviewed below.

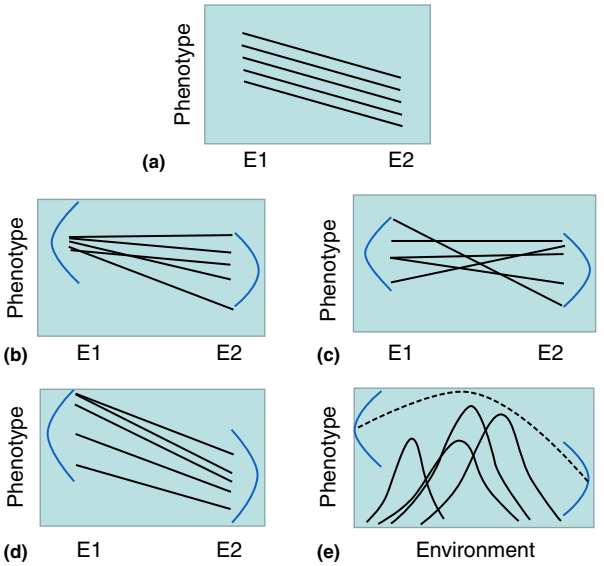

Figure 1 Norms of reaction depicting genotype-by-environment interaction and adaptive phenotypic plasticity. Within each panel, each line ('reaction norm') depicts the mean phenotype expressed by a given genotype in each of two discrete environments, E1 or E2 ((a)–(d)), or in a continuously variable environment (e). The curves on each side of each panel indicate stabilizing selection on the phenotype, whereby the optimal phenotype occurs at the peak of the curve. The optimal phenotype changes across environments. (a) Norms of reaction depicting plasticity, but no genotype-by-environment interaction, because all reaction norms are parallel. (b) Norms of reaction showing a genotype-by-environment interaction that results in the masking of genetic variation in E1 and the expression of genetic variation in E2. (c) Crossing norms of reaction that result in changes in the rank-order of genotypes across environments. The degree of genetic variation does not change across environments, but different genotypes have different relative phenotypes in each environment, and different genotypes are closest to the optimum in different environments. (d) Norms of reaction in which all genotypes exhibit phenotypic plasticity, and in which genotypes do not change rank across environments. In all cases of (b)–(c), some genotypes exhibit adaptive plasticity, such that plasticity results in the phenotype being closer to the optimum in each environment, but other genotypes do not. (e) Norms of reaction that show a 'function-valued trait,' in which the expressed phenotype varies continuously as a function of the environment. The dotted line indicates the optimal phenotype across the environmental gradient.

Predicting Genotype-by-Environment Interaction

Predicting genotype-by-environment interaction entails predicting the phenotype expressed by different genotypes in different environments. When a reaction norm is a continuous function, the plastic trait is referred to as a 'function-valued trait' (Stinchcombe *et al.*, 2012), and the reaction norm is described by the function of the response of the phenotype to the environmental factor (**Figure 1(d)**). In contrast, a discontinuous trait exhibits distinct phenotypes, or polyphenisms, even if the environment varies continuously. Functions can describe both sorts of phenotypic plasticity (with discontinuous traits being modeled by an underlying, continuously labile component combined with a threshold for switching from one phenotype to the next). Such functions can be estimated empirically for different genotypes.

A major challenge is to be able to predict environment-dependent phenotypes based on knowledge of physiological and developmental processes, as opposed to simply describing, interpolating, or extrapolating them based on empirical measurements. Process-based models have been applied to describe physiological responses to specific environmental factors, and then combine those functions to predict phenotypes in complex multi-factorial environments (e.g., Bradford, 2005; Morin *et al.*, 2007; Wilczek *et al.*, 2009; Andreini *et al.*, 2014). For example, enhanced photothermal models have been used to predict the timing of flowering or budburst; functions are combined, specifically those describing developmental rates in response to photoperiod, temperature, and 'vernalization' (exposure to cold temperatures, which switches off repressors of flowering or budburst), and the time required to attain a specific developmental threshold, such as competency for flowering or budburst, is calculated. Such process-based models are flexible because developmental progress is calculated at small time intervals; even if environments change over time, the developmental progress can be calculated for each time interval and summed over time. Thus, phenotypes that are the outcome of environment-dependent physiological or developmental processes can be predicted even in nonconstant environments.

Genotypes may differ in one or more physiological parameters in process-based models (e.g., plants may differ in the amount of cold required to induce flowering or in the optimum temperature for germination). When they do, the phenotypic consequence of genetic differences in each parameter can be assessed (Wilczek *et al.*, 2009). In this manner, not only individual phenotypes can be predicted under different environmental scenarios, but the differences among genotypes can also be predicted in each environmental scenario (Burghardt *et al.*, 2015). By providing predictions of the phenotypes expressed by specific genotypes under different environmental scenarios, these methods permit predictions of genotype-by-environment interactions.

In some cases, the genes that determine specific physiological parameters are known. Process-based models that use parameter values that represent known genetic variants in particular genes have been able to predict the phenotypic expression of known alleles. For instance, mutants in photoperiod-sensing genes are unresponsive to inductive long days and have predictably longer times to flower (Wilczek *et al.*, 2009). An ongoing goal is to be able to translate how complex genetic pathways translate into physiological parameters in such process-based models (Welch *et al.*, 2003; Promislow, 2005; Chew *et al.*, 2014).

Causes of Phenotypic Plasticity and Genotype-by-Environment Interaction

Environment-dependent phenotypes can be caused by environment-dependent gene expression, environment-dependent posttranscriptional modifications of RNA, and environment-dependent gene-product activity (West-Eberhard, 2003; Bossdorf *et al.*, 2008). If certain genes are expressed, or their gene products are active, only in some environmental conditions, then specific phenotypes will be manifest only under some conditions. Genetic (including quantitative trait locus (QTL)) studies conducted under multiple environments have clearly shown that genes associated with trait variation differ across environments, indicating some independent genetic basis of phenotypic expression in different environments (e.g., Ungerer *et al.*, 2003; Lacaze *et al.*, 2009; reviewed in Mitchell-Olds, 1995).

Environment-dependent gene expression is widely documented and contributes to phenotypic plasticity (reviewed in Aubin-Horth and Renn, 2009). Genome-wide expression studies have documented that entire genetic pathways are variously expressed according to the environment that an organism is exposed to. Transcriptional regulation of gene expression occurs via the recruitment of specific transcription factors and through chromatin remodeling (Russo *et al.*, 1996; Jaenisch and Bird, 2003; Grant-Downton and Dickinson, 2005; Berger, 2007; Mattick *et al.*, 2009). Chromatin remodeling can determine how accessible DNA regions are to transcription. Methylation, for example, alters chromatin structure (Bender, 2004) and typically converts cytosine to 5-methylcytosine. When methyl groups are added to nucleotides at the regulatory regions of genes, those genes are less transcriptionally active; the more highly methylated those regions are, the less transcriptionally active is the gene. Chromatin remodeling also occurs through changes in the histones (Grant-Downton and Dickinson, 2005; Berger, 2007). As the structure of the histone molecules is altered, the manner in which the specific DNA region it associates with is also altered, changing the accessibility of that particular sequence to transcription. Histones are modified in a variety of ways, including acetylation, phosphorylation, methylation, ubiquitylation, sumoylation, and isomerization. Acetylation of lysine is frequently associated with gene activation and de-acetylation with the repression of gene expression. However, it has been proposed that it is the combinations of modifications that determine specific responses in gene expression (Berger, 2007).

Posttranscriptional regulation includes alternative splicing (which determines the translated mRNA sequence itself), stability of the mRNA strand (which can be actively degraded in a regulated manner), transport of the mRNA to the ribosome, and binding of mRNA to the ribosome. Some of these processes depend on the production of other gene products, and as such have the potential to be regulated in an environment-dependent manner and therefore involved in phenotypic plasticity. For most of them, however, their environment-dependence has not been well elucidated, especially in regard to ecologically relevant environmental variation.

Environment-dependent gene-product activity can be a major contribution to phenotypic plasticity. Some gene products are direct environmental sensors and initiate the process of signal transduction by changing conformation in response to environmental stimuli. Photoreceptors, for example, change conformation in response to light, enabling them to bind to their interactors to initiate changes in gene expression; in contrast, other gene products might be degraded in light. Environmental factors such as temperature can alter the kinetic activity of proteins, binding properties, or propensity to denature. This could result in a continuous modulation of phenotype, or if the downstream response requires a threshold level of substrate, it could result in a discontinuous switch of phenotype (Pigliucci, 2001).

The environment itself may directly interact with enzymatic reactions by determining the presence of a substrate. If a substrate is supplied by the external environment, then the reaction will be initiated only under conditions in which the substrate is present, and the resulting phenotype will be environment-dependent. Phenotypes that vary with nutritional status, such as size or diet-dependent coloration, are examples. Other elicitors that resemble immune responses, such as insect herbivores or pathogens (reviewed in Howe and Jander, 2008), can initiate complex reactions such as the production of secondary compounds, trichomes or hairs, or other modifications of leaf form in plants.

Although the genetic basis of phenotypic plasticity can entail all of the above mechanisms – transcriptional regulation, posttranscriptional modification, gene-product activity, and contributions of substrates – the basis of genotype-by-environment interaction depends on which of those processes are genetically variable in natural populations. Genotype-by-environment interaction does not exist unless the genes that regulate plasticity harbor allelic variation. Variation in gene expression could be caused by variation in transcription factors or other *trans*-regulating factors, or variation in *cis*-regulatory

regions. Variation in posttranscriptional regulation could involve variation in splice sites or DNA sequence variation in the genes that regulate mRNA stability and transport. Genetic variation in gene-product stability would be determined by variation in coding sequences of those genes. Characterizing which genes that regulate phenotypic plasticity also vary in or among natural populations is important for understanding which genes have contributed to its adaptive or maladaptive evolution.

Quantitative-Genetic Consequences of Genotype-by-Environment Interaction

Genotype-by-environment interaction can influence the expression of genetic variation, the nature of genetic correlations among characters, and the ability of phenotypic plasticity itself to evolve.

When different genotypes exhibit different patterns of phenotypic plasticity, the magnitude of differences among genotypes can change with the environment (Falconer, 1952; Via and Lande, 1985). That is, genetic variation can be less ('masked') in one environment and greater ('released,' or 'expressed') in another (**Figure 1(a)**). Genetic variation is a key parameter of evolutionary potential and heritability: unless variation in a trait is genetically based, natural selection cannot cause a change in the mean trait from one generation to the next. The greater the genetic variation, all else being equal, the greater is the heritability and the greater the potential for an evolutionary response to selection (Falconer and Mackay, 1996). Therefore, genotype-by-environment interaction can influence which environments can produce evolutionary responses to selection and how large those evolutionary responses can be.

Because genotype-by-environment interaction can mask genetic variation in some environments, such that many genotypes have the same phenotype, genetic variation can persist in those environments (Via and Lande, 1985). In environments in which genetic variation is expressed, in contrast, natural selection can cull genotypes that produce less adapted phenotypes and deplete genetic variation. Masking and its consequence for the persistence of genetic variation can also allow the opportunity for the expression of genetic variation in a novel environment that has not yet experienced natural selection. Genotypes that exhibited similar phenotypes in one environment may differ in a novel environment, and thereby provide genetic variation upon which natural selection can act. In this manner, genetic masking can contribute to adaptation in novel environments.

Genotype-by-environment interaction can also influence genetic correlations among characters expressed in different environments. If different traits have different patterns of plasticity, then genetic correlations between those traits can be environment-dependent (**Figure 2(a)**). Genetic correlations among traits influence trait evolution (Falconer and Mackay, 1996). A trait (e.g., tall stems) can directly increase fitness, and that trait can increase in frequency as a consequence. If a second trait is correlated with that trait (e.g., large leaves), it too can change in frequency even though it did not influence fitness favorably (**Figure 2(b)**). It is said to be under 'indirect' or 'correlated' selection. If selection on the first trait is strong, and the correlation between traits is large, then indirect selection can actually be stronger than direct selection on the second trait, even causing that second trait to evolve maladaptively. When the strength (or direction) of the correlation among traits changes with the environment, the strength (or direction) of indirect selection also changes. Therefore, environment-dependent genetic correlations can influence whether and how much a trait evolves adaptively or maladaptively in a given environment.

Genotype-by-environment interaction may also change the phenotypic rank-order of genotypes in different environments (**Figure 1(b)**). This is the case when reaction norms cross. A genotype that has the greatest value of a phenotype in one environment may have an intermediate or small value in another environment. If those phenotypes are under natural selection, genotype-by-environment interaction determines which genotype has the highest fitness in each environment.

If different genotypes have different responses to the environment, then genetic variation for plasticity exists, and it can therefore respond to natural selection. Genotype-by-environment interaction is a necessary condition for the evolution of phenotypic plasticity. Greater genotype-by-environment interaction indicates more genetic variation for plasticity, and consequently a greater opportunity for responses to selection on plasticity.

The Evolution and Adaptive Value of Phenotypic Plasticity

The evolution of phenotypic plasticity depends on the adaptive value of expressed phenotypes within each environment, costs of being able to exhibit plasticity, and constraints on abilities to attain optimal phenotypes in any given environment (**Figure 3**).

The adaptive value of the expressed phenotypes depends on the strength and mode of natural selection in each environment. The original models of the evolution of phenotypic plasticity are formulated such that individuals of a given genotype are distributed across a heterogeneous environment and experience each environment with a given probability (Falconer, 1952, 1990; Via and Lande, 1985; Via, 1987). The optimum phenotype is considered to differ among environments. Barring any constraints or costs, the optimum level of plasticity would be that which results in the expression of the optimum phenotype in each environment.

Constraints do occur, however. The optimal degree of plasticity, considering these constraints, depends on the probability of experiencing each environment, the strength and mode of natural selection on the phenotypes in each environment, additional costs of the ability to alter one's phenotype (aka 'costs of plasticity') that are independent of selection on the expressed phenotypes per se (Via and Lande, 1985; van Tienderen, 1991; Dewitt *et al.*, 1998), and genetic constraints on the ability to express optimal phenotypes.

If a genotype experiences only one environment, there is no adaptive advantage to phenotypic plasticity, and the constraints and costs of plasticity would favor a specialist to that one environment. Likewise, if a genotype experiences one

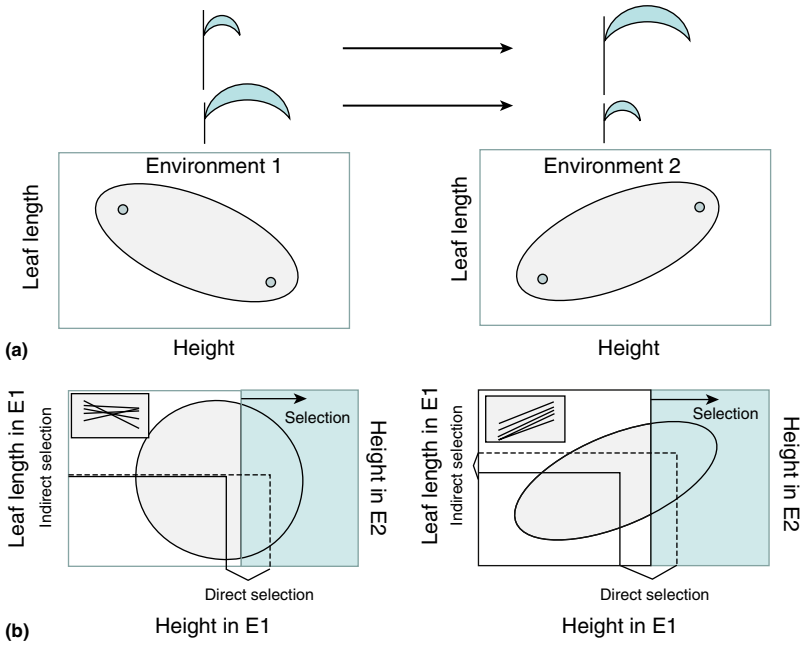

Figure 2 Environment-dependent genetic correlations caused by genotype-by-environment interaction, and their evolutionary consequences. (a) The cartoon shows two genotypes of plants in each of two environments. Stem height does not exhibit plasticity from one environment to the other, but leaf length does. When different traits exhibit different degrees of phenotypic plasticity, the correlation between them can change across environments. The correlation in Environment 1 is negative (long stem and short leaf, or short stem and long leaf), indicated in the graph below it; the two points represent the genotypes illustrated in the cartoon, and the ellipse represents a cloud of points from a sample of individuals that show a negative correlation between the traits. The correlation is positive in Environment 2. (b) Selection and response to selection with correlated characters. The left-hand graph shows an example in which the correlation between two characters (height and leaf length, both expressed within any given environment, E1) is zero, and the right-hand graph shows an example in which the correlation between the two characters is positive. Ellipses indicate a cloud of points from a sample of individuals, as above. The solid line intersecting each axis indicates the mean phenotype of the population for each trait. In each case, selection favors taller plants, and the shaded portion represents the proportion of the population that survives selection. The dotted line intersecting each axis represents the mean phenotype of the surviving population after selection. In the case of no correlation among traits (left), selection on height changes the population mean value of height (direct selection on height), but has no effect on the population mean value of stem length after selection (no indirect selection). In the case of a positive correlation between traits (right), selection on height changes the population mean value of height (direct selection on height), and also changes the population mean value of stem length after selection (indirect selection). Stem length therefore can evolve even if selection does not act directly on it, if it is correlated with a trait that is the direct target of selection (height in this example). Insets: The evolutionary consequences of correlations among traits also applies to correlations of the same trait expressed in different environment, in this case, height in E1 and height in E2 (indicated on the *y* axis on the right-hand side of graphs). The inset shows examples of reaction norms that result in zero correlations across environment (left) and positive correlations across environments (right). In the case of positive correlations across environment (right), selection on the trait in E1 can cause correlated selection of the phenotype that is expressed in E2.

environment much more frequently than another, all else being equal, its evolved phenotype should be closer to the optimum in the more frequent environment, presuming it cannot attain the optimum in both. Similarly, if natural selection is much stronger in one environment than another, all else being equal, the evolved phenotype would more quickly attain the optimum in the environment with stronger selection. The outcome, however, also depends on differences in the quality of each environment (and thereby whether natural selection is 'hard' or 'soft'): if one environment is so harsh that even highly adapted individuals produce very few offspring ('hard selection'), whereas a small phenotypic adjustment might increase fitness greatly in a high-quality environment, then phenotypes would evolve toward the optimum in the high-quality environment, in which they can attain a proportionally higher fitness advantage. The overall outcome therefore depends on the balance between the frequency of the different environments that are experienced, the strength of selection in each environment, and the quality of each environment (Via and Lande, 1985; van Tienderen, 1991; Gavrilets and Scheiner, 1993; Scheiner, 1993; DeWitt and Scheiner, 2004).

If a cost of being plastic exists, a plastic individual will have lower fitness in a given environment than a nonplastic individual even if it expresses the exact same phenotype in that environment as the nonplastic individual (van Tienderen, 1991). Such costs may be caused by the requirement to maintain sensory systems and signal transduction mechanisms that would not be maintained in nonplastic individuals who do not respond to environmental conditions (DeWitt *et al.*, 1998). The magnitude of that cost influences the adaptive value of plasticity directly; if large, it can favor a nonplastic specialist to one environment, or a nonplastic generalist with an intermediate suboptimal phenotype, depending on the

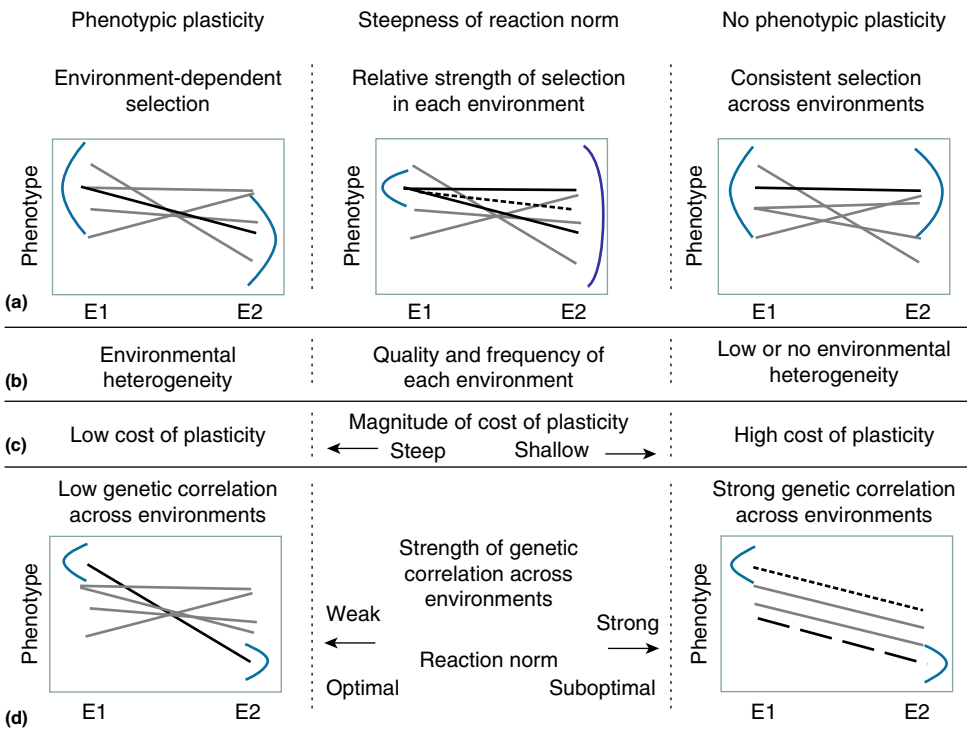

Figure 3 Factors that influence the evolution of plasticity. (a) Norms of reaction in response to two environments. The curves on each side of each panel indicate stabilizing selection on the phenotype, whereby the optimal phenotype occurs at the peak of the curve. Black lines show the reaction norm that produces the adaptive phenotype in both environments. Environment-dependent selection (left) favors plasticity, while consistent selection across environments (right) does not. The relative strength of selection in each environment (center) influences the slope of the evolved reaction norm. Selection is stronger in environment 1 (E1) than in E2. Two reaction norms give adaptive phenotypes in both environments, while four give equivalently adaptive phenotypes in the second environment. The mean adaptive reaction norm (dotted line) has a slope that is shallower than that in the left-hand panel, and it expresses a phenotype that is closer to the phenotype that is favored in the environment that has stronger selection (E1). (b) Plasticity is favored when heterogeneity exists in the selective environment. The slope of the evolved reaction norm is influenced by the frequency and quality of selective environments, favoring phenotypes that are adaptive in the more frequent and higher-quality environment. (c) Costs of plasticity disfavor the evolution of plasticity, and the magnitude of the cost influences the slope of the optimal reaction norm. (d) Low genetic correlations across environments (left) indicate genotype-by-environment interaction and genetic variation for phenotypic plasticity. They permit the evolution of phenotypic plasticity. High genetic correlations across environments (right) prevent the evolution of plasticity. The dotted reaction norm expresses the adaptive phenotype in E1 but not E2; the dashed line expresses the adaptive phenotype in E2 but not E1. No genotype expresses the optimum phenotype in both environments. More generally, strong genetic correlations across environments impede the evolution of an optimal reaction norm (center).

frequency of environments experienced and the strength of selection in each environment as discussed above.

Genetic constraints on the evolution of plasticity include a lack of genetic variance for a trait within any given environment; if no genetic variant exists that can produce the optimal phenotype in any given environment, then the phenotype cannot evolve to the optimum. Therefore, genetic variation must be expressed for the trait in each of the environments it experiences.

Genetic constraints on the evolution of plasticity also include genetic correlations. As with any set of correlated characters under selection, selection on one trait can constrain adaptive evolution of correlated traits, as discussed above. In the case of phenotypic plasticity, one must consider not only correlations among multiple traits expressed in any given environment, as in standard quantitative-genetic models of trait evolution, but also the correlations among traits expressed in different environments (Falconer, 1952, 1990; Via and Lande, 1985; Via, 1987; van Tienderen and Koelewijn, 1994) or 'across-environment genetic correlations' (**Figure 2(b)**). For example, if genotypes that are the tallest in one environment are also the tallest in the other environment, then height is positively genetically correlated across environments. If selection varies across environments, favoring tall individuals in the first environment but short in the second, tall genotypes would have high relative fitness in the first environment but low relative fitness in the second. The across-environment genetic correlations also influence the degree to which selection imposed by one environment can influence the expression of that trait in other environments (**Figure 2(b)**).

With such across-environment genetic correlations, possible outcomes include the evolution of a specialist genotype (which expresses a phenotype that is optimal in one environment but maladaptive in the other), a plastic generalist (which expresses suboptimal but different phenotypes in each environment), or a nonplastic generalist (which expresses a

constant but suboptimal phenotype in both environments; Bradshaw, 1965; Via and Lande, 1985; Via, 1987; Whitlock, 1996). The outcome depends on the degree to which plasticity is adaptive, as discussed above (including the strength and mode of natural selection on phenotypes in each environment and costs of plasticity), and on the strength of the genetic correlations within (and across) environments.

Ecological and Evolutionary Outcomes of Genotype-by-Environment Interaction

Genotype-by-environment interaction enables the evolution of plasticity. The evolution of phenotypic plasticity, in turn, has important ecological and evolutionary consequences including the ability to maintain fitness in variable environments (discussed above), the facilitation of adaptation to novel environments and the evolution of novel specialist phenotypes, and the persistence of populations in the face of environmental change (Figure 4).

Plasticity has been implicated in adaptation to novel environments. It has been proposed that phenotypic plasticity can enable the expression of a phenotype that is closer to the optimum in a novel environment than would be the case if plasticity were absent. While the trait need not express the actual optimum at first, a trait that is closer to the optimum would nonetheless provide a demographic advantage by slowing the rate of, or preventing, extinction long enough for the population to adapt (Baldwin, 1896; Bradshaw, 1965; Sultan, 1987; West-Eberhardt, 1989, 2003; Schlichting and Pigliucci, 1998; Price *et al.*, 2003; Yeh and Price, 2004). The success of plasticity in improving fitness in novel environments depends on how similar the novel environment is to the ancestral environment that elicits plasticity – both in terms of the cues that elicit plasticity and how well those cues predict fitness in that environment. That is, the direction of plasticity must be adaptive in the new environment. Some evidence that plasticity has contributed to local adaptation in this manner is in the form of 'co-gradient variation,' in which the direction of trait plasticity elicited by an environment is in the same direction as genetic differentiation in the trait (as opposed to 'counter-gradient variation' in which the direction of plasticity is opposite to that of genetic differentiation).

Plasticity is hypothesized to contribute to genetic adaptation to novel environments through a process called 'genetic accommodation' (Figure 4), a form of reaction-norm evolution whereby a phenotype that was originally induced by the environment contributes to adaptive evolution in that new environment and can cause the phenotype to be expressed even without the environmental cue (Waddington, 1953, 1961; West-Eberhard, 2003; Crispo, 2007; Braendle and Flatt, 2006; Schlichting and Wund, 2014). Genetic accommodation includes several types of reaction-norm evolution, but generally entails the evolutionary change of a plastic phenotype in the adaptive direction in the novel environment. This could occur through an initial increase in plasticity to attain the optimal phenotype in the novel environment, while the phenotype expressed in the ancestral environment remains the same (Figure 4(a)). Subsequently (or alternatively), the trait expressed in the ancestral environment can also change, recovering (or maintaining) the original function of response to the environment (e.g., the slope of the reaction norm). When this occurs, the trait expressed in the ancestral

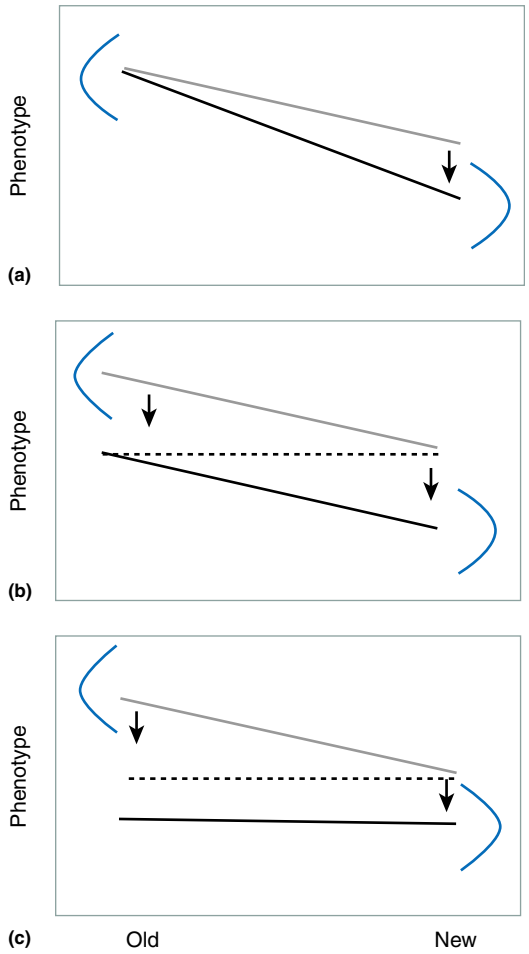

Figure 4 Scenarios of reaction-norm evolution leading to adaptation to novel environments. Mean reaction norms of a population in an 'Old' or ancestral environment and a 'New' environment. Gray lines indicate the reaction norm before evolution (the ancestral reaction norm), and black lines indicate the newly evolved reaction norm after colonization of the new environment. Arrows indicate the direction of evolution of the reaction norm. The curves on each side of each panel indicate stabilizing selection on the phenotype, whereby the optimal phenotype occurs at the peak of the curve. The optimal phenotype changes across environments. (a) The evolution of increased phenotypic plasticity caused by adaptation of the phenotype to the optimum in the new environment, with no change in the phenotype expressed in the ancestral environment. (b) Evolution toward the optimum phenotype in the new environment with no change in the slope of the reaction norm. The phenotype expressed in the ancestral environment also decreases. (c) Genetic assimilation: Evolution toward the optimum phenotype in the new environment, with a loss of plasticity, or 'canalization.' Dotted lines in (b) and (c) indicate the phenotype that was formerly expressed by the ancestral reaction norm in the new environment, in comparison to the phenotype expressed by the newly evolved reaction norm in the old environment; the phenotype that was expressed by the ancestral reaction norm only after exposure to the new environment is now expressed by the newly evolved reaction norm even without exposure to the environmental stimulus.

environment is closer to the phenotype that was originally only induced by the novel environmental stimulus (**Figure 4(b)**).

A more extreme manifestation of this sort of reaction-norm evolution is the process of 'genetic assimilation,' whereby a phenotype that was originally induced by the environment becomes expressed in a consistent (or 'canalized') manner in all environments, even when the environmental cue is absent (**Figure 4(c)**). That is, the phenotype, formerly plastic, becomes constitutively expressed in one form, nonplastic (Waddington, 1953, 1961; Schlichting and Pigliucci, 1998; Pigliucci *et al.*, 2006; Crispo, 2007; Lande, 2009; Schlichting and Wund, 2014). The first phase in this scenario is that plasticity facilitates adaptation to a novel environment, while the second phase is the constitutive expression of the adaptive phenotype in its new environment. As such, plasticity is hypothesized to contribute not only to local adaptation but actually to specialization to novel environments. Only a small number of experimental studies have documented this phenomenon (Waddington, 1953; Rutherford and Lindquist, 1998; Queitsch *et al.*, 2002). While it is generally accepted that adaptive plasticity can increase fitness in novel environments, what is more controversial is how plasticity would be lost, to result in canalization and specialization.

The ability of plasticity to improve fitness in novel environments has been also shown theoretically to increase the probability of persistence of populations under scenarios of environmental change (Lande, 2009; Chevin *et al.*, 2010). Plasticity to new environments, if it is in an adaptive direction, can increase the demographic performance of populations and reduce their risk of extinction in changing environments. It can also allow populations to persist under more rapid environmental change than would be possible without plasticity. Therefore, the role of phenotypic plasticity in mitigating adverse effects of rapid environmental change is a topic of great current interest.

Genotype to Phenotype: Insights from Evo-Devo

SH Rice, Texas Tech University, Lubbock, TX, USA

Glossary

Canalization Evolution of development to a state that minimizes the variation in phenotype.
Epistasis Nonadditive interactions between alleles at different loci.
Phenotype Any measurable property of an organism.
Phenotype landscape A function, potentially of many dimensions, mapping phenotype to underlying genetic and environmental factors.
Pliotropy A situation in which one genetic locus influences multiple phenotypic traits.

Nearly all questions about the mechanics of evolution come down to variation and transmission – how deterministic and stochastic processes shape the distribution of phenotypic variation, and how this variation is transmitted across generations? To the extent that genes are what is transmitted across generations, all theories of phenotypic evolution therefore must involve some sort of model, implicit or explicit, of how phenotype is related to genotype.

This key relationship is often described as the 'genotype–phenotype map' (Landry and Rifkin, 2012), though this term is somewhat misleading – since environmental factors that are not part of the genome play important roles in development. Thus, a particular genotype does not actually map to a particular phenotype, but rather may produce different phenotypes in different environments.

Genotype–phenotype maps are often represented as a network linking different genes to different phenotypic traits. This is a good way to capture pliotropy (Wagner and Zhang, 2011), but it does not allow us to describe the inherently nonlinear aspects of developmental processes. Another approach to visualization of the relationship between genotype, environment, and phenotype (which further allows us to construct mathematical models of developmental evolution) is to describe phenotype as a function of the expression of underlying genetic and environmental factors (hereafter referred to as underlying factors). Such a function is a phenotype landscape (Figure 1). Though the name implies a two-dimensional surface, we can apply the concept to any number of underlying factors. Given a phenotype landscape (in as many dimensions as are important) and a distribution of variation of underlying factors, we can solve analytically for how a population will evolve in response to any given selection regime. (Note that, properly, any measurable property of an organism is part of its phenotype – including its genotype.)

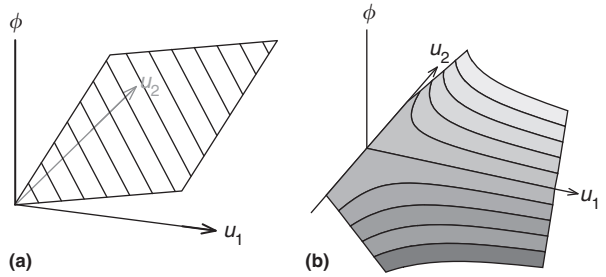

Figure 1 Phenotype landscapes. ϕ is a phenotypic trait. u_1 and u_2 are underlying genetic or environmental factors that influence ϕ. (a) A case in which the underlying factors contribute additively to phenotype. Additive landscapes are always uncurved. (b) A case in which u_1 and u_2 interact nonadditively (i.e., there is epistasis).

The various mechanisms by which genetic and environmental variation generate phenotypic variation are the subject of developmental biology, so one might expect development to be an explicit part of most evolutionary models. This is not the case. Though all evolutionary theories must involve some model of genotype–phenotype relationships, this model need not be explicit. In many cases, it is folded into simplifying assumptions. The most common such simplifying assumption is that phenotype is a linear function of genotype. This assumption is nearly universal in those fields, such as quantitative genetics and evolutionary game theory, that study morphological or behavioral evolution.

We can visualize the assumption of additive gene action as an uncurved phenotype landscape (Figure 1(a)). In this case, the landscape looks the same for all possible values of underlying genetic or environmental factors. Any nonlinear interaction between underlying factors induces epistasis (nonadditive gene action), which causes the landscape to curve (Figure 1(b)), and makes it so that the local geometry of the landscape is different at different places on it.

Taken literally, the assumption of linearity would mean that different genetic elements each make some contribution (generally assumed to be small), and that we could predict phenotype by simply adding up all of these contributions (as well as the contribution of the environment). In fact, nobody takes this assumption literally. Everything that we know about development, from the regulation of gene expression to tissue differentiation, suggests that underlying genetic and environmental factors interact nonadditively in the development of adult phenotype.

The assumption of additive gene effects is, however, sometimes a reasonable approximation. This is because of the fact that even traits that develop through highly nonlinear processes may look approximately additive if we follow their evolution over only a short time. Figure 2 illustrates this using a nonlinear phenotype landscape. At any given time, the distribution of variation in a population covers only a small region of the landscape. If this region is small enough, the

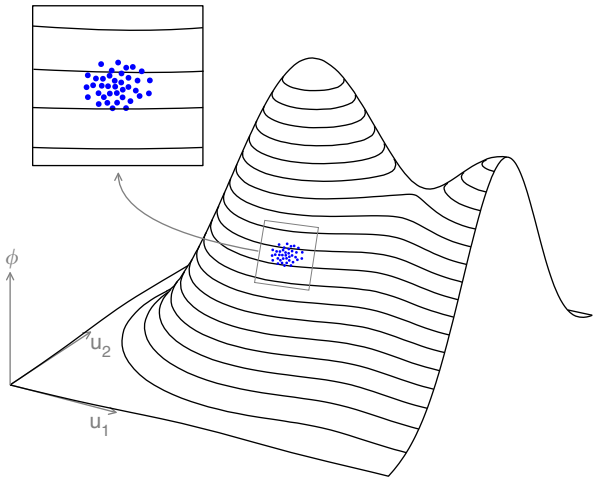

Figure 2 A nonadditive landscape may appear approximately additive to a population that covers only a small part of it. In this case, an additive model would be a reasonable approximation for a few generations.

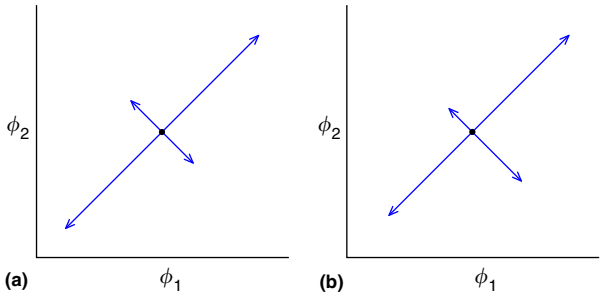

Figure 3 Responses to selection (arrows) on two traits that exhibit strong additive genetic covariance. (a) The prediction of additive models is that the response in opposite directions will be of the same magnitude. (b) We often see asymmetrical responses to selection in opposite directions. This can result from slight differences in patterns of epistasis for the two traits.

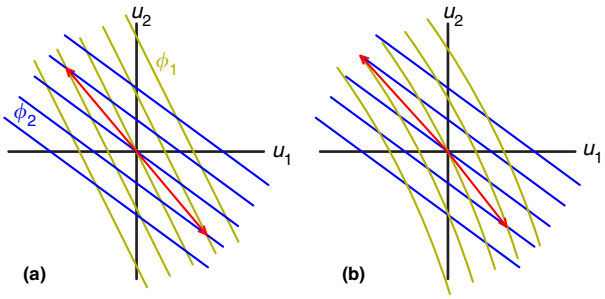

Figure 4 Phenotype landscapes (as contour lines) for two traits that are genetically correlated. The red arrows show the change in the underlying factors that would be necessary to increase one trait by one unit while decreasing the other trait by one unit. (a) In a completely additive case, the responses in opposite directions are symmetrical; it is just as easy to increase ϕ_1 (yellow contours) while decreasing ϕ_2 (blue contours) as to move in the opposite direction, increasing ϕ_2 while decreasing ϕ_1. (b) When the landscapes have slightly different curvature (corresponding to slightly different patterns of epistasis), the responses become asymmetrical. The direction of the asymmetry depends on the exact patterns of epistasis.

landscape will appear approximately linear to the population. In such a case, it will appear that most of the phenotypic variation in the population is due to the additive effects of alleles (Hill *et al.*, 2008). This is why quantitative genetics often works well on a local scale.

So, why should we be concerned with the complexities of development if models that ignore them often suffice? First, models that assume additive gene action are, at best, approximations. Sometimes they are acceptable approximations, but sometimes not. Second, some important questions lie outside the purview of additive models that focus on the variation currently existing in natural populations. These include questions about the evolution of quantitative genetic parameters, such as heritability, as well as why we do not see certain phenotypes in certain groups of organisms. Finally, we sometimes want to study the evolution of developmental processes in their own right, which we cannot do using models that assume that those processes are so simple that they can be ignored. I consider examples of each of these cases below.

When the Linear Approximation Does Not Suffice

Models based on the assumption of additivity are often good at predicting the general direction of evolution, given a selection regime and the current pattern of genetic variation and covariation between traits (Falconer and Mackay, 1996; Roff, 1997). For example, quantitative genetics theory predicts that when there is a nonzero genetic covariance between two traits, the population will be able to evolve more quickly in response to selection that goes with the genetic covariation, than in response to selection against it. Thus, if height and weight show a positive genetic covariance, then selection to increase both height and weight should produce a larger response than selection to increase height while decreasing weight. This prediction has been born out in both laboratory and agricultural studies.

Some other predictions, though, have not fared so well. For example, the standard theory (based on additive gene action) predicts that the response to selection in opposite directions should be symmetrical (Figure 3). Selection for decreased height and decreased weight should produce the same magnitude of change (though in the opposite direction) as does selection to increase both height and weight. The same should hold in selection against the correlation; selection for increased height and decreased weight should produce the same magnitude of change, in the opposite direction, as does selection for decreased height and increased weight. In fact, though, a number of studies have found that selection in opposite directions tends to yield different magnitudes of response (Frankham, 1990; Rice, 2008). In some cases, this asymmetry can be quite pronounced, making the population essentially unresponsive to selection in certain directions.

If genes really did contribute additively to phenotype, we would not expect such asymmetries. They are expected, though, when we allow for even weak epistatic interactions between genes (Rice, 2008). Figure 4 illustrates this. Two different traits correspond to two phenotype landscapes over

the same set of underlying factors. If the covariation between the traits results from shared developmental processes (being influenced in similar ways by many of the same loci or environmental factors), then the two landscapes nearly line up, as shown in Figure 4. (Covariation between traits can also result from covariation between the underlying factors, though this is more transient as it is subject to being broken up by recombination.) Because the two landscapes nearly line up, a slight change in the curvature of one relative to the other – corresponding to slightly different patterns of epistasis due to different developmental processes – can result in substantial asymmetry in the joint evolution of the two traits.

Note that this effect should be much less pronounced for landscapes that slope at different angles (corresponding to lower genetic covariance between the traits). In a sense, highly correlated traits amplify the effects of local epistasis, making the assumption of additivity a poor approximation for such traits.

Development and Morphological Diversity

One of the early goals of research in evolutionary developmental biology (evo-devo) was to explain why certain traits that might seem to be adaptive fail to evolve in particular groups of organisms because of 'developmental constraints.' The idea that developmental constraints impose hard boundaries on adaptive change was behind many of the early arguments for expanding evolutionary theory to more fully encompass development (Goldschmidt, 1940; Gould and Eldredge, 1977; Riedl, 1978). Unfortunately, some authors tended to underestimate the efficacy of local adaptation, and rejection of developmental constraints as a ubiquitous phenomenon was behind some of the early skepticism of evo-devo research (Charlesworth *et al.*, 1982; Maynard Smith *et al.*, 1985).

In fact, nearly all quantitative traits in natural populations exhibit enough heritable variation to respond quickly to directional selection. However, the fact that developmental constraints rarely impose hard limits on adaptive evolution does not mean that understanding development is not important for a full understanding of patterns of phenotypic diversity. We will consider two examples that illustrate how understanding development is important in determining why certain traits are not observed in certain groups of organisms. In one case, development itself provides the explanation. In the other case, understanding development allows us to rule out developmental constraint as an explanation.

Image forming eyes have arisen many times and in a number of metazoan phyla (Salvini-Plawn and Mayr, 1977; Land and Fernald, 1992; Ogura *et al.*, 2004). Since such eyes involve focusing an image on a field of receptors, it is tempting to think of them as analogous to cameras. Since a particularly simple camera uses a pinhole, with no lens, to focus the image, we might expect to see pinhole eyes arising in the evolution of image forming organs.

In fact, pinhole eyes have arisen at least twice in mollusks (in the chambered nautilus (*Nautilus pompilius*) and in the giant clam (*Tridacna gigas*) (Land, 2003)). By contrast, they do not appear to have ever arisen in vertebrates. One might speculate that a pinhole focusing mechanism was simply never selected for in vertebrates, but this would only make it more mysterious that this type of eye has arisen multiple times in mollusks.

This pattern makes sense when we consider the developmental differences between the molluskan eye and the vertebrate eye. The optic cup of mollusks develops as an inpocketing of the epithelium. In species with a lens, the lens forms as the outer part of the optic cup begins to close. If no lens forms, though, the closing optic cup naturally passes through a state in which there is a small opening – essentially acting like a pinhole camera (Figure 5).

By contrast, the vertebrate optic cup forms as an outpocketing from the developing brain. This neural-derived tissue ultimately induces the formation of a lens in the overlying ectoderm. Even if no lens formed, though, there would still be a layer of tissue overlying the presumptive optic cup. The vertebrate eye thus does not naturally pass through a pinhole stage. Note that this does not mean that a pinhole eye could not possibly evolve in vertebrates, only that it is unlikely in the absence of just the right kind of directional selection for that particular morphology.

Recent work by Ogura *et al.* (2013) has shown that the six 3/6 regulatory pathway, which is associated with lens formation in other organisms, is not active in *Nautilus*. Knocking out the homologous regulatory system in a vertebrate would produce a nonimage forming eye. Doing so in *Nautilus* produces a functional pinhole eye. It thus appears that the presence of pinhole eyes in mollusks, and their absence in vertebrates, is best explained in terms of the likelihood of that morphology arising through a relatively minor developmental change.

In some cases, an understanding of development can allow us to rule out developmental constraint as an explanation for an observed distribution of phenotypes. Ammonites were a group of shelled cephalopod mollusks that were highly diverse but went extinct during the end cretaceous mass extinction 66 mya. Most ammonites had planispitral shells – coiling in a single plane like modern Nautilus (to which they were not closely related). A few ammonite species coiled along an axis, like most modern snails, but some – called heteromorphs – had shell forms unlike any other mollusk. These included some that coiled in one manner then abruptly changed, as well as some that did not coil around any single axis at all (Figure 6). Because no modern mollusk exhibits such a strange shell form, whereas a number of ammonites did, we might be tempted to suspect that the developmental processes that allowed for diverse heteromorph shells went extinct with the rest of the ammonites.

In fact, though, it appears that the developmental potential to build heteromorph shells is present in modern gastropods. Using a model of shell growth, Rice (1998) showed that some of the most odd-looking heteromorph ammonite shells could be produced by a very simple mechanisms – having the animal rotate within the shell as it is producing new shell material (Figure 7). That this is what some heteromorphs were actually doing is suggested by the pattern of sculpture on the outside of the shell of *Dydimoceras* (Figure 7).

We know that the potential to rotate the mantle within the growing shell is present in modern day shelled mollusks. For

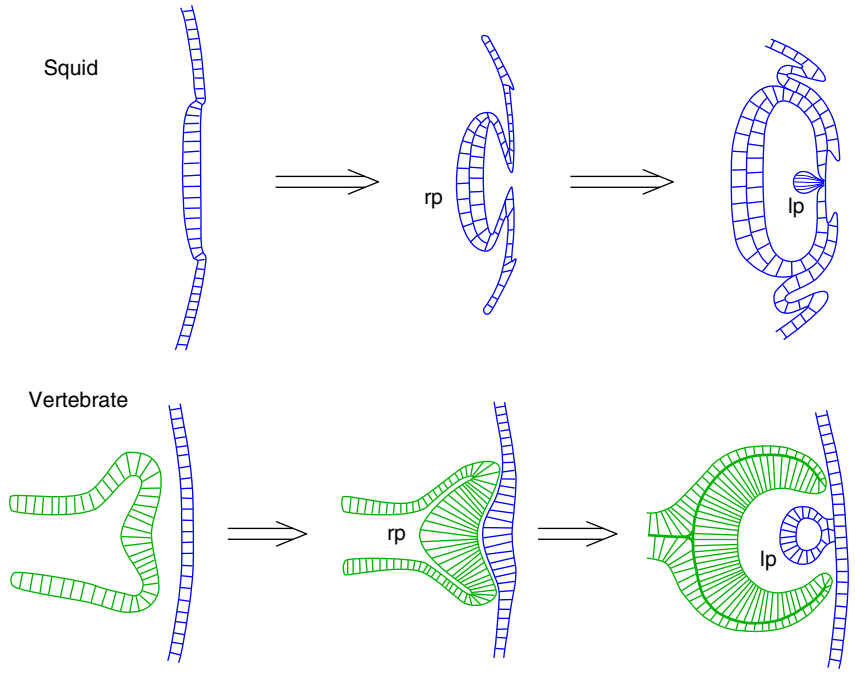

Figure 5 Development of image forming eyes in squid and vertebrates. rp = retinal primordium, lp = lens primordium. In the squid, both the retina and lens develop from a single epithelial optic placode. In vertebrates, the retina is derived from neuroectoderm (green), while the lens is induced to form in the overlying ectoderm (blue). Note that the squid eye passes through what is effectively a pinhole camera stage, whereas the vertebrate eye never does so, since the retina is always covered by layers of tissue.

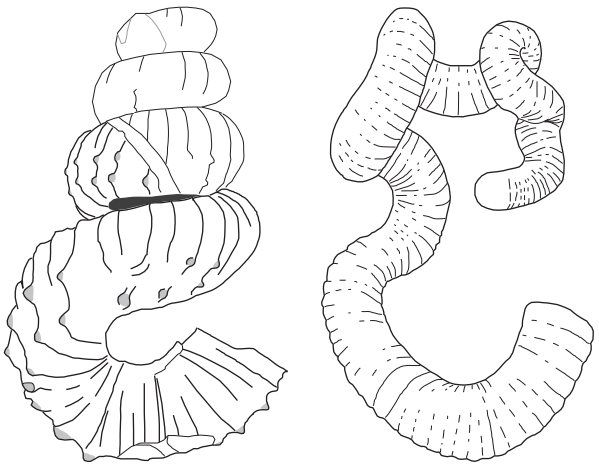

Figure 6 Two heteromorph ammonites (redrawn from Rice, S.H., 1998. The bio-geometry of mollusc shells. Paleobiology 24, 133–149). Left: *Didymoceras*. Right: *Nipponites*. Note the rows of sculptural bumps on *Didymoceras* (highlighted in gray).

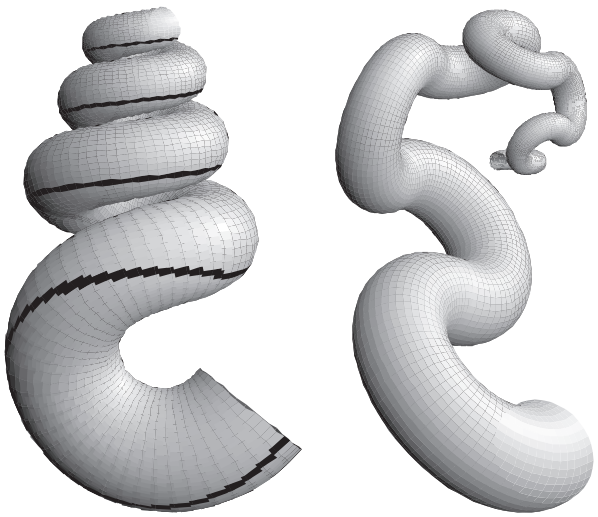

Figure 7 Models of *Didymoceras* and *Nipponites* produced by having the mantle rotate back and forth as the shell grows – with one cycle of rotation for *Didymoceras* and repeated cycles for *Nipponites*. The black line on the simulated *Didymoceras* traces the path followed by a particular point on the mantle. Compare with the trajectory of the sculptural bumps in **Figure 6**.

example, Liew *et al.* (2014) recently showed that the modern irregularly coiled gastropod *Plectostoma concinnum*, for which the last coil is upturned, achieves its odd shape by rotating the mantle within the growing shell. The same trick, though less pronounced, is seen in the snail appropriately named *Distorsio*, in which the axis of coiling changes slightly in alternate whorls (Checa and Aguado, 1992). Though none of these modern species produces a shell as spectacularly irregular as *Nipponites*, the difference is only a matter of degree – involving only the amount and timing of rotation. We thus conclude that the lack of heteromorph forms in modern mollusks is likely due to these morphologies not being selected for, rather than lack of variation on which such selection could act.

Note that though it seems that we can rule out 'developmental constraint' as an explanation for the lack of heteromorph

phenotypes in modern mollusks, we can conclude this only because we have a model of development of this trait. Understanding how a trait develops is thus sometimes essential even to confirming that observed phenotype distributions are structured by selection.

The Evolution of Development

Though much of the early interest in evolutionary developmental biology centered around explaining how development might constrain or facilitate different sorts of phenotypic evolution, a substantial amount of recent research focuses instead on how developmental processes themselves evolve. Additive models are of little use here, since they assume that the phenomenon under study – complex interactions between gene products – does not exist. We are thus forced to consider evolution on curved phenotype landscapes.

On an uncurved (additive) landscape, evolution along a contour is completely neutral with respect to selection, since moving along a contour does not change the distribution of phenotypic variation. On a curved landscape, though, things are different. The slope of the landscape changes as a population moves along a contour, and as it does so the amount of phenotypic variation that results from a particular amount of underlying genetic or environmental variation changes. In other words, movement along a contour leads to change in the shape of the phenotype distribution, even if the mean phenotype does not change (Rice, 2002).

The best understood kind of selection that acts on the shape, rather than the mean, of the phenotype distribution is stabilizing selection – defined as selection that reduces phenotypic variance (Lande and Arnold, 1983; Rice, 1998). Stabilizing selection favors the evolution of canalization, or phenotypic robustness in the face of underlying genetic or environmental variation.

On a phenotype landscape, the amount of phenotypic variation that results from a given amount of underlying genetic variation is determined in large part by the slope, or gradient, of the landscape. A low slope means that a large amount of underlying genetic variation translates into relatively little phenotypic variation. By contrast, a high slope amplifies the underlying variation – producing high phenotypic variance. We thus expect a population experiencing stabilizing selection to evolve toward points of minimum slope along a contour (the mathematical theory leading to this conclusion is presented in Rice (2002)).

This makes canalization something that we can test for empirically. Since most points on a phenotype landscape are not near a point of minimum slope, demonstrating that a particular population is at or near such a point is evidence that its development was structured in part by stabilizing selection. A more compelling case could be made if we could show that a population, in adapting to a new environment, moves from a point of minimum slope (i.e., maximum canalization) on one contour to a new point of minimum slope on a different contour. This has been demonstrated in at least one case.

Scoville and Pfrender (2010) studied *Daphnia* from mountain lakes with and without predatory fish. In the absence of visual predators, the high UV intensity at high elevations selects for high levels of melanin. However, this also makes individuals more visible; so the presence of predatory fish selects for lower melanin levels than would be optimum in the absence of visual predators.

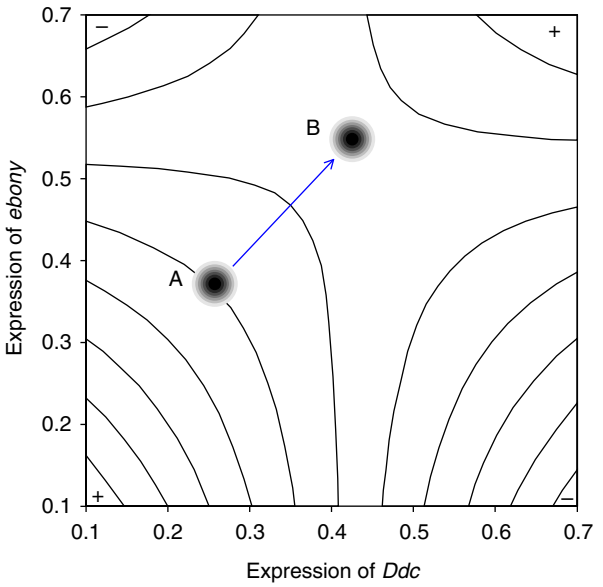

Figure 8 Reconstructed phenotype landscape for melanin production as a function of the expression of two genes that interact epistatically. A and B represent the position of populations in lakes without visual predators (A), and lakes into which visual predators were introduced (B). '+' and '−' represent, respectively, high and low points on the landscape.

In a number of high lakes, fish were introduced for sport fishing in the early to mid-twentieth century. In these lakes, the resident *Daphnia* populations responded by evolving lower melanin levels (lighter coloration) than is seen in similar lakes without introduced predators. Two loci were found to interact nonadditively to influence melanin production. By regressing melanin concentration on the expression of each gene individually, and on their product, the authors constructed a phenotype landscape for these underlying factors (**Figure 8**).

As expected, individual from predator-free lakes are higher up on the landscape – corresponding to higher melanin levels – than those subject to visual predation. Notably, both populations were very close to points of maximum canalization for their respective melanin levels, consistent with the expectation that this developmental system has adapted to maximize robustness. The authors note that, in evolving to lower levels of melanin, the populations followed the gradient of the phenotype landscape, as predicted by previous theory. It thus appears that selection for canalization plays an important role in the evolution of this trait, and that we could not understand the evolution of the two loci influencing the trait if we did not understand how they interact, nonadditively, with one another.

Conclusions

Models of evolution invariably involve assumptions – explicit or implicit – about the translation of genetic variation into

phenotypic variation. For most phenotypic traits, this means making assumptions about development. The simplest such assumption, which produces the easiest models to study, is that gene products contribute additively to phenotype. This is the basis of quantitative genetics, and it is often a reasonable approximation for studying short-term adaptive evolution.

There are a variety of cases, though, in which the assumption of additivity is unsatisfactory. Some of these are situations in which we would expect to have to consider development, such as when the goal is to study the evolution of canalization. In other cases, though, the nonadditivity resulting from development makes its presence known even when we are studying the short-term response of quantitative traits to directional selection. This is likely to be the case whenever we wish to predict the joint evolution of tightly correlated traits, or when we are studying how specific loci respond to selection on a trait that they influence epistatically. Overall, situations in which we can effectively ignore development should be seen as special cases.

Geographic Mosaic of Coevolution

TP Craig, University of Minnesota Duluth, Duluth, MN, USA

Glossary

Adaptive radiation The rapid divergence of a single phyletic line into a number of species occupying different ecological niches.

Character displacement The difference in resource use resulting from reciprocal selection to avoid competition between species.

Coevolutionary arms races The continuing escalation of reciprocally selected traits for defense and counter-defense in an antagonistic interaction.

Common garden experiment The transplantation of organisms from a range of different environments into a single environment to determine the contribution of local genetic variation among locations to phenotypic variation.

Horizontal transmission The transfer of a symbiont (parasite or mutualist) between unrelated individuals.

Maladaptation The low fitness of an organism due to the mismatch between its genotype and the environment. This occurs in geographic mosaic of coevolution when genotypes adapted to one local environment are found in another environment.

Negative frequency-dependent selection A mode of selection where the fitness of a genotype is inversely related to the proportion of that genotype in the population.

Reciprocal transplant experiment The movement of organisms from several different environments into each of the alternative environments in order to measure local adaptation.

Trait remixing The gene flow between populations adapted to different environments resulting in reduced fitness due to a mismatch between organism traits and their environment.

Vertical transmission The transfer of a symbiont (parasite or mutualist) from parent to offspring.

Introduction

Coevolution is the reciprocal adaptation among interacting organisms, and it is one of the major forces that organize biodiversity by linking the genomes of interacting species (Thompson and Cunningham, 2002). It is also one of the major forces creating biodiversity because diversifying coevolutionary selection can lead to speciation (Thompson, 2005, 2009). Measuring coevolution is difficult because it involves determining how two species interact through time, and without a time machine it is difficult to measure how traits of interacting species have changed through time. The difficulties in rigorously testing coevolutionary hypotheses led to questions about its importance as an evolutionary force. To solve the problems in testing the coevolutionary hypothesis, Thompson (1999, 2005) developed the geographic mosaic theory of coevolution that examines geographic variation in species interactions to use space as a proxy for time to measure coevolution. A geographic mosaic of coevolution (GMC) occurs when local variation in species interactions produces a spatially variable pattern of reciprocal adaptation in these species.

Coevolution involves at least three steps: first one species evolves a response to a trait of a second species, and this is followed by a response of the second species to the first (Janzen, 1980). These steps can be measured by comparing sites where two species are exerting reciprocal selection on each other that are termed coevolutionary hotspots, and sites where two species are not exerting reciprocal selection on each other that are termed coevolutionary coldspots (**Figure 1**). If coevolution is occurring, then it can be measured by comparing traits in coevolutionary hotspots versus coldspots. Interactions between species may also differ in different environments, with those environments changing the selection on coevolved traits, so coevolution can also be measured by comparing hotspots in different environments (**Figure 1**). The predicted outcome of geographic mosaics of coevolution is that populations of the interacting species should become geographically differentiated and locally adapted due to the presence or absence of diversifying selection, or by different strengths of selection between interacting species in two hotspots. However, if movement of individuals causes gene flow between populations adapted to environments with different coevolutionary forces then this can result in 'trait remixing' and 'maladaptation' (**Figure 1**). For example, if there is migration from a coldspot where the population is not adapted to an interacting species to a hotspot where the interacting species is present then non-coevolved individuals with low fitness may be found in the hotspot.

The geographic mixture of coldspots and hotspots produces a geographic selection mosaic, which consists of a matrix of interactions where the genotypes of one species interact with the genotypes of a second species in a specific environment, or a $G \times G \times E$ interaction. The $G \times G$ interaction that determines coevolution varies geographically from hotspots (**Figure 1**), where species frequently interact resulting in strong reciprocal selection, to coldspots, where interactions are rare or absent and reciprocal selection is weak (**Figure 1**). Geographic variation in the environment can alter the $G \times G \times E$ interaction so that selection differs among hotspots (**Figure 1**). The evolutionary outcomes produced by the divergent geographic selection mosaics can range from transient polymorphisms to speciation and adaptive radiation.

The pervasive patterns of geographic variation in selection and local adaptation that are found among natural populations

Coldspot: Selection in environment X on species 2 in the absence of species 1. (b) Hotspot: Reciprocal selection of species 1 and species 2 in environment X. (c) Hotspot: Reciprocal selection of species 1 and 2 in environment Y. Arrows represent gene flow among hotspots and coldspots that can produce maladaptation.

(see Kawecki and Ebert, 2004; Greischar and Koskella, 2008; Hokesema and Forde, 2008 for reviews) are consistent with the geographic mosaic of coevolution theory. However, to demonstrate that geographic population variation between interacting species is due to their reciprocal selection requires separating selection due to genotype × genotype interaction from those of a myriad of other species and abiotic factors represented by the E in the mosaic of G × G × E interactions. To completely describe a GMC it is necessary to measure the G × G × E coevolution mosaic, gene flow among populations, and the mosaic of local adaptation and maladaptation that these processes produce.

One approach to testing hypotheses generated by the GMC theory is determining whether observed ecological patterns are consistent with the predictions of the GMC. Thompson (2005) has made three such predictions, and these predictions are illustrated by the interactions between a predatory fish and three species of freshwater snail (Chaves-Compos *et al.*, 2011). First, Thompson predicts that geographic populations will differ in traits shaped by the interaction. In the fish–snail example, since the success of a fish that feeds on snails depends on snail shell thickness relative to fish crushing ability, then the geographic variation found in these traits indicates that they are coevolving. Thompson's second prediction is that if these species are coevolving, then traits of interacting species will be matched in some, but not all, of the populations (Thompson *et al.*, 2002). Chaves-Compos *et al.* (2011) found snail shell thickness and teeth morphology is matched in some areas as predicted if coevolution produced reciprocal local adaptation, but not matched in others because of gene flow. Finally, Thompson predicts that geographic variation in diversifying selection will result in few coevolutionary traits being fixed in all populations. In the snail–fish example, neither shell thickness nor fish tooth morphology is a fixed trait, but rather varies geographically.

A match with the ecological predictions is consistent with the existence of a GMC, but alternative hypotheses are also consistent with these patterns and additional studies are often needed to distinguish GMC from alternatives. Experimental measurements of the geographic mosaics of selection and local adaptation can provide rigorous tests of the GMC hypotheses. A variety of approaches have been used to measure and partition the effects components of $G_1 \times G_2 \times E_x$ to measure coevolutionary forces. The GMC predictions that the outcome of interactions of species 1, G_1, and species 2, G_2 from different locations will differ due to coevolutionary selection for local adaptation. To test this hypothesis, 'common garden experiments' measure interactions between a range of populations of a species from different areas (i.e., E_A, or E_B) in a single environment (either E_A, or E_B or a laboratory or garden (E_C)) in order to measure the effects of reciprocal selection by comparing the $G_{1A} \times G_{2A}$, $G_{1B} \times G_{2B}$, $G_{1A} \times G_{2B}$ interactions, in the absence of environmental variation (Lively, 1989; Lively and Jokela, 1996; Laine 2005). While these experiments can provide indications of geographic variation in the interaction of two species it cannot accurately measure coevolutionary forces because the crucial G × E interactions are not accounted for.

'Reciprocal transplant experiments' measure local adaptation of populations, a crucial prediction of the GMC theory, by comparing the performance of each population in their local environment and foreign environments, for example, the performance of the population G_{1A} is measured in the local $G_{1A} \times G_{2A} \times E_A$ and in the 'foreign' $G_{1A} \times G_{2B} \times E_B$ environments. Local adaptation is measured by either comparing whether a local population performs better within its own habitat than a foreign population does or whether a local population performs better in its local habitat than in a foreign habitat (Gandon, 1998; Kawecki and Ebert, 2004; Greischar and Koskella, 2008). However, merely demonstrating that populations are locally adapted does not demonstrate that coevolution has occurred between two focal species, because each species could be locally adapted to the abiotic environment or to other non-focal species. To measure coevolutionary forces, Nuismer and Gandon (2008) have developed an experimental design and mathematical analysis that allows full measurement of the G × G × E coevolutionary forces.

It requires a double reciprocal transplant experiment where multiple geographic populations interact in multiple environments.

Geographic Mosaics of Coevolution

Geographic mosaics of coevolution have been studied in a range of interactions allowing for an evaluation of how the characteristics of the interactions shape the outcomes. Interactions differ on several dimensions including: Interaction type (predator–prey, competition, mutualism), geographic scale, the amount of gene flow, the taxa involved, whether hotspot–coldspot interactions or hotspot–hotspot interactions are occurring, what sets the limits in the escalation of coevolving traits, and the time scale on which coevolution occurs. Variation on all of these axes has resulted in a wide range of evolutionary outcomes ranging from transient polymorphisms to adaptive radiations.

Geographic Mosaics of Diversifying Selection in Antagonistic Interactions

Antagonistic (-,-) interactions can result in 'coevolutionary arms races' where offensive and defensive weapons are produced in an escalating sequence. These arms races may continue indefinitely, or they may reach some limit. Alternatively, 'negative frequency-dependent' selection can create a coevolutionary chase in space and time where the predator or parasite becomes adapted to the most common genotypes of a host favoring a less common genotype that increases in frequency until its antagonist adapts to its defenses, and the cycle repeats. Gene flow among areas can produce a geographic mosaic where a genotype that is vulnerable to the adapted antagonists in one area escapes to another area where there are fewer adapted antagonists.

Morphological evolution of pinecones, squirrels, and crossbills

An arms race involving lodgepole pine, *Pinus contorta*, red squirrels, *Tamiasciurus* sp., and red crossbills, *Loxia curvirostra* provides an example of a large-scale GMC that has produced local adaptation and contributed to adaptive radiation in the interacting species. A mosaic of hotspots and coldspots in the interaction of squirrels and pine trees is found on the wet and dry slopes of the Cascade Mountain Range of the US Pacific Northwest. Smith (1970) conducted a classic study of a GMC in this interaction. A coevolutionary hotspot for squirrels and pines exists on the east side of the Cascades where a rain shadow results in periodic drought and fire. Periodic fire selects lodgepole pines to develop serotinous cones, which are cones that only open and disperse their seeds when a fire that creates opportunities for germination. Serotinous cones remain on the trees for extended periods between fires, providing a predictable supply of food for the squirrels, which exert strong selection on the cones to develop defenses. A coevolutionary coldspot in the squirrel–pinecone interaction occurs on the west side of the Cascades where high precipitation prevents frequent fires. In this area pinecones open yearly and drop their seeds, and they are not a dependable seed source for squirrels. As a result there is weak selection for the evolution of pinecone defenses, and counter-defenses by the squirrels. A comparison of pinecone and squirrel traits in the hotspot and the coldspot demonstrated that diversifying selection had resulted in reciprocal local adaptation. In the hotspot pinecones have several traits that inhibit squirrel predation. Cones are strongly attached to branches, and positioned so that they are difficult for squirrels to detach (**Figure 2**). Pinecones have evolved so that it requires the maximum amount of effort to extract the seeds from a cone with few seeds per cone, thick distal bracts, tough bracts, and scales (**Figure 2**). These traits are all lacking in the coevolutionary coldspot where squirrel predation is low. Squirrels in the hotspots are locally adapted to these tree defenses: they are larger, have stronger jaw muscles, and more pronounced sagittal crests which allows for stronger attachment of jaw muscles (**Figure 2**).

Red crossbills are also seed predators of lodgepole pinecones and coevolve with the lodge pole pine in a complex selection mosaic of hotspots and coldspots that depends on the presence or absence of squirrels which has been described by Craig Benkman and his colleagues (Benkman, 1999, 2003; Benkman *et al.*, 2001, 2003). Red squirrels are such effective cone predators that they largely exclude crossbills from utilizing the lodgepole seeds, and mountain ranges with squirrels are coevolutionary coldspots for the crossbill–lodgepole interaction. Pinecones in these ranges are primarily adapted to squirrel predation. Coevolutionary hotspots between crossbills and lodgepole pines are found in isolated mountain ranges in the Northern Rockies which were not colonized by squirrels after the last ice age, but which were colonized by crossbills. Crossbills have specially adapted bills for extracting pine seeds that coevolve with lodgepole pine in the coevolutionary hotspots when squirrels are absent. Crossbill bill shape and cone characteristics evolve differently in hotspots and coldspots resulting in a coevolutionary mosaic (**Figure 2**). Differences in the way that squirrels and crossbills extract seeds have led to different cone morphologies in areas where each is the predominant seed predator. Squirrels remove the entire cone and prefer cones with more seeds so in squirrel hotspots cones are massive, harder to detach, and contain few seeds. In contrast, crossbills attack the cone from the proximal end so in crossbill hotspots cones have thicker proximal scales to protect against crossbills extracting seeds from this end. In response, the bills of the crossbills in hotspots have coevolved with longer more decurved bills that allow them to more easily extract seeds from cones that have evolved these thicker proximal scales. A common-environment experiment demonstrated that the bills are locally adapted to lodgepole cone characters: crossbill populations from areas with and without squirrels were more efficient at attacking their local cones (Benkman *et al.*, 2001).

This GMC has been important in the adaptive radiation of crossbills (Benkman *et al.*, 2010). Reproductively isolated populations of crossbills adapted for feeding on cones of different morphologies have different call types. Coevolutionary diversifying selection to adapt to feeding on cones of different morphologies drives the evolution of this reproductive isolation (Smith and Benkman, 2007). Crossbills have undergone substantial adaptive radiation in sites where

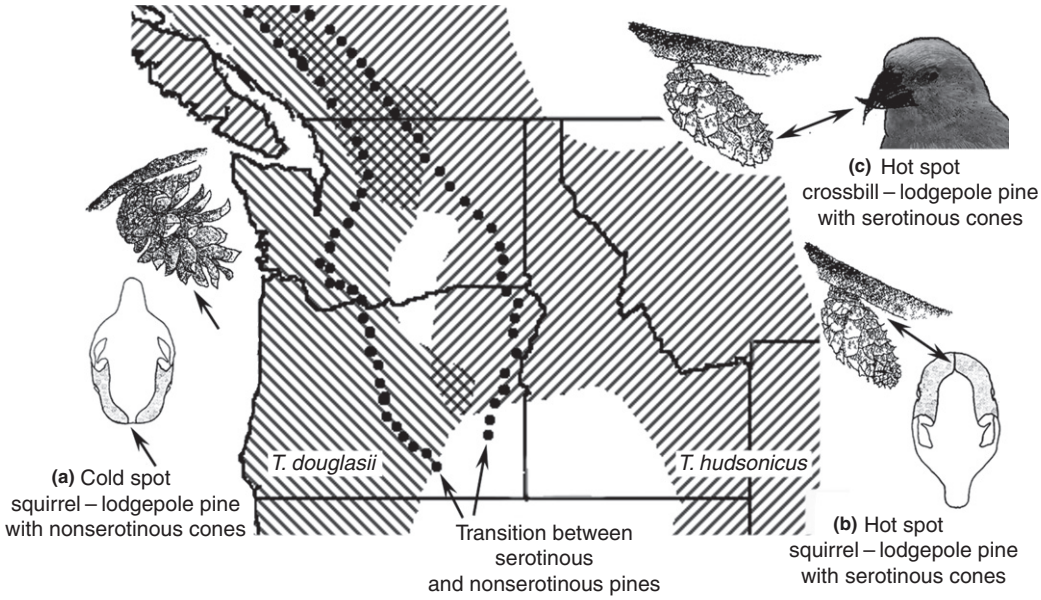

Figure 2 Hotspots and coldspots in the geographic mosaic of coevolution of lodgepole pine *Pinus contorta*, red squirrels, *Tamiasciurus* sp., and red crossbills *Loxia curvirostra*. Redrawn from Smith, C.C., 1970. The coevolution of pine squirrels (*Tamiascirus*) and conifers. Ecological Monographs 40, 349–371 and Benkman, C.W., 1999. The selection mosaic and the diversifying coevolution between crossbills and lodgepole pine. American Naturalist 153, S75–S91. (a) A coevolutionary coldspot in the interaction of pine trees and squirrels occurs where cones are non-serotinous and shed their seeds yearly. In these sites, the cones are not under selection to provide protection for seeds for extended time periods, and squirrels have not evolved strong jaw muscles that are necessary to open heavily defended cones. (b) A coevolutionary hotspot in the pine tree-squirrel interaction occurs where cones are serotinous and retain their seeds for several years necessitating the evolution of numerous seed protection mechanisms against squirrels, and squirrels have evolved strong jaw muscles to counter these defenses. (c) A coevolutionary hotspot in the pine tree-crossbill interaction occurs where pine cones are serotinous and squirrels are absent. Cones evolve seed protection mechanisms specific to defending against crossbill predation, and crossbills have evolved bill characteristics to counter these defenses.

squirrels are absent indicating that coevolution with lodgepoles and squirrels is driving their speciation (Benkman *et al.*, 2010).

Effects of environment on a geographic mosaic of variation in a plant–galler–natural enemies interaction

Antagonistic interactions involving a very different set of interactions involving tall goldenrod, *Solidago altissima*, a gall-inducing fly, *Eurosta solidaginis,* and the natural enemies of the galler, including birds and the parasitoid wasp *Eurytoma gigantea*, have also produced a GMC. The goldenrod–fly interaction has diverged in hotspots where different environments affect the reciprocal selection they exert on each other, and the fly–parasitoid interaction has hotspots and coldspots mediated by their interactions with other natural enemies. The fly larvae develop inside the gall, and they are attacked by the natural enemies, which varies in a geographic mosaic of hot and coldspots (**Figure 3**). In forested areas birds cause high mortality on larvae in large galls, and the parasitoid causes higher mortality on larvae in small galls, resulting in stabilizing selection. Gall size is partially due to heritable genetic variation in the fly, and the combination of these natural enemies exerts stabilizing selection on gall size in forested regions (Weis and Abrahamson, 1986). The tree-dwelling birds that feed on the larvae are absent or at low densities in prairie regions, creating a coldspot in the interaction of birds and the galler (Craig, 2007; Craig *et al.*, 2007). In the absence of birds there is a coevolutionary hotspot in the interaction between the fly and parasitoid resulting in an evolutionary arms race: flies produce larger galls and parasitoids are larger with longer ovipositors (Craig *et al.*, 2007).

The goldenrod plant and fly interaction is also affected by the local environment. Plants grow in both prairie and forest environments, where differences in soils, climate, competition with other plants, and herbivory produce very different selection on the goldenrod. Common garden experiments demonstrate that prairie and forest plants have strong genetically based differences in morphology and drought tolerance. Common garden experiments also showed that *Eurosta* are locally adapted to their host plants: survival was higher for both forest and prairie flies on plants from their local biome (Craig and Itami, 2011). Craig and Itami (2011) hypothesized that diversifying selection on the plant to adapt to the different forest and prairie environments has had cascading effects that select for diversification among the flies. *Eurosta solidaginis* inducing galls on prairie and forest *S. altissima* subspecies are partially reproductively isolated due to host-plant-mediated assortative mating and differences in mating times due to plant phenology. In turn, the plant has also become locally adapted to the fly. Gall production is costly to the plant, and the plant is under selection to minimize resources hijacked by the fly for the gall (Abrahamson and Weis, 1997). Gall size is influenced by both the geographical origin of the plant and the fly (Craig and Itami, 2011). In response to selection by natural enemies forest flies induce relatively small galls, and prairie flies induce large galls.

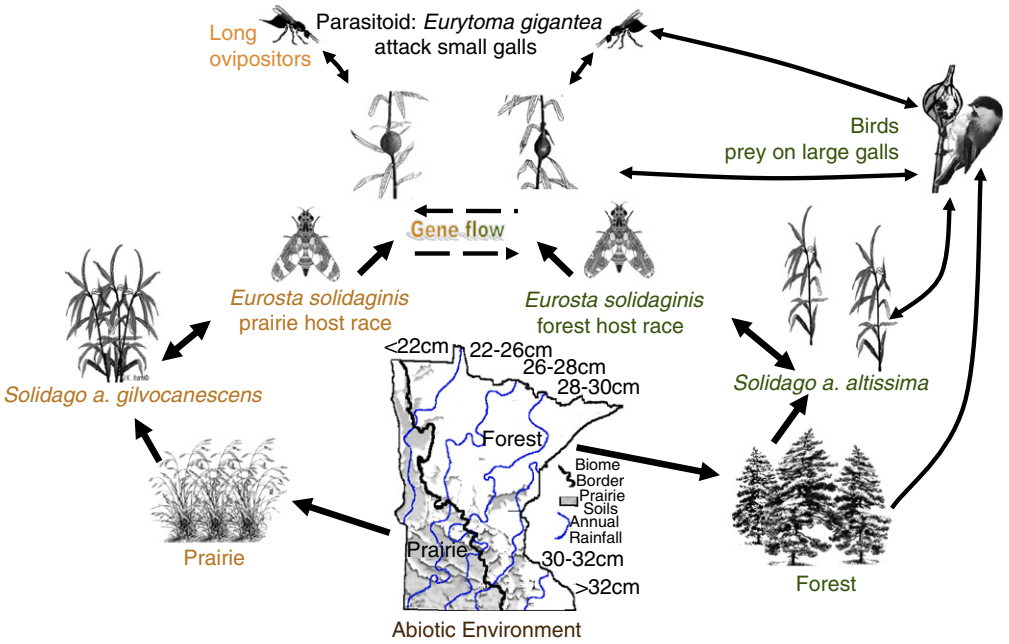

Figure 3 Geographic mosaic of selection in the interaction of *Solidago altissima*, *Eurosta solidaginis*, and natural enemies. The *Eurosta–Solidago* interaction in the prairie is a hotspot as is the *Eurosta–Solidago* interaction in the forest. The hotspot interaction of the *Eurosta–Eurytoma* in the prairie, in the absence of the birds, results in larger galls and longer *Eurytoma* ovipositors. The hotspot interactions of *Eurosta–Eurytoma*–birds in the forests, results in birds selecting for smaller *Eurosta* galls and indirectly for shorter *Eurytoma* ovipositors.

Geographic mosaics of competitive coevolution

Competition can also produce geographic selection mosaics when the presence or intensity of competitors varies among areas. 'Character displacement' is evidence of a competition geographic selection mosaic, and it is demonstrated in interactions where greater differences in a pair species occurs in sympatry, a coevolutionary hotspot, than in allopatry, a coevolutionary coldspot. It has been demonstrated by the coevolution sticklebacks in Canadian lakes (Schluter and McPhail, 1993). Three-spined sticklebacks, *Gasterosteus aculeatus*, were originally a marine species which invaded inland lakes that formed after the end of the last ice age. In each of four lakes that have two species there is a small limnetic species that feeds on plankton, and a larger benthic species that feed on macro-invertebrates (**Figure 4**). In contrast, in lakes with a single species body size is intermediate. The divergence of traits when there is competition is a local adaptation that increases fitness in each species by decreasing competition. Genetic analysis indicates that the divergence into benthic and limnetic forms had independently occurred multiple times following colonization of lakes by the marine species at two different times indicating that coevolution hotspots can produce parallel evolution and speciation (Schluter and McPhail, 1993).

Geographic Mosaics of Mutualistic Coevolution

Mutualists in obligate symbiotic interactions can also form geographic mosaics of coevolution. Mutualisms do not evolve to a point where both interacting species become fixed for optimally mutualistic beneficial traits. This is because while both species in a mutualistic interaction benefit from the interaction, mutualisms always maintain an antagonistic element as each species is trying to obtain the maximum benefit from its mutualist at the lowest cost. The location of a species along the mutualism–antagonism continuum depends upon specific characteristics of the interaction. The mode of transmission has a powerful impact on how an interaction will evolve along this continuum. If a symbiont (parasite or mutualist) is transferred among unrelated individuals, which is termed 'horizontal transmission,' then a reduction of the fitness of its host will have limited consequences for the symbiont. In contrast, when a symbiont is transferred from mother to offspring, which is termed 'vertical transmission,' then the symbiont must insure the survival of its host for it to survive. Vertically transferred parasites or mutualists will be under strong selection to evolve from the antagonistic toward the mutualistic end of the continuum. One prediction is that there will be selection on a host to maintain only a single genotype of their symbiont in order to eliminate the negative consequences of competition among strains. Such a mutualistic GMC is illustrated by the complex interaction of fungus-cultivating ants, *Apterostigma dentigerum*, the cultivated fungus in their gardens, a pathogen that infects the fungus gardens *Escovopsis*, and a bacteria, *Pseudocardia*, that controls the fungus (Caldera and Currie, 2012). *Pseudocardia* is therefore a mutualist of the ants, and it is transmitted vertically by the ants with the queen when she establishes new colonies. A GMC is indicated because each colony has a single strain of *Pseudocadria*, and the populations of the bacteria are strongly differentiated on a small geographic scale with little gene flow among them. The distribution of *Pseudocardia* strains and *Escoposis* strains indicates that there is a GMC among the mutualistic symbionts and their antagonist.

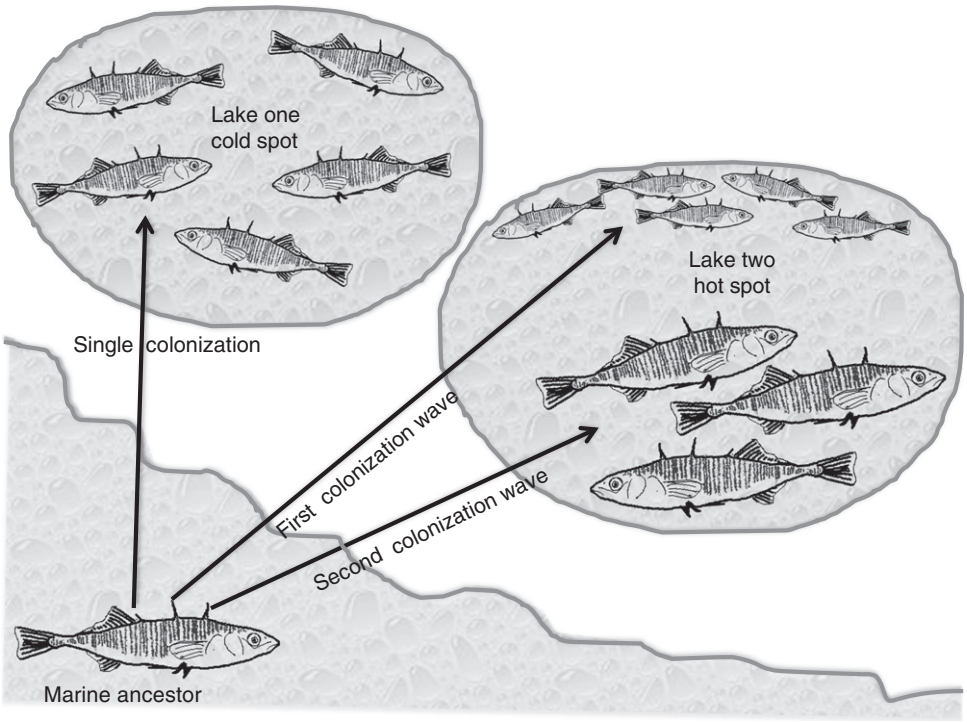

Figure 4 A geographic mosaic of coevolution between three-spined stickleback species resulting from competitive character displacement. (a) A coevolutionary coldspot where only one species colonized a lake and where without competition the species has evolved an intermediate feeding strategy and body size. (b) A coevolutionary hotspot where two species colonized a lake and where interspecific competition has produced character displacement leading to the evolution of a smaller limnetic planktivore and a larger benthic macroinvertebrate feeder.

The Geographic Mosaic of Coevolution in Human-Modified Environments

Humans have altered many ecological systems in ways that provide opportunities for studying the GMC. The extensive movement by humans of species and locally adapted populations to new locations creates many new coevolutionary hotspots and coldspots. Species introduced to new areas can encounter new natural enemies, competitors, and mutualists resulting in a significant change in the evolutionary trajectory of the interaction in a coevolutionary hotspot. Conversely, an introduced species can escape its enemies and competitors sometimes resulting in its evolution into a pest species. Released from selection imposed in its native environment the introduced species may lose adaptations to species it has formerly interacted with, as evidenced by the increased susceptibility of plants to herbivores from its previous habitat.

Solidago altissima is native to North America, and it was introduced to Japan about 100 years ago where it evolved in its new environment in the absence of phytophagous insects native to North America. In 2000, an herbivorous lacebug, *Corythucha marmorata*, was introduced from North America reuniting it with the goldenrod. It rapidly reached higher densities than in North America, but the density rapidly declined. In a common garden experiment, Sakata *et al.* (2014) demonstrated that goldenrod populations that had been exposed to herbivory for 12 years were much more resistant than populations that had not yet been exposed. This provides strong evidence of an intercontinental geographic mosaic of evolution with a hotspot in North America that led to reciprocal coevolution of defense by goldenrod and counter-defense by the lacebug. When selection by the lacebug was relaxed in the evolutionary coldspot established in Japan, goldenrod lost its resistance. When the lacebug was introduced and began to spread across Japan a new and rapidly shifting mosaic of hotspots and coldspots was established exerting geographically diversifying selection on the goldenrod. An as-yet untested hypothesis is that the differences among plants in these hotspots and coldspots are also exerting diversifying selection on the lacebug.

Humans in Geographic Mosaics of Coevolution

Agriculture and forestry practices alter the geographic mosaic of evolution as humans constantly alter the genetic composition of domesticated plants and animals and spatially redistribute this genetic variation in a way that continually alters the coevolutionary interactions with humans. One example is the coevolution of humans and cows. Adult *Homo sapiens* usually lose the ability to produce the enzyme lactase that allows them to metabolize the milk sugar lactose. When humans domesticated cattle, *Bos taurus*, they exerted strong selection that altered a large number of traits (Craig, 1981), and in turn cattle have exerted strong selection on humans producing a geographic mosaic due to local adaptation to milk consumption (Gerbault *et al.*, 2009). Utilizing cow's milk provides access to a significant source of protein that can give a significant fitness advantage to individuals who retain

production of the enzyme lactase. Dairy farming has been adopted in widely geographically isolated areas of northern Europe and Africa, and the distribution of dairy farming is strongly correlated with the frequency of the retention of lactase production in adults. Local adaptation to the use of cow's milk is an example of a GMC.

Conclusion

There is abundant evidence that the GMC is an important and widespread phenomena, and this has provided strong support the importance of coevolution in evolution. It occurs across a wide range of species interactions and kinds of interactions: predator–prey, host–parasite, between mutualists, and between competitors. Diversifying coevolution occurs as the result of both differences between hotspots and coldspots and between hotspots where the environment alters the interaction between species. It has been shown to operate at a range of scales from kilometers to continental scales. It has been shown to produce patterns of both local adaptation and local maladaptation. However, many questions remain to be answered. New experiments need to be conducted in order to measure the strength of coevolutionary forces in local adaptation, and to separate selection for reciprocal coevolution between focal species and selection for on each species from adaptation to other species and the abiotic environment. In addition, the importance of coevolution in complex interactions involving many species needs to be understood so that the importance of coevolution in structuring entire communities can be understood. Finally, there is much work to be done in applying what has been learned from natural systems to systems that are impacted or managed by humans.

Hardy–Weinberg Equilibrium and Random Mating

J Lachance, Georgia Institute of Technology, Atlanta, GA, USA

Glossary

Allele One of a number of alternative forms of a gene.
Assortative mating Non-random mating on the basis of phenotype.
Fitness The expected contribution of an individual or genotype to next generation's gene pool.
Genetic drift Changes in allele or genotype frequencies due to random sampling.
Genotype The pair of alleles present at a single locus.
Inbreeding Preferential mating between relatives.
Natural selection Differential survival or reproduction.
Phenotype The set of an organism's observable traits.
Ploidy The number of sets of chromosomes in a cell.
Single nucleotide polymorphism (SNP) DNA sequence variation at a single nucleotide position that differs between individuals.

History

Darwin's theory of evolution transformed biology in the mid-nineteenth century. However, Darwin had an inaccurate understanding of heredity and his belief in blending inheritance was problematic. Because blending inheritance ultimately results in homogenized populations full of intermediate genotypes, it is unable to explain how genetic variation can persist over evolutionary time (Charlesworth and Charlesworth, 2009). It wasn't until the rediscovery of Mendelian genetics in the early twentieth century that a potential solution could be found. Importantly, Mendel treated genes as discrete units, which enabled a mathematical formulation of population genetics. Despite the rediscovery of Mendelian genetics and the pioneering work of biologists and statisticians (Castle, 1903; Pearson, 1904) there was still some confusion, and during a 1908 meeting of the Royal Society of Medicine it was claimed that dominant mutations would increase in frequency until phenotypes reached 3:1 Mendelian ratios (Provine, 2001). Something about this claim seemed wrong to R.C. Punnett, who passed on the question to his cricket-playing friend G.H. Hardy. Hardy was one of the leading mathematicians in Britain and he quickly deduced a solution. In a 1908 letter to the journal *Science*, Hardy began by writing "I should have expected the very simple point that I wish to make to have been familiar to biologists" before using the binomial expansion to demonstrate that genotype frequencies will reach a stable equilibrium after one generation of random mating (Hardy, 1908). Unbeknownst to Hardy, a Germany physician named Wilhelm Weinberg had published a similar paper on the same topic six months earlier. Weinberg derived a general equilibrium principle for a single locus with two segregating alleles (Weinberg, 1908).

The Hardy–Weinberg Principle

The Hardy–Weinberg principle relates allele frequencies to genotype frequencies in a randomly mating population. Imagine that you have a population with two alleles (A and B) that segregate at a single locus. The frequency of allele A is denoted by p and the frequency of allele B is denoted by q. The Hardy–Weinberg principle states that after one generation of random mating genotype frequencies will be p^2, $2pq$, and q^2. In the absence of other evolutionary forces (such as natural selection), genotype frequencies are expected to remain constant and the population is said to be at *Hardy–Weinberg equilibrium*. The Hardy–Weinberg principle relies on a number of assumptions: (1) random mating (i.e, population structure is absent and matings occur in proportion to genotype frequencies), (2) the absence of natural selection, (3) a very large population size (i.e., genetic drift is negligible), (4) no gene flow or migration, (5) no mutation, and (6) the locus is autosomal. When these assumptions are violated, departures from Hardy–Weinberg proportions can result.

One useful way to think about the Hardy–Weinberg principle is to use the metaphor of a gene pool (Crow, 2001). Here, individuals contribute alleles to an infinitely large pool of gametes. In a randomly mating population without natural selection, offspring genotypes are found by randomly sampling two alleles from this gene pool (one from their mother and one from their father). Because the allele that an

 doi:10.1016/B978-0-12-800049-6.00022-6

individual receives from their mother is independent of the allele they receive from their father, the probability of observing a particular genotype is found by multiplying maternal and paternal allele frequencies. Mathematically this involves the binomial expansion: $(p + q)^2 = p^2 + 2pq + q^2$ (see the modified Punnett Square in Figure 1 for a graphical representation). Note that there are two ways that an individual can be an *AB* heterozygote: they can either inherit an *A* allele from their mother and a *B* allele from their father or they can inherit a *B* allele from their mother and an *A* allele from their father.

Additional insight can be found by considering an empirical example (Figure 2). Consider a population that initially contains 18 *AA* homozygotes, 4 *AB* heterozygotes, and 3 *BB* homozygotes. The alleles in the gene pool, 80% are *A* and 20% are *B*. After a single generation of random mating we observe Hardy–Weinberg proportions: 16 *AA* homozygotes, 8 *AB* heterozygotes, and 1 *BB* homozygote. Note that allele frequencies remain unchanged.

There are a number of evolutionary implications of the Hardy–Weinberg principle. Most importantly, genetic variation is conserved in large, randomly mating populations. A second implication is that the Hardy–Weinberg principle allows one to determine the proportion of individuals that are carriers for a recessive allele. Third, it is important to note that dominant alleles are not always the most common alleles in a population. Another implication of the Hardy–Weinberg principle is that rare alleles are more likely to be found in heterozygous individuals than in homozygous individuals. This occurs because q^2 is much smaller than $2pq$ when q is close to zero.

The Hardy–Weinberg principle can be generalized to include polyploid organisms and genes that have more than two segregating alleles. Equilibrium genotype frequencies are found by expanding the multinomial $(p_1 + \ldots + p_k)^n$, where n is the number of sets of chromosomes in a cell and k is the number of segregating alleles. For example, tetraploid organisms ($n = 4$) with two segregating alleles ($k = 2$) are expected to have genotype frequencies of: ${p_1}^4$ (*AAAA*), $4{p_1}^3p_2$ (*AAAB*), $6{p_1}^2{p_2}^2$ (*AABB*), $4p_1{p_2}^3$ (*ABBB*), and p^4 (*BBBB*). Similarly, diploid organisms ($n = 2$) with three segregating alleles ($k = 3$) are expected to have genotype frequencies of: ${p_1}^2$ (*AA*), ${p_2}^2$ (*BB*), ${p_3}^2$ (*CC*), $2p_1p_2$ (*AB*), $2p_1p_3$ (*AC*), and $2p_2p_3$ (*BC*). Genotype frequencies sum to one for each of the above scenarios. Although the Hardy–Weinberg principle can also be generalized to include genes located on sex chromosomes (e.g., X chromosomes in humans), it is important to note that it can take multiple generations for genotype frequencies at sex-linked loci to reach equilibrium values.

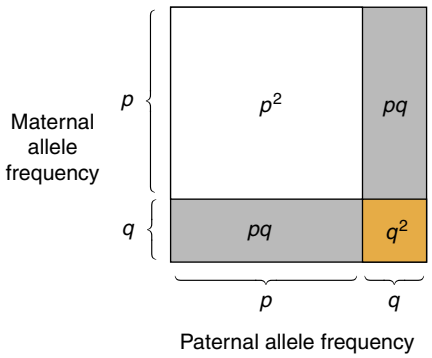

Figure 1 Graphical representation of the Hardy–Weinberg principle. The frequency of *A* alleles is denoted by *p* and the proportion of *B* alleles by *q*. *AA* homozygotes are represented by white, *AB* heterozygotes by gray, and *BB* homozygotes by gold. Shaded areas are proportional to the probability of observing each genotype.

Testing for Hardy–Weinberg Proportions

A Chi-square (χ^2) test with one degree of freedom can be used to determine whether a population is at Hardy–Weinberg equilibrium (Weir, 1996) (see Table 1 for an example). First, the observed numbers of individuals with each genotype are counted. These genotype frequencies are then used to obtain allele frequencies (p and q). The expected numbers of individuals with each genotype are calculated by multiplying the total number of individuals sampled by p^2, $2pq$, and q^2. Once observed and expected genotype counts are known, χ^2 statistics

Table 1 Chi-square test of Hardy–Weinberg proportions. Allele frequencies are $p = 0.7$ and $q = 0.3$. The expected number of individuals with each genotype are calculated by multiplying the total number of individuals by p^2 (*AA*), $2pq$ (*AB*), and q^2 (*BB*). A χ^2 of 8.724 with one degree of freedom yields a *p*-value of 0.00172, indicating that there is a statistically significant departure from Hardy–Weinberg proportions

Genotype	*Observed*	*Expected*	χ^2
AA	117	107.8	0.785
AB	74	92.4	3.664
BB	29	19.8	4.275
Total	220	220	8.724

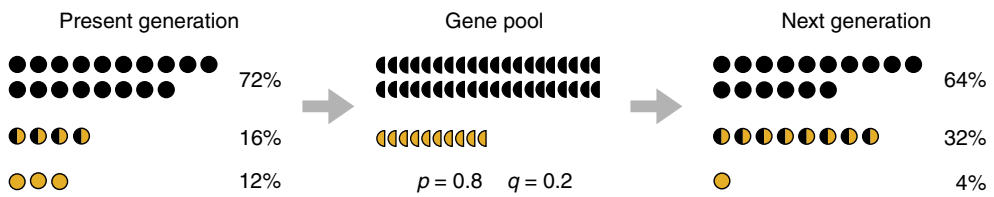

Figure 2 Hardy–Weinberg example. *AA* homozygotes (black circles), AB heterozygotes (black and gold circles), and *BB* homozygotes (gold circles) contribute to the gene pool. *A* alleles are shown as black half-circles and *B* alleles are shown as gold half-circles. After a single generation of random mating Hardy–Weinberg proportions are obtained.

can be calculated for each genotype using the equation $\chi^2 = (observed - expected)^2/expected$. These χ^2 values are summed, and if the overall χ^2 test statistic is greater than 3.84 the null hypothesis that the population is in Hardy–Weinberg equilibrium can be rejected (p-value <0.05). The power of this statistical test is directly related to sample size: departures from Hardy–Weinberg proportions are unlikely to be statistically significant if you have genotype frequency data from a small number of individuals.

Departures from Hardy–Weinberg Proportions

There are a number of reasons why one might fail to observe Hardy–Weinberg proportions, and these departures from Hardy–Weinberg equilibrium can involve either an excess of homozygotes or an excess of heterozygotes.

Genotyping Error

While it may not be the most interesting scenario from an evolutionary perspective, departures from Hardy–Weinberg proportions sometimes occur because of genotyping error. These errors can be due to low quality DNA samples, biochemical artifacts, or human error (Pompanon *et al.*, 2005). For example, low-coverage DNA sequencing can cause genotypes to be incorrectly inferred. To improve data quality, a common practice in genome-wide association studies is to filter out any single nucleotide polymorphisms (SNPs) that show significant departures from Hardy–Weinberg proportions (Turner *et al.*, 2011). However, this runs the risk of eliminating SNPs that have departures from Hardy–Weinberg proportions that are due to some other reason than genotyping error.

Non-Random Mating and Population Structure

Non-random mating leads to departures from Hardy–Weinberg proportions. For example, inbreeding and positive assortative mating (where individuals prefer to mate with phenotypically similar individuals) yield an excess of homozygotes. By contrast, negative assortative mating (where opposites attract and individuals prefer to mate with phenotypically different individuals) results in excess of heterozygotes. Population structure also causes departures from Hardy–Weinberg proportions. For example, consider what happens when samples are drawn from multiple populations instead of a single randomly mating population. If these samples are pooled together and there are allele frequency differences between source populations the resulting mixture will have an excess of homozygotes. This reduction in heterozygosity is known as the *Wahlund effect* (Wahlund, 1928). In practice, departures from Hardy–Weinberg proportions due to non-random mating and population structure tend to be genome-wide (i.e., their effects can be seen at multiple loci).

Natural Selection

Natural selection modifies allele and genotype frequencies and these effects depend on both the magnitude and type of selection present. Selection results in departures from Hardy–Weinberg proportions whenever genotypic fitnesses are non-multiplicative (i.e., $w_{AB}{}^2 \neq w_{AA} \times w_{BB}$) (Lachance, 2008). Not surprisingly, overdominance (heterozygote advantage) results in an excess of heterozygotes compared to Hardy–Weinberg expectations, and underdominance (heterozygote disadvantage) results in an excess of homozygotes. Strong directional selection, such as when one allele is a recessive lethal, leads to marked departures from Hardy–Weinberg expectations. However, weak directional selection has only modest effects on genotype frequencies, and detecting these effects can require sample sizes that are larger than 10 000 individuals (Lachance, 2009). Note that the effects of natural selection tend to be locus-specific rather than genome-wide.

Other Causes

Additional population genetic phenomena that can result in departures from Hardy–Weinberg proportions include genetic drift and mutation. In small populations the proportion of individuals with each genotype often differs from p^2, $2pq$, and q^2. The idea here is that sampling effects due to genetic drift yield a slight excess of homozygotes or heterozygotes. These effects are more pronounced in very small populations. This is akin to what happens when you flip a coin a small number of times and end up with an unequal number of heads and tails. Although mutation can lead to slight departures from Hardy–Weinberg proportions, these departures are difficult to detect. This is because mutation rates tend to be small (on the order of 10^{-8} mutations per base pair per generation in humans).

Ultimately, departures from Hardy–Weinberg proportions reveal the biological complexity of natural populations. By building upon the foundation of the Hardy–Weinberg principle, generations of population geneticists have been able to construct more complex models of evolution. These mathematical models have led to an increased understanding of how evolutionary forces shape natural patterns of genetic diversity.

Glossary

Anisogamy Literally meaning 'unequal marriage,' a condition where the fusing gametes are of unequal size, with the male sex by definition producing the smaller and the female sex the larger gametes, leading to an often highly unequal resource contribution to the zygote; more strictly, an additional distinction is sometimes made between anisogamy, where both gametes retain at least some motility, and 'oogamy,' where the larger gamete has lost motility entirely.

Dioecy See Gonochorism.

Gonochorism A term mainly used for animals: a sexual system where individuals only ever exhibit either the male or the female sexual strategy throughout their lives (synonymous with 'dioecy' used for plants and 'heterothallism' used for algae and fungi).

Hermaphroditism A term mainly used for animals: a sexual system where individuals usually exhibit both the male and female sexual strategy, either at different times of their lives (sequential hermaphroditism) or at the same time (simultaneous hermaphroditism) (synonymous with 'monoecy' used for some forms of hermaphroditism in plants and 'homothallism' used for algae and fungi).

Heterothallism See Gonochorism.

Homothallism See Gonochorism.

Isogamy Literally meaning 'equal marriage,' a condition where the fusing gametes are of equal size and make an equal resource contribution to the zygote, although they may exhibit different 'mating types.'

Local sperm competition Results from competition between related sperm, generally from the same sperm donor (or also from related sperm donors), for the fertilization of a given set of ova of a sperm recipient. It can thus be viewed as the mirror image of sperm competition, which represents the 'competition between the sperm from two or more (unrelated) males for the fertilization of a given set of ova.'

Mating conflict It occurs when two potential mating partners have incompatible sex role preferences, owing to asymmetries in the benefits of mating versus its costs between acting as a sperm donor or sperm recipient (so that both individuals may preferentially adopt the same sex role).

Mating types A genetic compatibility system that only permits gametes that have a different mating type to fuse with each other, possibly in order to avoid self-fertilization; often individuals are thought to produce gametes of only one type and in many organisms there are only two mating types, often called plus (+) and minus (−).

Monoecy See Gonochorism.

Oogamy See Anisogamy.

Protandry In sequential hermaphrodites, sex change from male to female; in simultaneous hermaphrodites, when the male function matures before the female function.

Protogyny In sequential hermaphrodites, sex change from female to male; in simultaneous hermaphrodites, when the female function matures before the male function.

Reproductive value Expected future reproductive success of an individual, of key importance in predicting sex-change decisions made by sequential hermaphrodites.

Sex allocation A decision about the amount of investment channeled toward the two sex functions; for example, the number of sons vs. daughters in gonochorists (the sex ratio), the timing of sex change in sequential hermaphrodites, or the investment toward the production of male vs. female gametes in simultaneous hermaphrodites.

Sexual conflict A conflict between the evolutionary interests of a sperm donor and a sperm recipient.

Size-advantage model A model to describe the idea that the sex-specific fecundity (or reproductive value) of an individual might change as it is growing, for example, being higher for the female function when small and higher for the male function when large, thus favoring sequential hermaphroditism with 'protogyny.'

Introduction

Hermaphroditism is common, occurring in >90% of plant genera (Renner and Ricklefs, 1995), >70% of animal phyla (Jarne and Auld, 2006), and being present also in many other multicellular taxa, such as volvocine algae (Coleman, 2012) and arguably also in the fungi (Nieuwenhuis and Aanen, 2012) (see 'Glossary' for related terms used in diverse organismal groups). The key distinguishing feature of hermaphroditism is that each individual can (at least potentially) gain fitness through both male and female reproduction, either by adopting the two sexes sequentially or simultaneously.

We first outline the evolutionary context for thinking about hermaphroditism, focusing on (1) it being a frequent outcome following the evolution of 'anisogamy,' (2) what might be the evolutionary advantages of maintaining two individual routes to fitness, and (3) how local competition drives individual investment decisions between the two sex functions (i.e., 'sex allocation'). We then apply this framework to highlight some of the key differences in the evolutionary biology of sex in hermaphrodites compared to gonochorists, firstly for sequential hermaphrodites and then for simultaneous hermaphrodites. Finally, we provide an outlook, and argue that studying sex in hermaphrodites is important for gaining a

 doi:10.1016/B978-0-12-800049-6.00160-8

comprehensive general picture of the consequences of the evolution of anisogamy.

Hermaphroditism in Context

The Evolution of Anisogamy and Its Consequences

Sexual reproduction usually involves the union of two haploid gametes stemming from two different parental individuals, leading to a diploid zygote in which each parent obtains an equal genetic representation. A common, but far from universal, observation among sexually reproducing eukaryotes is that the two fusing gametes differ substantially in size, a condition termed 'anisogamy.' A phylogenetic perspective suggests that anisogamy has evolved from 'isogamy' at least half a dozen times independently (Kirk, 2006), with well-known examples including land plants, some red, brown and green algae, malaria parasites, and animals. These multiple origins of anisogamy point to a fundamental phenomenon linked to sexual reproduction and suggest that common selective pressures are at work. In the following we focus largely on animals, but this simply reflects our own expertise and many of the points we raise have parallels in other organismal groups (see also Charnov, 1982; Lloyd, 1982; Charlesworth and Morgan, 1991; Bernasconi *et al.*, 2004).

The evolution of anisogamy probably results from a primordial 'sexual conflict' over which parent provides more of the resources needed for the successful development of the zygote, given that larger zygotes may often be fitter and develop into fitter individuals (Parker *et al.*, 1972; Lessells *et al.*, 2009; Parker, 2011). By making large gametes a parent can increase its probability of having fit offspring, but given limited resources, it will also make relatively fewer offspring (i.e., gamete size and number trade-off). Conversely, by making many small gametes, a parent may instead aim at finding and (preferentially) fusing with (more) large gametes, so that its genes also end up in large zygotes (thus exploiting other parents' gametic investment). Under broad conditions evolutionary models show that this leads to disruptive selection on gamete size, yielding two fundamentally different sexual strategies (Parker, 2011, 2014). By convention, making many small gametes is called the male strategy and making fewer large gametes is called the female strategy, resulting in a type of sexual reproduction – anisogamous sex – in which there are two fundamentally different routes to fitness, male and female reproduction.

When thinking about sexual reproduction, biologists (and especially zoologists) often presuppose that these two sexual strategies already exist and also that they are stably associated with two particular types of individuals, namely males and females, a sexual system called 'gonochorism.' But an important challenge for a more complete understanding of anisogamous sex is to acknowledge (1) that it has evolved multiple times independently and that the male and female sexual strategies are therefore convergent phenomena in different organismal groups, and (2) that these strategies can be distributed over individuals in a population in diverse ways, often involving 'hermaphroditism.' We therefore argue here that beyond the fact that hermaphrodites show striking sexual adaptations that are interesting in their own right (see below), they are also worth studying because they force us to reevaluate preconceived ideas about what we consider male and female, which – at root – is about anisogamy, and not about courtship dances, huge antlers, or colorful plumage (Schärer *et al.*, 2012).

The Adaptive Significance of Having Two Routes to Fitness

Arguably the biggest difference between gonochorists and hermaphrodites is that in the latter each individual has (at least potentially) access to both the male and female routes to fitness (**Figure 1**). It is currently unclear whether the evolution of anisogamy originally leads to gonochorism or hermaphroditism (Schärer *et al.*, 2014), and the answer may well depend on the specific organismal group. Despite this, many existing models for the evolution of anisogamy make assumptions that necessarily lead to the evolution of gonochorism (e.g., Lehtonen and Kokko, 2011; Parker, 2011), so broadening this theory base remains a significant challenge (as does conducting empirical work in extant groups where ongoing evolution of anisogamy can be studied). From a hermaphrodite perspective, it could be argued that gonochorists are a special case, where some individuals have lost (or given up) their ability to reproduce via one of the two routes, and an important aspect of understanding hermaphroditism is therefore to understand the conditions under which it may or may not be advantageous for individuals to maintain two routes to fitness.

Current thinking about the evolution of sequential hermaphroditism considers that the male and female functions may

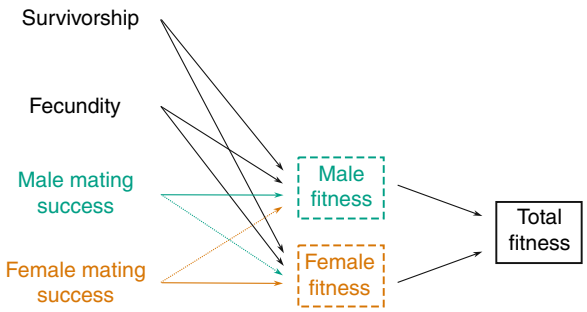

Figure 1 The two routes to fitness in hermaphrodites. In hermaphrodites, survivorship, fecundity, and mating success will often contribute to fitness separately via the male and female sex functions. Nevertheless, we can expect important feedback effects between these different fitness components, only some of which are illustrated here. For example, mating success in one sex function may impact upon reproductive success in the other sex function (so-called cross-sex effects; stippled arrows), as can occur if mating is reciprocal such that additional matings in the male role automatically correspond to more matings in the female role, with potentially negative consequences (see Anthes *et al.*, 2010 for further discussion). Note also that for simplicity only a single fecundity component has been plotted, but this could again be split into male and female components and these may often trade off against each other due to a sex allocation trade-off. Modified from Schärer, L., Janicke, T., Ramm, S. A., 2014. Sexual conflict in hermaphrodites. Cold Spring Harbor Perspectives in Biology doi: 10.1101/cshperspect.a017673, based on an original figure for gonochorists in Arnqvist and Rowe (2005).

have differing optimal body sizes, such that an individual may maximize its total fitness by first exhibiting one sex and later changing to the other (the 'size-advantage model'; Ghiselin, 1969; **Figure 2**). Stated more broadly, the size-advantage model predicts that an individual should want to change sex whenever it can increase its 'reproductive value' by doing so, emphasizing that social and ecological factors come into play in determining the optimal sex-change strategy (Warner, 1975, 1988; Charnov, 1982; Munday *et al.*, 2006). We consider the rationale of the size-advantage model in more detail in Section 'Local Competition and Sex Allocation,' and then provide examples in Section 'Sex in Sequential Hermaphrodites' below.

For simultaneous hermaphrodites, the benefits of dual sexuality may stem from reproductive assurance when the rate of encountering potential mates is low, for example under low population density (Ghiselin, 1969; Schärer, 2009). In contrast to gonochorists, for a simultaneous hermaphrodite each encountered conspecific is a potential mating partner (Tomlinson, 1966). Moreover, even in the complete absence of access to mating partners, exhibiting both sexes simultaneously – or in short sequence, such as in some *Caenorhabditis* nematodes – has the additional benefit of permitting self-fertilization (Charlesworth and Morgan, 1991; Jarne and Charlesworth, 1993; Jarne and Auld, 2006). However, simultaneous hermaphroditism is clearly not restricted to only organisms occurring at low density, and more generally, this sexual system is expected to be stable whenever there are strong diminishing fitness returns on investment into one of the sex functions (Charnov, 1982; Schärer, 2009), an argument that we develop more fully in Section 'Local Competition and Sex Allocation.'

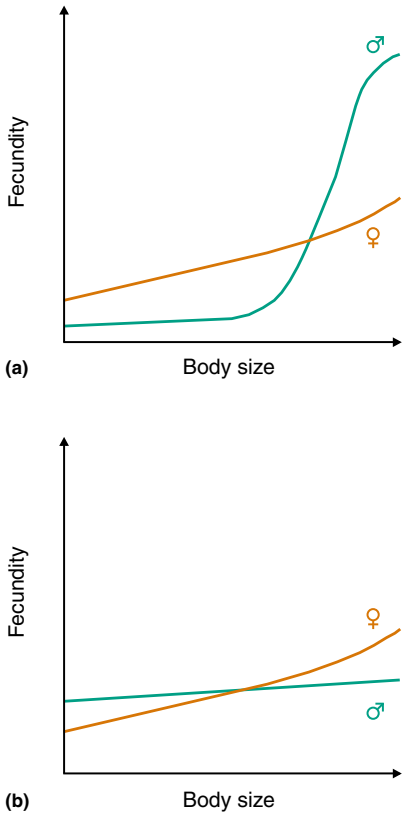

Figure 2 The size-advantage model for sequential hermaphroditism. If the expected fitness returns on operating as either a male or a female change predictably with size (or age), this may – provided that it is physiologically possible and the costs of doing so are not too high (see Kazancıoğlu and Alonzo, 2009) – favor reproductive strategies that involve sex change. (a) Protogyny (female-to-male sex change) is favored when the relationship between size and fecundity is shallower for females than males, for example, because large males are more successful at holding a territory in which they can mate with multiple females. (b) By contrast, if the size–fecundity relationship is steeper for females, for example, because larger females are more fecund, while a male's size is relatively unimportant for its fecundity, this may favor protandry (male-to-female sex change). Modified from Munday, P. L., Buston, P. M., Warner, R. R., 2006. Diversity and flexibility of sex-change strategies in animals. Trends in Ecology & Evolution 21, 89–95.

Whilst these adaptive explanations for hermaphroditism are undoubtedly important in understanding how it can evolve, the current taxonomic distribution of the different sexual systems among animals also reveals a strong degree of phylogenetic inertia (see Renner and Ricklefs, 1995 for data on plants). While some groups are (almost) entirely hermaphroditic (e.g., flatworms, arrow worms, and gastrotrichs) there are other groups that are (almost) entirely gonochoristic (e.g., insects, nematodes, and acanthocephalans), while yet other groups show more variable sexual systems (e.g., coelenterates, polychaetes, and molluscs) (see also Ghiselin, 1969; Schärer, 2009; Weeks, 2012; Collin, 2013).

Irrespective of the exact conditions under which hermaphroditism is favored or maintained, once two routes to fitness are present in the same individual, this leaves open the possibility of strategically varying the amount of resources invested into the two sex functions, both in terms of overall quantity and with respect to the timing during an individual's life history (i.e., simultaneously vs. sequentially). These are questions about 'sex allocation,' which we discuss next.

Local Competition and Sex Allocation

In anisogamous species, every zygote results from the fusion of one male and one female gamete, and so every individual in the population has exactly one father and one mother. This means that at the level of the population, the amount of fitness that can be obtained via the male and the female reproductive strategy is necessarily equal (despite the male gamete's usually minimal material contribution to the zygote). Under frequently made simplifying assumptions of random mating (i.e., any male gamete in the population has the same probability of fusing with any female gamete) and large populations size (i.e., mates and competitors are always unrelated) this then predicts equal resource investment in male and female reproduction (Düsing, 1884; Fisher, 1930; Charnov, 1982). However, in nature local competition between related entities often results from imperfect mixing of gametes, clustering of gametes into ejaculates and clutches, and limited dispersal of offspring leading to mate competition between relatives, meaning that these simplifying assumptions are probably broken more often than not. As a result the optimal resource allocation can differ drastically from equality, leading

to strongly biased individual and population sex allocation patterns (Hamilton, 1967; Charnov, 1982; Frank, 1987). Local competition can also affect the optimal distribution of the two sexual strategies over individuals in the population, so understanding the consequences of the evolution of anisogamy requires an understanding of the logic of sex allocation theory. While we cannot give a detailed account of sex allocation theory here (see Charnov, 1982; Schärer, 2009; West, 2009), we will highlight those aspects most relevant to the study of sex in hermaphrodites.

Local competition between related gametes means that investment toward making more gametes shows diminishing returns. If local competition is sex-specific, say affecting male more than female gametes, then there comes a point at which additional resources would be better invested in the alternative sex function: such individuals benefit from investing less than half of their resources into the production of male gametes, resulting in simultaneous hermaphroditism with a female-biased sex allocation (**Figure 3(a)**). Such 'local sperm competition' may regularly occur under conditions such as low population density, monogamy or in small groups (Charnov, 1982; Schärer, 2009), but it can also result from different processes of sexual selection, such as strong first or last male sperm precedence, cryptic female choice, or random paternity skews (Charnov, 1996; Greeff *et al.*, 2001; Schärer, 2009; Van Velzen *et al.*, 2009; Schärer and Pen, 2013). Exclusive selfing is an extreme example, involving maximal local sperm competition and thus strongly diminishing returns on male reproductive investment.

In a similar way, local competition between socially interacting individuals may curtail the reproductive opportunities more strongly for one than the other sex function. If this effect depends on, for example, body size, then reproducing in one sex early in life and later switching to the other sex, i.e., being a sequential hermaphrodite, might be the optimal sex allocation strategy (**Figure 2**; Charnov, 1982; Munday *et al.*, 2006). Conversely, if investment toward one sex function shows accelerating returns (say because a higher fighting ability or more attractive ornament makes winning in mating competition much more likely), then permanently specializing on one sex role may be the best strategy, thus favoring gonochorism (**Figure 3(b)**; Charnov, 1982). Here individuals can still optimize their sex allocation by producing offspring with biased sex ratios (although under a fairly broad range of conditions the optimal sex ratio may remain close to equality). Note, however, that a gonochorist's sex ratio adjustment is less direct than the sex allocation adjustment within an individual hermaphrodite's lifetime, as the former is played out only in the next generation.

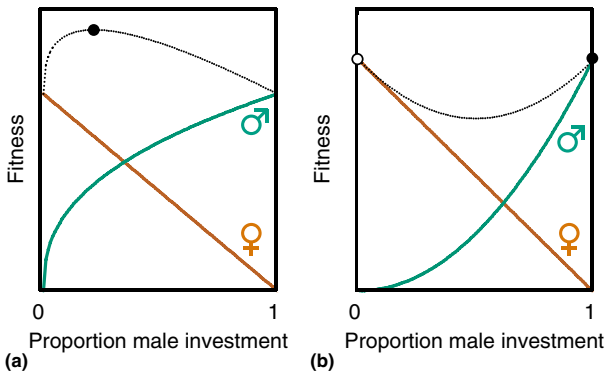

Figure 3 Fitness gain curves from basic sex allocation theory applied to simultaneous hermaphrodites. The graphs depict hypothetical fitness gain curves that represent the total fitness (stippled black line) that an individual can obtain when incrementally shifting the investment of a fixed resource budget from the female (solid orange line) to the male sex function (solid green line) (note that the fitness returns to the female function are here assumed to be linear). (a) If the marginal gains from increasing male investment show diminishing returns (here depicted as a power function with fitness $\propto$ resources$^{0.4}$) then total fitness is maximized (as indicated by the solid black circle) at an intermediate proportion of resources being allocated to the male function, in this case resulting in a somewhat female-biased sex allocation (a likely common scenario). (b) By contrast, if the marginal gains from increasing male investment show accelerating returns (here depicted as fitness $\propto$ resources^2) this does not result in a single fitness optimum, selecting instead for maximal investment in the male function in some individuals (which are then males, solid black circle), and – due to the frequency-dependent nature of sex allocation – an equivalent investment into pure females (open circle), i.e., for gonochorism. Based on Charnov (1979, 1982); see also Schärer (2009) and Kazancıoğlu (2009).

Sex in Sequential Hermaphrodites

The Role of Ecology and Social Interactions

Recall that the size-advantage model predicts that an individual should want to change sex whenever it can increase its fecundity (or reproductive value) by doing so (Section 'The Adaptive Significance of Having Two Routes to Fitness'). Here we emphasize that ecological and social factors combine in interesting ways to generate predictable sex differences in the size–fecundity relationship favoring sex change, but also that they can constrain individual sex-change decisions.

'Protandry' (male-to-female sex change) is often observed if the habitat leads to very small and stable groups of locally interacting individuals, such as is observed in slipper shells that form stable stacks of individuals (**Figure 4(a)**; Collin, 2006) or in anemone fishes that inhabit individual sea anemones (**Figure 4(b)**; Fricke and Fricke, 1977). In both cases, female fecundity is highly body size-dependent, whereas male fecundity is not, because the particular ecological conditions constrain the opportunity for male–male competition (**Figure 2(b)**). In the case of slipper shells, the number of mates that a male can obtain is inherently limited to only the neighbors in its stack (Collin, 1995) and paternity is biased toward the closer neighbors (Proestou *et al.*, 2008). In anemone fishes, there is a stable dominance hierarchy among the group members in which the highest ranking individual, a large female, uses aggression to constrain the reproductive decisions of the lower-ranking individuals, which comprise a smaller male (her only sexual partner) and a variable number of even smaller reproductively suppressed immature individuals (Fricke and Fricke, 1977). It is important to acknowledge, however, that such ecological constraints may also favor bidirectional sex change, as observed in some coral gobies

Figure 4 Sequential hermaphrodites. (a) In the protandrous common slipper shell, *Crepidula fornicata*, individuals form stacks in which the smaller (and younger) individuals closer to the top of the stack are males (the arrowheads indicate very small individuals), while the larger (and older) individuals toward the bottom of the stack are females (note that the individual in the bottom-most shell on the right has already died). Intermediate-size individuals that are in the process of changing from male to female often occur in the middle of the stack (see also Collin, 2006; image 'Stack of Crepidula' by Paul Morris from https://www.flickr.com/photos/aa3sd/5044549409/ licensed under CC BY-SA 2.0). (b) In the protandrous twoband anemonefish, *Amphiprion bicinctus*, many individuals live in stable pairs that inhabit and jointly defend a sea anemone (here the bubble-tip anemone, *Entacmaea quadricolor*). Pairs usually consist of two sexually mature individuals, a smaller male individual and a larger female individual, the latter has previously functioned as a male. Moreover, in some cases there are additional immature individuals that are cueing to take the place of the resident male and female (see also Fricke and Fricke, 1977; image by Lukas Schärer). ((c) and (d)) The protogynous sea goldie, *Pseudanthias squamipinnis*, shows considerable sexual dimorphism, with females (c) being much smaller and largely orange in coloration and males (d) being larger, more variably colored, and carrying a long dorsal fin ray. Males are territorial and can pair spawn with multiple individual females per day; all males start their life as females (see also Shapiro, 1979; images by Lukas Schärer). (e) Like most grouper species, the Red grouper, *Epinephelus morio*, is protogynous and mates in pairs where males experience low sperm competition, while (f) its sibling species the Nassau grouper, *Epinephelus striatus*, is gonochoristic and mates in groups where males experience high sperm competition, supporting the idea that strong sperm competition can make protogyny unstable (see also Erisman *et al.*, 2009; the public domain images are, respectively, from http://www.photolib.noaa.gov/bigs/fish3131.jpg and …/fish3129.jpg).

(Kuwamura *et al.*, 1994; Munday, 2002), or simultaneous hermaphroditism with strongly female-biased sex allocation (Baeza, 2010).

Conversely, in less ecologically restricted conditions that permit the formation of larger groups, male fecundity may strongly depend on an individual's ability to hold a territory, in which it can gain exclusive access to multiple females. Even if female fecundity is still strongly dependent on body size (as is often the case), a large body size may benefit males more than females, thus favoring 'protogyny' (**Figure 2(a)**). This sexual system is frequently encountered in a diversity of different fish families (Munday *et al.*, 2006; Avise and Mank, 2009; Erisman *et al.*, 2013), including some serranid reef fishes (**Figures 4(c)** and **4(d)**), and many labrid and scarid reef fishes (Robertson and Warner, 1978; Warner and Robertson, 1978; Warner, 1991; Schärer and Vizoso, 2003; Kazancıoğlu and Alonzo, 2010). Note that in such species only relatively few individuals may actually reach a size where they change sex and obtain significant reproductive success as male, leading to highly biased population sex ratios (Warner and Hoffman, 1980).

From a mating systems perspective, protandry is expected under conditions where sexual selection is weak, as individuals are often essentially living under monogamy. In contrast, there is ample scope for the evolution of sexual ornaments under protogyny, with multiple males vying for the attention of females. Indeed, males and females often look drastically different in protogynous species (**Figures 4(c)** and **4(d)**), while they often look very similar in protandrous species (**Figure 4(b)**).

Extensions to the Basic Theory

More recently the theoretical foundations of the size-advantage model have been extended in an attempt to explain some apparently counterintuitive empirical observations (see also Munday *et al.*, 2006), one of which is that in some protogynous species large females sometimes do not change sex when the opportunity arises. The Expected Reproductive Success Threshold model (Muñoz and Warner, 2003) incorporates variation in (1) sperm competition intensity (which reduces the payoffs that can be expected from changing to the male sex) and (2) female fecundity (which considers how much fecundity a female gives up when changing sex compared to the aggregate fecundity of the remaining females). In support of the sperm competition scenario, which may result from group spawning or small males that interfere in pair spawns, a recent comparative phylogenetic study showed that protogyny has shifted to gonochorism at least four times independently among groupers, and that these shifts were always associated with the evolution of group spawning (high sperm competition) from the ancestral pair spawning (low sperm competition) character state (Erisman *et al.*, 2009) (**Figures 4(e)** and **4(f)**). Moreover, the same study showed that relative testis size was much larger in gonochoristic than protogynous species, which also matches this scenario very well. Support for the female fecundity scenario stems from a study on the bucktooth parrotfish, *Sparisoma radians*, that initially motivated the extended theory (Muñoz and Warner, 2004; but see critique by Clifton and Rogers (2008) and response by Warner and Muñoz (2008)), and arguably also from a study that shows that in the bluehead wrasse, *Thalassoma bifasciatum*, females that become infected with an ovarian parasite – and thus have a lower female fecundity – change sex earlier and at a smaller size (Schärer and Vizoso, 2003).

Finally, a recent study in the protogynous sandperch, *Parapercis cylindrica*, suggested that there might be a role for intralocus sexual conflict in sequential hermaphrodites (Sprenger *et al.*, 2012), in that individuals were shown to exhibit a similar aggression level before and after sex change. Given the species' mating system, the authors argued that high aggression may be good when male, but potentially deleterious when female, which would make any allele affecting aggression sexually antagonistic (for a more detailed discussion of both intra- and interlocus sexual conflicts in sequential hermaphrodites, see Abbott (2011) and Schärer *et al.* (2014)). If such antagonistic alleles are widespread in sex changers, this could also affect the stability, expression, and timing of sex-change strategies, a field that would greatly benefit from further theoretical work.

Sex in Simultaneous Hermaphrodites

Pre- versus Post-Mating Sexual Selection

As originally conceived, sexual selection sought to account for conspicuous, sexually dimorphic traits that were difficult to attribute to natural selection for survival (Darwin, 1859, 1871). Given the absence of male and female individuals, sexually dimorphic traits cannot really exist in simultaneous hermaphrodites. Nevertheless, there are clearly many traits that might differentially influence reproductive fitness through one or the other sex function. An interesting question is whether the fact that all individuals in a simultaneously hermaphroditic population would have to express a (presumably costly) sexually selected trait and preference fundamentally alters the operation of sexual selection, or whether it just means that such traits are harder to identify (Morgan, 1994; Schärer and Pen, 2013). The conditions that were originally thought to favor hermaphroditism – low mate availability etc. – might tend to favor relatively indiscriminate mating, obviating the need for elaborate pre-mating mate choice mechanisms. Accordingly, most evidence of mate choice in hermaphrodites to date appears to relate instead to indicators of female fecundity or likely fertilization returns on male investment (Schärer and Pen, 2013).

The importance of post-mating sexual selection (Parker, 1970; Eberhard, 1996) in hermaphrodites is much more clearly established. Indeed, some of the earliest insights about how sperm competition, cryptic female choice, and sexual conflict would play out were those in the hermaphrodite-specific treatment of Charnov (1979). Many of the familiar post-mating sexually selected traits found in gonochorists have also been well described in various hermaphroditic taxa. Some of these adaptations even appear to be especially common in hermaphrodites, as is for example the case for devices that inject manipulative substances into the mating partner, for example, the love darts of various land snails (**Figure 5(a)**)

(Koene and Schulenburg, 2005; Nakadera and Koene, 2013; Kimura and Chiba, 2015), the copulatory setae of earthworms (Koene *et al.*, 2002) and the stylet-like penis appendages of some sea slugs (**Figure 5(b)**) (reviewed in Lange *et al.*, 2013; Schärer *et al.*, 2014). Moreover, large testes (e.g., **Figure 5(c)**) and prominent prostate glands (**Figure 5(d)**), sperm digesting organs (**Figure 5(e)**), and complex sperm (**Figure 5(f)**) are also frequently encountered. In fact, owing to the apparent scarcity of pre-mating sexual selection and the fact that two simultaneous hermaphrodites will often agree on (or due to reciprocity be unable to avoid) mating, there may even be an enhanced role for post-mating sexual selection compared to gonochorists (Schärer *et al.*, 2014). In Section 'Sex Allocation Manipulation as a Unique Post-Mating Arena of Conflict' we focus on one unique aspect of post-mating sexual selection in simultaneous hermaphrodites, the potential ability of an individual to manipulate the sex allocation of its mating partner (see also Abbott (2011) and Schärer *et al.* (2014) for a broader discussion of sexual conflict in hermaphrodites), but first we return to a unique pre-mating aspect of sex, namely the fact that two potential mating partners must first resolve which sex role or roles each of them will play in any mating interaction.

Sex Role Preference as a Unique Pre-Mating Arena of Conflict

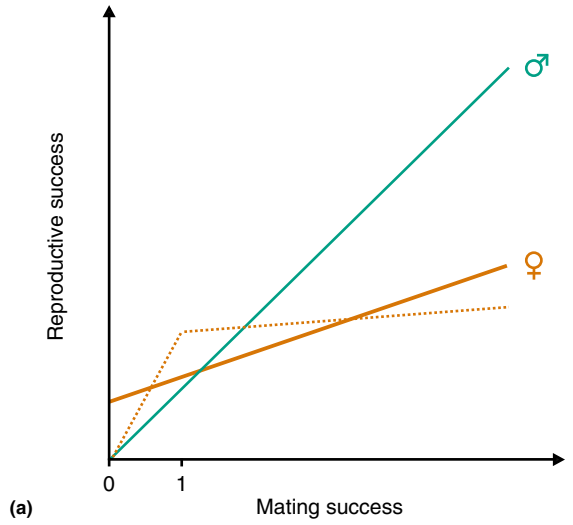
Applying Bateman's principle (Bateman, 1948) to simultaneous hermaphrodites, Charnov (1979) realized that hermaphroditic individuals may often wish to 'copulate not so much to gain sperm to fertilize [the own] eggs as to give sperm away,' basically because the female sex function is typically more limited by access to resources and the male sex function by access to eggs (**Figure 6**) (for a more thorough review see Anthes *et al.*, 2010). If two potential mating partners are then both male and female, this may often create a conflict over which of them adopts the male and female sex role in any particular mating interaction, i.e., a 'mating conflict' (Charnov, 1979; Michiels, 1998; Schärer *et al.*, 2014) (**Figure 7**). This need not always be the case, however, since the expected male preference refers to the average situation, not to a specific interaction in which the individuals may or may not have compatible mating interests; for example, for a virgin individual there may be a considerable fitness gain to be had from mating in the female role (**Figure 6**), so a virgin and a non-virgin individual might readily agree over their different, preferred sex roles.

Whenever there are incompatible mating interests, these could be resolved in various ways, either resulting in realized conflict or not (Charnov, 1979; Michiels, 1998; Schärer *et al.*, 2014). In the former category would clearly be behaviors such as penis fencing exhibited by some polyclad flatworms, in which each individual attempts to stab and hypodermically inject sperm into the partner whilst simultaneously avoiding the same fate itself (Michiels and Newman, 1998; **Figure 8(a)**). More peaceful resolutions occur in those species that agree to reciprocally exchange gametes, meaning they consent to adopt both the preferred and non-preferred roles through either conditional sperm receipt or conditional sperm donation. This could involve interactions during which two individuals may exchange sex roles, but each mating itself is unilateral (e.g., **Figure 8(b)**). For example, empirical evidence suggests that such a resolution of mating conflict manifests as egg trading in serranid reef fishes (**Figure 8(c)**). In one case of proposed sperm trading – in the sea slug *Chelidonura hirundinina* – the predicted conditionality of gamete trading has also been experimentally demonstrated: individuals are more reluctant to mate with non-reciprocating partners (Anthes *et al.*, 2005). In other cases, reciprocal exchange of gametes is achieved by both individuals acting simultaneously as sperm donor and sperm recipient, as in some land snails (**Figure 8(d)**) and flatworms (**Figures 8(e)** and **8(f)**).

Sex Allocation Manipulation as a Unique Post-Mating Arena of Conflict

It was again Charnov (1979) who first suggested that a common target of manipulation by a simultaneously hermaphroditic sperm donor might be the sex allocation of the corresponding sperm recipient. This could occur in two distinct ways, either by boosting the female function of the mating partner, or else by attacking its male function. The former mechanism should normally be straightforwardly

Figure 5 Adaptations to post-mating sexual selection in simultaneous hermaphrodites. (a) Mating in the garden snail *Cornu aspersum* (formerly *Helix aspersa*) involves the attempt to shoot a mucus-covered calcareous 'love dart' (arrow) into the body of the mating partner (here the shooter has missed). The transferred substances cause a conformational change in the female genital system that reduces the digestion of received sperm (see also panel e) and thereby increases the successful shooter's paternity share (see also Chase and Blanchard, 2006; Koene, 2006) (image courtesy of Alexandra Staikou). (b) Mating in the cephalaspid sea slug *Siphopteron* sp. 1 involves the reciprocal traumatic insertion of an accessory copulatory stylet into a precise position on the forehead of the partner (arrows), followed by the injection of a prostate secretion close to the partner's neural ganglia (see also Lange *et al.*, 2014; image courtesy of Nils Anthes). (c) The free-living flatworm *Macrostomum hystrix* has very large testes (te), which represent approximately 15% of the body volume, suggesting that this species experiences high levels of sperm competition (stitched image by Lukas Schärer). (d) The free-living flatworm *Macrostomum evelinae* has a copulatory stylet (st) that is associated, not just with a seminal vesicle (sv), but also with a very prominent prostate-like vesicula granulorum (vg), which is fed by numerous prostate gland (pg) cells that occupy a large portion of the animal's tail plate (image by Lukas Schärer). (e) The garden snail has a complex spermatophore receiving organ system that includes a bursa tract diverticulum (btd) involved in receiving the spermatophore (sp) and a bursa copulatrix (bc) involved in the digestion of most of the received sperm that emerges from the spermatophore (ag, albumen gland; fl, flagellum; ot, ovotestis; so, spermoviduct) (see also Koene, 2006; Garefalaki *et al.*, 2010; image courtesy of Alexandra Staikou). Whether such sperm digestion occurs at a net resource benefit or if it just serves to remove excess sperm is currently unclear (Schärer *et al.*, 2014). (f) The sperm of the free-living flatworm *Macrostomum lignano* are highly complex and carry stiff lateral bristles (arrowheads) that are considered to be a male persistence traits involved in a sexual conflict over the fate of received sperm (see also Vizoso *et al.*, 2010; Schärer *et al.*, 2011; still image extracted from a video taken by Lukas Schärer).



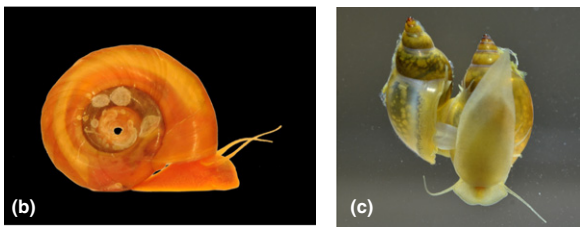


Figure 6 Bateman gradients in hermaphrodites. (a) Hypothetical plot showing the expected fitness returns (measured as reproductive success) on obtaining mating success in the male or the female sex function in hermaphrodites. As in gonochorists, it is often expected that the 'Bateman gradient' (i.e., the slope of the regression of reproductive success on mating success; Bateman, 1948; Arnold, 1994a) is steeper for males (solid green line) than for females (solid orange line). The dotted line illustrates a scenario whereby for the female function there is a large increase in fitness from an initial mating (where the individual's state switches from virgin to mated) but further matings then have little impact on fitness (e.g., because once mated the individual has access to stored sperm) (see also Anthes *et al.*, 2010; Schärer *et al.*, 2014). Recent empirical studies in two simultaneously hermaphroditic snails, (b) *Biomphalaria glabrata* and (c) *Physa acuta* (here engaged in a unilateral mating), confirm that the male sex function indeed exhibits a steeper Bateman gradient than the female sex function (see Anthes *et al.*, 2010; Pélissié *et al.*, 2012). (Images of *B. glabrata* and *P. acuta* courtesy of Nils Anthes and Tim Janicke, respectively.)

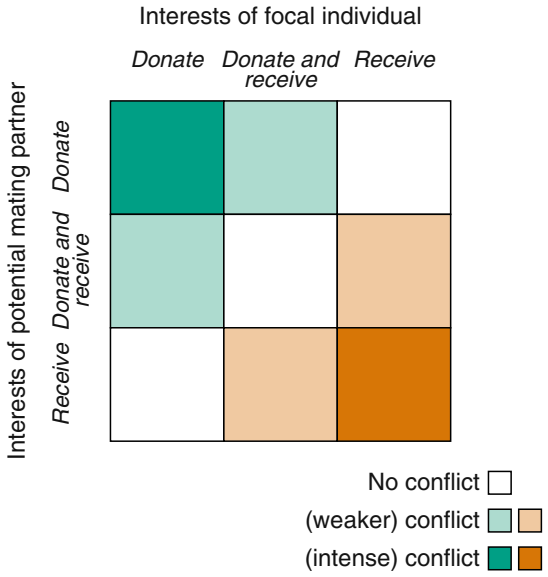

Figure 7 Potential mating conflicts over sex roles in simultaneous hermaphrodites. Two simultaneously hermaphroditic individuals that meet must each decide, not just whether they wish to mate, but also which sex role or roles they wish to play: donate sperm, receive sperm, or both. Mating conflicts arise whenever the two individuals have incompatible mating interests and they are strongest when both individuals either want to only donate (green-shaded square) or to only receive sperm (orange-shaded square), but they also occur wherever there is partial disagreement (lighter-shaded squares). Modified from Schärer, L., Janicke, T., Ramm, S. A., 2014. Sexual conflict in hermaphrodites. Cold Spring Harbor Perspectives in Biology doi: 10.1101/cshperspect.a017673, based on an original figure in Michiels (1998).

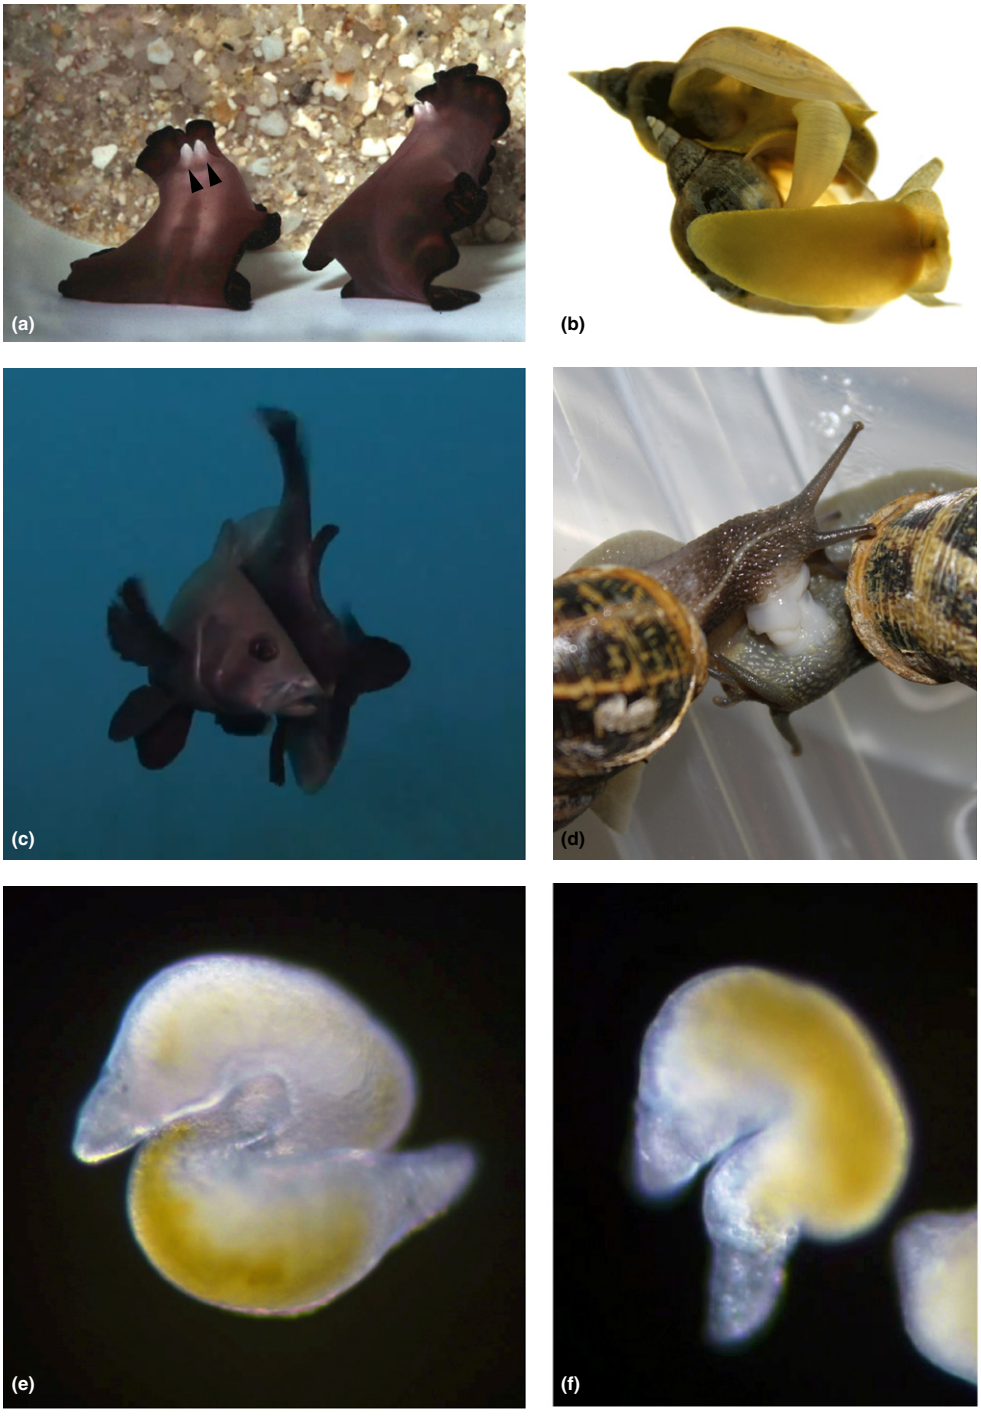
adaptive in the same way that gonochoristic males might attempt to boost the reproductive output of females with whom they mate (cf. Avila *et al.*, 2011), and the latter could be adaptive for a number of reasons (reviewed in Schärer, 2014; Schärer *et al.*, 2014) (**Figure 9**). Recent experimental work in the pond snail *Lymnaea stagnalis* has identified at least two seminal fluid proteins that indeed appear to manipulate the male sex function of the mating partner, reducing the number of sperm that an individual transfers during its next mating (Nakadera *et al.*, 2014). However, the exact adaptive significance of this effect remains to be determined (see also Schärer, 2014).

Outcrossing versus Self-Fertilization

As we already mentioned above, another unique aspect of sex in simultaneous hermaphrodites (and indeed certain sequential hermaphrodites, namely if the gamete type produced first can be stored prior to use) is the phenomenon of self-fertilization. Despite potential negative effects resulting from inbreeding depression, this may still offer a better alternative than being unable to reproduce at all, and current evidence of so-called delayed selfing bears this out: upon reaching sexual maturity, in the absence of outcrossing opportunities many simultaneous hermaphrodites at first wait for such an opportunity to arise (especially if inbreeding costs are high; Tsitrone *et al.*, 2003a; Escobar *et al.*, 2011), and if an opportunity does not materialize they later switch to selfing (e.g., Tsitrone *et al.*, 2003b; Escobar *et al.*, 2011; Ramm *et al.*, 2012). Note, however, that by far not all simultaneous hermaphrodites are capable of selfing, as there may be morphological constraints that prevent ready selfing (cf. Ramm *et al.*, 2012; Ramm *et al.*, 2015) or self-incompatibility systems that normally guard against it (Bishop, 1996; Bishop *et al.*, 1996) that would need to be overcome, and the precise costs and benefits of outcrossing versus selfing will depend strongly on the previous history of selfing within a population (Jarne and Auld, 2006; Escobar *et al.*, 2009; Escobar *et al.*, 2011).

Outlook

Even from this brief account, it should be clear that questions about the sexual system, sex allocation, and sexual selection are inextricably linked, and that we therefore need to learn more about how these processes operate in hermaphrodites compared to the much better investigated gonochorists. In a similar vein, it should be evident that there are important parallels between sex changers, simultaneous hermaphrodites, and gonochorists, and it is worth pointing out that these broad categories gloss over a much richer diversity of sexual systems, including for example mixtures of males and hermaphrodites (such as androdioecious clam shrimp; Weeks *et al.*, 2006), dwarf males with both gonochorists and hermaphrodites (as in barnacles; Yusa *et al.*, 2013), cyclical parthenogenesis in which one clone can make both male and female offspring (as in cladocerans; Innes and Singleton, 2000), and asexual propagation and fissioning in hermaphrodites (as in many



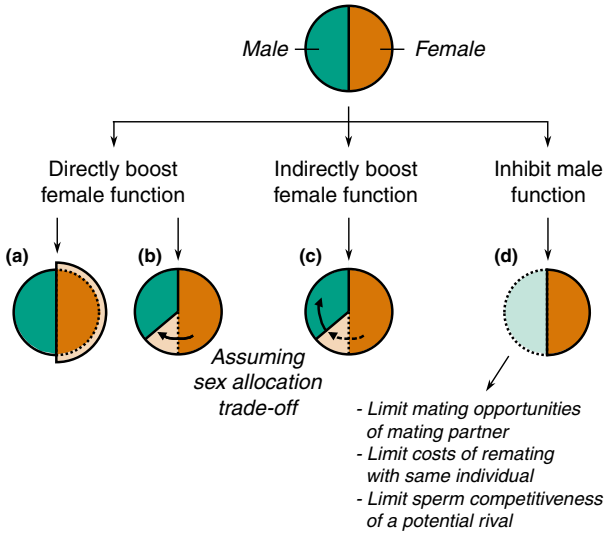


Figure 9 Hypotheses for sex allocation manipulation in simultaneous hermaphrodites. For a sperm donor, manipulating the reproductive allocation of the sperm recipient could be adaptive for a number of reasons. Most straightforwardly, the donor could divert resources toward the recipient's female function, and thereby gain from fertilizing a greater number of eggs ((a) and (b)). Depending on from where these resources are diverted, this may (b) or may not (a) result in a corresponding reduction in the recipient's male allocation (i.e., it may or may not affect the individual's sex allocation in the strict sense). Alternatively, it may pay the donor to directly target the recipient's male sex function, either because doing so results in a reallocation of resources toward the female function due to a sex allocation trade-off (c), or because reducing the recipient's male allocation is by itself beneficial (d). Possible adaptive scenarios for the latter include that it may constrain the ability of the recipient to re-mate (thus reducing the likelihood that the donors faces sperm competition to fertilize the recipient's eggs); that it may limit the costs when a donor re-mates as a recipient with that same mating partner (e.g., if fewer costly substances are transferred, or costly mating duration is reduced); or that the sperm competitive ability of a potential rival donor in other recipients in the population would be reduced. For further discussion, see also Schärer *et al.* (2014) and Schärer (2014).

cnidarians, flatworms, and different colonial marine invertebrates; Hughes, 2005; Janssen *et al.*, 2015; for plants see also Haig and Wilczek, 2006), to name just a few (see also Weeks, 2012). Studying the evolutionary biology of sex in hermaphrodites should therefore be seen as an important part of the wider goal of understanding the biochemical, morphological, and behavioral diversity resulting from the male–female phenomenon, i.e., the evolution of anisogamy and its consequences. The fact that there are multiple origins of anisogamy (Kirk, 2006) necessarily means that there is a mix of common, unifying themes (e.g., the usually greater variance in male reproductive success) coupled with a plethora of divergent solutions that involve considerable phylogenetic idiosyncrasies (e.g., the prominent role of the male gametophyte in plant reproduction vs. the greatly suppressed role of haploid sperm in animals due to their being largely transcriptionally silenced). Thus it is clear that more work to compare plant and animal sexual systems would be insightful (see also Arnold, 1994b; Bernasconi *et al.*, 2004; Bedhomme *et al.*, 2009; Vega-Frutis *et al.*, 2014), as would the better incorporation of insights gained from other anisogamous sexual systems (Coleman, 2012; Nieuwenhuis and Aanen, 2012). Sexual reproduction did not start, nor does it necessarily end, with separate males and females; as they evolved multiple times, the male and female sexual strategies instead explored a far greater parameter space, often settling on one of the different forms of hermaphroditism that we see today.

Figure 8 Types of mating in simultaneous hermaphrodites. Mating conflicts can be resolved in a number of ways, which may or may not result in realized conflict. (a) Two polyclad flatworms of the species *Pseudobiceros bedfordi* engage in penis fencing, which involves the attempt to traumatically inseminate sperm into the mating partner using paired copulatory stylets (double arrowheads), while trying to avoid being stabbed oneself (see also Michiels and Newman, 1998 for data on *Pseudoceros bifurcus*; image 'Two Individuals of *Pseudobiceros bedfordi* About to Have a Sperm Battle' by Nico Michiels from doi:10.1371/journal.pbio.0020183.g001 licensed under CC BY). (b) Unilateral mating in the freshwater snail *Lymnaea stagnalis*, with the male role individual at the top inseminating the female role individual below using its penis-carrying organ, the preputium (see also Koene *et al.*, 2010; image courtesy of Joris Koene and Cathy Levesque). (c) Two black hamlets, *Hypoplectrus nigricans*, engaged in an egg trading exchange in which the male role individual (the egg releaser) is facing downwards and the female role individual (the sperm releaser) has clenched jaws and is curled around the former. Roles are then usually exchanged multiple times in an iterated way (see also Fischer, 1980; Henshaw *et al.*, 2015; still image from a video by the BlennyWatcher.com website hosted at http://www.youtube.com/watch?v=5d2dXRKNCbg and courtesy of Ned and Anna DeLoach). (d) Two garden snails *Cornu aspersum* (formerly *Helix aspersa*) involved in a reciprocal mating, during which they assume a head to head position and reciprocally insert their male copulatory organs (see also Koene, 2006; Garefalaki *et al.*, 2010; image courtesy of Alexandra Staikou). (e) Two free-living flatworms of the species *Macrostomum lignano* engaged in a reciprocal mating, during which they curl around each other in the shape of two interlocking 'G's (see also Schärer *et al.*, 2004; Vizoso *et al.*, 2010; still image from a video by Lukas Schärer). (f) An *M. lignano* individual engaged in the postcopulatory 'suck' behavior, during which it places its pharynx over its own female genital opening and appears to be sucking, presumably to remove ejaculate components that it received during the preceding reciprocal mating (see also Schärer *et al.*, 2004; Vizoso *et al.*, 2010; still image from a video by Lukas Schärer).

Glossary

Acheulian Type of stone tools characterized by large handaxes first produced by *Homo erectus* in Africa after about 1.7 Ma, but later also widespread in Eurasia.
Arborealism The behavior of an organism living in, or spending the majority of time in, the trees.
Australopithecine Species in the genera *Australopithecus* and *Paranthropus*; a type of hominin largely preceding (with some overlap) the genus *Homo*.
Basicranial flexion Angle of the cranial base, which differs between hominin species.
Cranium The skull not including the mandible (lower jaw).
Derived Characteristics which are present in a daughter taxon, but not its parent taxon.
Edentulous An individual who has lost their teeth.
Encephalization Relative (taking body size into account) increase in brain volume.
Endocranium The inside of the cranial vault, which houses the brain.
Genetic drift Variation in relative frequency of different genetic make-ups resulting from chance, such as the failure of some individuals to reproduce.
Homoplasy Characteristics present in two taxa, but not in their last common ancestor and thus not shared due to shared ancestry. This is also called convergent evolution.
Hypodigm The fossil or group of fossils from which a taxon is defined.
Introgression Input of genetic material from one species to another.
ka Kiloannus, or thousand years ago.
Ma Megaannus, or million years ago.
Maxillae The paired bones forming the lower part of the face.
Mitchondrial DNA The genetic material in the energy-producing organelles found in cell nuclei, the mitochondria. Unlike the nuclear genome, the mitochondrial genome (the mtDNA) consists of a single ring of DNA, in mammals is inherited only through the female line and is not recombined between generations.
Nuclear genome/DNA The genetic material in the nucleus inherited from both parents and consisting of 23 paired chromosomes in living humans. The material from each parent is recombined in every new generation.
Nutritional cannibalism Cannibalism treating the consumption of human flesh as no different from any other food source, as opposed to ritual cannibalism.
Occipital Bone at the back and rear of the cranium.
Phalanx A finger bone, in the case of the Denisovan fossil, from the last knuckle to the finger tip of the fifth finger.
Pleistocene The geological epoch before present (the Holocene).
Postcrania The skeleton below the skull.
Primitive Characteristics present in a daughter taxon that are also present in its parent taxon.
Prognathism Facial projection.
Sexual dimorphism Difference in size and morphology between males and females of the same species.
Speciation The process by which a new species is born.
Supraorbital tori Browridges or bony protrusions above the eyes.
Taxon (plural: taxa) A taxonomic group (e.g., species, genus, or order).
Temporal Pair of bones forming the lower sides of the skull and housing the ear region.

Homo Habilis and *Homo Rudolfensis*

Homo habilis was named in 1964 by Louis Leakey and colleagues based on fossils from Olduvai Gorge (Tanzania) (Leakey *et al.*, 1964) now dated to 1.9–1.6 Ma (Antón, 2004). *H. habilis* was regarded as intermediate between australopithecines and *Homo sapiens*, due to its larger brain and smaller posterior dentition (Leakey *et al.*, 1964). This 'handy man' purportedly had manual adaptations that facilitated tool-making, although now the earliest currently known stone tools are more than 3 Ma, considerably predating this species (Harmand *et al.*, 2015). Tool use is argued to coincide with changes in cognition and diet, including increased meat eating (Wood, 2012), another supposed distinction between *Homo* species and australopithecines (Lockwood, 2013). Postcranially, body proportions in *H. habilis* are very different to later *Homo*, with long arms probably demonstrating continued reliance on arborealism (Lockwood, 2013). *H. habilis* has always been controversial, initially because it was considered insufficiently distinct from the australopithecines and then, as more material was included in the hypodigm, because some considered that it subsumed too great a morphological diversity (Antón *et al.*, 2014). In particular, the fossils included a larger morph with a flatter face and perhaps less apelike body proportions and a smaller morph with less encephalization and a more apelike postcrania, but a more derived upper face (Wood, 2012; **Figure 1**). Opinions differ as to whether this level of dissimilarity is evidence of sexual dimorphism or of two different species at this time period in East Africa (Wood, 2012). Those who argue for two species have used the name *H. rudolfensis* to distinguish the larger material (Wood, 2012). In 2012, new fossils from Koobi Fora (1.8–2 Ma), similar in

Figure 1 *Homo rudolfensis* (left, shown by a replica of KNM-ER 1470) material has a relatively large, flat face, relatively small anterior teeth and moderately sized posterior teeth, a squared off tooth row and a short palate. The *H. habilis* (right: a replica of KNM-ER 1813, as a possible example) tooth row is more curved and the face flatter (Leakey *et al.*, 2012). Copyright: The trustees of the Natural History Museum, London (NHM).

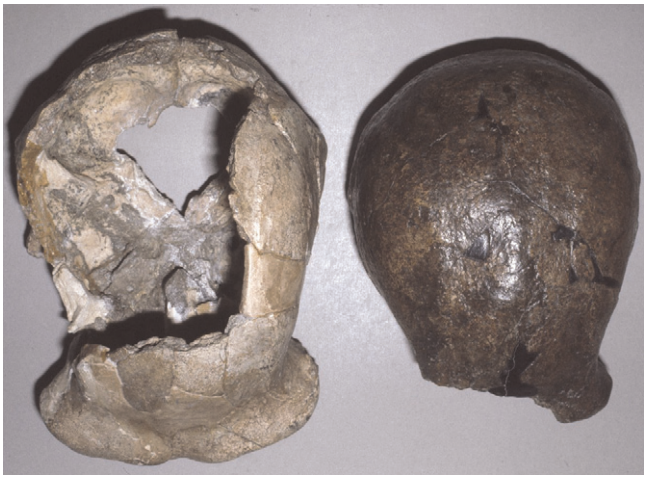

Figure 2 African (left, OH9, Tanzania) and Asian *Homo erectus* (right, Sangiran, Java) skull caps. Copyright: C. Stringer.

shape, but not size, to the larger morph were published, supporting the existence of two taxa (Leakey *et al.*, 2012). The association of facial and mandibular material from one individual in the new material also precludes the coexistence in one species of some of the material previously grouped together in *H. rudolfensis*, further demonstrating considerable complexity in this phase of human evolution (Leakey *et al.*, 2012; Spoor *et al.*, 2015).

Homo Erectus

Homo erectus fossils show larger mean endocranial volumes than *H. habilis*/*H. rudolfensis* combined with very large supraorbital tori (**Figure 2**), thickened bone in the occipital region (Hublin, 2014), and body proportions similar to later *Homo* (Stringer, 2012a). The earliest known *H. erectus* material may come from the Lake Turkana region (Kenya) (**Figure 3**) and the species is traditionally thought to have evolved ~2 Ma, before becoming the first hominin to leave Africa (Stringer, 2012a). Some researchers, however, suggest a Eurasian origin and into-Africa dispersal, due to the early (~1.8 Ma), material from Dmanisi, Georgia (Wood, 2011a, see below). *H. erectus* dispersal may be associated with increased meat eating, as carnivore species are usually wide-ranging (Lockwood, 2013). *H. erectus* might also have been the first hominin to control fire and both cooking and increased meat consumption may be linked to its encephalization and gut reduction (Aiello and Wheeler, 1995; Wrangham *et al.*, 1999). There is a concomitant change in technology; early African and Asian *H. erectus* used tools similar to those of *H. habilis*/*H. rudolfensis*, but from ~1.7 Ma, African *H. erectus* produced larger, multipurpose tools, such as handaxes. These were also used in western Asia and possibly Europe from ~1 Ma (Lepre *et al.*, 2011).

The Dmanisi fossils are as primitive as early African *H. erectus* and it has even been argued that some of the material might demonstrate a new species, '*H. georgicus*' (Gabounia *et al.*, 2002). The Dmanisi material now includes several very complete crania, associated mandibles, and postcrania (Lordkipanidze *et al.*, 2013). There seems to have been a (relatively) rapid accumulation of fossils at the site, representing a short time period and leading the authors to propose a single

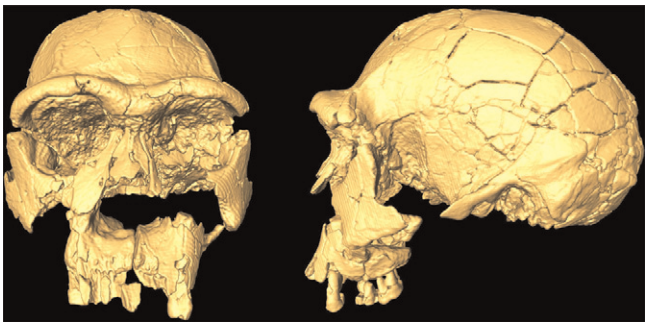

Figure 3 KNM-ER 3733 (Kenya). *Homo erectus* is characterized by larger average brain sizes than *H. habilis*, but the braincase is relatively longer, flatter, and more angular. The browridges are prominent and the face is less projecting than in typical *H. habilis* fossils, with a more prominent, human-like nose. Figure shows virtual reconstructions from CT data. Copyright, L.T. Buck, CT data from National Museums of Kenya.

species, despite considerable variation between individuals (Lordkipanidze *et al.*, 2013). They argue that the range of morphology at Dmanisi, which they propose is comparable to that in recent *H. sapiens* or chimpanzees, may well encompass material otherwise diagnosed as *H. habilis* and *H. rudolfensis*, suggesting that these species should be subsumed in *H. erectus* (Lordkipanidze *et al.*, 2013). Critics argue that the Dmanisi team's measures of variability are flawed and fail to capture characteristic differences between species (Hublin, 2014; Spoor, 2013). There is also criticism of the inclusion of an elderly, endentulous, and juvenile individuals in the analyses and the failure to consider the postcranial material, suggesting that *H. habilis* and *H. rudolfensis* are still best described as separate species from *H. erectus* (Hublin, 2014; Spoor, 2013).

Asian *H. erectus* is best known from 'Java Man' discovered in the 1890s and 'Peking Man' in the 1920–1930s, although many additional finds have since been made in both Indonesia and China, the former being generally older. The Asian finds show some differences from the African material; the skulls are more strongly reinforced with ridges of bone, and the walls of the skulls are generally thicker. Asian *H. erectus* was a very successful species, surviving perhaps into the last 250 ka (Antón, 2013).

Homo naledi

To date, the newest member of the genus *Homo* is *H. naledi*, discovered in the Rising Star cave system near Johanesberg, South Africa and published in September 2015 (Berger *et al.*, 2015; Dirks *et al.*, 2015). The assemblage from this remarkable site comprises over 1500 fossils from at least 15 individuals. A new species has been created by the discovers, due to the fossils' combination of primitive characteristics, such as the small brain, curved fingers, shoulder, hip and trunk morphology, and derived characteristics such as the morphology of the wrist, legs, hands, and feet, which most closely resemble those of Neanderthals and *H. sapiens* (Berger *et al.*, 2015). It is unclear as yet how *H. naledi* fits into the genus *Homo*, in part because of the important issue of the unknown age of the fossils, but they are perhaps morphologically most similar to early, small-bodied *H. erectus*, such as those from Dmanisi (Stringer, 2015, see above).

Homo Floresiensis

In 2003 a tiny skeleton (LB1) was discovered in Liang Bua cave on Flores, Indonesia. Despite its size, the skull was mature and its primitive characteristics, such as the lack of chin and distinct supraorbital tori, led the authors to declare it a new species: *H. floresiensis* (Brown *et al.*, 2004). LB1 is currently dated to <20 ka and was suggested by the discoverers to be the result of insular dwarfism, a process whereby island-living, large-bodied mammals reduce in size due to reduced resources and threat from predators. The potential large-bodied ancestor for *H. floresiensis* was given as Asian *H. erectus* (Morwood and van Oosterzee, 2009). LB1's status as a distinct species has been extremely controversial and many recent *H. sapiens* pathologies that could lead to such a morphology have been suggested (e.g., Henneberg *et al.*, 2014; Martin *et al.*, 2006; Hershkovitz *et al.*, 2007). This controversy reached a nadir when the remains were appropriated by a rival team who, in trying to replicate them, damaged some of the fossils to the detriment of future research (Morwood and van Oosterzee, 2009; Brown, 2012). However, subsequent analyses and the recovery of further individuals from Liang Bua have uncovered a combination of traits inexplicable by any single pathology and, arguably, more similarities with australopithecines than later *Homo* (Morwood and Jungers, 2009; Orr *et al.*, 2013; Brown, 2012). Currently, the interpretation of *H. floresiensis* as a valid species is the best explanation of the data, but the ultimate ancestral species is unsure, as derivation from either *H. erectus*, or an earlier hominin (**Figure 4**), would still require substantial evolutionary reversals or homoplasies. This debate is only likely to be settled with the discovery of more fossil material from Flores or surrounding regions (Stringer, 2014).

Homo Antecessor

The enigmatic remains attributed to *H. antecessor* date to around 850 ka (Parés *et al.*, 2013). The species is known from a single site – Gran Dolina (Atapuerca, Spain), where more than 100 fossils from at least 10 individuals have so far been recovered (Wood, 2011b). The fossils were considered to show craniodental features more derived than *H. erectus*, but more primitive than either Neanderthals or *H. heidelbergensis* and so a new species was created: *H. antecessor* (Bermúdez De Castro *et al.*, 1997;

Figure 4 (From left to right) replicas of KNM-ER 1813 (*'Homo habilis'*), D2700 (*H. erectus*) and LB1 (*H. floresiensis*). LB1 is female of about 1 m in height, with a brain volume of around 400 ml (about the same as a chimpanzee) (Stringer, 2014). LB1 has robust limbs with relatively long arms, short legs, and large feet, which lack the longitudinal arch characteristic of *Homo*. The clavicle is short, the scapula protracted, there is little humeral torsion, and the carpal morphology is primitive; these all link *H. floresiensis* with pre-*Homo* hominins, such as the australopithecines (Stringer, 2014). Copyright: NHM.

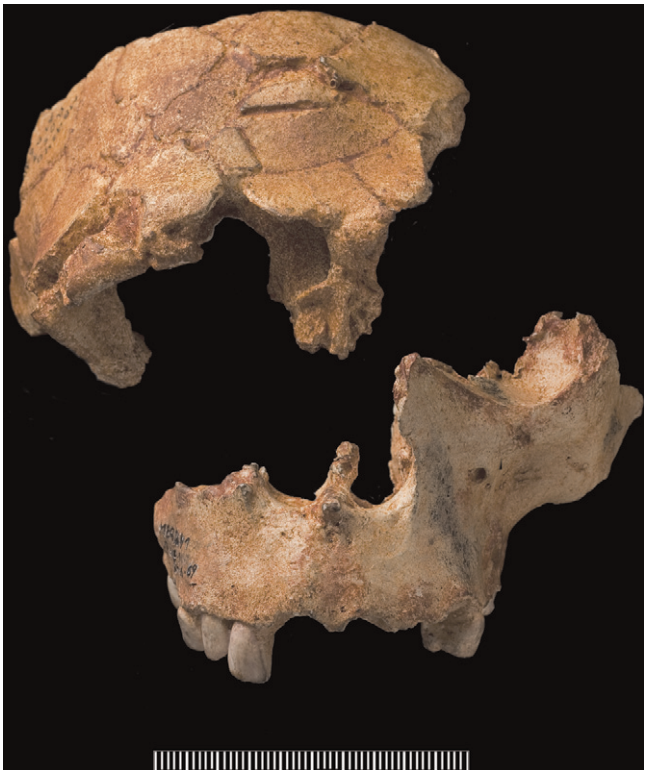

Figure 5 A cast of the most complete *Homo antecessor* fossil, a juvenile partial face, ATD6-69. Copyright: NHM.

Arsuaga *et al.*, 1999). Suggested Neanderthal and *H. sapiens* traits in the fossils have led their discoverers to propose that *H. antecessor* is a common ancestor of both (Arsuaga *et al.*, 1999). Critics, however, suggest that the *H. sapiens*-like facial morphology seen in ATD6-69 facial fragment (**Figure 5**) might be due to its immaturity (Wood, 2011b), whilst the Atapuerca team have themselves noted similarity to the *H. erectus* fossils from Zhoukoudian (China). Most of the hominin remains from the site show human modification and are treated in the same way as fauna in terms of damage and distribution. This suggests that the assemblage is anthropogenic and the result of nutritional cannibalism (Fernández-Jalvo *et al.*, 1999; Saladié *et al.*, 2014). In May 2013, investigations at Happisburgh, UK, revealed the oldest known hominin footprints outside Africa (~1.0–0.78 Ma) in the estuary sediments of an extinct river. Since it is the only known hominin species in western Europe of a similar age, and foot sizes and estimated stature from Happisburgh fall within its estimated range, these footprints are tentatively assigned to *H. antecessor* (Ashton *et al.*, 2014).

Homo Heidelbergensis

Homo heidelbergensis is named for a mandible (~600 ka) found at Mauer, near Heidelberg (Germany) in 1907. The hypodigm is disputed, but the most wide-ranging, and currently

Figure 6 Top and bottom, left to right: Bodo (Ethiopia), Petralona (Greece), and Broken Hill (Zambia). *Homo heidelbergensis* exhibits *H. erectus*-like large browridges (albeit often with distinctively large frontal sinuses), occipital morphology, wide interorbital breadth and pelvic morphology alongside more derived (*H. sapiens*/*H. neanderthalensis*-like) traits including an expanded braincase, reduced overall facial projection, temporal bone morphology, and in some cases, inflated, swept-back maxillae like those seen in *H. neanderthalensis*. *H. heidelbergensis* endocranial volumes overlap the higher end of variation for *H. erectus* and lower end of *H. sapiens/H. neanderthalensis* (Stringer, 2013). Figure shows virtual reconstructions from CT data, fossils scaled to approximately equal size. Copyright: L.T. Buck, CT data from University of Vienna/University of Thessaloniki/NHM.

Figure 7 *Homo heidelbergensis*. Artist's reconstruction of the Boxgrove individual. Copyright: John Sibbick/NHM.

best supported, interpretation of the data includes African, European, and possibly Asian Mid-Pleistocene material and is thought to be the most probable last common ancestor between *H. sapiens* and Neanderthals (Buck and Stringer, 2014; Stringer, 2012b). Similarities between Mauer and remains from Arago (France), which are allied with comparable fossils from Europe and Africa, enable the whole group to be called *H. heidelbergensis*. This Mid-Pleistocene Euro-African (and possibly Asian) group shares a distinctive mosaic cranial morphology (**Figure 6**). The little postcranial evidence that exists shows that *H. heidelbergensis* adults were tall and robust with possible climatic variation in their body shapes (Stringer, 2013). Archeological finds show *H. heidelbergensis* produced sophisticated tools, such as the beautiful Acheulian handaxes from Boxgrove, UK (Roberts *et al.*, 1994) (**Figure 7**). In contrast to the Euro-African hypodigm, some researchers maintain that *H. heidelbergensis* is restricted to Europe and is ancestral solely to Neanderthals. However, this viewpoint is largely dependent on Neanderthal traits in remains from Sima de los Huesos (Atapuerca, see **Figure 8**), which have recently been redated to a younger ~400 ka and are thus probably best viewed as early Neanderthals, rather than *H. heidelbergensis* (Buck and Stringer, 2014; Stringer, 2012b). In this scenario, shared traits linking the African and European material are largely primitive retentions from *H. erectus* (Stringer, 2012b). By comparing mitochondrial DNA (mtDNA) from *H. neanderthalensis* and *H. sapiens*, a divergence date (~410–440 ka) for the two species has been estimated, providing calibration for the potential split of *H. heidelbergensis* into its descendent species (Endicott *et al.*, 2010).

Homo Neanderthalensis

Neanderthals (**Figure 9**) were a successful and long-lived species with a geographical spread from Gibraltar (**Figure 10**) to Siberia and chronologically from ~400–40 ka, if we assume fossils from Swanscombe and the Sima represent very early members of the lineage (Higham *et al.*, 2014; Stringer and Hublin, 1999). The traditional image of Neanderthals as brutes is gradually eroding; over the last few years, evidence of the supposed hallmarks of 'modern humans' has been attributed to Neanderthal agency. This includes pigment use (Zilhão *et al.*, 2010); apparent symbolic use of feathers

Figure 8 Replicas of Sima de los Huesos 5 (Top, Spain, ~400 ka) and Swanscombe (bottom, UK, ~400 ka), which we argue are two early Neanderthals from different sites showing the mosaic accumulation of Neanderthal traits in different populations across Europe (Stringer and Buck, 2014). (Finlayson *et al.*, 2012; Peresani *et al.*, 2011); dietary breadth (Stringer *et al.*, 2008); burial of the dead (e.g., Rendu *et al.*, 2014); and the Châtelperronian industry (Bailey *et al.*, 2009; Bar-Yosef and Bordes, 2010; Higham *et al.*, 2010; Zilhão *et al.*, 2006). Although all these findings are controversial individually, as a whole, they point to the reduction in the perceived cognitive demarcation between *H. sapiens* and *H. neanderthalensis*. Improvements in genetic analyses have also enabled exciting new discoveries; the sequencing of the Neanderthal nuclear genome in 2010 has shown that most extant *H. sapiens* populations from outside sub-Saharan African have ~2% Neanderthal introgression (Green *et al.*, 2010). This varies between populations, with a greater extent observed in east Asian populations (Wall *et al.*, 2013), which may be due to the differential effect of genetic drift on separate populations across Eurasia (Prufer *et al.*, 2014) or to multiple interbreeding events (Vernot and Akey, 2014).

The Denisovans

In 2010 a fossil phalanx from the Siberian site of Denisova Cave yielded mtDNA and revealed an unexpected additional hominin in late Pleistocene Eurasia (Krause *et al.*, 2010). As the fossil remains (dated to ~50 ka) attributed to the Denisovans are still limited to the phalanx and three very large molars (from other individuals), their overall morphology is still unknown and their relationships to other Pleistocene hominins are incompletely understood. The ancient DNA (aDNA) preservation in this cold, dry cave was such however, that it could be determined that, although Denisovan mtDNA differs from both Neanderthals and *H. sapiens*, their nuclear DNA suggests they are a sister group to Neanderthals (Reich *et al.*, 2010). Evidence of interbreeding with recent *H. sapiens* in Southeast Asia and Melanesia shows that the Denisovans were once widespread in the region (Reich *et al.*, 2010). As there are Mid-Pleistocene fossils from Asia (e.g., Maba and Dali from China, **Figure 11**), it is possible they could represent a branch of *H. heidelbergensis* ancestral to the Denisovans (Stringer, 2013). Recent advances in aDNA analyses mean that recovering diagnostic genetic material from Mid-Pleistocene fossils (e.g., Meyer *et al.*, 2014) such as the remains from Asia is now a real possibility, which could clarify the evolutionary origins of the Denisovans.

Homo Sapiens

The diagnosis of our own species is controversial in the fossil record. Different diagnoses depend on their underpinning models of speciation and dispersal (Stringer and Buck, 2014). For example, multiregionalists propose a single, diverse species from >1 Ma onwards, with significant gene flow between regions preventing speciation (e.g., Wolpoff *et al.*, 1994).

Figure 10 The Forbes' Quarry (Gibraltar I) female Neanderthal. The species is diagnosed cranially by a long, low cranium, distinctive occipital morphology (Stringer, 1985; Vandersmeersch, 1985; Balzeau and Rougier, 2010), mid-facial prognathism with large nose and swept-back cheek bones (Stringer, 1985), and large, double-arched browridges (Stringer, 1985; Tattersall and Schwartz, 2006). Copyright: NHM.

Figure 11 The Maba fossil from China. Could this Middle Pleistocene hominin and other similarly enigmatic remains from sites such as Dali and Jinnuishan be related to the Denisovans (Stringer, 2013)? Copyright: C. Stringer.

In contrast, the better-supported (by the fossil and genetic data) Recent African Origin model suggests *H. sapiens* originated in Africa relatively recently, and dispersed globally to replace regional archaic populations (Stringer, 2002; Stringer and Buck, 2014). Recent genetic analyses (see above) have shown that living humans retain small contributions from extinct species, thus the currently most plausible explanation of *H. sapiens* origins is one of African beginnings and 'leaky replacement' of regional, preexisting non-*sapiens* populations (Stringer and Buck, 2014). Variation in early *H. sapiens* fossils in Africa and the Near East shows there was no simple, linear change from *H. heidelbergensis* to *H. sapiens*. There was instead

a gradual coalescence of *H. sapiens* characteristics (Stringer and Buck, 2014). This could be the result of climatic variation on population size and expansion/contraction (Stringer, 2012a; Blome *et al.*, 2012; Stewart and Stringer, 2012; Ziegler *et al.*, 2013). 'Anatomically modern humans' (fossils closer to living humans in morphology than to any other species) in the African fossil record (**Figures 12** and **13**) date to ~200 ka, while the origin of the *H. sapiens* lineage is likely to be ~400 ka (Stringer, 2012c). The oldest complete *H. sapiens* genome sequenced to date, from the Ust'-Ishim femur from Siberia (~45 ka), shows evidence of a similar amount of Neanderthal interbreeding to recent non-African humans (Fu *et al.*, 2014). Longer lengths of Neanderthal DNA in this individual suggest that time since introgression was ~55 ka (Fu *et al.*, 2014; Seguin-Orlando *et al.*, 2014). Since this Neanderthal contribution seems to be present in all recent non-Africans, Ust'-Ishim suggests a relatively late date for the global dispersals of *H. sapiens*. However, the possibility of earlier dispersal (as has been suggested by material from middle eastern sites such as Skhul and Qafzeh) is still

plausible (Reyes-Centeno *et al.*, 2014; Reyes-Centeno *et al.*, 2015), and larger amounts of Neanderthal introgression in the ~40 ka Oase mandible from Romania suggest that limited interbreeding continued until this time (Gibbons, 2015). *H. sapiens* in the fossil record are recognized by their cranial globularity, facial diminution and retraction, basicranial flexion, dental microstructure, inner ear morphology and pelvic shape (Stringer and Buck, 2014; **Figure 13**). It has been asserted that *H. sapiens* cannot be diagnosed purely morphologically because of our unique reliance on culture (Wolpoff and Caspari, 1997). '*H. sapiens* behavior,' however, appears in the fossil record in different places at different times (McBrearty and Brooks, 2000) and increasingly there is also potential evidence for such behavior in Neanderthals (see above). Furthermore, where 'anatomically modern' *H. sapiens* are found, they are not always associated with the whole *H. sapiens* behavioral package (Brumm and Moore, 2005). In our view, these problems preclude the utility of cultural evidence for diagnosing *H. sapiens* (Stringer and Buck, 2014).

Human Life Histories, Evolution and

LL Sievert, University of Massachusetts Amherst, Amherst, MA, USA

Glossary

Adrenarche When the adrenal glands mature and the zona reticularis starts to produce increased levels of androgens such as DHEA and DHEAS. In humans this is associated with the appearance of pubic hair and body odor in children around the ages of 6 to 8.
Allometry The study of the relationship between various measures of body size and shape.
Antagonistic pleiotropy When one gene or allele affects more than one trait, and where at least one of the traits is beneficial to the organism's survival and reproduction and at least one is detrimental to the organism's survival and reproduction.
Encephalization Increasing brain size relative to body size.
Gestation Pregnancy, or carrying an embryo or fetus inside the female body.
Hominin Refers to modern humans and extinct human-like bipedal species (including members of the genera *Homo*, *Australopithecus*, and *Ardipithecus*).
Interbirth interval The length of time between births.
Lactational amenorrhea The temporary postnatal cessation of menstruation, associated with infertility.
Life history theory How a species allocates energy across the competing physiological demands of growth, reproduction, and somatic maintenance.
Menarche The first menstrual period.
Menopause The last menstrual period, recognized in retrospect after 12 months without menstruation.
Metabolic load The amount of energy required, for example, to carry a pregnancy to term, or to breastfeed.
Neonatal period From birth through the first 4 weeks of an infant's life.
Obligate bipedalism The form of bipedalism (walking on two legs) that is carried out as the habitual means of locomotion.
Secular trend Generally refers to increases in height and decreases in ages at menarche over a long period of time, i.e., 100 years.
Senescence Age-related changes, both structural and functional, that decrease the ability of an individual to withstand stress, reduce the probability of reproduction, and increase the likelihood that an individual will die.
Subfecundity Having a low probability of conceiving during a month of exposure to unprotected intercourse.

Introduction

Over the course of the past 6 or 7 million years, humans have evolved some unique life history characteristics. Compared to other primates, humans have the slowest-growing offspring, the latest age at first birth, and the longest life span. Human females experience a universal menopause and prolonged post-reproductive life. Although human offspring are slow-growing, they are weaned at earlier ages than chimpanzees and gorillas, and interbirth intervals are shorter, resulting in more offspring during the reproductive period (Bogin and Smith, 2012; Robson *et al.*, 2006).

Life history theory, a branch of evolutionary biology that focuses on the timing of life cycle events, has been applied to explain the uniqueness of the human life span. Life history theory is concerned with the optimal allocation of energy across energetically expensive physiological demands: somatic maintenance, immune function, physical activity, growth, reproduction, and energy stores. Everything has a cost (Jasienska, 2013), and life history theory presumes that when the body's energy is directed for one purpose (e.g., growth), that same energy cannot be used for something else. Through most of human evolution, energy was not consistently available, and trade-offs occurred (Trevathan, 2010). Life history theory is, therefore, about trade-offs, as a species balances limited energy across competing physiological demands (Stearns, 1992).

This article will use life history theory to provide a coherent framework to explain why humans evolved unique life history characteristics. Human life history will be compared with our closest living relatives (chimpanzees, gorillas) and sometimes with the more distantly related macaque. Evidence will also be drawn from fossil hominins. Contemporary foraging populations will be referred to, albeit with caution, as their ways of life may be somewhat like that of our hominin ancestors. Human life history cannot be understood apart from the development of human culture and sociality (Sears and Gibson, 2009).

This article is organized around the life events of gestation, infancy, childhood and adolescence, adulthood and reproduction, and menopause and post-reproductive life. Although these life cycle events are universal across all humans, there is variability in the timing of life events both within and between populations. The conditions for natural selection include heritability and variation in the traits of interest (Langdon, 2005), thus the variability observed in the timing of life events in contemporary populations suggests how natural selection was able to shape the unique trajectory of the human life span. Of course, the third condition for natural selection is an association with reproductive success, and that is the central premise of life history theory (Ellison, 2003). Ultimately, the species-specific pattern of energy allocation across the human life span results in reproductive success.

 doi:10.1016/B978-0-12-800049-6.00295-X

Gestation

One perplexing life history question associated with human gestation pertains to why humans are not more fully developed at birth given the amount of time they spend *in utero*. Humans have a longer length of gestation (38–40 weeks) than chimpanzees (32 weeks) and gorillas (37 weeks); however, human infants are behaviorally more altricial at birth compared to other primates. Whereas chimpanzees are born with brains that are about 40% of their adult brain size, humans are born with brains less than 30% of their adult brain size (DeSilva and Lesnik, 2006). Human infants are born helpless, highly dependent, and require prolonged care from mothers and others (Hrdy, 2000, 2009).

Birth cuts short the period of prenatal development. Some have argued that the timing of birth is an evolutionary trade-off made necessary by pelvic changes associated with obligate bipedalism and an enlarged brain (Krogman, 1951; Lovejoy, 1981; Rosenberg and Trevathan, 2002; Trevathan, 2010). The changes to the pelvis and cranial capacity relevant to birthing date to about 2 million years ago (Langdon, 2005); however, the true conflict between pelvic morphology and encephalization occurred much more recently, probably during the last few hundred thousand years (Weaver and Hublin, 2009). Natural selection favored a shorter gestation and less developed offspring in order to accommodate the passage of a big-brained neonate through a pelvis modified for locomotion and heat dissipation (Weaver and Hublin, 2009).

Other investigators have addressed the uniqueness of long gestation coupled with slow intrauterine development with a focus on the trade-offs associated with fetal demands and maternal metabolic load (Ellison, 2001). Life history theory suggests that energetic considerations constrain how large a fetus can grow before its energetic needs cannot be met within the mother's body (Martin, 1996; Peacock, 1991). Dunsworth *et al.* (2012) note that, although human brains are small at birth compared to their adult brain size, relative to other primates the human neonatal brain is larger than expected after controlling for the relationship between neonatal brain size and mothers' body size. In other words, there is more maternal investment than expected up to the point at which maternal metabolic constraints limit maternal support. By 9 months, the metabolic demands of the fetus threaten to push maternal energy requirements beyond the mother's metabolic capacity.

During her lifetime, a woman has a finite quantity of energetic resources that she can allocate to reproduction. By limiting the length of gestation, she can allocate resources to more offspring, increasing her lifetime reproductive success (Peacock, 1991). Of course, the developing fetus might wish for a little more time *in utero*.

Infancy

The parent–offspring conflict that starts in gestation continues in infancy. 'Parent–offspring conflict' describes the trade-off between parental investment that benefits a particular offspring and the cost of that investment to the parent and the parent's ability to invest in other offspring (Trivers, 1974). The length of gestation is a species-level compromise between the human mother and her fetus. Life history theory points to the duration of breast-feeding as another point of potential conflict between mother and child. Related to breast-feeding is the question of when mothers should get pregnant again (i.e., what is the human interbirth interval?)

The determination of how long women should breast-feed is complicated by human culture. For example, the Quran instructs women to breast-feed for 2 years (Al-Jassir *et al.*, 2006). The World Health Organization advocates exclusive breast-feeding for up to 6 months, and supplemented breast-feeding for up to 2 years or beyond. Dettwyler (1995) addressed the question of how long humans should breast-feed with a comparative approach across species and across cultures. She found that humans in traditional cultures breast-feed for 2 to 5 years, and chimpanzees breast-feed for 4 to 5 years. After examining a variety of allometric relationships across primate species (e.g., age at weaning in relation to gestational length, birth weight, and eruption of the first permanent molar), Dettwyler argued that the hominin 'blueprint' for breast-feeding is between 2.5 years and 6 years of age. She suggests that the wide range of variation is due to the variety of ecological conditions to which early hominins adapted, the influence of cultural norms, the ability to process food that infants can eat, and the hominin capacity for social support.

High maternal metabolic investment in breast-feeding constrains the energy available to support a new pregnancy (Ellison, 2003). This results in a period of lactational amenorrhea, during which ovarian function is suppressed. The length of time spent in lactational amenorrhea varies across populations and is associated with breast-feeding intensity, energy availability, and maternal workload (Valeggia and Ellison, 2001). The resumption of ovulation has a direct impact on the interbirth interval and lifetime reproductive success.

It is in the interest of the infant to gain as much nutritional and immunological benefit from breast-feeding as possible, for as long as possible. There is, however, a point at which it is in the interest of the mother to allocate energy to subsequent offspring. The interbirth interval is about 4 years in gorillas and about 5 years in chimpanzees (Harvey and Clutton-Brock, 1985; Knott, 2001). Humans have a faster fertility rate than apes and can conceive every 2 years. Walker *et al.* (2008) suggest that more energy is available for rapid reproduction in humans due to slow offspring growth and social assistance in provisioning.

Childhood and Adolescence

Childhood is defined as a period of postweaning dependency, from approximately 3 to about 7 years of age. It is characterized by slow and steady growth, with a high percentage of energy devoted to the growth and development of the brain. Bogin and Smith (2012) argue that human childhood is characterized by immaturity in a suite of features related to growth, dentition, and cognition. They suggest that human children remain dependent on their caretakers to a degree unique among mammals because of their need for a low-volume diet dense in energy, lipids, and proteins. Human children do not have the appropriate dentition, or the motor

and cognitive skills necessary to prepare such food for themselves. By the end of childhood, brain growth is complete and children are able to find, process, and eat adult foods.

Around the ages of 6 to 8 years, there is a slight acceleration in growth velocity and adrenarche occurs. Adrenarche is associated with a prepubertal increase in circulating adrenal androgens, DHEA and DHEAS. The slight acceleration in growth appears to be unique to humans (Bogin and Smith, 2012), although adrenarche occurs in great apes and may occur in other primates as well (Conley *et al.*, 2012). In humans, increased DHEAS production continues into the 20s and may promote brain maturation, learning, and the acquisition of skills (Campbell, 2006, 2011).

A juvenile stage, characterized by very slow growth, occurs between childhood and adolescence. In human females, this occurs between about 7 and 10 years of age and lasts for another 2 years in males (Bogin and Smith, 2012). This period may be especially important for social learning.

Adolescence begins with the hormonal changes associated with puberty. Adolescence in girls is characterized by breast development, increased pubic hair, development of the external genitalia, sexual dimorphism in body shape and composition, and the adolescent growth spurt. The first menstrual period (menarche) occurs on the downside (end) of the growth velocity curve. Following menarche, gorilla, chimpanzee, and human females have a period of adolescent subfecundity that lasts for about 2 years (Knott, 2001; Wood, 1994). In boys, adolescence is characterized by an increase in pubic hair, facial hair, development of the external genitalia, sexual dimorphism in body shape and composition, and a deepening of the voice. These changes occur on the upside (at the beginning) of the adolescent growth spurt. The pubertal growth spurt is unique to humans (Bogin, 1999; Bogin and Smith, 2012).

Relative to other primates, humans spend a long period of time between infancy and the onset of puberty, and another long period of time between puberty and first birth. The delay between puberty and parenthood is less than 3 years in monkeys and apes, but about 10 years in humans (Bogin and Smith, 2012). Life history theory provides a commonly accepted explanation for the timing of the adolescent growth spurt: energy is directed to the development of the brain during infancy and childhood, to somatic growth during adolescence (Campbell, 2006; Gluckman and Hanson, 2006), and finally to reproduction during adulthood (Trevathan, 2010).

Trade-offs in the allocation of energy are particularly visible in the relationship between female stature and reproductive success. Growth and reproduction are both energetically costly, and a woman's final height is partly determined by when the body stops directing energy to growth and starts to allocate energy to reproduction (Sear, 2010). In environments where energy is not consistently available, children have the option of growing faster during periods of plenty, or growing for a longer period of time. As Sear (2010) points out, both 'growing fast' and 'growing longer' are associated with reproductive costs. Growing for a longer period of time delays the start of reproduction which may mean fewer offspring overall. On the other hand, it is disadvantageous for a woman to enter the reproductive stage too early. The pelvic dimensions do not reach their maximal size until several years after menarche (LaVelle, 1995), and, when energy is shifted from growth to reproduction, shorter height is associated with lower reproductive success (Nettle, 2002).

Much attention has been given to variation in age at menarche, and human biologists are in agreement that there has been a secular trend toward an earlier age at menarche since the turn of the twentieth century (see Eveleth and Tanner (1990) for a classic summary). A more provocative idea has been put forward by Gluckman and Hanson (2006). They suggest that menarche occurred between the ages of 7 and 13 in Paleolithic times. They base this on the earlier age of puberty experienced by chimpanzees (6 to 9 years), and on estimates of life expectancy at birth for Neolithic humans corrected for the likelihood of maternal mortality, childhood mortality, probable interbirth interval, and a 1% population growth per generation. They propose that human females evolved to enter puberty at a relatively young age, but with the transition to agriculture about 10 000 years ago the average age of menarche was delayed due to childhood disease and postnatal undernutrition. Delayed menarche was a good match for the need to learn how to function socially in an increasingly complex society; however, with modern hygiene and improved nutrition, the constraints on puberty were removed and age at menarche now occurs at earlier ages. This has resulted in a mismatch between physiological and psychosocial maturation in contemporary adolescents (Gluckman and Hanson, 2006).

Adulthood and Reproduction

In life history theory, the function of adulthood is the same in all mammals. Adulthood is a time of reproduction: finding mates, defending mates, pregnancy, lactation, provisioning, and protecting offspring. Although humans are rapid reproducers relative to chimpanzees and gorillas, humans are similar to monkeys and apes in their focus on the quality of their offspring.

During adulthood, the trade-off between reproduction and somatic maintenance becomes a salient feature of life history as females outlive males. Human biologists who focus on the reproductive ecology of males have been particularly interested in how androgens (e.g., testosterone) influence somatic, reproductive, and immune metabolisms. The same hormone that contributes to male success in competition for mates (e.g., bigger muscles) comes with a cost of compromised immune function. There is a trade-off between reproductive effort and survivorship (Bribiescas, 2001; Muehlenbein and Bribiescas, 2005). Although females regularly outlive males, they do not complement their longer lives with continued reproduction.

Menopause and Post-Reproductive Life

Human females are not unique in their capacity to outlive their ability to reproduce (Cohen, 2004; Ward *et al.*, 2009). Among primates, a longitudinal study of Japanese macaques found that reproduction ceased after the age of 25; however, only 3% of the monkeys lived to the age of 26 (Pavelka and

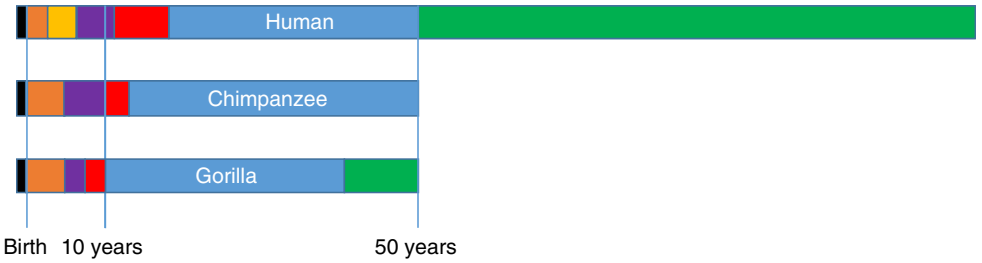

Figure 1 Gestation, infancy, childhood, juvenile period, adolescence, adulthood, post-reproductive period to maximum potential life span. Proceedings of the National Academy of Sciences of the United States of America 110, 13440–13445. Maximum longevity based on Atsalis, S., Margulis, S.W., 2008. Perimenopause and menopause: Documenting life changes in aging female gorillas. Interdisciplinary Topics in Gerontology 36, 119–146.

Fedigan, 1999). Among gorillas and chimpanzees, the completion of fertility is not universal before death (Alberts *et al.*, 2013; Atsalis and Margulis, 2008; Emery Thompson *et al.*, 2007). In contrast, women in hunting/foraging groups without access to modern healthcare universally demonstrate a capacity for menopause and long post-reproductive life (Alberts *et al.*, 2013; Hawkes, 2004; Hawkes and Blurton Jones, 2005). It is post-reproductive longevity, rather than menopause, that sets humans apart from other primates in the latter part of the life span (see **Figure 1**). Hominin longevity most likely exceeded 50 years of age more than 1 million years ago (Smith, 1991), and fossil remains from Paleolithic Neanderthals and early *Homo sapiens* suggest that 10% to 24% of the population survived beyond the age of 40 years (Kennedy, 2003; Trinkaus, 1995, 2011).

Anthropologists have argued that menopause may have been selected for to ensure that old eggs are not fertilized (Hrdy, 2000), or to ensure that mothers are young enough to survive pregnancy, delivery, and the infancy of their offspring (Hill and Hurtado, 1991; Peccei, 2001; Pavard *et al.*, 2008). The 'grandmother hypothesis' is probably the best known argument for the evolution of menopause and post-reproductive longevity. This hypothesis asserts that post-reproductive grandmothers provide care and food for their grandchildren (Hawkes, 2004; Scelza, 2009; Sear *et al.*, 2000), and increase their own inclusive fitness by investing in their daughters' fertility and their grandchildren's survival rather than continuing to produce children of their own.

There is ethnographic and historical support for the idea that menopause and post-reproductive aging were selected for by the evolutionary benefits gained through grandmothering (Lahdenperä *et al.*, 2004). However, not all studies have shown positive effects of maternal grandmothers, or of paternal grandmothers, or grandfathers on the survival of grandchildren (Gibson and Mace, 2005; Jamison *et al.*, 2002; Madrigal and Meléndez-Obando, 2008; Voland and Beise, 2002).

Some anthropologists argue that menopause is a type of antagonistic pleiotropy. Waves of developing follicles are needed to produce hormones during pre-reproductive life and the reproductive period. However, this pattern of follicular development and degeneration results in the exhaustion of ovarian reserves because we are a long-lived species (Wood *et al.*, 2001). Menopause can also be understood as the by-product of the highly conserved mammalian pattern of oogenesis and follicular atresia coupled with a lengthened life span (Sievert, 2011).

The lengthened life span, for both males and females, is associated with senescence. From an evolutionary perspective, human senescence has been explained by three (not mutually exclusive) theories. The disposable soma theory follows the tenets of life history theory by proposing that energetic resources are limited and must be allocated for growth, maintenance, and/or reproduction (Kirkwood, 1977). Once growth has finished, natural selection favors investment in reproductive success; however, with increasing age there is a loss of reproductive potential. As reproductive potential declines, natural selection loses its strength. For example, there is less pressure to repair degeneration in somatic tissues. Natural selection allocates energy to reproduction at the expense of somatic maintenance and, with increasing age, senescent changes begin to emerge (Rose, 1991).

The second theory of senescence suggests that deleterious mutations that act late in life are not selected against because most of our ancestors who carried the mutations died at an earlier age from environmental hazards (Medawar, 1946). As a result, deleterious alleles accumulate within populations, and when life spans lengthen the accumulated late-acting deleterious mutations are expressed. The visible effect of late-acting deleterious mutations is senescence.

Finally, Williams (1957) proposed that some genes could have beneficial effects early in life, but detrimental effects late in life. Because the effects are counteracting, the theory is called 'antagonistic pleiotropy.' Testosterone activity in men is

one example of antagonistic pleiotropy because testosterone contributes to secondary sex characteristics, the regulation of puberty, and reproductive success early in life. These are positive effects. Unfortunately, this same hormone may contribute to the risk of prostate cancer and cardiovascular disease later in life (Bribiescas, 2006). As a theory for aging, antagonistic pleiotropy has gained traction recently due to the increasing popularity of evolutionary medicine (Trevathan *et al.*, 2008; Williams and Nesse, 1991). Antagonistic pleiotropy has been used to explain many aspects of human physiology that may be beneficial early in the life span, but deleterious later on.

In Conclusion

Evolutionary theory contributes an understanding of how natural selection shaped species-level patterns of life history within particular environmental contexts. Life history theory focuses on energy appropriation. Every question about the human life span, from length of gestation to reproductive senescence, is approached from the perspective of the kinds of trade-offs that occur when energy is finite (Trevathan, 2010). Humans are developmentally immature at birth, in spite of a long gestation, because of maternal physical and metabolic constraints. Although humans have evolved to breast-feed offspring for as long as 6 years, there is a trade-off between continuing to nourish individual offspring and producing more offspring quickly. Human brains grow during infancy and childhood, and then energy is directed toward an adolescent growth spurt and growth of the body. Energy is then allocated to reproduction during adulthood, at times at the expense of immune function and somatic maintenance.

This article of human life history has been done with very broad brush strokes. There are certainly finer details to be examined in the application of life history theory to ovarian sensitivity in response to specific ecological and energetic constraints (Ellison *et al.*, 1993), the early biological responses of offspring to variation in maternal conditions (Gluckman and Hanson, 2006; Hales and Barker, 2001; Kuzawak, 2008), and population-level variation in ages at menarche and menopause (Eveleth and Tanner, 1990; Sievert, 2006).

Hybrid Speciation

BA Counterman, Mississippi State University, Mississippi State, MS, USA

Glossary

Allopolyploid speciation Hybridization of two different species that results in the origin of a new hybrid species that has double the chromosome complement of the progenitor species.

Cytotypes It is a characteristic of the cell, referring to variations in chromosome number and genome structure.

Dosage compensation It is equalization of gene expression in males and females, which differ in the number of sex chromosome copies.

Gametic imbalance An imbalance of the nuclear and cytoplasmic sizes (nuclearcytoplasmic ratio) that can interfere with proper cell division during meiosis.

Genetic incompatibilities A failure of the interaction between genes from different parents required for proper function.

Homoploid hybrid speciation (HHS) Hybridization that results in the origin of new hybrid species without a change in chromosome number (ploidy).

Hybrid swarm It refers to a population of hybrids generated by multigenerational intercrossing between hybrids and parental types or species.

Incomplete lineage sorting (ILS) When same allelic variants at a locus are inherited by two or more lineages (e.g., species) from a common ancestor it is called incomplete lineage sorting.

Magic trait Traits under divergent selection that also influence nonrandom mating.

Minority cytotype exclusion It refers to the loss of low frequency cytotypes, such as polyploids, due to swamping out effects of the more common cytotype.

The concept of hybridization being involved in the origin of new species has a long history that began with Linnaeus in 1744 (Rieseberg, 1997). Over the past couple hundred years, the importance of hybridization in adaptive evolution has become clear and evident, as seen in numerous hybrid, domesticated plants and animal strains. The potential for hybridization to produce offspring that have a higher fitness than their progenitors and has been championed as a major force in adaptive radiations (Rieseberg *et al.*, 1999; Seehausen, 2004). If hybridization can have such a major influence adaptive divergence, then surely hybridization could also influence the evolution of reproductive isolation between the hybridizing groups. More importantly, can hybridization result in the origin of a new species, and if so, how often does this happen in nature?

What Is Hybrid Speciation?

Hybrid speciation can be broadly defined as the hybridization between two or more distinct lineages that contributes to the origin of a new species. More specifically, hybridization must result in a hybrid population that is at least partially reproductively isolated from the parental species. Recently, three criteria were established to demonstrate hybrid speciation: (1) there must be evidence of hybridization between species, (2) the hybrids must be reproductively isolated from the parental species, and (3) there should be evidence that hybridization is the cause of the isolation (Schumer *et al.*, 2014). Studies of potential examples of hybrid speciation in nature and the lab over the past 100 years have shown that there are several ways that hybridization can lead to origin of a new hybrid species.

The most well-known route to hybrid speciation is through the doubling of chromosome numbers in hybrids (allopolyploidy), so hybrids have twice the number of chromosomes as their parents. These allopolyploid hybrids can be reproductively isolated from the progenitor species that have a different ploidy, due to improper chromosome pairing during meiosis (Grant, 1981) and genetic incompatibilities between the hybridizing genomes (Abbott *et al.*, 2013). Therefore, the doubling of chromosomes offers a rapid route to hybrid speciation. Examples of allopolyploidy provide some of the clearest evidence of hybrid speciation, since the increased ploidy of hybrids resulting from hybridization directly causes reproductive isolation.

Hybrid speciation can also occur with no change in chromosome number, which is referred to as homoploid hybrid speciation (HHS) (also known as recombinational speciation, see Grant, 1981). In HHS, viable, true-breeding hybrids evolve that are reproductively isolated from the parental species. Homoploid hybrids do not have the advantage of being immediately isolated from the parent species, like allopolyploids do. Therefore, HHS requires the evolution of reproduction isolation while gene flow is ongoing with the parental species, which may explain why HHS is unlikely or more difficult to demonstrate than allopolyploid hybrid speciation (Barton, 2001; Coyne and Orr, 2004).

It is also important to understand what hybrid speciation is not. Hybrid speciation is not simply the production of F1 or backcross offspring between distinct species, as it requires the establishment of a third, distinct species. Therefore, interspecific hybrids such as ligers and geeps, which are sterile like mules and cannot persist beyond a single generation, are not examples of hybrid species. Similarly, hybridogenesis, a reproductive strategy that involves backcrossing between hybrids and a parental species with different ploidy (as seen in edible European frog *Rana esculenta* (Tunner and Nopp, 1979)), does not qualify as hybrid speciation since the hybrids are

 doi:10.1016/B978-0-12-800049-6.00072-X

obviously not reproductively isolated from the parental species. Additionally, hybrid speciation should also be considered distinct from reinforcement where natural selection against deleterious hybridization drives the evolution of increased reproductive isolation. Although reinforcement involves both hybridization and speciation, it does not necessarily involve the origin of a new, hybrid species.

The concept of hybrid speciation may seem counter-intuitive to some. If species are defined as reproductively isolated groups, then by definition, hybridization should not occur. Hybrid speciation requires that the reproductive barrier between the parental species is either incomplete or has been lost, so that hybridization can occur. When considering hybrid speciation, it may be more useful to define species as distinguishable groups of individuals with clusters of shared genotypes that remain distinct in the face of gene flow (Mallet, 1995). Importantly, this definition, referred to as the Genotypic Cluster Species Concept, acknowledges that divergence and speciation can occur even with hybridization and gene flow.

Theory and Background

Hybridization has long been considered an opposing force to the speciation process. Hybridization and the subsequent mixing of genetic variation among sexually reproducing organisms was thought to most often result in 'despeciation,' the collapse of the two species into a single lineage. Even worse, the hybrids themselves often suffered developmental, physiological, and behavioral abnormalities that made them less fit than the parental species, suggesting at best they may be mere 'hopeful monsters' (Dittrich-Reed and Fitzpatrick, 2013). These preconceptions made it difficult for many to envision that hybridization could have a positive impact on the speciation process. However, it was the rediscovery of Mendel's 'Experiments in Plant Hybridization' by Hugo de Vries, Carl Correns, William Jasper Spillman, Erich von Tschermak that rekindled interest in the question: can hybridization lead to the origin of a true-breeding hybrid lineage? Tschermak was particularly intrigued by the 'hybrid vigor' phenomenon, where many of his experimental crosses that involved 'foreign pollen' yielded offspring with greater fitness than either parent (Tschermak, 1902). Would it not be possible for these vigorous hybrids to persist as their own distinct species? In 1914, John Gerould formally hypothesized that species may be 'built' through hybridization, based on a review of breeding experiments in several insects (Gerould, 1914). Over the past 100 years, we have established theoretically and empirically that under certain conditions hybrid species may frequently evolve in both plants and animals.

Allopolyploid Speciation

The major advantage of alloplyploids, and perhaps why it is the more common form of hybrid speciation, particularly in plants, is the instantaneous postzygotic isolation from the parental species due to the differences in ploidy. However, allopolyploid hybrids still have major hurdles to overcome in order to persist. When the hybrids and parent species continue to hybridize, the rare cytotypes will rapidly be lost, a well-known phenomenon called "minority cytotype exclusion" (Levin, 1975). Therefore, the allopolyploids will often rapidly go extinct, if there is no isolation from the parental species.

There are two factors that can enable an allopolyploid species to persist: pre-zygotic isolation and ecological divergence. Pre-zygotic isolation can alleviate the risk of extinction, and allow the hybrids to breed true. Polyploid plants and insects are often larger and more robust than their diploid parents, which could result from larger cells and slower development in polyploids (Levin, 2002, 1983; Otto and Whitton, 2000). It is possible that increased ploidy can confer rapid pre-zygotic isolation and ecological divergence, due to the physical change in cell sizes (the 'gigas effect'). Interestingly in plants, flowering time asynchrony and pollinator shifts are often associated with changes in ploidy, which may reflect the slower development associated with larger cells (Ramsey and Schemske, 2002; Levin, 1983, 2002). Similarly, the larger allopolyploid cells of the hybrid gray tree frog, *Hyla verisicolor*, appears to directly impact their mating call, thereby isolating the hybrids from the progenitors (Keller and Carl Gerhardt, 2001). Ecological divergence can also provide the isolation necessary for a hybrid species to persist in the presence of its progenitors. Hybridization can often generate hybrid genotypes that can persist in certain environments that their progenitors are disadvantaged, which could be an effective ecological barrier that facilitates hybrid speciation (Barton, 2001; Rieseberg, 1997).

Homoploid Hybrid Speciation

The traditional model of HHS, formalized by Stebbins (Stebbins, 1950) and Grant (Grant, 1981) (referred to as 'recombinational speciation'), involves chromosomal rearrangements between progenitor species that typically cause low fertility in F1 hybrids. Hybridization results in chromosomal deficiencies and duplications that confer low F1 fertility. However, through hybridization and recombination, novel 'genetically balanced' genotypes with recovered fertility can form. These viable hybrids can mate with each other, but are intrinsically isolated from the parental species, since there is gametic imbalance between the hybrids and progenitors. Simulations of this model reveal that HHS is definitely possible if F1 hybrids are at least partially fertile, and that the chances of HHS are much higher when there are extended periods of hybridization and/or the organisms are self-reproducing (Mccarthy *et al.*, 1995). In addition, simulations that include extrinsic barriers, such as ecological barriers, showed that strong ecological selection greatly increased the chance of HHS (20% of simulations resulted in HHS) (Buerkle *et al.*, 2000), and that factors that contribute to ecological or intrinsic isolation can become quickly stabilized in a hybrid genome (Buerkle and Rieseberg, 2008), demonstrating that ecological barriers can be a major factor in the establishment of a hybrid species.

There are two models of HHS that have been described, which involve quite different evolutionary processes and genomic signatures: *mosaic genome hybrid speciation* and *hybrid trait speciation* (Jiggins *et al.*, 2008; **Figures 1(a)**, **1(b)** and

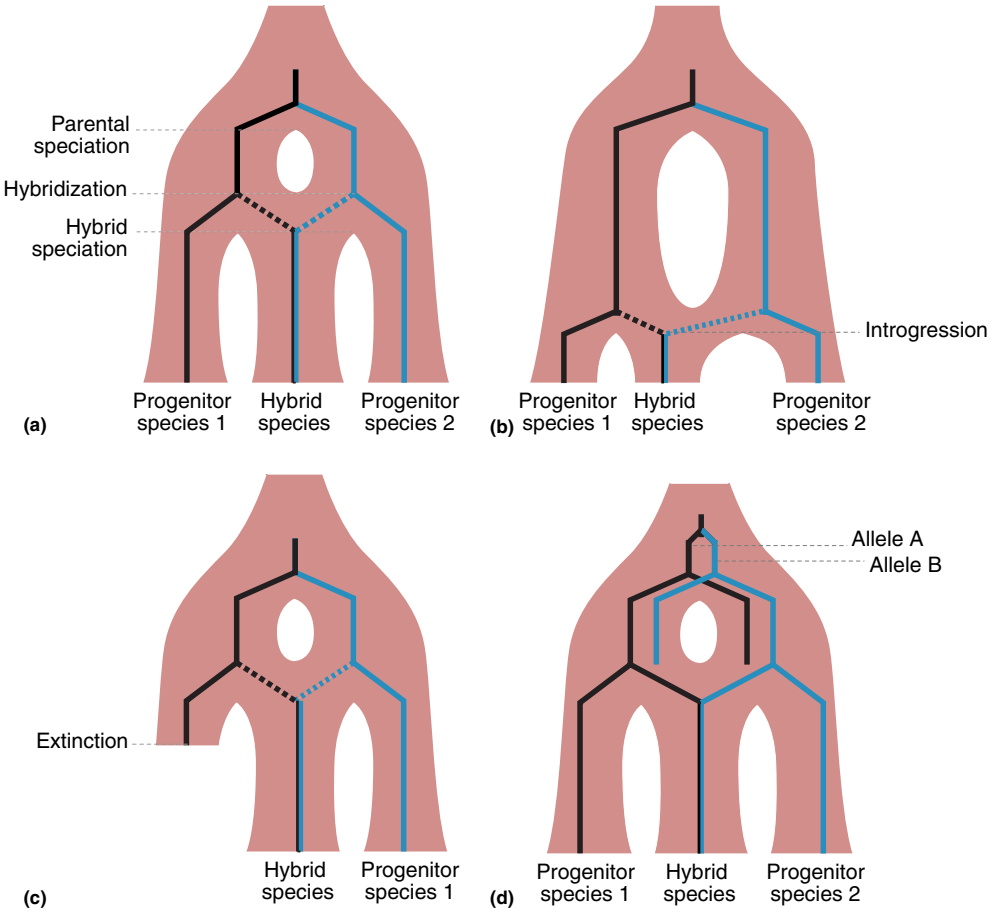

Figure 1 Paths to hybrid speciation. For each panel, shaded regions reflect the species tree, the solid lines reflect gene trees and the dotted lines reflect hybridization. (a) Classic form of hybrid speciation that can be generated through allopolyploidy or homoploid hybrid speciation (HHS) (e.g., mosaic genome hybrid speciation). (b) Hybrid trait speciation model with introgression from species 2 into a genomic background that is predominantly from species 1 (e.g., through repeated backcrosses) drives the origin of new hybrid species. (c) Demonstrates how extinction can prevent the inference of a hybrid origin. (d) Example of how incomplete lineage sorting (ILS) of A and B alleles from a common ancestor can generate similar patterns predicted from hybrid speciation.

Figure 2(a)). The mosaic genome hybrid speciation follows the traditional model discussed above, where a 'genetically balanced' hybrid species differs from its progenitor species at several loci that confer intrinsic reproductive isolation (e.g., hybrid sterility or inviability) and/or ecological divergence. The genomes of these hybrid species would be true mosaics of the parental genomes, although not necessarily with equal contributions from both parents. Hybrid trait speciation may be considered a more extreme case of HHS where introgression drives rapid ecological divergence *and* reproductive isolation. The key difference in this model is that introgression at only a single or few loci may be sufficient for hybrid speciation (Figures 1 and 2). The model posits that introgression of a so-called evolutionary 'magic trait' that influences both adaptive divergence and reproductive isolation can rapidly, if not instantaneously, lead to hybrid speciation. Importantly, hybrid trait speciation does not require intrinsic barriers and provides a model for ecological divergence to drive hybrid speciation that needs further exploration. These two models of HHS are not mutually exclusive; rather these models represent different ends of the spectrum when considering the patterns of hybridization that can drive HHS.

Evidence of Hybrid Speciation

Allopolyploid speciation is the most commonly known route to hybrid speciation. This is not surprising with 40–70% plant species being polyploidy. A review of ploidy in plants suggests that polyploidy was involved in speciation events of ~2–4% of flowering plants and 7% of ferns (Otto and Whitton, 2000). Perhaps the most familiar examples are the numerous allopolyploid crops that humans have domesticated (including wheat, cotton, tobacco, strawberry, and rapeseed). There are also multiple examples of recently formed allopolyploid species (<200 years old; for example, *Cardamina* (Mandáková *et al.*, 2013), *Mimulus* (Vallejo-Marin *et al.*, 2015), *Senecio* (Abbott and Lowe, 2004), *Spartina* (Ainouche *et al.*, 2004b), *Salsola* (Ayres *et al.*, 2009), and *Tragopogon* (Soltis *et al.*, 2004)), that have provided insights into the types of genetic changes

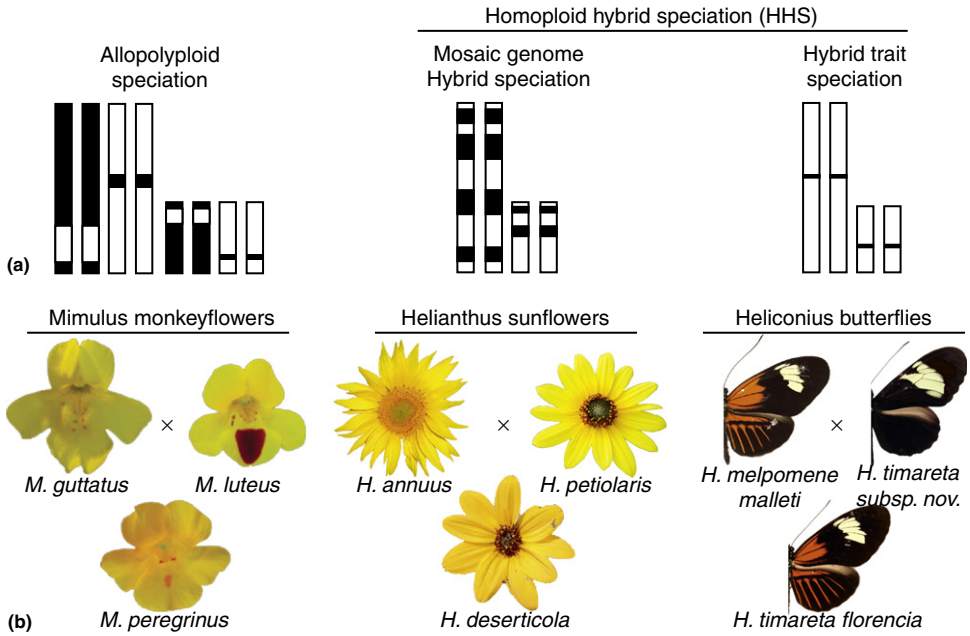

Figure 2 Examples of hybrid speciation. A genomic representation (a) and well-documented examples (b) of the three models for hybrid speciation.

involved in origin of hybrid species (Matyášek *et al.*, 2007; Lim *et al.*, 2008; Tate *et al.*, 2009; Ainouche *et al.*, 2004a; Salmon *et al.*, 2005, also see Soltis and Soltis, 2009 for a review).

Allopolyploid speciation appears to often involve hybridization of recently introduced, potentially invasive species, as seen in the *Mimulus* monkey flowers introduced to Scotland only 140 years ago (Vallejo-Marin, 2012; **Figure 2(a)**). Hybridization between *Mimulus guttatus* and *Mimulus luteus* in their native North American range results in sterile, vegetatively vigorous, triploid offspring. *Mimulus peregrinus* is found in Scotland where the two introduced species co-occur and is vegatatively vigorous like the triploid hybrids, but has twice as many chromosomes (polyploid) and is highly fertile (Vallejo-Marin and Lye, 2013; Vallejo-Marin, 2012). Population genomic sequencing of *M. peregrinus* confirmed the genome is mosaic from the two progenitors, and that allopolyploidy has independently evolved at least twice since the species introductions (Vallejo-Marin *et al.*, 2015).

In animals, allopolyploid speciation appears to be rare, since there is no overrepresentation of species with even-numbered chromosome counts (Otto and Whitton, 2000). In general, ploidy is uncommon in sexually reproducing animals, likely due to the presence of sex chromosomes and improper *dosage compensation*, the mechanisms that balances the gene products between the sexes, which can become unbalanced in polyploids (Orr, 1990). However, in the fishes polyploidy is very common and appears to have evolved repeatedly (Leggatt and Iwama, 2003). The repeated origin of polyploidy and frequent hybridization among polyploid fish in nature suggests allopolyploidy may be more common in fish than other animals. As expected, most allopolyploid examples in animals are often parthenogenetic or self-reproducing such as stick insects (*Bacillus*) and freshwater snails (*Bulinus truncatus*) (Otto and Whitton, 2000). The allopolyploid gray tree frog with the distinct mating calls mentioned previously is also a clear example of a sexually reproducing allopolyploid, where the evolution of female preference for the hybrid call could quickly result in speciation. Perhaps the best evidence of allopolyploidy speciation in animals comes from laboratory strains of tetraploid hybrid silk moths (*Bombyx mori* × *Bombyx mandarina*) (Astaurov, 1969). These tetraploid hybrids were laboratory engineered using a 'triploid bridge' strategy that involves the fusion of rare, unreduced (diploid) gametes of one species with a normal haploid gamete of the other species to form a fertile tetraploid hybrid offspring. Although these hybrids are synthetically engineered and do not necessarily constitute a distinct species, this example demonstrates a possible route to allopolyploidy in animals.

Similar to allopolyploidy, HHS has been more commonly reported in plants than animals. However, the number or putative hybrid species has dramatically increased across a broad range of organisms that demonstrate the many routes to hybrid speciation, such as: chromosomal rearrangements in hybrid yeast species (Greig *et al.*, 2002), host-choice shift in hybrid honeysuckle-maggot flies (*Rhagoletis*) (Schwarz *et al.*, 2005), the outperformance of intermediate hybrid cyprinid fish (*Gila seminude*) in the Virgin River (Demarais *et al.*, 1992), the invasion of hybrid sculpin fish (*Cottus gobio* group) in the murky waters of the Rhine River (Nolte *et al.*, 2005), host plant divergence and altitudinal differences in intermediate hybrid alpine butterflies (*Lycaeides*) (Gompert *et al.*, 2006; Nice *et al.*, 2013), the allopatric establishment of hybrid daisies on the British Isles (*Senecio squalidus*) (James and Abbott, 2005), the hybridization-derived 'swordtail' mating signals in *Xiphophorus* (Schumer *et al.*, 2013; Meyer *et al.*, 2006), the introgression of wing color mating cues in hybrid *Heliconius* butterflies (Sanchez *et al.*, 2015; Salazar *et al.*, 2010), the sorting of genetic incompatibilities and plumage-based mate choice in the

hybrid Italian sparrows (Hermansen *et al.*, 2014; Bailey *et al.*, 2015), and the establishment of rock-edge adapted, genotypic hybrid *Penstemon clevelandii* in Southern California (Straw, 1955; Wolfe *et al.*, 1998).

In plants, there are over 20 well-documented examples of HHS (Rieseberg, 1997; Gross and Rieseberg, 2005), with the best evidence coming from multiple hybrid species of desert sunflowers (*Helianthus*). Hybridization between the common sunflower (*Helianthus annuus*) and the prairie sunflower (*Helianthus petiolaris*) lead to the establishment of at least three desert-adapted homoploid hybrid species: *Helianthus anomalus* (Ungerer *et al.*, 1998), *Helianthus deserticola* (Gross *et al.*, 2003), and *Helianthus paradoxus* (Welch and Rieseberg, 2002; Rieseberg *et al.*, 2003a; **Figure 2 (b)**). The *transgressive segregation* of variation from the two parental species resulted in individuals with a mosaic genomic makeup and 'hybrid vigor' that allowed them to persist in extreme environments where the progenitors could not, which appears to be a common result of hybridization (Rieseberg *et al.*, 1999, 2003b). Laboratory crosses were able to reconstruct the chromosomal arrangements and transgressive phenotypes found in the desert species (e.g., small leaf size, seed dormancy, and high drought and salt tolerance), which supports the predictions of the *mosaic genome hybrid speciation* model (Rieseberg *et al.*, 2003a; **Figure 2**). For these desert sunflower species, chromosomal rearrangements and ecological isolation appears to have been the key to their establishment (Gross *et al.*, 2007; Gross *et al.*, 2003; Gross and Rieseberg, 2005, 2004).

Heliconius butterflies, particularly the *Heliconius melpomene/cydno* species complex, provide one of the most thoroughly examined cases of HHS. *H. melpomene* and *H. cydno* are closely related, divergently colored species that geographically overlap in Central America and the northern Andes. In nature, they are isolated ecologically (i.e., divergence in larval host plant and adult food plant preferences) and altitudinally, as well as through hybrid F1 female sterility (reviewed in Jiggins, 2008). However, hybrid males are fertile and backcrossing facilitates introgression between the species (Salazar *et al.*, 2008). *Heliconius hueripa* is a putative hybrid species of *H. cydno* and *H. melpomene* that has an intermediate color pattern, comes into geographic contact with *H. melpomene* (Salazar *et al.*, 2005) and clusters phylogenetically in the *H. cydno* species complex (based on nuclear gene sequences and genome-wide markers) (Quek *et al.*, 2010; Flanagan *et al.*, 2004; Beltrán *et al.*, 2007). In the wild, *H. hueripa* is isolated from its progenitors by color pattern-based mate choice (Mavarez *et al.*, 2006). Surprisingly, the first-generation backcrosses that resemble *H. hueripa* also preferred mates with their own color pattern, suggesting at least partial reproductive isolation may be able to rapidly evolve in *Heliconius* hybrids (Melo *et al.*, 2009). A custom spatial, individual-based, multilocus evolutionary model was built to explicitly examine the likelihood of the HHS scenario for *H. hueripa* (Duenez-Guzman *et al.*, 2009). The model showed clear support for the possibility of a hybrid origin of *H. heuripa* when the initial hybridization is followed by an extended period of geographic separation from the progenitor species.

Genomic evidence suggests *H. huerripa* may be a hybrid trait species. Genetic mapping has identified the color pattern loci responsible for color pattern differences between *H. heurripa* and its progenitors. Population genomic analyses across these color pattern loci and neutral regions, uninvolved in color pattern variation, reveal a hybrid genomic makeup, with relatively few *H. melpomene*-derived alleles in a predominantly *H. cydno* background (Salazar *et al.*, 2010). At the color pattern loci, *H. hueurippa* is homozygous for the same *H. melpomene* and *H. cydno* allelic combinations that produced the *H. hueripa*-like color pattern in the laboratory backcrosses. Although the data thus far support HHS of *H.* hueripa (however, see Brower, 2012 for a critique), the observed mosaic genome makeup in *H. heurripa* could also result from the incomplete sorting ancestral variation (see **Figure 1(d)**). However, unlike most *Heliconius* color patterns, *H. heuripa* has a unique non-mimetic color pattern not found in any other *Heliconius* species, which makes it unlikely to have been an ancestral form. Further evidence comes from another member of the *H. cydno* species complex, *Heliconius timareta*, where genomic evidence suggests introgression of a novel wing color pattern, from the sympatric species *H. melpomene*, has resulted in a new reproductively isolated hybrid lineage of *H. timareta* that has melpomene-like color pattern (Dasmahapatra *et al.*, 2012). In the laboratory, backcross individuals with the reconstructed *H. timerata florencia* color pattern showed clear males clearly preferred to approach and court females with the same hybrid color pattern, providing an excellent case of hybrid trait speciation (Sanchez *et al.*, 2015; **Figure 2(b)**). Again, it appears that with only a few generations of crosses, hybridization and introgression of warning color patterns that also act as mating cues can result in the establishment of a homozygous, true-breeding hybrid lineage. These examples demonstrate the efficacy of 'magic traits' in evolutionary diversification and highlight the importance of hybridization during adaptive radiation.

Is Hybrid Speciation Important?

A corollary question to whether hybrid speciation is important is: how common is hybrid speciation? It is estimated that 25% plant and 10% of animal species hybridize (Mallet, 2005), providing ample opportunity for hybrid speciation. Polyploid speciation is rare in animals and explains about 2–7% of vascular plant species (Otto and Whitton, 2000). Potential cases of HHS are fewer, but reports have dramatically increased and there are now several likely examples in a broad range of plants and animals (Schumer *et al.*, 2014). However, a critical review of 'How common is HHS' suggests there are few examples with sufficient evidence to satisfy the three criteria for hybrid speciation, particularly the evidence of reproductive isolation required for criteria 1 and 3 (**Table 1**). Many factors likely contribute to there being so few examples, which has

Table 1 Proposed cases of HHS that meet the three criteria of Schumer *et al.*, 2014

	Criterion 1	*Criterion 2*	*Criterion 3*
No. of proposed HHS cases (fungal/animal/plant)	8 (2/4/2)	43 (8/22/13)	4 (0/1/3)
%	19%	100%	9%

likely resulted in a gross underestimation of the importance of hybrid speciation.

The greatest difficulty with HHS is that theoretically it seems unlikely to occur. The concern is that the hybrid lineage will be swamped out by backcrosses with the progenitor species, if isolation is incomplete. However, genomic studies have revealed that ecological divergence can be extremely effective at maintaining the species boundary, even in the face of gene flow (reviewed in Seehausen *et al.*, 2014). The role of ecological divergence in the establishment of hybrid species needs to be further explored, as this is a key step in most models of hybrid speciation and there are novel genotypes continuously being generated by hybridization to explore. Both theoretical developments and empirical examples demonstrate that hybrid speciation does occur, but also that there are conditions that greatly increase the chance of hybrid speciation occurring.

Evidence for the hybrid origin of a species will always be difficult, if not impossible, to attain. Perhaps the most obvious difficulty is extinction. If either progenitor species becomes extinct after the hybrid species becomes established and leaves no little or no fossil record, then it is very unlikely that anyone would hypothesize hybridization was involved in the divergence of the extant species (**Figure 1(c)**). Even with whole genome sequencing of the extant species it would be unlikely to be able to infer a hybrid origin, since the extinct progenitor would not have been sampled. The other major difficulty is distinguishing between genomic evidence of hybrid speciation versus the incomplete sorting of ancestral variation (referred to as incomplete lineage sorting, ILS; **Figure 1(d)**), since both could result in highly mosaic genomic compositions. Both of these processes will result in shared alleles between the putative hybrid and the parental species, however the species are expected to share a certain number of alleles by chance alone, simply because they share a recent common ancestor. One approach to this problem has been the development of phylogenetic models that can account for ILS when testing genomic evidence of hybridization (Yu *et al.*, 2013; Meng and Kubatko, 2009). Another difficulty is that there is only a limited window of evolutionary time that hybrid speciation is likely to be detectable. If there are too few differences between the progenitors and hybrids, then they may appear to be nothing more than a hybrid swarm. If there are too many differences and too few shared phenotypes, then a hybrid origin may never be hypothesized or tested. For these and many more reasons, the frequency of hybrid speciation in nature will always be underestimated, but the theoretical and empirical evidence suggests that the importance of hybrid speciation should never be underappreciated (Abbott *et al.*, 2013).

Inbreeding and Nonrandom Mating

PW Hedrick, Arizona State University, Tempe, AZ, USA

Glossary

Autozygosity The proportion of the genome that is homozygous because it is identical by descent.
Identical by descent Probability that the two homologous alleles in a diploid individual are derived from one particular allele possessed by a common ancestor of the parents.
Inbreeding Mating between relatives that results in an increased level of identity by descent in the progeny of the mating.
Inbreeding depression The detrimental effect on fitness due to increased inbreeding.
Lethal equivalents Group of genes that, when made homozygous, on average would cause $2B$ deaths.
Negative-assortative mating An increase in the frequency of mating between individuals with different phenotypes compared to random mating.
Positive-assortative mating An increase in the frequency of mating between individuals with the same or similar phenotypes compared to random mating.
Run of homozygosity Segment of genome that is autozygous based on homozygosity of a number of adjacent SNPs.

In much of population genetics, it is assumed that the individuals in the population choose mates by chance, that is, there is 'random mating' among the potential mates in the population including relatives. Here we will discuss two exceptions to this pattern, inbreeding and assortative mating, where there are deviations from this assumption. 'Inbreeding,' which is the result of mating between relatives greater than expected by chance, results in an increase of homozygotes and a decrease in heterozygotes throughout the genome. On the other hand, assortative mating, which is based on the tendency of particular phenotypes to mate, only influences the genes determining those phenotypes. We will discuss both 'positive-assortative mating,' an increase in the frequency of matings between individuals with the same or similar phenotypes compared to random mating, and 'negative-assortative mating,' an increase in the frequency of matings between individuals with different phenotypes compared to random mating.

Inbreeding

A major exception to random mating is when relatives mate and consequently their resulting progeny are inbred. For example, inbreeding in some plants is high when there is a high proportion of self-fertilization (both the female and male gametes come from the same parental individual). Small captive populations of endangered species often have high inbreeding because of past and present mating between related individuals. Inbreeding levels are generally low in human populations, where only a small proportion of matings occur between relatives, but in some societies first-cousin matings are the norm.

Inbreeding by itself does not cause a change in allele frequency, but it causes a reorganization of the alleles into genotypes. In a population that is inbred, the frequency of homozygotes is increased and the frequency of heterozygotes is reduced relative to random-mating (Hardy–Weinberg) proportions. The genotype changes caused by inbreeding are expected to equally influence all loci in the genome. However, the effect on genotype frequencies may be quite ephemeral if the mating system changes. For example, the excess frequency of homozygotes resulting from self-fertilization can be eliminated completely in one generation of random mating.

Inbreeding and genetic drift appear to have similar overall effects on heterozygosity when averaged over loci or over populations, but when examining a given locus within a population, the predicted effect is different. Inbreeding (such as self-fertilization in a large plant population) can result in a deficiency of heterozygotes with no change in allele frequency for a given locus within a population. On the other hand, genetic drift may cause a chance change in allele frequency at a locus but generally causes little or no deficiency of heterozygotes compared to Hardy–Weinberg proportions within a population.

The level of inbreeding is generally quantified by the inbreeding coefficient, f. The inbreeding coefficient is the

Table 1 The three different parent genotypes when there are two alleles and self-fertilization, the frequency of these genotypes in the population, and the frequency of the three types of progeny

Parent	*Frequency*	*Progeny*		
		A_1A_1	A_1A_2	A_2A_2
A_1A_1	P_0	P_0	–	–
A_1A_2	H_0	$H_0/4$	$H_0/2$	$H_0/4$
A_2A_2	Q_0	–	–	Q_0
Total	1	$P_0 + H_0/4$	$H_0/2$	$Q_0 + H_0/4$

Table 2 Several types of matings between relatives and the inbreeding coefficient in the offspring from the different matings

Mating	*Inbreeding coefficient (f)*
Self-fertilization	0.5
Full-sibling	0.25
Parent–offspring	0.25
Half-sibling	0.125
Uncle–niece or Aunt–nephew	0.125
First cousin	0.0625
Second cousin	0.0156

probability that the two homologous alleles in a diploid individual are 'identical by descent (IBD)' – that is, that they are derived from one particular allele possessed by a common ancestor. The proportion of the genome that is homozygous, because it is IBD, is called the level of 'autozygosity.' This concept can be illustrated with self-fertilization, the most extreme type of inbreeding generally found.

As shown in Table 1 with complete self-fertilization and two alleles, there are just three parental genotypes, A_1A_1, A_1A_2, and A_2A_2, and they occur in the relative proportions of the genotypes in the population before inbreeding, P_0, H_0, and Q_0, respectively. Allowing for segregation in the heterozygote, the proportions of the genotypes in the progeny generation are

$$P_1 = P_0 + H_0/4 \qquad H_1 = H_0/2 \qquad Q_1 = Q_0 + H_0/4$$

In the progeny from the heterozygous parent A_1A_2, half the progeny are IBD, either A_1A_1 or A_2A_2, and therefore the inbreeding coefficient after one generation of self-fertilization is $f=0.5$. Notice that due to the inbreeding, the frequency of heterozygotes is half what it was in the parents and the frequency of both the homozygotes are increased by $H_0/4$.

To illustrate that inbreeding does not change allele frequency, the frequency of allele A_1 in the next generation p_1 is the frequency of genotype A_1A_1 plus half the frequency of genotype A_1A_2 or

$$p_1 = P_1 + H_1/2 = (P_0 + H_0/4) + H_0/4 = p_0$$

A general formulation of the proportion of the three genotypes in a population with inbreeding level f is (Wright, 1931)

$$P = p^2 + fpq \qquad H = 2pq - 2fpq \qquad Q = q^2 + fpq$$

where the first term is the Hardy–Weinberg proportion and the second is the deviation due to inbreeding from that value. The size of the coefficient of inbreeding reflects the deviation from Hardy–Weinberg proportions of the genotypes such that when f is 0, the zygotes are in Hardy–Weinberg proportions, and when f is positive, there is a deficiency of heterozygotes. Because f as we have defined it here is a probability, it has a range from 0 to a maximum of 1 when all the individuals are homozygotes. Estimates of f can sometimes be less than 0, either due to chance or to the impact of other evolutionary factors.

Other matings between relatives also result in an increase in the inbreeding coefficient in their progeny (Table 2). For example, a mating between two full siblings and between a parent and an offspring (sometimes called first-degree relatives) result in an inbreeding coefficient of 0.25 in their progeny. A mating between two first cousins results in $f=0.0625$ in their progeny, a much lower level but one that results in an increase in the frequency of rare recessive diseases (see below).

Often, in captive populations of endangered species or in livestock breeds, there might be complicated pedigrees with multiple matings between relatives resulting in inbreeding. There are approaches, such as the chain-counting technique based on the count of the number of links between the two parents through a common ancestor, to calculate inbreeding in these cases. As an example of a more complicated pedigree, Figure 1 gives the pedigree of the wolves on Isle Royale National Park (Hedrick *et al.*, 2014).

In pedigrees, squares indicate males, circles indicate females, and in this wolf pedigree, the numbers in them indicate their studbook or identification numbers. When there are multiple individuals from a mating that cannot be identified, or it is not important to identify them, a diamond is used with a number that indicates the number in this group. In pedigrees, the oldest individuals are generally at the top and their offspring and later individuals are lower in the pedigree.

For example, in the wolf pedigree, male 93 and female 99 (considered founders in this pedigree) had 13 offspring (individuals 58, 70, 62, and 102, plus 9 additional offspring that are not identified individually here). After several years, female 99 died and male 93 subsequently mated with his daughter 58, a consanguineous (between relatives) mating that is indicated by a double line. The 21 offspring of this mating (individuals 135, 147, and 152, plus 18 others), all had inbreeding coefficients of 0.25. Two full sibs from this mating, 135 and 147, mated and the two progeny from this mating had an $f=0.375$ because inbreeding accumulated over two generations. The eight individuals alive in 2014 are indicated by shading and have inbreeding coefficients ranging from 0.0 for 160 (she has no known inbreeding in her ancestry) to 0.312 for 193, who is the offspring from a mother–son (160 and 183) mating, and the son 183 was himself inbred.

This example illustrates that IBD is always defined with respect to an ancestral population but this base population might be arbitrary (Powell *et al.*, 2010; Speed and Balding, 2015). For example, in the analysis of the wolf population, it was assumed that oldest animals born on Isle Royale, females 99, 55, and 67 and male 61 were unrelated (male 93 was an immigrant from Canada). However, if the base population and pedigree information were available more generations in the past, there was probably contemporary IBD from common ancestors in this older reference population as well as from recent matings.

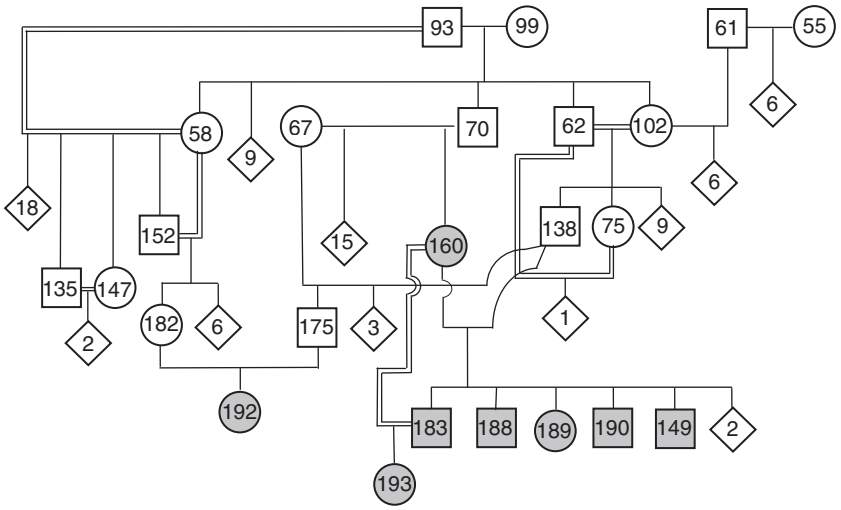

Figure 1 The pedigree of the Isle Royale National Park wolf population (Hedrick *et al.*, 2014).

Inbreeding and Selection

Because inbreeding increases the frequency of homozygotes, the frequency of rare, recessive diseases is increased in inbred individuals. For example, in a sample from Japan, approximately 5% of the marriages were between first cousins, but the proportion of first-cousin marriages among families with offspring having albinism was 10-fold higher, approximately 56%. In a European sample, approximately 2% of the marriages were between first cousins, but 20% of the marriages that had offspring with albinism were among first cousins.

To demonstrate the basis of this, we can compare the proportion of recessive homozygotes for a given inbreeding coefficient (Q_f) to that in a non-inbred population (where the frequency of recessive homozygotes is $Q=q^2$). The ratio of these two quantities is

$$\frac{Q_f}{Q}=\frac{q^2+fpq}{q^2}=1+\frac{fp}{q}$$

This ratio is very large for low allele frequencies (small values of q), as is generally seen for recessive diseases, and increases with the level of inbreeding. For example, when there is a first-cousin mating, $f=0.0625$ and $q=0.01$, the ratio above is 7.2. That is, there are more than seven times as many affected individuals in the inbred group as in the random-mating group, an excess similar to the differences discussed above for albinism.

Inbreeding also has a general detrimental effect on fitness and results in the decline of fitness due to increased inbreeding, called 'inbreeding depression' (Charlesworth and Willis, 2009). Although inbreeding depression seems to be a nearly universal phenomenon, the extent of inbreeding depression varies for different species and even for different populations of the same species, depending upon the evolutionary history of the population.

An example of inbreeding depression is in the Australian tree *Eucalyptus grandis*, which is used for timber production throughout the world. For a group of 28 progeny produced by self-fertilization from a single parental tree, the whole genome was sequenced (Hedrick *et al.*, 2016a). Overall, 9560 genes were heterozygous in the parent and were examined in the progeny group. As we have discussed above, it would be expected that 50% of these progeny would be homozygous (IBD) for these heterozygous loci, given that there was no selection. However, only 34% of these genes were homozygous in this progeny group, a deficiency that was present on all 11 chromosomes. **Figure 2** gives the observed proportion of the three genotypes for 1019 genes along chromosome 1 and except for a short region on the far right end of the chromosome, the proportion of heterozygotes is much greater than 0.5 and averages 70%. This effect appears to be the result of very strong selection at many genes, or genes associated with them, that cause high mortality when made homozygous by this one generation of self-fertilization.

To quantify the effects of inbreeding on survival, Morton *et al.* (1956) developed a model that assumes that the loci affecting survival act independently and multiplicatively. In this case, the fitness of individuals with inbreeding f becomes approximately

$$w_f=w_0e^{-Bf}$$

where w_0 and w_f are the mean fitnesses when there is no inbreeding or inbreeding to the level f. B is the regression coefficient that measures how fast fitness decreases with inbreeding; it is equal to 0 when there is no inbreeding depression. This expression can be solved to give the number of lethal equivalents as

$$2B=-\frac{2}{f}\ln\left(\frac{w_f}{w_0}\right)$$

The number of 'lethal equivalents' in a diploid zygote is defined as a group of genes that, when made homozygous, would on average cause $2B$ deaths. For example, if there is one lethal allele present as a heterozygote, there would be one lethal equivalent. Using data documenting the survival proportion for different inbreeding categories, investigators have used this relationship extensively to determine how much inbreeding depression is present in a number of different

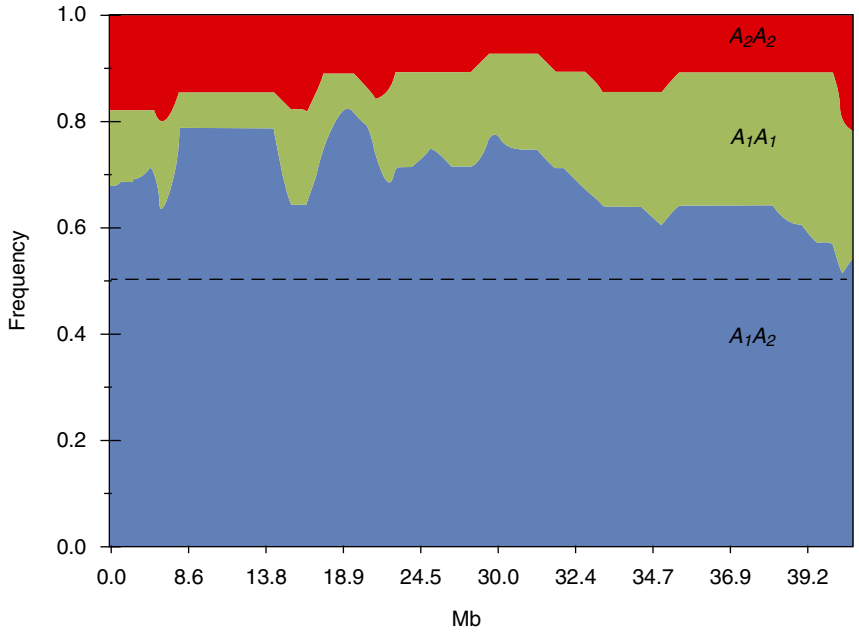

Figure 2 The frequency of heterozygotes A_1A_2 and homozygotes A_1A_1 and A_2A_2 in 28 progeny from a plant heterozygous for 1019 genes along chromosome 1 (location of genes given here are in Mb) in *Eucalyptus grandis* Hedrick *et al.*, 2016a). The broken horizontal line indicates the 50% heterozygosity expected.

species. In particular, this approach has been used to examine the amount of inbreeding depression for survival in a number of captive endangered species.

Arkush *et al.* (2002) determined the survival of outbred ($f=0$) and inbred (from brother–sister matings, $f=0.25$) endangered winter-run chinook salmon exposed to the whirling disease parasite. In this case, survival of the outbred salmon was 82.2% and survival of salmon from full-sib matings was only 59.4%. Using the expression above, then

$$2B = -\frac{2}{0.25}\ln\left(\frac{0.594}{0.822}\right) = 2.6$$

That is, the equivalent of two to three genes were segregating in the winter-run chinook salmon population that if IBD would result in mortality from whirling disease.

Assortative Mating

Assortative mating is nonrandom mating based on phenotypes rather than between relatives. Positive-assortative mating or negative-assortative mating occurs if the mated pairs in a population are composed of individuals with the same phenotype more often, or less often, than expected by random mating, respectively. Positive-assortative mating is in some ways analogous to inbreeding in that similar phenotypes, which might have similar genotypes, are more likely to mate than random individuals from the population. Some types of assortative mating are also similar to inbreeding in that they do not change allele frequencies but do affect genotype frequencies. On the other hand, negative-assortative mating may result in balancing selection and the maintenance of genetic variation. Many assortative mating models do change allele frequencies because the proportion of individuals in the matings differs from the proportion in the population. An important point to remember is that assortative mating affects the genotype frequencies of only those loci involved in determining the phenotypes for mate selection (and genotypes at loci nonrandomly associated with those loci), whereas inbreeding affects all loci in the genome.

In a survey of assortative mating studies, Jiang *et al.* (2013) found that most of the examples of assortative mating were for positive-assortative mating. There appears to be positive-assortative mating for a number of traits in humans, such as height, skin color, and intelligence, although the consequent phenotypic correlation is often not very large. In addition, there also appears to be positive correlations among mates in humans that have particular phenotypes, such as deafness, blindness, or small stature. Of course, there are many different genetic (and nongenetic) causes for deafness, blindness, or small stature so that such a phenotypic correlation may not result in a genetic correlation (for deafness, see Nance and Kearsey, 2004). Rather strong positive-assortative mating may occur in plants when a pollinator forages at a given height or is attracted to a given flower color and, as a result, tends to pollinate plants similar to the ones where the pollen was collected. Similar effects may also occur when flowering time is variable, and only plants that flower simultaneously pollinate each other.

Jiang *et al.* (2013) found few examples of negative-assortative mating in their review. Some examples are, however, in some plants where successful fertilization occurs only between individuals with different flower types. Although less generally accepted, another example is in populations where rare males (or females) have a mating advantage over more common types. Some reports suggest that negative-assortative

Table 3 The number of matings observed between gray and black wolves in Yellowstone National Park from 1995 to 2014 (Hedrick *et al.*, 2016b)

Mating		*Observed*	*Expected*	*Observed – Expected*
Male	*Female*			
Gray	Gray	54	71.0	−17.0
Gray	Black	67	50.1	16.9
Black	Gray	99	82.0	17.0
Black	Black	41	57.9	−16.9
Total		261	261	

mating in mammals and other vertebrates may be based on major histocompatibility complex (MHC) differences.

The overall support for MHC-based, negative-assortative mate choice in humans is mixed and contentious. The most widely known example is the 't-shirt study' in which female Swiss university students ranked the smell of t-shirts worn by male students on characteristics such as pleasantness (Wedekind *et al.*, 1995). The findings of this study suggested that females preferred the odor of males that differed at MHC genes, except when they were on birth control pills, in which case they preferred males that were similar at MHC genes! Further, a follow-up study examining some of the same pairs found no correlation between the rankings for the two different studies.

Several recent studies have examined the correlation of mates for MHC in humans compared to the correlation of genes in the rest of the genome. The first such study found a small but significant (partly due to high statistical power) negative correlation in 30 couples at the MHC region of −0.043 compared to the average in the rest of genome of −0.00 016 (Chaix *et al.*, 2008). However, this level of assortment appears small in a biological sense and nine other genomic regions had higher levels. Subsequently, Derti *et al.* (2010) concluded that the findings of Chaix *et al.* (2008) were not statistically robust and they found nonsignificant results in another small-sized, independent sample. These sample sizes appear much too small to draw inference about genomic assortative mating but a study underway of assortative mating in about 10 000 pairs using genome-wide SNP data (P. Visscher, personal communication) should give definitive estimates.

A striking example of negative-assortative mating is in wolves from Yellowstone National Park for gray and black coat color (Hedrick *et al.*, 2016b). Black coat color in wolves is caused by a dominant allele at a beta-defensin gene. In the surveys of mating pairs at Yellowstone from 1995 to 2014, 166 out of 261 (64%) of the matings were between different color wolves, either gray males × black females or black males × gray females (**Table 3**) with a significant negative correlation of −0.27.

Future for Inbreeding

The major change in population genetics in recent years is the advent of genomic data (around tens of thousands of SNPs or more) in many organisms to accurately document factors important in population genetics. In particular, genomic estimates of the level of inbreeding have enabled a higher degree of resolution, a topic that we will discuss here. In addition, genomic estimates have begun to identify genes that result in inbreeding depression and genes involved with assortative mating, developments that will bring new detailed information for those areas. For example, estimates of genomic inbreeding appear to predict inbreeding depression for a number of traits in humans (Joshi *et al.*, 2015).

Traditionally, the use of pedigree data to estimate inbreeding (f_{PED}) has been thought to be the best approach. However, relatedness and inbreeding of pedigree founders and the limited depth of most pedigrees can result in an underestimation of actual inbreeding levels when pedigrees are used. The estimation of inbreeding using genomic data can potentially overcome these problems and provide more information in many situations (Keller *et al.*, 2011; Kardos *et al.*, 2015). For example, if the homozygosity of many SNPs are determined, then an estimate of inbreeding is

$$f_H = \frac{O(\text{Hom}) - E(\text{Hom})}{N - E(\text{Hom})}$$

where O(Hom) and E(Hom) are the observed and expected numbers of homozygotes in an individual and N is the number of loci examined. This is actually the same as the fixation index

$$f_H = \frac{H_E - H_O}{H_E}$$

where H_E and H_O are the expected and observed frequencies of heterozygotes. This expression can also be derived from the expression for heterozygosity that we gave earlier for deviations from Hardy–Weinberg due to inbreeding, $H = 2pq - 2fpq$, assuming that $H_E = 2pq$.

Given genomically mapped data in a diploid individual, genetic regions in which there are 'runs of homozygosity (ROH)' can be identified. To indicate autozygosity, these ROH consist of a given number of homozygous, adjacent SNPs over a given number of Mb (Keller *et al.*, 2011). The inbreeding coefficient f_{ROH} estimated from these data is the total length of these ROH for a given individual divided by the total length of the examined genome, or

$$f_{ROH} = \frac{\sum L_{ROH}}{\sum L_{AUT}}$$

where the numerator is the sum of the lengths of all the ROH of a given size or larger and the denominator is the sum of the length of autosomal genome covered by the SNPs utilized.

Keller *et al.* (2011) and Kardos *et al.* (2015) provided the following reasons why such genomic estimates of inbreeding might be superior to estimates from pedigrees:

1. Genomic estimates, which directly measure the homozygosity in given individuals, can be more accurate than pedigree estimates. The pedigree estimate of inbreeding (f_{PED}) is the expectation of the inbreeding level for a given individual and there is a substantial variation among progeny from a given mating. For example, the percentage of the genome that is expected to be autozygous from a first-cousin mating is 6.25% but the standard deviation of this is 2.4% (Hill and Weir, 2011).

2. Genomic estimates incorporate autozygosity from distant common ancestors well beyond that given in most pedigrees which generally only go back a few generations. For example, Woods *et al.* (2006) examined 38 individuals that were the result of a first-cousin mating. Instead of having an average of 6.25% of their genomes IBD, they observed 11.0% IBD, a difference probably the result of other more distant common ancestors contributing to IBD. Further, because longer ROH are thought to be the result of more recent inbreeding (recombination has had few generations to break them up) and shorter ROH are more likely to the result of more distant common ancestors, the time to common ancestors can potentially be estimated.
3. Genomic estimates of inbreeding can be calculated in many organisms in which pedigree information is not available or the pedigree is only known for a few individuals or generations (e.g., f_H in harbor seals by Hoffman *et al.*, 2014 and ROH in wooly mammoths by Palkopoulou *et al.*, 2015). For estimation of f_H, the SNPs do not need to be mapped while for estimation of f_{ROH}, they do.
4. Genomic estimates of inbreeding when the SNPs are mapped can potentially be used to examine whether the level of estimated inbreeding is specific to particular regions of the genome or particular chromosomes. Comparison of such genomic data over different chromosomes and genomic regions and to pedigree expectations can provide insight into the impact of factors such as different types of selection, recombination, and mutation on genetic variation.
5. Genomic estimates can also avoid the problem of defining a reference population when working with the IBD probabilities. Further, precise genomic estimates of kinship and inbreeding among founders, or another cohort in later generations, can provide a baseline or a reference population from which to predict future kinship and inbreeding using traditional pedigree analysis.

Industrial Melanism, History of

DW Rudge, Western Michigan University, Kalamazoo, MI, USA

Glossary

Evolution Evolution refers to changes in the composition of a population over long periods of time that reflect an underlying change in the frequencies of genes within the population's genetic pool. Some evolutionary changes, such as the phenomenon of industrial melanism, are referred to as 'microevolutionary,' to indicate they are short term reversible changes. Other evolutionary changes, such as the extinction of an entire species, are irreversible, and are often referred to as 'macroevolutionary.'

Lamarckian inheritance A discredited mechanism for evolutionary change popularized by Jean Baptiste de Lamarck (1744–1829) that posits changes that occur over the course of an individual organism's lifetime can be passed on to its offspring. For example, Lamarck suggested that the reason why modern giraffes have such long necks is because their shorter necked ancestors habitually stretched their necks to reach foliage high up in the canopy of trees, and this continued stretching by generations of giraffes had resulted in their offspring being born with longer necks.

Mutation A mutation is a rare change in the DNA (deoxyribonucleic acid) that serves as the hereditary material in nearly all organisms. DNA is a long molecule that contains long segments called genes that code for specific traits and behaviors. Because mutations occurring within a gene may affect the sequence of the gene, they have the potential to alter the code, and therefore how the trait or behaviour is expressed. Mutations occasionally arise due to copying errors when the DNA is duplicated in cells, despite the presence of repair mechanisms. Certain environmental stimuli, such as radiation, may increase the rate at which mutations occur.

Natural selection A well-documented mechanism for evolutionary change that accounts for, among other things, the origin of adaptations in nature. It was first proposed by Charles Darwin (1809–82) and Alfred Wallace (1823–1913) who drew attention to the predictable consequence of three circumstances in nature. First, populations in nature exhibit variation, i.e., the individuals that comprise a population do not all look and behave exactly alike, and at least part of this variation is inherited. Second, some of this variation affects the ability of organisms to survive and find mates. And third, there is a competition in nature, owing to the fact that not all who are born can possibly survive owing to limits on the availability of resources, mates etc. Darwin and Wallace pointed out that when all three of these circumstances take place, a logical and entirely predictable consequence is that those individuals that vary in ways that help them survive and reproduce will contribute more to the next generation. And as a consequence, the frequency of the favored variations will gradually, over many generations, increase.

Saltationism A discredited mechanism for evolutionary change endorsed by Étienne Geoffroy Saint Hilaire (1772–1844) that attempted to account for the origin of new species and new adaptations by means of sudden dramatic changes. In the early twentieth century, saltation was thought to occur by means of large mutations.

Industrial melanism refers to a trend toward darker coloration in many moth species that has been observed in areas affected by large-scale air pollution. It was first noticed in Britain and Continental Europe in the wake of the Industrial Revolution. It has since been observed in hundreds of other moth and insect species throughout the world wherever large-scale air pollution occurs.

The Peppered Moth

The most famous and well-documented example of the phenomenon of industrial melanism is the peppered moth, *Biston betularia*, a common moth in Britain and Continental Europe. Like other moth species, the adult form of this moth is nocturnal (active at night), spending most of the day motionless on trees, rocks, and other resting sites. The peppered moth was first described by Moses Harris (1766), who in a brief description of the moth drew attention to the 'white, freckled' appearance that gives it its common name. Harris was an acute observer of nature, and his failure to mention the adult form as having any other form strongly implies the existence of another dark form was unknown at the time of his writing.

Naturalists initially greeted the chance discovery of a melanic (dark) form of the peppered moth (ca. 1848) in the vicinity of Manchester, a large manufacturing center at the time, as simply an anomalous sport of nature. But over the course of just a few decades, an ever increasing number of subsequent additional sightings by other naturalists led commentators to recognize something dramatic was taking place before their eyes. The dark form had gone from being unknown to being quite common in the vicinity of Manchester in the space of just a few decades. A similar trend was also noticed in other industrial areas in both Britain and Europe, not merely in the peppered moth, but also in many other moth species.

Multiple explanations were proposed to account for this trend among insects in the vicinity of manufacturing centers. Some, such as Nicholas Cooke (1877), suggested that the general darkening of moths in the affected areas was a direct response to changes in the environment. He pointed out that increased humidity or large-scale air pollution had the effect of

darkening the resting sites of the moth, and suggested the moths became darker in order to match their surroundings to avoid predators. In other words, moths have a physiological ability to darken to match their backgrounds over the course of their lives, and they pass this on to their offspring. This is often referred to as Lamarckian inheritance. James Heslop Harrison (1927–28) alternatively proposed that the general darkening in the affected species was due to the ingestion of pollutants by larvae (caterpillars) that feed on leaves covered by soot. In particular, he proposed lead salts had mutagenic properties that led the caterpillars to mutate to the dark form on the basis of a series of experiments he conducted in the 1920s. These investigations were subsequently called into question by others who were unable to reproduce his remarkable results. A third explanation popularized by James W. Tutt (1896) explained the phenomenon in terms of Darwin's theory of natural selection. According to this explanation, the dark form initially arose by means of a chance mutation. In unpolluted environments, the resulting dark form was easily spotted by birds and thus quickly removed from the population. This explains why it is virtually unknown in unpolluted environments. But in polluted environments, such as those visibly darkened by air pollution (owing to the dying off of pale lichen that covered the trees and the slow accumulation of soot), the dark form was no longer at a disadvantage. Indeed, in soot-darkened forests, it is the pale form that is now at a disadvantage, and as such, the pale form that is removed. Comparing the moths as they rest on pale and dark backgrounds associated with the two environments reveals the basic intuition behind this explanation (see **Figure 1**).

E.B. 'Henry' Ford, founder of the Oxford School of Ecological Genetics that championed the systematic study of natural selection in field populations openly questioned whether Tutt's analysis was sufficient to account for the speed of the spread. Ford doubted it could be that simple. His own explanation, in terms of pleiotropy (the possibility a gene might have more than one affect on the phenotype of an organism), was that the spread was the result of two selection pressures. The first, documented by breeders who had established that the gene responsible for dark coloration was invariably dominant in the affected species, was that the dark form was 'hardier' or better able to survive toxins in their environment. This physiological advantage accounted for the rapidity of the spread. To account for why the spread had been limited to the vicinity of manufacturing centers, Ford drew attention to the obvious handicap of dark coloration in unpolluted environments, where the dark form would be readily spotted by predators.

To the modern eye, explaining the phenomenon of industrial melanism in terms of natural selection seems obvious. But it wasn't at the time of Kettlewell's investigations. The discovery of the phenomenon of industrial melanism coincided with what historians refer to as the 'Eclipse of Darwinism,' around the turn of the century when relatively few biologists believed that natural selection was the primary mechanism of evolution. During this time, scientists considered numerous alternative mechanisms, such as the possibility that new forms might arise at once my mutation (Saltationism), or evolution might be driven by the inheritance of changes that occurred during the

Figure 1 *Biston betularia*: one typical and one *carbonaria* resting on a lichen-covered tree in unpolluted country (Dorset); and, one typical and one *carbonaria* resting on blackened and lichen-free bark in an industrial area (the Birmingham district). These photos originally appeared separately as Plates 14 and 15 in Ford (1975).

life of an organism (neo-Lamarckianism). The phenomenon of industrial melanism, as witnessed in the peppered moth, represented a particularly striking example of natural selection in action, both by virtue of the fact that it appeared to be the result of selection operating on a single gene and also the sheer speed of the spread. J.B.S. Haldane (1924) seized upon the example of industrial melanism as illustrated in the peppered moth in an influential mathematical paper to draw attention to just how rapid natural selection could operate and the strength of the selective pressure involved, well in excess of what anyone previously would have believed.

H.B.D. Kettlewell

It is in this context that H.B.D. Kettlewell enters the story. Kettlewell was trained as a medical practitioner, but in midlife decided to change careers to pursue his boyhood love of natural history in E.B. Ford's newly established subunit of Genetics at Oxford University. Kettlewell's work on industrial melanism began with a large-scale survey of moth frequencies throughout Britain. The survey was conducted over many years with the assistance of literally hundreds of amateur entomologists, who collected yearly records of the frequencies of the pale and dark forms of the peppered moth in their local environments. In this way Kettlewell documented that rises in the frequencies of the dark form of the peppered moth were indeed correlated with areas of large-scale air pollution (Kettlewell, 1958).

Kettlewell is most famous for a series of field experiments he conducted in the early 1950s as an attempt to account for why the spread was occurring. It was quite clear at the start of his investigations that he was a proponent of Ford's explanation in terms of two selective forces mentioned above. In his initial report on the subject, Kettlewell states that he regarded Ford's suggestion that the dark form was physiologically superior to the pale form as established (Kettlewell, 1955). His task, in his early papers on the subject, was to document the second part of Ford's explanation, namely that birds preferentially remove moths that rest on non-matching backgrounds. At the time Kettlewell began his work on the subject it was neither obvious that birds were significant predators on moths, nor that they had the same difficulty humans do when we attempt to spot a moth when it rests on a matching background.

Kettlewell pursued his investigation by a mark–release–recapture experiment, a technique Ford and Ronald Fisher had previously used to estimate population size in insects that (unlike moths) persist in the form of colonies. As the name suggests, Kettlewell marked a combination of bred and local adult moths representing the pale and dark forms with a dab of cellulose paint on the underside of the wings. He then released large known quantities of these marked specimens onto tree trunks in a relatively well-confined area in a soot-darkened countryside near Birmingham, another manufacturing center where the phenomenon had been observed. As the final step, Kettlewell subsequently attempted to recapture as many marked moths as possible over the course of several nights by means of a combination of mercury light and assembling traps. The logic behind his investigation was that, all things being equal, the recapture rates for the pale and dark forms should be the same. If, on the other hand, one form was at an advantage in this polluted environment compared to the other, for example, the dark form was better able to hide from predators, one would expect the recapture rates to favor the dark form. And this is what Kettlewell found – in the polluted environment the recapture rate for the dark form was nearly twice that of the recapture rate for the pale form. A companion experiment, conducted a couple of years later in an unpolluted forest in Dorset, documented the reverse – here the recapture rate for the pale form was much greater than for the dark form. During the course of these investigations, Kettlewell also filmed the order in which birds preyed on moths. With the assistance of Niko Tinbergen, he demonstrated that, given a choice, birds would regularly pass over the inconspicuous form that matched its background in favor of the more conspicuous form (Kettlewell, 1955, 1956).

The dramatic nature of Kettlewell's results, namely the fact he was able to document selection pressures well above what previously been considered possible in nature, caused quite a stir among scientists and the lay public. Kettlewell's pictures and films of the relative order of bird predation were particularly influential in this regard (Rudge, 2003). The results came at a particularly auspicious time, when American textbook publishers were searching for simple examples to illustrate natural selection. Kettlewell's work on the subject fit the needs of educators beautifully. The phenomenon of industrial melanism represents the simplest kind of natural selection: directional selection acting in response to one effect of a single gene. The selective environment, soot-darkened and pale lichen-covered trees, was familiar to students. The selective mechanism, namely birds having difficulty finding moths when they rest on matching backgrounds, was intuitively obvious. The experimental design was also simple and the mathematics straightforward. Kettlewell's field investigations, conducted by means of field experiments further demonstrated that evolutionary biology (which was largely regarded at the time as an observational science, could conform to the standards of good science (Hagen, 1999). For all of these reasons, starting in the early 1960s, the phenomenon of industrial melanism became the example of choice to illustrate natural selection among textbook writers in the United States and elsewhere (Rudge and Fulford, 2012).

Kettlewell's research was received differently by the lay public and scientists. The vast majority embraced Kettlewell's work as a particularly well-documented example of natural selection that was perfect for use in science teaching. Fellow scientists who actually worked on the phenomenon were much more skeptical. Some objected to how he released the moths onto trees, a procedure he introduced out of reasonable assumption at the time that moths spend the day at rest on tree trunks. Others objected to the large numbers of moths used for the experiment. Kettlewell used large numbers in order to increase the odds he would be able to detect a difference between the different forms, but doing so raised a fundamental question about whether birds that normally do not eat moths at all might do so if moths were present in large enough numbers. Still others objected to his use of a combination of both bred moths for which he knew the

underlying genetics and moths caught on the site for whom the genetics was unknown, because the dark form could result from the melanic gene being heterozygous or homozygous (Berry, 1990; Grant, 1999).

As one might expect, critics of evolution, such as Jonathan Wells, have seized upon discrepancies between how the phenomenon is depicted in biology textbooks and what scientists say about it in their research publications as an indication that the phenomenon of industrial melanism is no longer regarded as a good example of natural selection (Wells, 2000, but see Rudge, 2002). Judith Hooper, in the first book-length study of Kettlewell, implies Kettlewell committed fraud, an allegation that is completely without merit (Hooper, 2002, but see Rudge, 2005). We should note the standards by which scientific investigations are judged have changed over time, so it should come as no surprise that an investigation conducted in the early 1950s might fall short when it comes to contemporary standards.

Current Status

At least eight follow-up studies, many of which were conducted specifically to address problems in Kettlewell's original investigations have all documented that Kettlewell's basic conclusion, i.e., the phenomenon is due to natural selection and the most important selective factor is differential predation by birds, is still correct. An impressive study conducted on two continents documented a similar rise and predictable fall in the frequency of dark peppered moths in Britain and the United States following the advent of clean air legislation (Grant *et al.*, 1998). More recently, a large-scale six-year predation experiment specifically designed to address perceived problems associated with the conduct of Kettlewell's original investigations conducted by the late Michael Majerus provides the most direct evidence yet for the selective role of bird predation (Cook *et al.*, 2012). The phenomenon of industrial melanism is still regarded as a great example of natural selection and selective predation by birds remains the primary selective force responsible. What this additional research documents is that the situation is far more complicated than textbooks would have us believe. Sulfur dioxide concentrations and differential migration might both play a role in accounting for the spread of the dark form (Cook, 2003). Discussion of the problems associated with the original conduct of Kettlewell's investigations does not undermine this example. These problems actually augment the continued use of the phenomenon of industrial melanism and Kettlewell's work on it for science teaching, because doing so draws attention to a variety of issues associated with the nature of science often lost on students, such as the tentative nature of scientific knowledge (Rudge, 2000).

Inheritance: From Quantitative Genetics to Evolutionary Stable Strategies

T Coulson, University of Oxford, Oxford, UK

Glossary

Adaptive landscape The association between a phenotype and fitness; the phenotype can be univariate or multivariate.
Additive genetic variation Variation in the phenotype that is attributed to the additive effect of genes, usually estimated across parents.
Evolutionarily stable strategy The strategy with the greatest fitness that is expected to increase in frequency until it dominates the population.
Inheritance function A function in an 'integral projection model' that describes the association between a parental character measured at time t and an offspring character measured at time $t+1$ when it recruits to the population.
Integral projection model A structured population model where individuals are classified by at least one continuous character.
Phenotypic variance Variation in the phenotype, usually estimated across parents.
Structured model A class of population model where individuals are classified by discrete or continuous characters.
Trade-off function An association between two characters and fitness where fitness is maximized at some midpoint of the function.

Population Level Means and Variation Around Them

Many descriptors of life history, including life expectancy, age at first reproduction and generation length, describe averages across individuals within a population. For example, generation length can be defined as the average age of mothers when they give birth (Caswell, 2001). However, there can be considerable variation among these quantities both between individuals within a population, and between populations. For example, within populations of iteroparous species, different individuals can reach sexual maturity at different ages, can reproduce at different ages, and can have reproductive lives of different lengths (Clutton-Brock, 1988). This means that the average age at which females give birth can vary substantially among individuals.

How important is this within population variation? Ecologists frequently ignore much of it, as do comparative life history theorists who focus on variation among species. But for those researchers who are interested in within population evolutionary change, this variation is crucial (Stearns, 1992). Evolution requires such variation, and requires differences between individuals to be heritable. Without differences between individuals, populations cannot evolve, and species cannot adapt to changing environments. So how important is understanding this variation for life history research? And how do biologists study it? To a large extent the answer to this question depends upon the question the researcher is asking. But in addition, assumptions about whether, and how, this variation is transmitted between generations are also important.

In this article, the author considers individual variation in life history and how it is inherited. He discusses how it is treated in analyses and models, and some of the insights that the work has yielded.

Individual Variation

Individual variation is ubiquitous. Individuals differ in their rates of development, their propensity to survive and reproduce, and the way they respond to different environments. Some of this variation can be attributed to measurable differences between individuals. For example, Jones *et al.* (2008) describe how age influences both survival and reproduction in mammals, birds, and plants. But traits like personality, ability to fight disease, genotype, and body size can independently influence the propensity of an individual to survive and reproduce. Indeed, there are potentially so many sources of individual-level life history variation that even when measurable characteristics have been corrected for, there is still considerable unexplained variation that varies between individuals (Tuljapurkar *et al.*, 2009). Much of evolutionary ecology has focused on characterizing this variation, and attributing it to measurable characteristics of individuals.

It is preferable to identify sources of individual variation but sometimes this is not possible. For example, many characters cannot be easily measured on individuals living in the wild. Life history researchers have recently championed powerful statistical methodologies, including linear mixed effect models, to partition variation unexplained by measured fixed effects in regression models into that attributable to repeated measures on individuals (Cam *et al.*, 2002). This has revealed that considerable differences between individual variations can exist even when measured characteristics are corrected for. However, the role that this variation plays on life history varies as a function of how it is inherited.

The inclusion of traits like age and body size into models of life history dynamics influences quantities like generation length, the variation around generation length, and life expectancy (Coulson *et al.*, 2011). For example, Plard *et al.* (2015) have shown that the way age is incorporated into integral projection models of roe deer influences macroscopic life history parameters like generation length, but impacts on the population growth rate is substantially less. Vindenes demonstrated that non-normal distributions of unmeasured individual differences can also generate impacts on population dynamics (Vindenes and Langangen, 2015). In contrast, Ellner and Rees (2006) and Coulson (2012) concluded that

normally distributed unmeasured individual differences were unlikely to generate substantial effects on summary statistics of life history and population growth.

In order to understand why different studies may have reached different conclusions it is informative to understand how population structure can impact life history (and population dynamics). Life history, and the dynamics of populations, is determined by survival, recruitment, and dispersal. If the distribution of a character, like body size, fluctuates over time within a population, then the life history and population dynamics will also change depending upon the way population fluctuations influence population structure (Coulson *et al.*, 2001). Those studies that capture fluctuations in the structure of fitness-associated traits will likely conclude that individual differences matter, while those studies that do not capture such fluctuations will likely reach the opposite conclusion. In reality, population structure does fluctuate, and it should be incorporated in models – for both analyses of transient dynamics, as well as for those of longer-term dynamics.

The models of Plard, Coulson, Rees, and Vinderes assume a particular type of inheritance, but there are other ways that inheritance is dealt within models. In the remainder of this article we consider different ways in which inheritance is treated.

Finessing Inheritance in Life History Research

Genetic inheritance is necessary for evolutionary change. It describes how genes are passed from one generation to the next. It might consequently initially seem surprising, then, that genetic inheritance itself is rarely included in life history research. Instead, assumptions are made about what is inherited, and what different patterns of inheritance mean. The reason life history theorists finesse inheritance is that our understanding of the genetic architecture of life histories is usually so rudimentary we have very little idea about the role that genotypes at specific loci play (Falconer, 1960). In this section, the author briefly considers the theoretical underpinnings that have led to life history theorists treating inheritance in the way they do. The theory has arisen from the way that inheritance is treated in population models.

Often the focus of life history research is on life history traits – for example, age-specific body size, or age at first reproduction (Stearns, 1992). Stage structured and age–stage structured models describe the life history of the group of individuals over which they are parameterized – usually the entire population (Caswell, 2001). The models dynamically iterate forwards the distribution of a character from one time step (usually a month, or a year) to the next. In order for the approach to work, it is necessary that phenotypic characters in adults are mapped to phenotypic characters in offspring (Easterling *et al.*, 2000; Coulson, 2012). This map is referred to as the inheritance function. This function requires that traits are measured at different ages in the adult and the offspring; models consequently capture the birth process. In many animal studies, individuals with relatively large adult trait values often produce offspring with relatively large offspring traits, and the inheritance function has a positive slope (Coulson *et al.*, 2010). Models such as these are termed integral projection models (Easterling *et al.*, 2000), and they are agnostic to the inheritance mechanism that the inheritance function captures, and whether it is genetic, environmental, or both. These population level models are usually analyzed at equilibrium, which means that parameter values in the model remain constant with time. A consequence of this is that the mean of the phenotype shows no temporal trend as no evolution occurs (Coulson *et al.*, 2010). Nonetheless, the models can be used to analyze evolutionary change through the use of sensitivity analysis and by asking what happens to the life history if parameters in the inheritance function, or in any other parts of the model, evolve?

As well as using models to study evolution over fixed time steps like the integral projection models described above, population level models are also used to study evolution on a per generation time step. The most widely used such model is the breeders equation (Lande, 1979). Instead of iterating a distribution of a phenotypic character forward one fixed step, it iterates the mean of the character value forward by one generation. The model is static, not dynamic. Because the model assumes a per generation time step, the component of the model that captures inheritance provides a map not from parents to offspring, but from the parental generation to the offspring generation – i.e., from age a in the parental generation to age a in the offspring generation (Falconer, 1960). Models do not capture the birth process. A positive association between parental and offspring character on this per generational scale is interpreted as meaning the trait is (at least partly) determined by genes. The trait iterated forwards can be measured at any point in the life course – for example, at birth, as a juvenile, or as an adult – but it must be measured at the same age in each generation. These models assume blending inheritance. These models can only be used to predict evolution across a single generation; they cannot be used to predict multigenerational evolutionary change. The reason for this, as we discuss below, is that they are population level models, with parameters describing what happens across all individuals within the population. If evolution occurs, then parameters in the model would change. This is why many models can only be used to predict forwards one generation at a time. If model parameters were held constant over multiple generations, the assumption would be that no evolution occurs, as by definition evolution will lead to changes in model parameters. To explicitly study evolution in models it is necessary to have different classes of individuals within a population, with the life history of each class determined by its model's parameter values. But the first framework we will consider that uses this approach assumes clonal life histories.

The above population level approaches assume that the trait itself is inherited. The third approach, evolutionary game theory, assumes something different. It assumes that life-history strategies are inherited (Childs *et al.*, 2003). One way to view this is that a structured model, like the population models described above, describes the dynamics of a single strategy. A mutant strategy – a new model with a slightly different set of parameter values – is released to compete with a resident strategy. If the mutant strategy increases in frequency it is predicted to displace the resident strategy. This approach is known as evolutionary game theory or adaptive dynamics. It

assumes that strategies do not mix – they are pure breeding clones. There is consequently no blending inheritance: strategies are passed with very high fidelity. Over time, the frequency of different strategies changes. In most cases one strategy dominates, but under some circumstances competing strategies can coexist.

The astute reader will be thinking why are these different strategies not genetically determined, and strategies inherited via Mendelian inheritance? This is a good question, and there has been considerable theoretical work where different genotypes at a single locus have different structured models, and consequently different life histories and fitnesses (Charlesworth, 1994; Coulson *et al.*, 2011). These models reveal the processes that erode, and maintain, genetic variation – for example, spatial variation in selection pressures, frequency, or density-dependent selection and selection-mutation balance. However, application of such models to real systems is rare as the number of examples where fitness related traits are under simple genetic control is limited. And for this reason, for most species, and for most life history traits, assumptions about patterns of inheritance are consequently required. This means that when the genetic architecture is not known, evolutionary ecologists and life history theorists have to make a decision on how to treat inheritance, and they usually turn to the structured model (Coulson *et al.*, 2010), quantitative genetic (Falconer, 1960) or game theoretic (Childs *et al.*, 2003) approaches described above.

But when should the approach be used, and what can each tell us?

Structured Models

The strength of the structured modeling, or integral projection modeling, approach is that models are dynamic, and very flexible. They can include multiple traits, environmental stochasticity, demographic stochasticity, frequency dependence, and density-dependence (Childs *et al.*, 2004; Rees and Ellner, 2009; Coulson *et al.*, 2011). They can also be used to simultaneously study how population dynamics, life history, character distributions, and selection change as model parameters are altered. This allows the theoretical study of ecological and evolutionary dynamics. However, the approach can also be applied to real systems. For example, if model parameter values change from one period to the next, as a result of environmental change or evolution, integral projection models can be used to give a broad description of how multiple aspects of the system are expected to change (Ozgul *et al.*, 2010). The weakness of this class of model is that most are not evolutionarily explicit; evolution can only be examined in a phenomenological manner through sensitivity analysis, and these methods (usually) make the assumption that model parameters will change independently of one another. Models have been extended to include simple genetic architectures (see Section Simple Genetic Inheritance) but this has only been done once.

Application of these models has shown that population dynamics, life history, the strength of selection, and character distributions are expected to simultaneously respond to environmental change. Ecology, evolution, and life history should be studied together, not in isolation (Smallegange and Coulson, 2013). Models will only provide accurate predictions if (1) they are appropriately specified and (2) it can be assumed that parameter values will not evolve over the time period over which projections are made. As evidence of rapid evolutionary change in the wild is scarce (see Section Quantitative Genetics) it seems that this assumption is probably appropriately for the few generations over which population, or life history, projections are required.

Quantitative Genetics

The great strength of the quantitative genetic approach is that it has proven extremely successful in artificial settings. The approach was devised to predict the evolutionary consequences of artificial selection on one or a few traits across a single generation. In such circumstances the environment is usually benign and constant, artificial selection is strong, and is very precisely targeted at one or a few traits. This means that most individuals survive (unless they are deliberately culled) while only those with desirable trait values do all the reproduction.

The great limitation of the quantitative genetic approach is that predictions should only be made for a single generation (Lande, 1979), and that when applied to free-living populations predictions rarely match observation (Merila *et al.*, 2001). The reason for this is natural selection on one, or a few, characters is typically weaker than artificial selection (Kingsolver *et al.*, 2001), that the environment is often far from benign, and that selection is not so specifically targeted, but instead operates on the entire life history (Childs *et al.*, 2011). In spite of this, application of the approach to free-living populations has provided useful insight. In order to understand these insights, it is useful to have a brief background on implementation of the quantitative genetic approach to the field.

The approach assumes the phenotype is, in part, determined by a large number of loci of small, additive effect. Each locus contributes to the phenotype independently of the other. Most research has focused on estimating how much variation between individuals in phenotypic characters can be attributed to these numerous, small effects. This means that quantitative genetics, when applied to field systems, is primarily concerned with decomposing phenotypic variation across individuals within the population into a component due to additive genetic contributions and other non-additive genetic components. This is done by comparing (statistically corrected) phenotypic traits among individuals of known relatedness, using either midpoint parent–offspring regression or the animal model (Kruuk, 2004). The heritability describes the proportion of phenotypic variation that is attributable to the additive genetic differences between individuals. A heritability of zero means that all variation in the trait among individuals is due to environmental variation. In contrast, a heritability of unity means all variation is attributable to additive genetic differences.

What has the application of this approach shown? Most life history traits in free-living populations appear to have some additive genetic variation. Most life history traits in the field

have a heritability of 0.1 to 0.2 (Kruuk, 2004). Values substantially higher than this are outliers, potentially suggesting there have been issues in implementing the approach.

The heritability frequently declines, the more strongly a trait is correlated with lifetime reproductive success (Kruuk *et al.*, 2000) as predicted by Fisher (Fisher, 1930). In other words, in traits that are strongly correlated with lifetime reproductive success, most of the variation among individuals cannot be attributable to the additive effect of genes. However, even these traits have some genetic variation – selection has not eroded all of it, as standard theory would predict.

This research, and others like this, suggests that life history traits are subject to directional selection, and that there is sufficient additive genetic variation for evolution to occur. However, convincing evidence of rapid microevolution from the application of the quantitative genetics approach is scarce (Merila *et al.*, 2001), and much of quantitative genetics in the wild is concerned with explaining why we fail to see microevolutionary change.

Clonality and Evolutionarily Stable Strategy

The great strength of the evolutionarily stable strategy (ESS) approach is the expected end point of evolution can be identified. The ESS is the peak of an adaptive landscape and populations are predicted to evolve toward this point (Maynard-Smith, 1982). Whether they can achieve the ESS will depend upon whether genetic constraints allow it. The weakness of the approach is that it is often hard to identify trade-offs within populations (Cam *et al.*, 2002). In addition, the approach cannot be expected to accurately capture transient dynamics, which are likely determined by the details of inheritance mechanisms. This weakness has not stopped people using the approach to study transients, but results on short-term life history evolution should be treated with caution.

As previously mentioned, evolutionary game theory competes strategies against one another. In order to apply the approach, a trade-off between two components of the life history needs to be identified, and strategies at points along this trade-off function are competed against one another. Most applications focus on the trade-off between offspring number and offspring size (Childs *et al.*, 2003, 2004, 2011), although other trade-offs can be used. The fittest strategy is the one that cannot be invaded by any other.

Application of this approach, primarily to monocarpic perennial plants, suggests that most life histories appear to be close to the ESS (Metcalf *et al.*, 2008). This would suggest we would expect to see little evidence of evolutionary change. However, ESSs are environment dependent, with different ESSs in different environments. In those cases where environmental variation is included, populations appear to be close to the ESS for the average environment (Childs *et al.*, 2004).

One very nice insight from the ESS approach is that selection on the life history is very different to selection on specific traits (Childs *et al.*, 2011). In other words, selection on a trait like body size is very different to selection on the entire life history. In artificial settings it is sensible to think of selection operating on individuals traits, as these are what selected. However, in natural settings, it is more sensible to think about selection operating on the entire life history, as natural selection cannot be as targeted as artificial selection. Studies of life history evolution in the wild should ideally focus on selection estimated over the entire life history, and to do that it is necessary to work with the structured models that underpin the ESS approach, and the integral projection approach described above.

Simple Genetic Inheritance

Instead of assuming a particular map between genotype and phenotype it would be preferable to work with cases where the genetic architecture underlying a phenotypic character is known. Unfortunately, however, this is rarely possible because traits that influence life history that biologists are interested in are usually under the control of multiple loci. Two cases where they are not are sickle cell anemia in humans and coat color in gray wolves – both traits that are determined by genotype at a single genetic locus. In both cases inheritance is Mendelian. The great strength of this approach is the life history of each of the three competing genotypes can be calculated, and their fitnesses assessed. The limitation of this approach is few traits are under simple genetic control.

Within North America there is a cline in wolf coat color. To the North, black wolves are rare and often absent. As one moves further Southwest, the frequency of black wolves increases. Wolf coat color is determined by genotype at a single locus – CBD103. The locus is a β-defensin locus with two alleles. The heterozygote is black. Initial hypotheses proposed that the black coat was found at a higher frequency to the Southwest because the Southwest is more forested. Black wolves were hypothesized to have a fitness advantage through improved hunting success in shade (Anderson *et al.*, 2009). There are two problems with this hypothesis. First, wolves are not ambush hunters – they do not rely on cover, or camouflage, when hunting prey. Instead, they are cursorial hunters in that they run their prey down. Camouflage is not important for wolves. Second, the black homozygote and the black heterozygote have the same coat color, but they have very different fitness. Black homozygotes never fare well, while black heterozygotes have higher fitness than either of the homozygotes – in Yellowstone National Park at least (Coulson *et al.*, 2011). Recent genetic work by Robert Wayne and colleagues hints that genotype CBD103 may play a role in immunity. Perhaps the coat color cline found in North America, and possibly aspects of wolf life history, are determined by the frequency of disease outbreaks rather than by the amount of shade?

Sadly until we have a better understanding of the map between genotype and phenotype, being able to measure the life history and fitness of genotypes with known phenotypic consequence will be limited to a few special cases like the North American wolves.

The Challenge of Inheritance

Adaptive evolution requires variation among individuals, selection, and genetic inheritance. There is considerable variation among individuals in terms of their life history strategies

within populations. Occasionally some of this variation is under simple genetic control, and when that is the case, studying life history evolution within a population is (relatively) straightforward. Unfortunately, this is rare and in cases where the genetic architecture is not known, assumptions about the mechanisms of inheritance are required. The additively assumption of quantitative genetics suggests many traits are under partial genetic control, and that additive genetic variation for the traits is frequently present. In spite of this important insight, little can be done with it, as mutigenerational predictions of evolutionary change are not possible with current theory.

The second widely used assumption is of clonality. In sexually reproducing species this assumption is violated. This doesn't preclude the predictions of where evolution is likely to take the population in the long-term, but it does limit the utility of predictions of short-term change.

Until we gain a better understanding of the (likely complex) genetic architecture of life histories and life history traits we will need to continue to make assumptions about the modus operandi of inheritance. The clonal assumptions of game theory, and the blending inheritance of quantitative genetics are very sensible assumptions, but both have their limitations, as does use of the inheritance function. A useful focus while we await better characterization of genotype–phenotype maps would be to explore the consequence of assumptions for both long-term and short-term evolution. Currently, researchers often seem to just champion one approach while being dismissive of the others. This is a shame. All approaches have merit, with perhaps fruitful gains being possible from attempting to integrate the approaches together. Inheritance is certainly key to understanding life history evolution in the field, but it is frustrating, as it is so hard to mechanistically characterize.

Insects and Ecdysozoa, Diversification of

DM Takiya and APM dos Santos, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Insecta: Animal's Major Radiation

Comprising around one million described species, insects are by far the most species-rich animal group. Nevertheless, estimates of the actual number of insect species considering the high proportion of undescribed ones, range from 5 to 30 million species (Erwin, 1982; Gaston, 1991). The known diversity of the Class Insecta is classified into 31 recent orders (Grimaldi and Engel, 2005), including some notorious terrestrial invertebrates, such as beetles (Coleoptera), bees, wasps, and ants (Hymenoptera), butterflies and moths (Lepidoptera), and cockroaches (Blattodea). Not only are insect orders species-rich, most are also highly abundant, consequently causing a great impact in their natural systems. Few continental niches have not been occupied by some insect group, which are distributed on every continent, including Antarctica. Insects are intrinsically responsible for nutrient recycling in terrestrial and aquatic habitats and plant reproduction and dispersal, besides from interacting with other biota as population regulators or food resources and sometimes being considered as keystone species of ecosystems.

The vast majority of insects and their related entognathan classes (Collembola, Diplura, and Protura) comprising the subphylum Hexapoda (**Figure 1(a)**), dwell in terrestrial habitats. Extinct marine hexapod lineages were still present until 390 million years ago during the early Devonian (Haas *et al.*, 2003). However, at that point hexapods had already invaded continental habitats where they diversified and flourished, based on the earliest fossil of an extant hexapod order, a typical marshy-habitat collembolan, from 400 to 410 million years ago from the early Devonian of Scotland (Pragian) (Hirst and Maulik, 1926). Molecular dating methods suggest a much earlier diversification of the crown group of continental Hexapoda than diversification dates based on fossil data, estimating it to be between 510 (Cambrian) and 450 (Ordovician) million years ago (Misof *et al.*, 2014). Despite this extraordinary terrestrial radiation, approximately 3% of the known insect diversity inhabit, at least as immatures, aquatic habitats. Of these, approximately several hundred species are marine or intertidal, but individuals of these species are never submerged throughout their whole life (Cheng, 1976a). Proposed reasons why insects did not successfully invade the marine environment include respiratory and osmoregulatory limitations and competition with the already diverse and abundant marine arthropods, the crustaceans (Cheng, 1976b).

Several adaptive features have been named as contributing to insects' remarkable diversity. A chitin-based exoskeleton certainly provided an evolutionary advantage in the provision of protection of internal organs, large area for muscle attachment and development, and evaporation control, the latter being extremely important when taking into account radiation of the Hexapoda in terrestrial environments. Even though many animal lineages share this exoskeleton, a unique arthropod characteristic, articulated limbs, made possible an extreme adaptability of these limbs performing highly dissimilar functions in different insect groups (Ross *et al.*, 1991). For example, the three pairs of head appendages, usually referred to as mouthparts, are strongly modified in different insect groups allowing feeding of the most varied sources, such as the plesiomorphic chewing mouthparts for grinding solid animal or plant matter or piercing–sucking mouthparts, which evolved many times independently in different insect groups, to suck internal fluids of other animals or plants.

Considering that half of the number of insect species are herbivores, the phytophagous habit is also hypothesized to be an important cause of diversification (Mitter *et al.*, 1988; Wiens *et al.*, 2015). Plants, however, are not an ideal food source, because of their low nitrogen composition and unbalanced profile with low concentration of many of the animal's essential amino acids, and because plants have evolved many defense mechanisms against herbivores, such as chemical and mechanical protection. Nevertheless, energy resources for herbivores are greater than those available to higher trophic levels, plants did provide diverse new host niches with different ecologies or chemistry driving insect diversification, and as a result interspecific competition is probably low (Southwood, 1973; Mitter *et al.*, 1988).

Unique to the insects, but not present in all of them, there are two other characteristics, which definitely helped shape the current diversity of the Hexapoda. Insects are the sole invertebrate group able to fly and the first organisms to do so, between 90 and 170 million years before the first flying vertebrates (Engel and Grimaldi, 2004). Their two pairs of thoracic wings enhance their dispersal ability, being advantageous for fleeing threats, finding new resource opportunities, mates, or oviposition sites; besides acting in protection, courtship, and thermoregulation. Two main theories address their origin: either insect wings have originated from lateral expansions of the thoracic dorsal sclerites (Quartau, 1986) or from basal processes (exites and endites) of the thoracic legs (Kukalová-Peck, 1983; Trueman, 1990).

Lastly, the great majority of insect species, comprising the Holometabola, share a synapomorphic complete metamorphosis in their post-embryonic development, which is considered a key innovation in the diversification of insects (Rainford *et al.*, 2014). These insects, after hatching from eggs, have characteristic immature wingless larval stages, which are responsible for most of the feeding and resulting growth of the insect. Larvae usually utilize a completely different food resource, for example, caterpillars are leaf chewers, while butterflies are nectarivorous, and live in a different microhabitat than adults. Adults, when they do, have to feed only to maintain its metabolism and sometimes maturation of sperm and eggs, and adapt to particular roles of dispersal and reproduction. Morphologically and anatomically, larvae and adults are completely different and the transition between the two is through the pupal stage, another immature and mostly

quiescent stage responsible for an extreme internal organs rearrangement and development. Nevertheless, this niche segregation between larvae and adults helped eliminate their competition for resources and open up a wide variety of niches for holometabolans to explore and diversify into 65% of all animals species. Stem lineages of many of the holometabolous orders are estimated to be present in the Late Carboniferous (~310 million years ago), but it was not until the Early Cretaceous (~120 million years ago) that the true diversification of these megadiverse orders occurred, contemporary with the radiation of flowering plants (Misof *et al.*, 2014).

Arthropod Evolutionary Relationships

Arthropods are familiar animals and encompass, besides insects, crustaceans, millipedes, centipedes, spiders, scorpions, mites, ticks, and others. The Phylum Arthropoda is divided into the extinct Trilobitomorpha (**Figure 1(d)**) and four extant subphyla: Cheliceriformes (**Figures 1(c)** and **1(e)**), Myriapoda (**Figure 1(e)**), Crustacea (**Figure 1(b)**), and Hexapoda (**Figures 1(a)** and **1(f)**). Arthropods are represented amongst the oldest fossil invertebrates dating back to the Cambrian explosion (~540 million years ago), and more questionably suggested to be present in the late Precambrian faunas, approximately 60 million years before (Waggoner, 1996). Representatives of crown groups of Crustacea (Anostraca) and Cheliceriformes (Pycnogonida) were already present in the Late Cambrian, between 500 and 490 million years ago (Edgecombe and Legg, 2013). Trilobites also originated in the Cambrian and became one of the most abundant arthropod groups of the Paleozoic seas, but going extinct by the most extreme mass extinction event, the end-Permian (Erwin, 1994). Considerably before the first hexapods and any other animal group, by the mid-Silurian (428 million years ago), scorpions (Cheliceriformes) and millipedes (Myriapoda) had already invaded the terrestrial habitat (Dunlop *et al.*, 2013).

Monophyly of Arthropoda is almost universally accepted, strongly supported by morphological, molecular, and developmental evidence (Edgecombe, 2010). On the other hand,

relationships among major arthropod lineages are still controversial. In the last two decades, addition of new data, especially molecular, has challenged traditional views about phylogenetic relationships among arthropod lineages, and even widely accepted clades were questioned.

Considering the extant arthropod subphyla, most published phylogenies support a traditional clade including Myriapoda, Crustacea, and Hexapoda – the Mandibulata (e.g., Giribet *et al.*, 2001; Regier *et al.*, 2010; Rota-Stabelli *et al.*, 2011). However, the placement of Myriapoda is still controversial, being sometimes recovered as a sister to Cheliceriformes, in a clade named Paradoxopoda or Myriochelata, based on rDNA data (Pisani *et al.*, 2004; Mallatt *et al.*, 2004) and also in more recent studies with large datasets from complete mitochondrial genomes or transcriptomes. Paradoxopoda, however, is seen in many of these more widely sampled studies as an artifact of outgroup choice or saturation of fast evolving sites (Rota-Stabelli and Telford, 2008; Rota-Stabelli *et al.*, 2010; Andrew, 2011).

Within mandibulates, traditionally, hexapods and myriapods were seen as sister taxa, forming a group named Atelocerata (in reference to the loss of the second pair of antennae) or Tracheata (in reference to their tracheal respiratory system), a hypothesis almost undoubted until the end of twentieth century (e.g., Snodgrass, 1938; Hennig, 1981; Bitsch and Bitsch, 2004). However, recent studies based on molecular data and reinterpreted anatomical information, consistently recover Hexapoda nested within Crustacea, a clade named Pancrustacea or Tetraconata (in reference to ommatidia tetrapartite crystalline cones) (e.g., Shultz and Regier, 2000; Cook *et al.*, 2001; Regier *et al.*, 2010; Rota-Stabelli *et al.*, 2011). Thus, hexapods can be viewed as the 'crustacean' lineage, which successfully invaded and diversified on the terrestrial habitat. Consequently, synapomorphic traits of Atelocerata, such as the tracheal system and Malpighian tubules (specialized excretory organs), are more likely adaptive convergences to life on land by hexapods and myriapods. Unfortunately, few studies included a wide taxonomic sampling of Crustacea to address which is the extant sister group of Hexapoda, and results are inconsistent, but often involve Branchiopoda, Remipedia, and Cephalocarida (Regier *et al.*, 2005, 2010; Oakley *et al.*, 2013).

Panarthropoda

Two small animal phyla, Onychophora (velvet worms, **Figure 1(g)**) and Tardigrada (water bears, **Figure 1(h)**), are considered to be closely related to arthropods – the three phyla together being known as Panarthropoda (sometimes also referred as Aiolopoda, see Ortega-Hernández, 2014). Monophyly of Panarthropoda is supported by several morphological synapomorphies (Nielsen, 2012), but of particular importance are the paired segmental ventrolateral claw-bearing appendages operated by intrinsic and extrinsic muscles. These appendages are also found in several extinct lineages of panarthropods, including the lobopodians (Edgecombe, 2010). Lobopodians also originated in the Cambrian explosion and are known from various Paleozoic (541–252 million years old) deposits around the world, thus a major component of early metazoan-dominated ecosystems (Ortega-Hernández, 2015). They were initially thought to be marine ancestors of onychophorans, but are now regarded as a polyphyletic assemblage of stem-groups of Arthropoda, Onychophora, and Arthropoda + Onychophora (Legg *et al.*, 2013; Yang *et al.*, 2015). Neither Onychophora nor Tardigrada have Cambrian fossil representatives.

All possibilities of relationships among these three groups have been proposed and received some support, even recently. However, a closer relationship between Onychophora and Arthropoda is most commonly accepted based on molecular analyses (e.g., Dunn *et al.*, 2008; Rota-Stabelli *et al.*, 2013) and several morphological synapomorphies, including segmental musculature, nephridial derivatives that arise from the walls of coelomic cavities, addition of segments from a posterior growth zone, and arthropod-type hemocyanin (Edgecombe, 2010; Nielsen, 2012). Placement of Tardigrada remains uncertain, since recent studies with broad sampling has recovered it as closely related to the nematode clade (Philippe *et al.*, 2005; Nesnidal *et al.*, 2010).

Ecdysozoans: The Molting Animals

At the same time that molecular data has overturned the phylogenetic understanding among main lineages within Arthropoda, leading to the proposal of the so-called Pancrustracea hypothesis, the position of Panarthropoda in the animal tree of life has also changed dramatically. Until the first papers addressing metazoan relationships based on molecular data, Panarthropoda and Annelida (segmented worms, such as polychaetes, earthworms, and leeches) constituted a robust taxon, named Articulata established in beginning of the nineteenth century (Cuvier, 1817). Morphological features supporting Articulata are mainly related to body segmentation (or metamerism) and segmental substructure (Scholtz, 2002). Rejecting this hypothesis means assuming independent origins of metamerism in panarthropods and annelids or a more ancient origin of this body organization pattern in animal evolution, followed by independent losses in several animal groups. However, despite the strong morphological support, since the first single gene phylogenetic analyses based on 18S rDNA sequences (Giribet *et al.*, 1996; Aguinaldo *et al.*, 1997) to the current phylogenomic era (Nesnidal *et al.*, 2010; Giribet, 2015), Articulata has no support from molecular data. Panarthropoda is commonly recovered within a clade of molting animals, the so-called Ecdysozoa (Philippe and Telford, 2006; Edgecombe *et al.* 2011). Even before the first molecular study proposing Ecdysozoa (Aguinaldo *et al.*, 1997), some morphological studies have questioned the close relationship between arthropods and annelids, recovering annelids most closely related to mollusks instead (Eernisse *et al.*, 1992). Recent alternative hypothesis to Ecdysozoa and Articulata have placed arthropods closer to chordates than other molting animals (specifically Nematoda) based on genomic data calling for a 'Coelomata' group (Blair *et al.*, 2002, Telford, 2004, Wolf *et al.*, 2004; Longhorn *et al.*, 2007). There is little morphological support for this group and molecular support is apparently an artifact of poor and distantly related taxon sampling, while better sampling usually recovers a robust Ecdysozoa.

Besides the three panarthropod phyla, Ecdysozoa includes the five Cycloneuralia phyla: Nematoda (**Figure 1(h)**), Nematomorpha (**Figure 1(f)**), Kinorhyncha, Priapulida, and

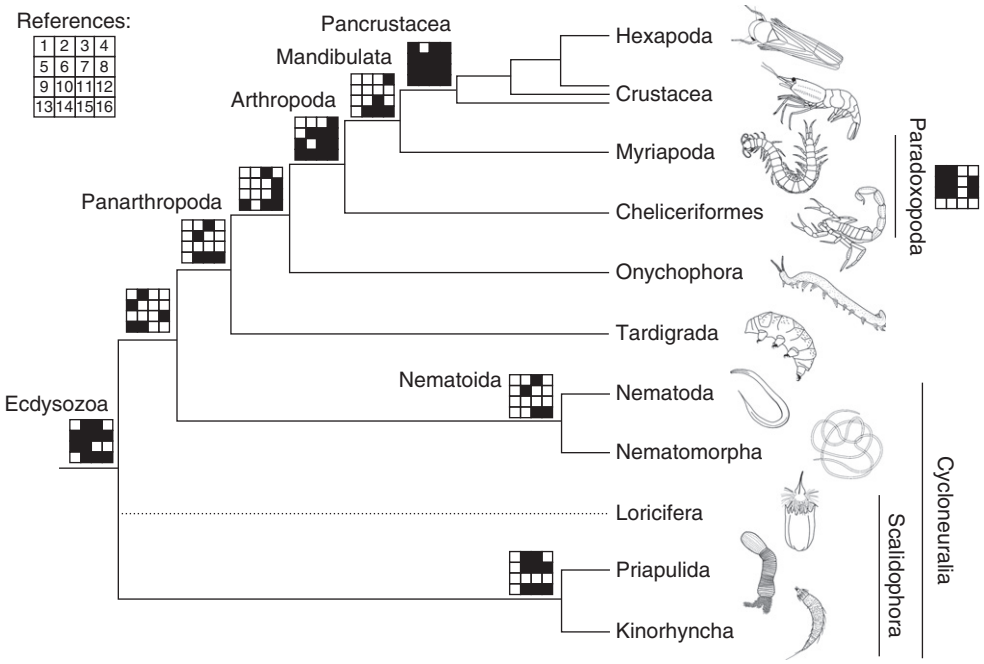

Figure 2 Summary phylogeny of major groups of ecdysozoans based on molecular analyses. Support for respective group is given by black boxes according to the following studies: (1) Friedrich and Tautz (1995), (2) Aguinaldo *et al.* (1997), (3) Garey (2001), (4) Giribet *et al.* (2001), (5) Mallatt *et al.* (2004), (6) Mallatt and Giribet (2006), (7) Park *et al.* (2006), (8) Dunn *et al.* (2008), (9) Sørensen *et al.* (2008), (10) Hejnol *et al.* (2009), (11) Regier *et al.* (2010), (12) Meusemann *et al.* (2010), (13) Andrew (2011), (14) Rota-Stabelli *et al.* (2011), (15) Campbell *et al.* (2011), (16) Rota-Stabelli *et al.* (2013).

Loricifera (see **Figure 2** for a summary of current phylogenetic hypotheses). All cycloneuralians together comprise less than 600 obscure species of marine benthos or arthropod parasites, except of the diverse Nematoda with approximately 30 000 described species. Nematodes are one the most abundant animal groups, occurring in almost all habitats, both aquatic and terrestrial, and can be free-living or parasites of animals and plants, those having great economic importance (Brusca and Brusca, 2003; Nielsen, 2012). Close phylogenetic relationships among cycloneuralians have long been hypothesized based on the shared unique belt-like brain (without paired ganglia) (Nielsen *et al.*, 1996; Brusca and Brusca, 2003), previously thought to be homologous to the one of the non-molting phylum Gastrotricha (Nielsen *et al.*, 1996). Nevertheless, recent molecular analyses do not recover Cycloneuralia monophyly, mostly because of the close relationship between Nematoida (Nematomorpha + Nematoda) and Panarthropoda (Aguinaldo *et al.*, 1997; Mallatt *et al.*, 2004; Rota-Stabelli *et al.*, 2011) and the few data to support the position of Loricifera (Park *et al.*, 2006; Sørensen *et al.*, 2008).

The most remarkable feature uniting all Ecdysozoans is cuticle molting or ecdysis regulated by ecdysteroid hormones, but other morphological apomorphies, such as loss of ciliated epithelia and secretion of epicuticle by the tips of epidermal microvilli (which are both related to the molting process) and loss of primary larvae (Aguinaldo *et al.*, 1997; Schmidt-Rhaesa *et al.*, 1998; Nielsen, 2012) were also proposed. Besides morphological features, an additional apomorphy of Ecdysozoa is the immunoreactivity to horseradish peroxidase by the nervous tissue, found in all ecdysozoans, but no other metazoan studied (Haase *et al.*, 2001). Although, some researchers were initially skeptical in accepting Ecdysozoa (Wägele *et al.*, 1999; Nielsen, 2001; Brusca and Brusca, 2003), it is currently widely accepted by zoologists (Telford *et al.*, 2008; Nielsen, 2003, 2012; Dunn *et al.*, 2014) and certainly the greatest monophyletic radiation of all metazoans.

Acknowledgments

Authors are greatly indebted to Claudia Russo (Universidade Federal do Rio de Janeiro) and Ann Ray (Xavier University) for reviewing of an initial version of this article. James Zahniser (United States Department of Agriculture) and Christopher Dietrich (University of Illinois at Urbana-Champaign) greatly helped with providing important bibliography. Christopher Dietrich and Arthur Anker (Museu de Zoologia, Unversidade de São Paulo) shared some of the beautiful photographs in **Figure 1**. The senior author is research productivity fellow from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq proc. 306.897/2014-8).

Intraspecific Coevolutionary Arms Races

AD Stewart, Canisius College, Buffalo, NY, USA
A Pischedda, University of California, Santa Barbara, CA, USA

Glossary

Copulatory plug A gelatinous male secretion that hardens in the female reproductive track after mating to prevent/delay female remating. Also called a 'mating plug.'
Cryptic female choice Generically a form of sexual selection where the female is able to influence the sire of her offspring *after* mating. This can be manifested by either a change in overall fertilization success from the sperm of a single male, or preferentially using the sperm of one male over that of another male.
Intersexual conflict An antagonistic coevolutionary process between the sexes of the same species, where an increase in the fitness of males reduces fitness of females, and vice versa.
Interspecific coevolution An evolutionary process between two *different species*, where a change in the fitness of species 'A' directly affects the fitness of species 'B', and vice versa.
Intrasexual conflict An antagonistic coevolutionary process within one sex of the same species, where an increase in the fitness of one male (female) reduces fitness of another male (female), and vice versa.
Intraspecific coevolution An evolutionary process between two individuals of same species/population, where a change in the fitness of individual 'A' directly affects the fitness of individual 'B', and vice versa.
Polyandry A mating system where each female in a population typically mates with multiple males.
Polygynandry A mating system consisting of exclusive mating groups of multiple males and females.
Polygyny A mating system where each male in a population typically mates with multiple females.
Promiscuity A mating system where each individual in a population has multiple mating partners and is characterized by a lack of any pair-bonding between mating partners.
Sperm competition A form of sexual selection where the sperm of two or more males are simultaneous residents in a female's reproductive tract and compete for fertilizations.
Traumatic insemination The practice where a male pierces the body of a female with his phallus and injects his sperm directly into her abdomen.

Introduction: Intraspecific Arms Races

Simply stated, coevolution is the process where two populations evolve directly in response to changes in each other. Typically coevolution is thought of as occurring between two different species, where a change in the fitness of species 'A' directly affects the fitness of species 'B'. Similarly, changes in the fitness of species 'B' directly affect the fitness of species 'A.' Given its general form, coevolution can either occur as a positive or negative process depending on the fitness effects that each species has on the other.

In mutualistic coevolution, each species influences the fitness of the other in a positive way. Evolutionary advances in species 'A' increase the fitness of species 'B'; evolutionary advances in species 'B' increase the fitness of species 'A.' Therefore, over evolutionary time, both players can become increasingly dependent on the other, resulting in mutualism. Examples include the coevolution between insectivores and herd animals, plants and pollinators, and eukaryotes and mitochondria. In contrast, antagonistic coevolution occurs when increases in fitness of one species reduces the fitness of the other species, and vice versa. As the fitness of species 'A' increases, the fitness of species 'B' decreases, and as the fitness of species 'B' increases, the fitness of species 'A' decreases. This ongoing antagonistic relationship is often referred to as a 'coevolutionary arms race,' with each species evolving strategies to mitigate the harmful effects of the other, potentially leading to never-ending cycles of adaptation and counter-adaptation. Common examples of these arms races include the evolutionary dynamics between predators and prey, hosts and parasites, and plants and herbivores.

While the above formulations are frequently applied to interactions between separate species (interspecific coevolution), the same evolutionary dynamics can occur between individuals within a species (intraspecific coevolution). When applied to the different sexes within a species, it seems logical that mutualistic coevolution could operate, with male fitness increasing along with increasing female fitness, and vice versa. Although feasible, this mutualistic intersexual coevolution is only associated with strict life-long monogamy between a male/female pair. Under these conditions, the fitness of a male equals the fitness of his mate, so any reduction in female fitness will result in an equal reduction in male fitness.

Strict monogamy is extremely rare, however, and when one or both sexes have multiple mating partners (i.e., polyandrous, polygynous, polygynandrous, and promiscuous mating systems), the evolutionary interests of males and females diverge, creating sexual conflict. This conflict occurs when the optimal outcome of sexual interactions differs for males and females (Rice and Holland, 1997), causing each sex to evolve strategies that maximize their own fitness, even if they are costly to their mates. Just as mutualistic coevolution can operate within a species, so, too, can antagonistic coevolution. Within a species, antagonistic coevolution results from the diverging

 doi:10.1016/B978-0-12-800049-6.00197-9

reproductive interests of males and females who are dependent on one another to reproduce. This situation is analogous to many species of parasites that depend on a host to reproduce: just as a parasite can evolve strategies that increase its fitness at a cost to its host, males and females can evolve strategies that are costly to their mates. In both situations, selection should act to minimize the costs experienced by the host/harmed sex, resulting in antagonistic coevolution.

While it may seem counterintuitive that individuals would evolve strategies that harm members of their own species, let alone their own mating partners, it important to remember that different individuals within a species have different evolutionary interests. Selection acts on the individual, not on a species or population, so it is possible for an individual to increase his/her fitness at the expense of others. Intraspecific coevolutionary arms races can involve any individuals that have divergent optimal fitness strategies, and can include conflict between competing males or competing females (i.e., intrasexual conflict), conflict between parents and their offspring, conflicts between siblings, and conflict between the sexes (i.e., intersexual conflict). Here, we focus specifically on coevolutionary arms races between males and females over mating and fertilization, describing the male–female interactions that are likely to lead to these arms races, and including examples from a variety of mating systems.

Coevolutionary Arms Races Over Mating

Intersexual arms races can evolve whenever male and females interact, and sexually antagonistic coevolution commonly involves the optimal mating rate of males and females within a population. This conflict over mating rate is rooted in anisogamy (the production of gametes of different sizes by males and females); while males tend to produce numerous small and relatively inexpensive gametes (sperm), females tend to produce fewer large and relatively expensive gametes (eggs). Male reproductive success (the number of offspring a male can sire) is, thus, primarily limited by his number of successful fertilizations, whereas female reproductive success is limited by the number of her eggs. Bateman (1948) was the first to demonstrate that this imbalance can lead to conflict over mating frequency. In the fruit fly, *Drosophila melanogaster*, male reproductive success increased much more rapidly with each successive mating than did female reproductive success; the optimal mating rate for males is thus substantially higher than the optimal mating rate for females. Under these conditions, a trait that increases male mating success will be favored by selection even if it is harmful to females (Parker, 1979), and females will then be selected to minimize this harm by mating less often.

Conflict over mating frequency occurs whenever the optimal mating rate is different for males and females, which is the case for the majority of species. As we describe above, the optimal mating rate for males is often higher than it is for females, and this conflict leads to a variety of coevolutionary arms races between males and females.

Grasping and Anti-Grasping Structures

In order for fertilization to occur in many species, a male must physically interact with a female (mount) and insert an intromissive organ (i.e., penis/phallus) inside, or near, the female's reproductive tract. This often leads to overt struggles between males and females over whether or not a male's mating attempt will be successful, with females struggling to actively dislodge mounting males (Blyth and Gilburn, 2011; Rowe *et al.*, 1994). In several species of water striders, males have evolved specialized structures that they use to grasp females once they have mounted, thus reducing their likelihood of being dislodged (Rowe *et al.*, 1994). Males of some species have evolved elongated genitalia that serve a clasping function (Arnqvist and Rowe, 2002b), while males in other species have evolved specialized antennae with hooks or spikes that fit into a groove next to the female's eye (Khila *et al.*, 2012). In these species, females have evolved a number of different 'anti-grasping' structures, such as abdominal spines that aid in dislodging males (Arnqvist and Rowe, 2002b). These male and female structures reflect the current state of the arms race: species of water striders in which females have smaller abdominal spines also show elevated mating rates, likely because these females are less able to dislodge mounting males (Arnqvist and Rowe, 2002a).

A similar male grasping structure is seen in the sagebrush cricket, a species in which females mount the males to mate. During mating, females chew on their mate's fleshy hind wing and ingest hemolymph that seeps from the wounds. This sexual cannibalism provides a nutritive benefit to females, but is harmful to males, reducing their future mating success (Johnson *et al.*, 1999; Sakaluk *et al.*, 2004). Females prefer to mate with virgin males that have intact hind wings (Eggert and Sakaluk, 1994), and will mount males to determine the status of their hind wings, dismounting without mating if the hind wings are not intact. In response to this female behavior, males have evolved a specialized abdominal pinching organ referred to as a 'gin trap' that clasps mounted females and prevents them from dismounting until they mate (Sakaluk *et al.*, 1995).

Male Harassment and Female Resistance

Instead of using specialized grasping structures, males of many species use behavioral adaptations to coerce females to mate. Perhaps the most widespread male approach is to persistently court and harass females that are resisting mating attempts (Clutton-Brock and Parker, 1995). Persistent male harassment that is harmful to females has been documented across a diverse range of species, including seed beetles (den Hollander and Gwynne, 2009), guppies (Magurran and Seghers, 1994), mallard ducks (Titman and Lowther, 1975), and sheep (Reale *et al.*, 1996).

In the fruit fly (**Figure 1**), *D. melanogaster*, females exhibit a variety of rejection behaviors toward an undesirable courting male (Spieth, 1952). Males often continue to pursue females in spite of these rejection behaviors, and this persistent male courtship is harmful to females, shortening their life span (Partridge and Fowler, 1990) and reducing female lifetime fecundity (Rice *et al.*, 2006). Moreover, this conflict over mating can intensify when males are able to detect differences in female fitness (i.e., via body size; Byrne and Rice, 2006; Edward and Chapman, 2012; Long *et al.*, 2009) and direct their antagonistic harassment toward higher quality females,

Figure 1 A male fruit fly (*Drosophila melanogaster*). *Drosophila* males exhibit a number of sexually antagonistic traits, including harassment and toxic seminal fluid proteins. Wikimedia Commons http://en.wikipedia.org/wiki/Drosophila_melanogaster#mediaviewer/File:Drosophila_melanogaster_-_side_(aka).jpg

such that these females suffer proportionally more harm than lower quality females (Long *et al.*, 2009). Importantly, females show genetic variation in their ability to resist the harm inflicted by males; this variation accounts for ~17% of the total variation in female fitness (Linder and Rice, 2005) and is largely mediated by how resistant females are to male mating attempts (Lew *et al.*, 2006).

In the red-backed water strider, males use a more specialized behavior to coerce females to mate. In this species, females have evolved a specialized shield over their vulvar opening that acts like a drawbridge; this gives females control over mating frequency, as they must expose their genitalia for copulation to proceed. Mating occurs on water, and when females refuse to expose their genitalia to mounted males, the males tap the surface of the water with their mid-legs (Han and Jablonski, 2009). This male behavior attracts aquatic predators; because females are directly on the water surface, they are more likely to be attacked by these predators (**Figure 2**). This male intimidation is very effective: females expose their genitalia in response to male water tapping, and do so more quickly when the risk of predation is higher (Han and Jablonski, 2010).

Figure 2 Male coercion in red-backed water striders (*Gerris gracilicornis*), where the male attracts potential predators by 'tapping' the surface of the water until the female submits to a mating. Chang Seok Han http://changshan.egloos.com

Figure 3 Traumatic Insemination in the bedbug (*Cimex lectularius*), where the male bypasses the genital tract of the female and instead uses hypodermic genitalia to inject sperm directly into the female's abdomen. Wikimedia Commons http://en.wikipedia.org/wiki/File:Traumatic_insemination_1_edit1.jpg

Traumatic Insemination

Males of some species have evolved a unique way to circumvent female resistance to mating attempts. Instead of attempting to mount and copulate with a female via her genitalia, these males penetrate the female body wall using specialized 'hypodermic' genitalia and inject sperm directly into the female's body cavity. This 'traumatic insemination' has evolved several times in invertebrates, but is most widely studied in bed bugs (**Figure 3**), where it has been shown to increase male fertilization success but decrease female longevity and reproductive success (Stutt and Siva-Jothy, 2001). In response to this harmful male adaptation, females have evolved a counter-adaptation that minimizes these costs. The 'spermalege' is a specialized region of the female abdomen with a thickened cuticle that lies directly over a pocket on the inner surface of the abdominal wall (Carayon, 1966) that mitigates female injury and defends against pathogens (Morrow and Arnqvist, 2003; Reinhardt *et al.*, 2003).

Coevolutionary Arms Races Over Fertilization

Given the imbalance in gamete investment between the sexes (i.e., males produce many 'cheap' sperm, while females produce few 'expensive' eggs), females have a vested interest in ensuring that the highest quality males fertilize their eggs. This process is generally referred to as sexual selection, and results in males competing for access to females or territories and/or females being selective about their mating partners. The most direct way for females to ensure fertilization only occurs by preferred males is to be choosy about their mates. However, as discussed above, females do not always have complete control over which males they mate with. When females mate with multiple males, however, female choice can continue after mating if females can 'choose' which sperm to use or store, a

Figure 4 The phallus of the seed beetle (*Callosobruchus maculatus*). Males with a phallus that is more damaging to females sire more offspring. Wikimedia Commons http://en.wikipedia.org/wiki/Callosobruchus_maculatus#mediaviewer/File:Callosobruchus_maculatus_penis.jpg

process called 'cryptic female choice' (Eberhard, 1996; Thornhill, 1983).

Female orb spiders (*Argiope keyserlingi*) typically mate with multiple males throughout their life, and consume the males shortly after mating has started. Despite the fact that males vigorously attempt to escape, most are captured and consumed. Capture of the male by the female immediately terminates copulation, and hence can be used by females to control mating duration. It has been found that females preferentially delay capture of smaller males, thus allowing them to fertilize more eggs, and giving females control of offspring paternity (Elgar *et al.*, 2000). This cryptic female choice creates the potential for coevolutionary arms races between the sexes to continue after mating.

Sperm Competition

In the same way that female choice can continue inside the female reproductive track after mating, so too can male competition: when females mate with multiple males, their sperm must compete with one another for fertilizations. Sperm competition is ubiquitous among nonmonogamous mating systems, and has led to a number of diverse adaptations in males to increase their fertilization success (Birkhead and Møller, 1998; Parker, 1970). These male adaptations often lead to conflict with females over which sex controls offspring paternity (Stockley, 1997).

The genitalia of male seed beetles (*Callosobruchus maculatus*) (**Figure 4**) possess a large number of spines that penetrate the reproductive track of females during copulation and cause internal injuries (Crudgington and Siva-Jothy, 2000; Hotzy and Arnqvist, 2009). Males with longer genital spines cause more injuries to females than males with shorter spines. While the mechanism is unknown, when females mate multiply, males with longer spines sire significantly more offspring than those with shorter spines, despite the increase in female harm (Hotzy and Arnqvist, 2009). Similar genital-induced harm to females is seen in dung-flies (Blanckenhorn *et al.*, 2002), but has not been linked to an increase in sperm competition.

Figure 5 A copulatory plug in a female Richardson's ground squirrel (*Urocitellus richardsonii*). Copulatory plugs are common in rodents, and serve to prevent or delay female remating. Wikimedia Commons http://en.wikipedia.org/wiki/Rodent#mediaviewer/File:Mating_plug.jpg

Copulatory plugs are particularly common in insects, reptiles, and some mammals. The components of the plugs are transferred in the ejaculate during mating, and then harden into a plug that fills the female reproductive track (**Figure 5**). Copulatory plugs are larger and stronger in species with higher levels of sperm competition (Ramm *et al.*, 2005), and females cannot remate while the plug is present. Eastern gray squirrel and fox squirrel females physically remove the plug shortly after mating (Koprowski, 1992), while female house mice secrete enzymes after mating that degrade the plug (Dean *et al.*, 2011).

Forced Copulations

One of the most extreme outcomes of persistent male harassment is a forced copulation, whereby a female is physically overpowered, or rendered unable to resist the mating attempt of a male(s). It is in these extreme cases when it would be most advantageous for a female to prevent fertilization from occurring. Forced copulations are particularly common in waterfowl, where they appear to have generated sexually antagonistic genital coevolution (Brennan *et al.*, 2007). For example, male muscovy ducks have corkscrew-shaped penises, while females have anti-corkscrew vaginas with bends and blind alleys (Brennan *et al.*, 2009). This complex female vaginal morphology limits penile access during forced copulations, such that they result in very few fertilizations.

When given the choice, female feral fowl prefer to mate with dominant males over subordinate males. However, the majority of copulations are forced in this species, so females are rarely able to choose their mates (Pizzari and Birkhead, 2000). Instead, females have evolved a morphological counter-adaptation to this male behavior. Females are able to eject ejaculate from their reproductive track after mating with subordinate males, allowing them to preferentially store and use sperm from dominant males.

Toxic Seminal Proteins in *Drosophila*

When a male mates with a female, he not only transfers sperm, but also a seminal fluid containing a cocktail of different seminal fluid proteins. In *Drosophila*, these proteins are usually called accessory proteins (Acps), and they serve a variety of roles. *D. melanogaster* males transmit at least 138

different Acps (Findlay *et al.*, 2008), and many of these proteins undergo rapid evolutionary change, indicating that they are under strong positive selection (Swanson *et al.*, 2001). While the function of the majority of these proteins is unknown, several seem to aid in sperm competition (Chapman, 2001; Wigby *et al.*, 2009), and at least one has been identified as a contributor to the male–female arms race. Sex peptide (Acp70A) increases oogenesis (Kubli, 2003) and directly affects female behavior and physiology. In addition to increasing female fecundity after mating, sex peptide also makes females less receptive to subsequent mating attempts (Peng *et al.*, 2005; Wolfner, 2002), increases female locomotor activity, decreases the time females spend sleeping (Isaac *et al.*, 2009), and increases female feeding rates (Carvalho *et al.*, 2006). While all of these actions serve to greatly increase the male's relative fitness, sex peptide is toxic to females, shortening female life span (Chapman *et al.*, 1995) and lowering female lifetime reproductive success (Wigby and Chapman, 2005). Other Acps show similar involvement in sperm competition (Fiumera *et al.*, 2005) and fecundity induction (Herndon and Wolfner, 1995), so several Acps have the potential to be involved in a postmating arms race in *Drosophila*.

Conclusions: Who Wins an Intraspecific Arms Race?

Given the cyclical nature of antagonistic coevolutionary arms races, can one participant be considered the 'winner'? When applied to an interspecific context (i.e., predator/prey or parasite/host interactions), whichever population can more rapidly overcome the adaptations of the other will move ahead in the arms race and 'win.' Although this win is often temporary, in extreme cases one population can cause the local extinction of the other. If the prey/host species is 'victorious,' then its population will persist and no longer be negatively impacted by the predator/parasite species. If the predator/parasite 'wins,' then either the prey/host population will go locally extinct, or continue to exist in lower numbers than would occur in the absence of the predator/parasite. Extinction of the prey/host, however, does not necessarily mean the demise of predator/parasite, as they may be able to shift to new prey/host species.

Unlike a traditional coevolutionary arms race between two different species, an intraspecific arms race cannot have a 'winner,' even over shorter time periods: males cannot exist without females as reproductive partners, and vice versa. So, while males do not necessarily increase in frequency in the population, the alleles that improve their relative performance do. Similarly, while counter-adaptation does not necessarily cause an increase in the number of females in a population, it will cause an increase in the frequency of the associated resistance alleles. It is this interlocus conflict between the harming and resistance alleles that drives intraspecific antagonistic coevolution and leads to interesting, yet conflicting, potential evolutionary outcomes.

As alleles that increase male fitness at the expense of female fitness accumulate in the population, the fitness of the population as a whole also decreases (because the mean population fitness is limited by the mean female fitness; Holland and Rice, 1999). Therefore, if female resistance alleles do not accumulate sufficiently quickly, it is possible that populations with high levels of conflict will go locally extinct. Although theory suggests that intraspecific antagonistic coevolution increases the extinction risk of populations/species (Kokko and Brooks, 2003), there is only limited empirical support from phylogenetic studies in birds (Morrow and Pitcher, 2003) and mammals (Morrow and Fricke, 2004).

Alternatively, the back-and-forth nature of an intraspecific arms race may promote speciation. Given that any new male-benefit adaption arises through random mutation, it is very unlikely that the same, specific adaptation will arise independently in two separate populations. Female counter-adaptations that reduce or remove the associated male-induced harm will generally need to be specific to the male adaptation. Therefore, each population within a species proceeds down its own unique evolutionary trajectory, such that after each cycle of adaptation and counter-adaptation, populations can become phenotypically distinct. As these differences accumulate, populations can become reproductively isolated, potentially leading to speciation. In addition to being theoretically possible (Gavrilets, 2000; Parker and Partridge, 1998; Rice, 1998), there is supporting evidence that sexual conflict leads to speciation in insects (Arnqvist *et al.*, 2000), but not in birds (Morrow *et al.*, 2003).

Here we have focused specifically on arms races as they pertain to the separate sexes (intersexual) in the context of mating and fertilization, but there are numerous other ways in which antagonistic coevolution can operate within a species. Just as males have adaptations to coerce females to mate, males also have to compete for these matings with other males, and females may need to compete with one another for access to resources or breeding grounds. These intrasexual conflicts can lead to a wide variety of 'solutions,' including different morphologies and/or alternative behaviors. Similar conflicts can occur between parents and their offspring or between siblings over the amount of resources allocated to each offspring (Trivers, 1974; Godfray and Parker, 1992), and between males and females over the amount of parental care each provides to their offspring, if this care comes at the expense of future mating/reproductive opportunities (Westneat and Sargent, 1996). Despite being members of the same species, or even the same population, different individuals have selfish genetic interests. As a result, arms races that occur within species may be equally as important as arms races between species for adaptive evolutionary change.

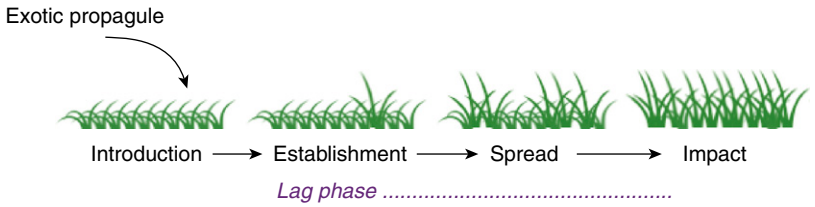
Invasion Biogeography

GK Roderick, University of California, Berkeley, CA, USA

An invasive species is a nonindigenous species that is expanding its range and that causes some impact, either environmental or economic. Researchers debate as to whether impact is important for the definition, for example, some argue invasive species include all nonindigenous widespread species, or of these, only those that are also expanding their range (Sax *et al.*, 2007; Valéry *et al.*, 2008; Colautti and Lau, 2015). Regardless of the definition, two features characterize invasive species, colonization of new ecological environments and subsequent geographical spread. Only relatively recently have researchers recognized that biological invasions necessarily involve not only ecological, but also evolutionary processes. This understanding is not solely academic. Knowledge of how invasive species evolve and what limits their evolution provides insights into predicting whether and how species will respond to global change, especially changes in climate and land/water use.

In 1965, Herbert G. Baker and G. Ledyard Stebbins published the *Genetics of Colonizing Species* (Baker and Stebbins, 1965). This volume provided the 'ah-ha moment' for many biologists to realize that evolutionary forces were important in the geographical spread of species, and in particular, the role of genetic mechanisms, which were becoming better understood at that time. It was already recognized even since Darwin that certain ecological features were critical in species range expansion, including ecological attributes of either the invasive species themselves, or the invaded habitats, and/or their interaction (Elton, 1958; Sax *et al.*, 2007). For example, commonly cited ecological characteristics of invasive species include high dispersal, rapid generation time, and generalist life style, among others, while characteristics of invaded habitats include disturbance and species poor communities with few competitors and predators (Williamson, 1996). With their volume, Baker and Stebbins brought new genetic insights into what determines the success of colonizing species, especially by linking approaches including detailed natural history, novel methods of genetic characterization, observations from natural experiments, and common garden manipulations. For the 50th anniversary of the Baker and Stebbins volume, a group of researchers reexamined the genetics of colonizing species (Barrett, 2015; Bock *et al.*, 2015), which along with an earlier, and in retrospect now visionary, perspective by Lambrinos (2004), provides a framework for this review.

Biological invasion is best thought of as a process, with several identifiable key stages (**Figure 1**; Kolar and Lodge, 2001;



Evolutionary process	Introduction	Establishment	Spread	Impact
Migration	Dispersal traits Pathways Numbers of propagules Multiple colonization events Life history variation	Bet-hedging Hybridization	Dispersal within range New population structure Hybridization	Dispersal within range
Drift		Founder events Inbreeding		
Mutation			New variation Genetic rearrangement	
Selection		Preadaptation Climate matching Phenotypic plasticity	Local adaptation Life history evolution	Life history evolution

Figure 1 Stages of invasion and associated evolutionary processes. Redrawn from Kolar, C.S., Lodge, D.M., 2001. Progress in invasion biology: Predicting invaders. Trends in Ecology & Evolution 16, 199–204; Sakai, A.K., Allendorf, F.W., Holt, J.S., 2001. The population biology of invasive species. Annual Review of Ecology and Systematics 32, 305–332.

Sakai *et al.*, 2001; Lambrinos, 2004). In the invasion process, organisms are introduced, either naturally or anthropogenically, and a fraction of those become established. Of the established species, a proportion spread, and of those, only some species cause some type of environmental or economic impact. Often, but not always, invasive populations may take some time to reach a population size that is noticed or causes a significant problem, a period called the 'lag phase' (Figure 1). At each stage in this process, ecological and evolutionary forces operate as filters, resulting in only a small proportion of species at each stage in the process making it to the next stage. This phenomenon has been termed the '10's rule,' noting an arbitrarily small 10% of species making it to the next stage (Williamson, 1996). Evolutionary forces involved in the invasion process include migration, drift, mutation, and selection, all of which can cause changes in the frequencies of genes within populations.

The invasion process itself places some constraints in dictating how the forces of evolution can interact and when. For example, both drift and selection require genetic variation on which to act, yet many invasions are thought to have originated by a small set of founding propagules, presumably with a small and random sample of the genetic variation of the source population. One might naturally ask, how important then can drift and selection be for the success of invaders, given initial low genetic diversity? This is a central evolutionary challenge facing invasion biologists.

Introduction Phase

Which species are introduced depends on dispersal, termed migration in a genetic/evolutionary context. Some organisms disperse on their own, some are vectored by other organisms, and some disperse in association with human activities. Spiders ballooning on threads of silk are an example of natural dispersal, with individuals being predictably among the first to arrive on newly created islands (Gillespie *et al.*, 2012); widow spiders that move around the world associated with produce, such as bananas, illustrate the effects of anthropogenic factors in dispersal. Of critical importance is how many individuals arrive in the new habitat, either at one time or sequentially over time. This magnitude of dispersal from a source area to the new habitat over time is termed propagule pressure – i.e., how many individuals arrive. Propagules can disperse in many ways reflecting the nature of available habitat, but also the mechanism of introduction (Figure 2). In addition to propagule pressure, patterns of life history and ability to disperse are important in the introduction phase, with the result being that some types of species repeatedly arriving at new localities, and their

	Description
Leading-edge dispersal	A gradual change in range is initiated by individuals colonizing new areas from the edge of the range
Corridor	A physical connection of suitable habitat forms, linking a portion of the original range to another area
Jump dispersal	Propagules disperse over sometimes substantial distances, but still with a connection between the new and original ranges
Extreme long-distance disperal	Propagules move far beyond the dispersal range seen over ecological time scales
Mass dispersal	A dispersal route is established such that many individuals can move from different parts of the range to many new sites
Cultivation	Propagules are actively moved and provided with resources to establish and persist

Figure 2 Types of modes of dispersal. Redrawn from Lockwood, J.L., Hoopes, M.F., Marchetti, M.P., 2013. Invasion Ecology. New York: John Wiley & Sons.

representation can be nonrandom, especially in remote locations (Carlquist, 1966).

Establishment Phase

Carlquist (1966) noted, "Difficulties of establishment seem much greater than those of transport. To establish, the number of founding individuals and their genetic make up becomes important." It is well known that small numbers of founders carry only a subset of the genetic variation in the source population, and such founder events may lead to negative effects associated with eventual establishment, such as inbreeding. Many studies are now showing that multiple founder events by the same species are common for invasive species (Bock *et al.*, 2015). Further, when these colonists come from different places, the genetic pool in the invasive population can be sizable. A now classic example is that of multiple colonizations of a Caribbean lizard, *Anolis sagrei*, (**Figure 3**) from different locations in the Caribbean into Florida (Kolbe *et al.*, 2004). When *Anolis* individuals from these different sources mixed, the genetic diversity in the resulting invasive population was highly significantly greater than any of the sources individually. Such admixture of individuals from multiple populations may be far more important than realized in contributing to genetic variation in invasive species, and may allow invasive populations to have high levels of genetic variation early in the invasion process. In a similar way, invasive species can mix genetically, or hybridize, with indigenous species or other invaders. Examples of invasive species exhibiting hybridization include, *Spartina* plants, *Rhagoletis* flies, *Anas* dabbling ducks, and *Bemisia* whiteflies among others (Vellend *et al.*, 2007).

Another key to establishment is the extent to which invasive species are already adapted to the novel habitat. This adaptation can be a result of the new environment closely matching the source, for example, in climate variables, or similarities in the biotic composition, including symbionts, competitors or predators. Alternatively, conditions in the source environment may have 'preadapted' the organism for high fitness in a new different set of environmental conditions found in the novel habitat, such as Mediterranean species that invade areas of similar climates worldwide (Barrett, 2015).

Figure 3 *Anolis sagrei*, photo credit: Wikipedia.

Another form of preadaptation is phenotypic plasticity, in which species can naturally cope with a diverse set of natural conditions, as seen for at least some traits of the soapberry bug, when presented with an introduced plant. Phenotypic plasticity also provides the opportunity for an expression of diverse phenotypes upon which selection can act, perhaps in different environments (Lande, 2015).

As with introduction, those species that establish are not a random subset of the set of possible species in a source community. Indeed, one predictor of whether a species is likely to be invasive is whether it has been observed to be invasive elsewhere (Lonsdale, 1999; Bock *et al.*, 2015), and such serial invasions are common. What studies of such species are not able to observe are all the introductions that failed to establish, which is no doubt is a considerably high number (Carlquist, 1966). Thus, similar to a 'non-reporting bias' in statistical sampling, we observe only those species that are able to establish for whatever reasons. Because monitoring the fate of unsuccessful propagules under natural conditions is very difficult, understanding the importance of this non-reporting bias of successful invasive species is extremely difficult.

The importance of genetic variation in establishment remains elusive and, for reasons noted above, genetic variation may not be limiting. While theory predicts genetic variation is necessary for adaptation and even preadaptation, many successful invaders have little genetic variation (Sax *et al.*, 2007; Bock *et al.*, 2015); for example, the spreading Japanese knotweed in Britain appears to be a single genetic clone. Additionally, an invasive species that has already been selected for coping with limited genetic variation in a previous invasion elsewhere may not necessarily require genetic variation to be successful in a novel habitat.

Spread Phase

Once established, invasive species typically expand their range geographically. Individuals may move to new areas of the same type of environment, or to different types of habitats, where there may be selection as a result of the new environmental conditions. Populations in different areas may become differentiated genetically, either through drift or through local adaptation (Vellend *et al.*, 2007). Genetic variation may again be increased when individuals from such populations hybridize upon later contact. By contrast, if founding populations are small and deleterious mutations accumulate in expanding populations, expansion success could be limited; this little studied phenomenon is termed expansion load (Peischl *et al.*, 2015). Several other related questions remain unanswered, including the relative importance of adaptation at this phase compared to preadaptation, the importance of local adaptation in farther geological spread, and the extent to which population structure of invasive populations resembles that of species with a longer history in the environment (Gillespie *et al.*, 2008; Barrett, 2015).

During this phase of invasions, populations are necessarily growing. Often the time from introduction to the time of a significant population size can be long, for example, 10s or even 100s or more of generations, resulting in the 'lag phase' noted above (**Figure 1**). There are both ecological and

Figure 4 Garlic mustard, *Alliaria petiola*, photo credit: Wikipedia.

evolutionary explanations for this lag phase. Population growth of invasive species can result from invasive populations responding sufficiently in numbers to new biotic pressures including competitors and predators, or in overcoming *Allee effects* at small population size. Large-scale monitoring programs measuring the same characteristics across a wide invasive range, such as implemented for the garlic mustard, *Alliaria petiola* (Colautti *et al.*, 2014; **Figure 4**) offer a comparative framework for understanding the role of novel environments. It may also be that additive genetic variation has increased since establishment through a variety of possible mechanisms, including mutation, genome rearrangements, and horizontal transfer of novel genetic elements. New genomic tools offer unprecedented opportunities to understand the relative importance of each genetic mechanism in the success of invasive species.

Selection is also critically important at the phase of geographical spread; selection can act to favor those individuals that are able to make it to new environments, and/or to make it to these environments first. For example, extensive studies of the cane toad, *Rhinella marina*, show selection for morphology and life history traits that favor dispersal, especially at the invasion front (Phillips and Shine, 2006; Shine, 2010; **Figure 5**). The process of geographic spread itself creates conditions that may accelerate evolution, through drift, selection, or genetic rearrangements (Kirkpatrick and Barrett, 2015).

Impact

Eventually, invasive populations build in numbers and geographic area to have a noticeable impact on ecological communities or on human activities with economic consequences. Here, selection can act on life history variation, including

Figure 5 Cane toad, *Rhinella marina*, photo credit: Wikipedia.

dispersal, in response either to biological or environmental conditions in the novel habitat, or anthropogenic conditions, such as pest control. For example, resistance to pesticides including antibiotics is well known throughout the diversity of life, including microbes, plants, and animals, allowing many organisms to spread uncontrolled.

Invasion Biogeography

The study of biological invasions can offer insights into the dynamic nature of patterns of biogeography (Sax *et al.*, 2007). While much remains to be understood, some patterns are beginning to emerge. First, while colonizations and large-scale biotic exchange have been ongoing in geological time, human activities have accelerated the rate of exchange. Not only is turnover more rapid (Burns, 2015), but also species have become more homogenized among regions, as has species richness among regions (Sax and Gaines, 2006; van Kleunen *et al.*, 2015). The rate at which these effects have occurred, including the development of global patterns of biodiversity suggest that long-term explanations of global biodiversity are not necessary – for example, traditional latitudinal gradients of biodiversity may have a more recent explanation. Second, the number of indigenous species seems to be correlated, suggesting that biological communities are not saturated. However, this result is complicated (Sax and Gaines, 2006). For example, more species are invading low temperate latitudes, although with smaller geographical ranges. By contrast, fewer species are invading at higher latitudes, though with larger geographic ranges. Islands appear to be disproportionally affected (Sax and Gaines, 2008). Finally, the impact and spread of biological invasions depends on the species involved and their interactions. Climate and dispersal limitation explain only a portion of the distribution of invasive species, suggesting a key role of species interactions (Capinha *et al.*, 2015).

Summary

Perhaps the most important evolutionary insight from the study of invasive species is that rapid adaptation of invaders is common (Bock *et al.*, 2015). It appears that genetic variation is

not necessary limiting, which can be the result of many possible mechanisms, including nonrandom sampling of invasive propagules, multiple colonization events, hybridization, preadaptation, phenotypic, plasticity, mutation, and novel genetic mechanisms (Vellend *et al.*, 2007). A second main insight is that each of the phases of the invasion process is associated with important evolutionary, as well as ecological forces, and both contribute to the success of invasive species. Third, biological communities are not saturated, such that even in the most diverse assemblages species are able to establish and persist (Sax *et al.*, 2007).

Looking forward, studies of invasive species have much to offer in understanding biological evolution associated with novel environments, especially in understanding the limits of evolutionary response to global change. Such systems offer natural experiments, in which the same species is introduced to multiple environments, but also the opportunity for experimentation through purposeful, controlled introductions, such as in biological control, 'common garden' designs, and controlled studies of selection. New genomic tools promise to offer insights into genetic mechanisms associated with invasion, particularly with respect to the importance of mutations, novel genetic variation, and genetic rearrangements. Interactions of species are paramount. The tricky part, as noted by Baker and Stebbins (1965), is how to combine these approaches.

Invasive Species, Evolution and

CJB Sorte, University of California, Irvine, CA, USA

Glossary

Admixture Population composed of individuals from previously separated source populations.
Biotic homogenization Increasing genetic and taxonomic similarity between regions
across the globe which is promoted by species invasions.
Invasion vector Mechanism of human transport of nonnative species from their native, source region to a nonnative, recipient region.
Invasive species Nonnative species that have been introduced by humans and have established and spread in their introduced range.
Propagule pressure The total number of introduced individuals, which is a function of number of introduction events and number of propagules released during each event.

Background

The study of species invasions is important both from the perspective of biodiversity conservation and because it provides general insights into ecology and evolution (Sax *et al.*, 2005, 2007). One of the most important and defining characteristics of invasive species is that their evolutionary history with species in the invaded region is relatively short (Strauss *et al.*, 2006a,b; Sorte *et al.*, 2010a). To explore the role of evolution in species invasions in more detail, it is first important to define invasive species, the steps species must undergo to become invasive, and the scope of the invasive species problem.

Defining Invasive Species

Invasive species are defined as nonnative species that have been introduced by humans and have established and spread in their introduced range. These last two characteristics – establishment and spread – imply impacts on native communities, although impacts have been quantified for only a small proportion of introduced species (e.g., Williams and Smith, 2007). In some cases, when the term invasive is synonymous with weedy, some subset of native species could also fit this definition (Vigueira *et al.*, 2013). This article focuses on nonnative invasive species; however, certain evolutionary concepts related to invasive species will also apply to native pests.

The Invasion Pathway

Species invasions occur via a stepwise process known as the invasion pathway (**Figure 1**; see also Theoharides and Dukes, 2007). First, individuals of a species are transported by humans from the source region in their native range to the recipient region in their nonnative range via an introduction vector. This transport can be either intentional (e.g., plants sold in the horticultural trade; Mack and Lonsdale, 2001) or unintentional (e.g., hitchhikers in commercial shipping vessels; Westphal *et al.*, 2008). Second, colonization occurs if the transported individuals are able to survive and reproduce in the nonnative range. Third, the introduced species is considered established if it has formed a reproducing and self-sustaining population. The final step in the invasion pathway is secondary spread, in which the species extends its range within the nonnative region. By definition, an invasive species must not only become established in its new location, but it must also expand its range beyond the original introduction site.

Whether or not a species is successful in becoming invasive depends upon its ability to pass through filters imposed by the different stages of the invasion pathway (**Figure 1**). For example, before even arriving in their new territory, future invasive species must find – or be chosen for – transport and

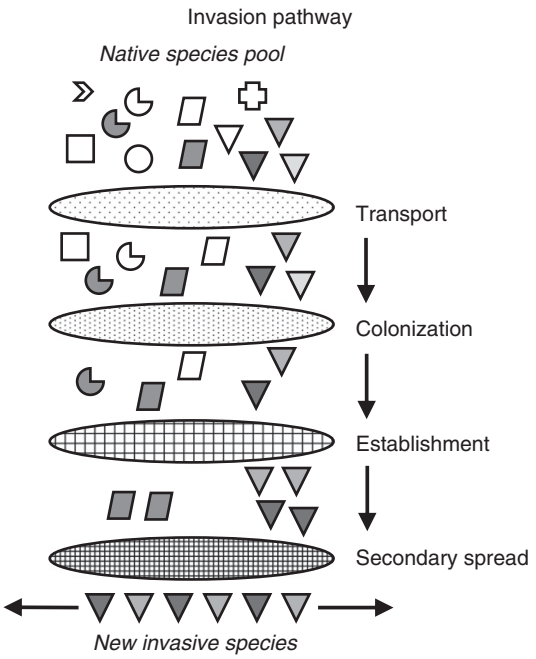

Figure 1 In order to become invasive, species (different shapes) must pass through four stages (listed on the right). Each stage acts as a filter to decrease the species pool as well as genetic diversity (indicated by shading in the shapes) within each species.

 doi:10.1016/B978-0-12-800049-6.00303-6

survive the journey. Once in the new habitat, invasion success depends on the ability to tolerate climatic conditions, attain resources, and avoid consumption in the nonnative range under a potentially novel set of abiotic and biotic conditions. The sequential narrowing of the potential invasive species pool is illustrated by the tens rule, which suggests that only 10% of introduced species become established, and only 10% of these become invasive (Williamson, 1996). Actual proportions rarely conform to such a simple scheme and are taxon-specific; however, establishment and subsequent invasiveness only occur in the minority of introductions (Jeschke and Strayer, 2005).

Scope of the Invasion Problem

Despite the fact that most species do not become invasive, those that do can have extremely large ecological impacts and economic costs (Pimentel *et al.*, 2005), and the invasion problem is increasing (Butchart *et al.*, 2010) concurrent with globalization. There were approximately 120 000 nonnative species in the United States, Europe, Australia, South Africa, India, and Brazil as of the census by Pimentel *et al.* (2002) (**Figure 2**), and the control of – and damages by – invasive species in those countries cost more than $300 billion per year. Even a relatively small-scale introduction of the killer alga, *Caulerpa taxifolia*, one of the world's '100 worst' invasive species, near San Diego, California, USA, cost >$6 million for local eradication (Williams and Grosholz, 2008).

In ecological terms, invasive species have driven declines in native populations, as well as extinctions. The impact of each invasive species is expected to increase directly with range size, population size, and per capita effect (Parker *et al.*, 1999). Although extinction causes are often equivocal and occasionally disputed, invasive species are implicated as a leading cause of animal (particularly bird and fish) extinctions (Gurevitch and Padilla, 2004; Clavero and Garcia-Berthou, 2005). In fact, invasive species are considered one of the primary threats to global biodiversity across terrestrial and aquatic ecosystems (Sala *et al.*, 2000; Millennium Ecosystem Assessment, 2005) and, more specifically, to an estimated 42% of species on the threatened and endangered species lists (Pimentel *et al.*, 2005). Extinctions are particularly likely on islands, where potential for avoidance of invasive predators via niche displacement or rapid evolution is relatively low (Mooney and Cleland, 2001). For example, the invasive brown tree snake appears to have driven extinctions of native birds on Guam, in the tropical western Pacific Ocean (Savidge, 1987). The invasion problem is becoming exacerbated as introductions are not only continuing but are increasing in many regions (Cohen and Carlton, 1998; Millennium Ecosystem Assessment, 2005), leading to rapid biotic homogenization (see Olden *et al.*, 2004).

Evolutionary Characteristics of Invasive Species

Introduced species can be prone to founder events and population bottlenecks imposed by filters in the invasion pathway, leading to declines in genetic diversity within nonnative populations as compared to their native, source populations. In a review of 80 species of animals, plants, and fungi, diversity of alleles and heterozygosity were significantly lower in introduced populations than in source populations, although decreases were less than 20% (Dlugosch and Parker, 2008; also see Wares *et al.*, 2005). Furthermore, Dlugosch and Parker (2008) found a U-shaped relationship between genetic

Figure 2 Invasive species are a global issue, leading to economic, ecological, and evolutionary impacts on native ecosystems. Examples of recent invaders include (a) the Cuban tree frog, invasive in the USA (Florida and Hawaii) and throughout the Caribbean; (b) a suite of invasive tunicates that are now found in coastal waters worldwide and foul docks, boats, and shellfish; and (c) the cordgrass *Spartina alterniflora* which has hybridized with a native species, *Spartina foliosa*, and is shown here invading San Francisco Bay, California, USA.

(allelic) diversity and time since first introduction, suggesting that selection and genetic drift continue the loss of genetic diversity during the first several decades after colonization. Over longer time scales, multiple introductions can cause genetic diversity to rise again via the mechanisms discussed below. Thus, it is perhaps not surprising that a lag phase often occurs between the colonization and spread stages in the invasion pathway (see Crooks, 2005), in which population growth and subsequent spread are inhibited either directly by low population sizes or by low level of genetic variation within the populations.

Propagule pressure – or the total number of introduced individuals – is one of the best supported correlates of invasion success (Kolar and Lodge, 2001; Lockwood *et al.*, 2005; Colautti *et al.*, 2006) and can counteract the effect of founder events on genetic diversity within introduced populations (Roman and Darling, 2007). Simberloff (2009) reviewed examples – from birds to ungulates – of cases where introductions failed until the number of introduced individuals exceeded a minimum threshold. Increased propagule pressure is associated with increased population sizes and increased genetic diversity within populations (Simberloff, 2009). Furthermore, multiple introductions may lead to the formation of admixtures, new populations composed of individuals from previously separated source populations. Such introduced admixture populations can have equivalent (Dlugosch and Parker, 2008) or even increased levels of genetic diversity as compared to individual source populations (Kolbe *et al.*, 2004; Gillis *et al.*, 2009).

In addition to the invasion process influencing genetic diversity, there is some evidence that genetic diversity also influences invasion success. For example, genetic diversity has been linked to colonization ability in the plant *Arabidopsis thaliana* (Crawford and Whitney, 2010) and productivity and clonal spread in a perennial grass (Lavergne and Molofsky, 2007). It is important to note, however, that there are a number of counter-examples to the trends presented above. Successful invasions of a broad range of species – including a European solitary bee to North America and the North American muskrat to Europe – are thought to have derived from only one to a few introduced individuals (see Simberloff, 2009). There are also examples where invasion success was associated with decreases rather than increases in genetic diversity (e.g., Schmid-Hempel *et al.*, 2007), particularly when loss of genetic variation increased the frequency of a genotype that proved to be beneficial (e.g., increase population sizes) in the nonnative habitat (e.g., Tsutsui *et al.*, 2000).

Evolution of Invasive Species

The invasion process drives evolution in invasive species via both non-selective and adaptive evolutionary mechanisms. The genetic characteristics of invasive species, discussed above, are indicators of the types of non-selective mechanisms at work. Low genetic diversity may indicate the influence of genetic drift, the random change in allele frequencies that more strongly impacts smaller populations. Genetic drift is likely in founder populations, including of introduced species, due to their small sizes (Sakai *et al.*, 2001). High genetic diversity, on the other hand, has been related to the number of separate introduction events occurring over time (Dlugosch and Parker, 2008). Gene flow can be high when introduced individuals are sampled from a large geographic area and also when multiple introductions create admixtures, with increased propagule pressure decreasing the negative impacts of genetic drift and increasing potential for adaptive evolution in the nonnative range. Invasive success can be increased by hybridization both within and between species, including between natives and nonnative (Ellstrand and Schierenbeck, 2000; Schierenbeck and Ellstrand, 2009). For example, hybrids of the introduced cordgrass *Spartina alterniflora* and native species *Spartina foliosa* grow larger and are more invasive than either of the parent species in San Francisco Bay, California, USA (Grosholz, 2002; **Figure 2**).

Adaptive evolution is promoted in invasive species as they experience strong selection pressures at each stage in the invasion pathway. Initial transport might favor individuals that associate with and survive human transport, whereas secondary spread has been associated with increases in reproduction (Colautti and Barrett, 2013) and innate dispersal ability (Phillips *et al.*, 2006). For example, cane toads with longer legs are the first to arrive at and colonize new populations in Australia, and this shift in toad morphology could explain why the invasion front is extending faster over time (Phillips *et al.*, 2006). Within its nonnative habitat, a successful new invader must be capable of surviving environmental conditions, attaining resources, and avoiding predation. Novel environments and biotic interactions can select for shifted climatic tolerances (e.g., Sexton *et al.*, 2002; Lee *et al.*, 2003; Sorte *et al.*, 2011) or increased predator defense (e.g., Miehls *et al.*, 2014). On the other hand, some invasive species experience relaxed selection in the nonnative habitat due, for example, to release from their native enemies or competitors (the enemy release hypothesis (ERH); Keane and Crawley, 2002) or encounters with naïve prey (Cox and Lima, 2006). The evolution of increased competitive ability (EICA) hypothesis describes how this relaxation could allow a reallocation of resources from, for example, predator defense to competitive traits such as faster growth rate (Blossey and Nötzold, 1995). A review of pair-wise experiments suggested that invasive plants were better competitors than native species (Vilà and Weiner, 2004) and a meta-analysis of several hundred species indicated that invasive species had higher values for performance-related traits than non-invasive and native species (Van Kleunen *et al.*, 2010). However, the role of evolution in these competitive and trait differences is unknown, and there are many counter-examples. For example, Seabloom *et al.* (2003) found that native perennials were better competitors than invasive annual grasses, and they attributed the greater dominance of invasive species in their system to differential propagule pressure.

Although there is an increasing number of observations consistent with adaptation, it is important to note that natural selection is not the only explanation for observed phenotypic differences (Keller and Taylor, 2008). Phenotypes are reflections of both genotypes and environmental conditions, and many reports of phenotypic variation are based solely on observational data used to compare individuals of a species from within versus outside its native range or between multiple invasive populations. To determine whether phenotypic

variation is driven by genetic differences versus environmental plasticity, researchers often employ transplant – or 'common garden' – experiments in which the environmental factor is removed or accounted for in the experimental design (e.g., Sexton *et al.*, 2002; Lee *et al.*, 2003; Colautti and Barrett, 2013 cited above). Parker *et al.* (2003) used common-garden experiments to compare morphological traits across 10 populations of an invasive weed inhabiting a range of elevations across the Sierra Nevada Mountains, California, USA. They found that the great majority of phenotypic variance was at the individual (not family or population) level, indicating that differences between samples collected from the field were primarily due to phenotypic plasticity. There is even evidence that invasive species have higher levels of phenotypic plasticity than noninvasive species, as indicated by a meta-analysis of 75 plant species pairs (Davidson *et al.*, 2011). Clearly, population-level differences of invasive species across their native and nonnative ranges could reflect influences of myriad processes, including genetic drift, gene flow, hybridization, phenotypic plasticity, and natural selection.

Invasive Species as Drivers of Native Species Evolution

Observations across time (before and after invasion) and space (within vs. outside invasive species' ranges) have uncovered evidence of invasive species impacts on native species, including cases of rapid evolution in native populations (Mooney and Cleland, 2001; Lambrinos, 2004; Strauss *et al.*, 2006b; Vellend *et al.*, 2007). As an example, Phillips and Shine (2006) suggested that native black snakes in Australia have evolved increased resistance to cane toad toxin and decreased prey preference for the toads after less than 23 generations. Invasive species have also impacted native populations via positive interactions. A native checkerspot butterfly in Nevada, USA incorporated the invasive European weed *Plantago lanceolata* into its diet, and breeding studies indicated a genetic basis to the butterfly's feeding preference (Singer *et al.*, 1993). In some cases, utilizing novel resources requires further adaptation, and a native Australian soapberry bug has evolved longer mouthparts in order to feed on an invasive vine (Carroll *et al.*, 2005). Hybridization between invasive and native species appears to be widespread (Mooney and Cleland, 2001), such as the *Spartina* cordgrass example, above. Invasive species can even promote hybridization between two native species by providing a novel resource and, thus, leading to novel niche overlap between native species that would otherwise not meet nor reproduce (Schwarz *et al.*, 2005). It is, therefore, clear that invasive species have driven evolution of native species although, as for the evolution of the invasive species themselves, the relative contribution of genetic adaptation to observed changes is often unknown.

Implications for the Future: Applying an Evolutionary Perspective to Invasive Species Management

In the words of Charles Elton, called the 'father' of invasion biology, "we are seeing one of the great historical convulsions in the world's fauna and flora" (Elton, 1958, p. 31). Invasive species are contributing to the homogenization of both species and genetic material on a global scale, including driving extinctions of native species and diversification in their invaded habitats. They are an ecological, economic, and evolutionary threat of our own making: while we facilitated invasions initially, we now spend billions of dollars on their control. In so doing, we are driving adaptation of characteristics that allow the invasive species to avoid control and persist in their invaded range (Lee, 2002), including mimicry of the crops they invade and resistance to herbicides and pesticides (Vigueira *et al.*, 2013). Furthermore, we are indirectly contributing to the increased threat of invasive species by our role in driving global climate change, which appears to favor invasive species over native species (Sorte *et al.*, 2010b, 2013).

Future attempts to prevent, control, and eradicate invasive species could benefit from the incorporation of an evolutionary perspective (Whitney and Gabler, 2008). Although protocols are increasingly being implemented to prevent unintentional introductions of nonnative species, intentional imports continue, including through the horticultural trade (Bradley *et al.*, 2012). Importation suitability should be informed by Weed Risk Assessments, which, in the version used by the Australian government, includes population biology characteristics such as hybridization potential and reproductive strategies. Many invasive species start out as seemingly innocuous species introductions, and eradication efforts would ideally start during the establishment and lag phases. Efforts to prioritize nonnative species for control and eradication could be aided by an understanding of population genetics and ecological interactions, in order to identify species that are likely to become invasive, cause ecological and evolutionary damage (i.e., hybridization, extinctions, etc.), and evolve resistance to control methods (Allendorf and Lundquist, 2003). Finally, issues of invasive species developing evolved resistance should be acknowledged, with control practices including fluctuation of multiple herbicides, pesticides, or biological control agents, and potentially assisted spread of nonresistant genotypes (Stockwell *et al.*, 2003). A multipronged approach to invasive species management that incorporates an evolutionary perspective will help us to meet future challenges as invasion rates continue to increase (Millennium Ecosystem Assessment, 2005; Simberloff *et al.*, 2013).

L

Land Animals, Origins of

PA Selden, University of Kansas, Lawrence, KS, USA

Glossary

Coprolite Fossil feces are called coprolites.
Cryptobiosis The ability of an animal to enter a state of reduced metabolism in order to overcome adverse environmental conditions.
Detritivore An organism which eats detritus is called a detritivore.
Epifauna Organisms which live above (i.e., not within) the substrate are called epifauna.
Hexapoda Hexapoda is a group of arthropods including insects, springtails, and their close relatives.
Interstitial Living between grains of sediment is called interstitial.
Isotonic Solutions with the same concentration of solute, so that osmosis does not occur.
Metazoa Multicellular animals are called Metazoa.
Osmosis The passage of water from a solution of higher concentration to one of lower concentration is called osmosis.
Phylum (pl. phyla) A major group of animals with a distinctive body plan; e.g., Arthropoda, Mollusca.
Tetrapod A vertebrate animal with legs (rather than fins) is called a tetrapod.

Introduction

Terrestrialization – the colonization of the land habitat from the sea by plants and animals – was the third most important event in the history of life on Earth, after the origin of life and the development of multicellularity. Here, we look particularly at the origin of land animals. For many people, that brings to mind fish acquiring legs and crawling out of the mud for the first time onto dry land. However, the first tetrapods were preceded onto land by invertebrate animals many millions of years previously. Moreover, what constitutes a terrestrial animal? How much of its life cycle must it spend on land to be considered part of the terrestrial fauna?

There is no doubt that land animals originated in the sea; the isotonicity between the solute concentrations of animal cells and sea water is a testament to this. Osmotic concentration in terrestrial animals is a useful clue to the route they took onto land. Not many animals have managed to move from the sea to the land: of over 30 phyla, only the vertebrates, arthropods, mollusks, and annelids have significant numbers of macroscopic terrestrial representatives. A greater number of phyla include very few terrestrial species (e.g., platyhelminths; Figure 1), cryptobiotic representatives, or internal parasites on terrestrial organisms. The body plans of some highly successful marine phyla have apparently precluded their terrestrialization; these include the sipunculid, echiuroid, and priapulid worms; cnidarians; lophophorates; chaetognaths; pogonophores; hemichordates; and echinoderms. No phylum originated on land, and no major terrestrial taxon has become extinct, as far as we know.

Physiology

In order for marine animals to colonize the land, a number of physiological barriers need to be overcome. These include: changes to methods of respiration, water management and osmoregulation, digestion, temperature control, reproduction, dispersal, sensory perception, and support and locomotion. Water is essential to life, as a medium for biochemical reactions, and for the transport of cell solutes, for example. It is the variability of its availability on land that is problematic for terrestrial life – inundation can be as fatal as dehydration for a

land animal. Four groups of land animals can be defined based on their management of water availability.

- Aquatic organisms avoid the problem by living in interstitial water in soils; these include microscopic nematodes, protozoans, and micro-arthropods.
- Cryptic forms differ from those in the first group in being larger, but similarly inhabit environments of constantly high humidity, such as soil and tropical forest litter. Included in this group are earthworms, leeches, flatworms (Figure 1), isopods, slugs, insect larvae, some amphibians (Figure 2), and myriapods (Figure 3).
- Poikilohydric (desiccation-tolerant) animals require high humidity to function, but can tolerate desiccation by drying out and rehydrating when conditions become favorable again. Cryptobiotic rotifers, mites, and tardigrades occur in this group; also included are animals with desiccation-tolerant resting stages such as the eggs of fairy shrimps.
- Homoiohydric organisms have achieved the true conquest of the land by the use of waterproof cuticles, transport systems, and osmoregulation. In this group are most tetrapods, insects (Figures 4 and 5), arachnids (Figures 6 and 7), and some isopods and mollusks (Figure 8).

Another important barrier to terrestrialization is the necessity to change from obtaining oxygen from water to

breathing air. Oxygen is more abundant in air (8.65 mol m^{-3}) than in water (0.262 mol m^{-3}), but its availability to animals depends on other factors, such as the rate of diffusion and the efficiency of oxygen-binding molecules in the blood. Many littoral animals can survive out of water for periods, but those that spend their whole lives out of water need lungs rather than gills. The problem is compounded by the fact that the CO_2 and O_2 molecules are larger than the H_2O molecule, thus membranes for gas exchange leak water. This means that respiratory surfaces need to be internalized and valves are required to regulate air flow, spiracles in insects, for example, so that water is not lost.

For support and locomotion on land, small animals such as slugs and worms can use their hydrostatic skeletons, but larger arthropods and tetrapods have evolved a hanging stance for stability, and both groups developed an ankle joint to prevent the newly acquired plantigrade foot from twisting on the ground. Eyes used in air differ from aquatic visual organs because of the differences in refractive index of the two media, and organs of hearing used in air are capable of perceiving higher-frequency sounds than in water. Reproduction and dispersal is much easier in the sea, where gametes can be simply released into the water, and larvae disperse in ocean currents. On land, internal fertilization and courtship is the norm. Crabs (Figure 9) and amphibians (Figure 2), for example, need to find water to breed, but the amniote egg of higher tetrapods (Figures 10 and 11) has removed the dependence on aquatic environments. Insect eggs have a complex coat to prevent both drowning and water loss.

Terrestrial adaptations can be determined in living animals from their anatomy and physiology, but to determine the sequence and timing of events during the major phase of terrestrialization in the Palaeozoic, the fossil record holds the only clues. Complex terrestrial biotas, based mainly on arthropods and plants, had developed by the Devonian period; colonizations by vertebrates, mollusks, and crustaceans followed these early pioneers much later, into already well-established ecosystems.

The Fossil Record

Fossil evidence for the colonization of the land by animals (Figure 12) comes from two sources: indirect evidence from the sedimentary environment, such as fossil soils or traces of terrestrial organic molecules, and trace fossils; and direct morphological evidence from the fossils themselves. Trace fossils are evidence of the existence of organisms without any actual remains; examples include fossil footprints and trackways, worm trails, feeding structures, burrows and nests, resting traces, and chemical signatures. Body fossils, as the name implies, are actual remains of the organism, though these need not consist of the original material, which may have been replaced by other substances and, indeed, impressions of the animal's body in the sediment are also included here.

Trace Fossils

Fossil trackways indicating that aquatic animals hauled themselves out of the water and across subaerially exposed sediments date back to the latest Cambrian period (ca. 488 Ma: MacNaughton *et al.*, 2002). However, whether these animals were habitually terrestrial or were aquatic animals sprinting from one pool to another to survive desiccation is not clear. Moreover, evidence for the sediment being exposed to the air (e.g., mud cracks) does not necessarily tell us whether the tracks were made under water and then exposed, or the mud was already drying and cracking when the trackway was made (Braddy, 2004). Nevertheless, a Cambro-Ordovician origin of terrestrial animals was suggested by Rota-Stabelli *et al.* (2013) using molecular clock analyses of extant Ecdysozoa.

Many of the early Paleozoic trackways have been ascribed to myriapod-like animals, but it would be unwise to accept them as explicit evidence for the existence of myriapods (millipedes, Figure 2, and centipedes, Figure 13) as we know them. It is conceivable that there were other extinct arthropods around at this time with multiple limbs capable of leaving such impressions (see discussion in Dunlop *et al.*, 2013).

Body Fossils

While with trace fossils, sedimentological evidence is used to reveal terrestriality, to interpret body fossils, we need to find morphology that indicates land life unequivocally. For example, a lung is clearly a terrestrial adaptation; but legs need not be: they occur in amphibians, for example. Similarly, it is unwise to assume that a fossil is of a terrestrial animal just because its modern relatives live on land today. For example, while all modern onychophorans live in damp forests, their Paleozoic relatives were marine.

The earliest multicellular animals on land may well have been tardigrades. These tiny 'water bears' are extremophiles; that is, they can live in environments which would be lethal to other animals, including deep oceans, under ice, the tops of the highest mountains, hot springs, and they can even survive the vacuum of space (Jönsson *et al.*, 2008)! These tiny animals undergo cryptobiosis: if the environment becomes extreme, they metamorphose into cyst-like tuns, from which they emerge when circumstances become favorable again. Their oldest fossils are Cambrian in age (ca. 509 Ma: Müller *et al.*, 1995), from marine sediments. However, their propensity to form tuns, which can then be dispersed by the wind, means that they would have easily accessed emergent land surfaces, and likely survived there. Unfortunately, their small size means that they are rare as fossils, and the oldest terrestrial tardigrade fossil comes from amber of Cretaceous age (ca. 80 Ma: Cooper, 1964).

Excluding a very dubious record of an Ordovician mite, the oldest metazoan fossils that can confidently be considered terrestrial are millipedes from the Silurian (ca. 428 Ma) of Scotland (Wilson and Anderson, 2004). This fossil, *Pneumodesmus newmani*, shows spiracles along the side of the body; these are openings of the tracheal system by which the animal would have breathed air. Thus, there is direct morphological evidence of terrestriality. Coprolites occur in rocks of late Silurian age of the Welsh Borderland which have been attributed to detritivorous animals, probably millipedes (Edwards *et al.*, 1995). A few scorpion fossils are known from rocks of middle and late Silurian age (ca. 430–420 Ma). For example, *Dolichophonus loudonensis*, also from Scotland (Laurie, 2012) is the oldest known arachnid, and is about the same age as *Pneumodesmus*. However, there has been a debate for many years about whether the early scorpions were terrestrial or aquatic. An aquatic mode of life for early scorpions was the prevailing opinion for most of the twentieth century but, more recently, this has been questioned because of the lack of obvious morphological evidence. Some, younger, scorpion fossils do seem to have had gills, but it has been argued that these animals migrated into the freshwater habitat from the land. So, it seems that, based on trackways, coprolites, and body fossils, millipedes were the earliest recognizable animals on land.

Ludford Lane

Not far behind the millipedes, in terms of their fossil record, came the centipedes (Figure 13) and arachnids (Figures 6 and 7). Late Silurian fossils from the ca. 419 Ma locality at Ludford Lane, Shropshire, England, consist of tiny pieces of cuticle which are extracted from the sediment using acid (Figure 14). These

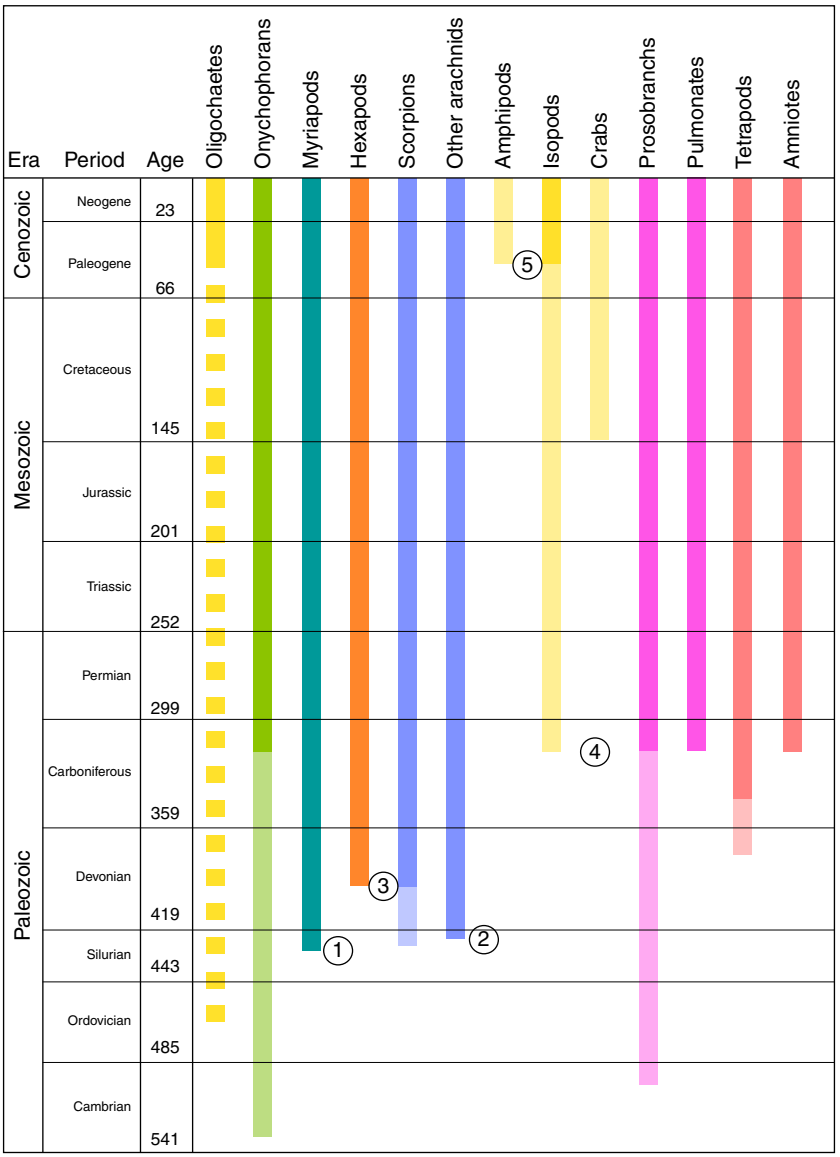

Figure 12 The body fossil record of terrestrial animals. Lighter colors refer to earlier aquatic record; dashed line refers to uncorroborated fossil record. Numbered points refer to important localities in the record of terrestrial animals: (1) Stonehaven, Scotland (earliest land animal, a millipede); (2) Ludford Lane, England (early terrestrial biota, including arachnids and myriapods); (3) Rhynie Chert, Scotland (early terrestrial biota); (4) Late Carboniferous sites such as Mazon Creek, Illinois; (5) Baltic amber; © the author.

fragments include the oldest centipede (Figure 15), probably related to the modern House centipede *Scutigera* (Jeram *et al.*, 1990; Shear *et al.*, 1998). Scutigeromorphs (e.g., Figure 13) are thought to be fairly primitive among centipedes. There is also a millipede belonging to the extinct arthropleurids (Shear and Selden, 1995). Also at Ludford Lane is the oldest non-scorpion arachnid, belonging to the extinct spider-like trigonotarbids (Figure 16). Younger trigonotarbids show book lungs, indicating true terrestriality, so this habitat is also assumed for the Ludford Lane fossil too. The detritivore coprolites, mentioned above, come from this famous locality.

Ludford Lane presents a very early terrestrial ecosystem based on detritus feeders (e.g., millipedes), which were preyed upon by carnivores (e.g., centipedes, arachnids). There is no evidence for herbivorous animals, as we would understand them today: i.e., animals chewing leaves and other green parts of plants. It appears that this type of food web prevailed until the late Paleozoic, by which time the symbiotic fungi and bacteria in the guts of herbivores had developed to allow internal decomposition of green plants (Shear and Selden, 2001).

Rhynie Chert

Returning to Scotland, the next youngest locality bearing terrestrial animals is of early Devonian age: the Rhynie and Windyfield cherts of Aberdeenshire, Scotland, of ca. 410 Ma age. These two adjacent localities preserve an entire terrestrial ecosystem of early plants and animals, in extraordinary

three-dimensional detail, in siliceous rock produced by a Devonian hot spring (Figure 17). More trigonotarbid arachnids occur here (Figure 18), as well as the oldest mites, for example, *Protacarus crani*, the harvestman *Eophalangium sheari* (Dunlop *et al.*, 2004). Also of significance in the Rhynie fauna are the oldest hexapods (including insects). There is a springtail, *Rhyniella praecursor* (Hirst and Maulik, 1926; Scourfield, 1940), and also the oldest true insect, *Rhyniognatha hirsti*, known only from its mandibles (Engel and Grimaldi, 2004). To complete the fauna known from Rhynie and Windyfield, there are enigmatic euthycarcinoids, centipedes, and another possible hexapod (Fayers and Trewin, 2005).

Gilboa

The Middle Devonian (ca. 390 Ma) Gilboa, New York, locality records the oldest terrestrial fossils in North America. It has

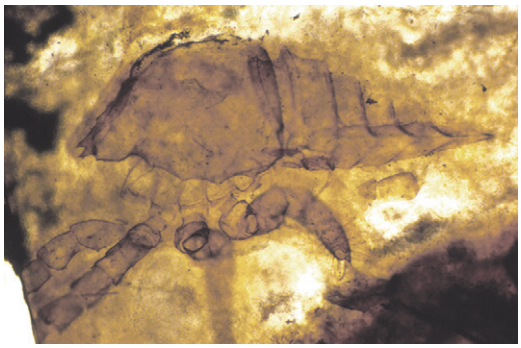

Figure 18 *Palaeocharinus*, a trigonotarbid arachnid from the Rhynie Chert (Devonian, Aberdeenshire, Scotland); © the author.

yielded trigonotarbid arachnids, as well as oribatid and alicorhagiid mites, the oldest pseudoscorpion, and the enigmatic uraraneid arachnids. *Attercopus fimbriunguis* was originally thought to be an odd trigonotarbid (Shear *et al.*, 1987), but was later reinterpreted as the oldest spider (Selden *et al.*, 1991). More recently, it was shown to be an extinct, spider-like animal, and named as a new arachnid order: Uraraneida (Selden and Shear, 2008). *Attercopus* produced silk, but lacked the typical spinneret organs which define true spiders. The Gilboa locality also has centipedes, including another scutigeromorph (Shear and Bonamo, 1988; Shear *et al.*, 1998).

Younger Records

Fossil insects from the Devonian are surprisingly rare. The record of a bristletail from Gaspé, Canada (Labandeira *et al.*, 1988) has been seriously questioned as to whether it is a real fossil or a modern contaminant (Jeram *et al.*, 1990). More recently, Garrouste *et al.* (2012) reported the discovery of a terrestrial insect, *Strudiella devonica*, from the late Devonian (ca. 365 Ma) of Belgium. This find, too, has been disputed (Hörnschemeyer *et al.*, 2013). So, it appears that hexapods, including the insects, did not become common in the fossil record until later in the Paleozoic.

Crustaceans did not get onto land until much later, and even today only a few groups are fully terrestrial. The oldest terrestrial isopods are known as fossils from Eocene (ca. 49 Ma) Baltic amber; the oldest known amphipods are even younger, Miocene in age (ca. 16 Ma), from Mexican amber; and land crabs date back only to Quaternary times (ca. 3–2 Ma).

The review so far has dealt mainly with arthropods. Having a fairly tough cuticle, these fossilize fairly readily, unlike earthworms, for example. It was also in the Devonian that the first vertebrates began to attempt terrestrialization. Tetrapods (limbed vertebrates) had evolved by Devonian times and there was a high diversity, but they are thought to have been aquatic, similar to salamanders of today (Clack, 2009). Following the Devonian, there is a barren time period known as Romer's Gap (after the vertebrate paleontologist A. S. Romer who first recognized it), which stretches from ca. 360–345 Ma into the early Carboniferous period. The first tetrapod fossils to appear after Romer's Gap include terrestrial forms; however, fossils are now appearing which hint at morphological adaptations for land life, at least, from within this gap (Clack and Finney, 2005).

Routes onto Land

It has already been hinted that animals adapted to the extremes of life on the seashore are already pre-adapted to life on land. This route proved the most successful for invertebrate colonizers, and was apparently taken by nemertines, polychaetes, many land mollusks, most crustaceans, chelicerates, and probably myriapods and hexapods (Little, 1983). Evidence comes from study of the osmoregulation abilities of the living animals; that for a marine route onto land for Crustacea and Mollusca is strong, but is less so for other groups. Interstitial environments allow a more gradual transition in salinity from marine to terrestrial than that encountered by the epifauna. Arthropods show relatively high osmotic concentrations which, in the case of the relatively small myriapods and hexapods, can be compared with the high osmotic concentrations in small crustaceans, and so a marine route is suggested. Conversion of the book-gill into the book-lung in arachnids is a good example of the use of an existing aquatic respiratory organ to breathe air.

A freshwater route onto land was apparently used by platyhelminths, annelids, prosobranch mollusks, crayfish, some crabs, and vertebrates (Little, 1983). The correlation between osmotic concentration and routes onto land shown by crustaceans can also be seen in the mollusks. The most successful are the pulmonates (slugs and snails), which have a relatively high osmotic concentration; in contrast, prosobranchs have a low osmotic concentration and are generally restricted to humid tropical forests where fatal desiccation is less likely.

The success of terrestrial vertebrates, having taken the freshwater route onto land, contrasts with those successful invertebrate groups with largely marine ancestors. The larger tetrapods could spend longer on land without the threat of desiccation because of their relatively low surface area to body mass ratio. Also, freshwater origins conferred the ability to osmoregulate efficiently, and a large size and waterproof skin allowed them to overcome the problem of water availability on land. Littoral animals need to breathe air fairly continuously for long periods while awaiting the return of the tide, so many have adapted pre-existing gill structures for air breathing. In contrast, animals in poorly oxygenated freshwater are intermittent air-breathers (e.g., coming to the surface to gulp air) and so many developed new organs to take in large volumes of air at a time. Palaeontological evidence also points to a freshwater route for the terrestrial vertebrates.

Some animal groups evolved from already terrestrial ancestor; hexapods for example, for whom the problems of terrestrialization had already been solved by their ancestors.

Conclusion

It seems likely that, among metazoans, small, cryptobiotic animals were the first to reach land from the sea. Fossil evidence for this is, however, sparse. The oldest recorded land animals are millipedes, which would have lived on detritus from early land plants. There is evidence for these in the form of body fossils and traces fossils (coprolites). Other arthropods

followed, with tetrapods emerging later, possibly within the barren period known as Romer's Gap (ca. 360–345 Ma).

Once on land, animals went on to do quite remarkable things. A number of groups took to the trees, which had appeared in Devonian times, and later the air between the trees. As insects took to the skies, so their main predators, the spiders, followed them up with their elaborate webs. The tetrapods then took to the air: pterosaurs and birds, and later, bats. Finally, many land animals returned to the water; freshwater insects, for example, and marine mammals: the whales and dolphins.

Land Vertebrates, the Origin and Evolution of

JA Clack, University Museum of Zoology, Cambridge, UK

Glossary

Anoxic Anoxic refers to depleted oxygen content, lacking or almost lacking available oxygen.
Autopod The distal subdivision of a limb (hand or foot) is called autopod.
Buccal The mouth cavity is called buccal cavity. In buccal pumping, expansion and contraction of the mouth cavity powers breathing, promoting movement of either water or air into the gills or lungs.
Cladogram A diagram showing the branching pattern of relationships between groups and taxa.
Distal Something further away from the body.
Monophyletic Part of a single group containing all the descendents of a single ancestor.
Phylogeny The pattern of relationships between animal species and among monophyletic groupings.
Proximal Something nearer to the body.

Who Are the Land Vertebrates?

Land vertebrates today are a very diverse set of creatures, but their origins go back to the Paleozoic era, when vertebrate animals first ventured onto the land. Since then they have radiated into every continent, and undergone often radical evolutionary changes. They don't only live on land: some have taken to flight (birds, bats), others to swimming (whales, manatees), some have reduced the number of fingers and toes (horses, many salamanders), or lost their legs altogether (snakes, caecilians). Nonetheless, they belong to a single lineage or monophyletic group known as tetrapods. The name means 'four legs.' Their early ancestors evolved four limbs with elbow, wrist, knee, and ankle joints, and which ended in fingers and toes (digits). These limbs could both support their weight against gravity and provide enough flexiblity to allow a walking step. Today, the tetrapods consists of two quite distinct groups: the Amphibia, which includes salamanders, frogs, and caecilians; and the Amniota, which includes mammals, turtles, lizards, crocodiles, and birds (Figure 1). These two groups have been separate for at least 300 million years. They have a rich fossil record that can help us understand their evolutionary history, but to understand how early tetrapods worked it would be ideal to look at modern analogs. However because modern tetrapods and the earliest fossil examples are very different in many respects, it is a challenge to find modern analogs for understanding things like the early tetrapods' physiology and sensory systems, their locomotory capabilities, and their reproductive strategies. While taking information from modern groups into account, we must also make inferences from skeletal features and phylogenetic relationships of the earliest tetrapods and their relatives.

Modern amphibians are highly specialized animals with many unique features (Figure 2). The earliest fossil record of representatives of modern groups is actually relatively recent, from only about 200 million years ago (mya). The earlier history and origin of this group is strongly debated by paleontologists. Today, amphibians are united by the possession of features of the skin and sensory systems that do not fossilize well or at all. They are not defined by their reproductive system. In fact, amphibians as a whole show the most diverse evolutionary strategies to be seen among tetrapods. They are defined by their relationships to each other and to amniotes. Amniotes are defined by possession of egg membranes supporting the embryo during its development (Figure 3). These may be contained in an egg with a shell, or within the mother's body. These membranes do not usually fossilize either. In both cases, for fossils, we have to use skeletal anatomy to work out relationships to modern forms (see any vertebrate biology text book such as Kardong, 2014).

For many fossil species, it is clear where they belong – for example, dinosaurs are evidently related to birds and crocodiles, and snakes are evidently related to lizards. However, for other, usually older species, this is not always straightforward. Early in their evolutionary history, the first creatures with limbs and digits are not obviously related to either modern group, but pre-date the split. Thus, they are neither amphibians, nor amniotes, but simply 'early tetrapods.'

A Phylogeny and Timescale for Tetrapod Origins

Tetrapods, both recent and extinct, belong to sucessively wider groups that includes their ancestors, 'fish' with fins and scales. Tetrapods belong to a group called tetrapodomorphs, and this includes many species that became extinct about 360 mya, at the end of the Devonian period (Figure 4). The group is characterized by having an internal nostril called a choana, and by having bones equivalent to the two forearm bones – radius and ulna – of tetrapods (Figure 5). It is seen for example in the tetrapodomorph *Eusthenopteron* (Figures 6 and 7). In turn, this group sits within the lobe-finned fishes or sarcopterygians, characterized by fins that are attached to the body via a single bone, equivalent to the tetrapod humerus and femur. The earliest lobe-fins are found in rocks about 420 mya, near the beginning of the Devonian. Today, the only other living lobe-fins are lungfishes and coelcanths. The sarcopterygians are quite distinct from the main array of fishes in waters today, the ray-finned fishes, or actinopterygians.

At the present time, the earliest skeletal fossil record of tetrapods that had digits dates from around 380 mya in the Late Devonian (Ahlberg, 1998), although possible trackways

 doi:10.1016/B978-0-12-800049-6.00276-6

Figure 2 Photograph of a salamander, a modern amphibian.

made by tetrapods have been found dating from nearer 390 mya in the Middle Devonian (Niedzwiedzki *et al.*, 2010). The earliest modern-type foot with five digits has been found in rocks about 345 mya in the Early Carboniferous.

What Were Conditions Like during the Late Devonian?

The Late Devonian was a time of biotic crisis caused by glaciations in the southern hemisphere. In the rocks there is a record of black shales formed in anoxic water conditions, the cause of which is disputed, but which is indicative of some great changes in environmental conditions. Falls and rises in sea levels coincident with glaciations and their melting are one possible explanation, or the evolution of large and deciduous

Figure 3 Photograph of a turtle hatching. A turtle is a modern amniote, having an egg with a protective shell.

plants is another (McGhee, 2013). Global temperatures are thought to have been relatively cool during this time interval. It is known that in the latter stages of the Late Devonian, known as the Famennian stage, oxygen levels were at or possibly above those of the present-day atmosphere, although earlier in the Devonian, levels had been much lower.

What Stimulated the Evolution of Land-Going by Vertebrates?

This is a question that is often asked, but is hard to answer definitively. In fact there was probably not a single cause, but the interaction of many influences. Some ideas include the fact that land had been colonized earlier by plants, and by the Late Devonian, these included large tree-like forms and a diversity of ground-covering species. These must have provided shelter from desiccation for emerging early tetrapods. In the undergrowth, many invertebrates were to be found, providing food for the tetrapods, in an environment devoid of any predators. In the water were large predatory fish that could have preyed on the early tetrapods or their young, perhaps pushing the tetrapods to the water's edge (McNamara and Selden, 1993). Prior to the emergence of tetrapods with limbs, the low oxygen regime of the Early and Middle Devonian stages might have given advantage to air-breathing forms living in waters that were anoxic (Clack, 2007).

Among Lobe-Fins, What Advantages Were Crucial to the Move onto Land?

It is sometimes mistakenly assumed that breathing air was the great advance of early tetrapods, but there is evidence to suggest that air-breathing to some degree was found in all bony vertebrates, including ray-fins, during their early evolution. Lobe-fins appear to have specialized in this, being bimodal breathers using both gills and lungs, as do modern lungfish. Thus tetrapods were already air-breathers before they redeveloped their fins into limbs.

The internal fin skeleton of lobe-finned fishes (Figure 5) is built of robust bony elements that were not characteristic of ray-finned fishes. The type of bone is called endochondral, in which the bone replaces a cartilaginous precursor. It allows the development of new features as it is remodeled in response to different conditions. This kind of bone is also readily adapted to form the vertebral column and ribs that are greatly developed in tetrapods. The single bone forming the most proximal element of the fin or limb is joined to the body via a ball and socket joint that allows a wide range of motion at the shoulder or hip. It also facilitates the alternate movement of fore- and hind limbs on opposite sides of the body, typical of tetrapods, but also seen in lungfishes and coelacanths (It is also seen independently in some bottom-dwelling sharks.). This may have been an advantage to animals living in shallow waters, or in an ambush predator, moving one limb at time, slowly advancing through the weedy undergrowth.

What Were the Earliest Tetrapods and Their Immediate Ancestors Like?

The fossil record suggests that the tetrapodomorph lobe-fins were mainly large species, reaching a meter or more in length. Some, such as *Tiktaalik*, from the early Late Devonian (**Figure 8**), indeed are known that were at least 2.75 meters long (Daeschler *et al.*, 2006; Shubin *et al.*, 2006; Shubin, 2009). They typically had large heads in relation to their bodies as compared with modern amniotes, and they appear to have been rather flat. There is an argument about whether the flattening is due to compression during fossilization, but certainly the breadth of the head is unlikely to be exaggerated in that way.

Fishes use their gill skeletons to ventilate their gills, and early tetrapods almost certainly used the same muscles and bones to ventilate their air bladders in a form of buccal pumping. Modern amphibians still use this mechanism. This form of breathing necessitates a large buccal cavity to acquire as much air as possible with each movement, making sense of the large and broad heads of these early tetrapods and their ancestors.

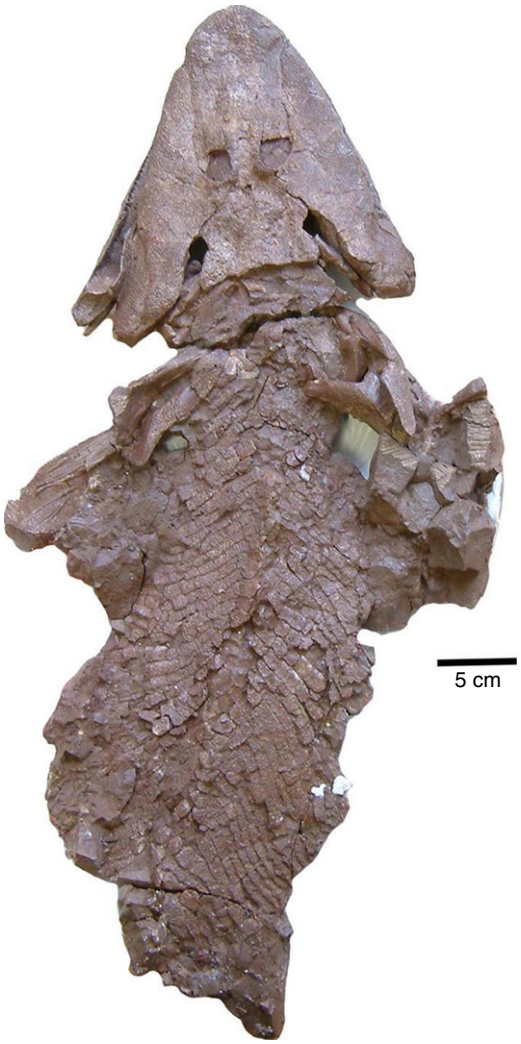

Figure 8 Photograph of *Tiktaalik roseae* (photograph by J. A. Clack).

Primitively, vertebrates used their noses for only olfaction, as is the case still in ray-fins and chondrichthyans (sharks and rays). They have two nostrils on each side of the head, one for water in, and one for water out after it has passed over the sensory tissue in the nasal capsule. In tetrapodomorphs, the port for water out, now called the choana, moved inwardly to lie inside the mouth. This can be seen in the early Late Devonian fish *Eusthenopteron* (Porro *et al.*, 2015). What advantage that conferred is not clear, but it laid down the conditions that were conducive to air-breathing in later forms. It allows air to pass into the mouth and thence into the pharynx and air bladder (i.e., lung).

Tetrapodomorph fishes and early tetrapods had skulls reinforced by dermal bone, formed directly in the skin. In the fishes, this covering was attached at the top to similar bones in the shoulder girdle, forming a smooth hydrodynamic profile. The cheek plates were mobile, and a slot lower down between the cheek and shoulder allowed water that had passed over the gills to flow out. This meant that the head was effectively kept in line with the body. In tetrapods with limbs, this connection was lost and the joining bones disappeared. The head could thus be moved relative to the body, both up and down and side to side. The beginnings of a neck was formed. This is seen in the tetrapodomorph *Tiktaalik* (**Figure 8**).

The proximal element of the forefin, the humerus, was particularly robust, and bore processes and flanges to which substantial muscles must have attached. Articulating with this bone were the equivalent of the radius and ulna, although their proportions were different from what they became in tetrapods. The radius was a long narrow bone and the ulna was a short stout one. Beyond those lay a series of smaller elements whose pattern varied according to the species, but which like the other bones were robust with substantial joint surfaces (**Figure 5**).

One major difference between tetrapodomorph fish and tetrapods with limbs and digits is the size of the hind fin or limb and its associated pelvic girdle. In the fish, as in almost all fishes today, the pelvic fin and girdle were all small elements, much smaller than the forefin and shoulder girdle. At some point in their evolution, the tetrapods with limbs enlarged the hind limb and girdle, joining the latter to the vertebral column. The beginnings of changes to the pelvis can now be seen in *Tiktaalik* although the fin skeleton itself including the femur equivalent is not known (Shubin *et al.*, 2014).

The earliest tetrapods in which the more distal bones are true digits are from the late Late Devonian, and are best known in three taxa: *Acanthostega*, *Ichthyostega* (**Figure 9**), and *Tulerpeton*. In this case, the most distal elements are more organized, with the elements arranged in succession with joints between them, as in modern digits. Essentially that is the definition of a digit. However, unlike modern tetrapods, these animals all had more than five digits, namely, eight, seven, and six respectively (Clack, 2012). In *Acanthostega*, the joints of the fore- and hind limbs were not capable of bearing weight, nor of rotating at the wrist of ankle (**Figure 9**). Effectively, they were paddles. In *Ichthyostega*, the hind limb was also a paddle-like structure, although the hand remains unknown (Coates and Clack, 1990; Coates, 1996). In both these forms, the

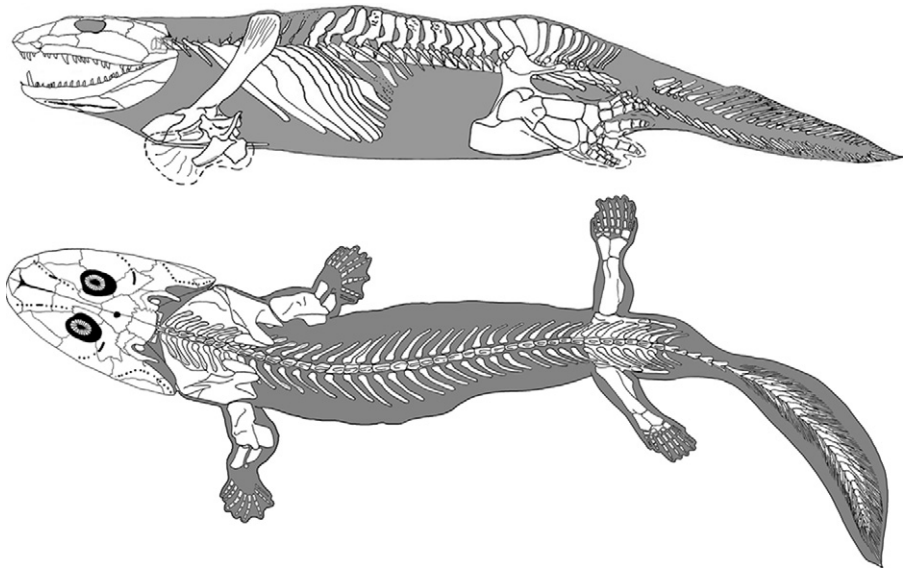

Figure 9 Two Late Devonian tetrapods: Top, *Ichthyostega*. Lower, *Acanthostega*. Reproduced from Clack, J.A., 2012. Gaining Ground: The Origin and Evolution of Tetrapods, second ed. Indiana: Indiana University Press. Material appears courtesy of Indiana University Press. All rights reserved.

Figure 10 A Photograph of the skull and a life model of *Acanthostega gunnari*. The skull is about 120 mm long.

femur and humerus were of similar sizes (Figures 9–11). These two also retained bony fin rays along the tail, features otherwise only seen in fish.

How Did These Early Tetrapods Move?

Given their paddle-like nature, the limbs of these early tetrapods suggest that the animals were mainly aquatic. That is particulary true of *Acanthostega*, and it seems very likely that even if it made forays onto land, it would not have supported its body off the ground, but used a limb-assisted wriggle. Some salamanders use this form of locomotion today, especially for fast movement. The giant Japanese salamander is an example of this, and in fact from the point of view of size and habits is quite a good model for *Acanthostega*.

Recent work on *Ichthyostega* using cutting-edge computer techniques has allowed an assessment of the range of movement of the limbs permitted by the bone morphology. This study showed that the shoulder and hip joints were highly restricted in their range of motion, in a way that suggested the forelimbs were used to provide the main propulsive force. The humerus bore massive muscles holding the forearm more or less horizontal, while the elbow joint was relatively mobile, and took the weight of the forequarters of the animal. The hind limb would move effectively as a paddle when the animal was swimming, but on land would be used only as a stabilizer. It also emerged that it was likely to have used a gait in which both forelimbs moved in concert rather than alternately, producing a shuffling motion. The nearest analogy seems to be with mudskippers rather than any modern tetrapod (Pierce *et al.*, 2012, 2013).

The overall picture seems to suggest one of experimentation with ways of moving on land, and that walking in the conventional sense was not an immediate development.

When Did True Terrestrial Locomotion and Terrestrial Living Develop?

As far as we can tell from the current fossil record, the earliest development of the five digited – pentadactyl – limb did not appear until the Early Carboniferous. A fossil from the earliest Carboniferous, the Tournaisian stage, of Scotland shows a five-digited autopod, although whether it came from a fore- or hind limb cannot be established. Slightly later but also in the

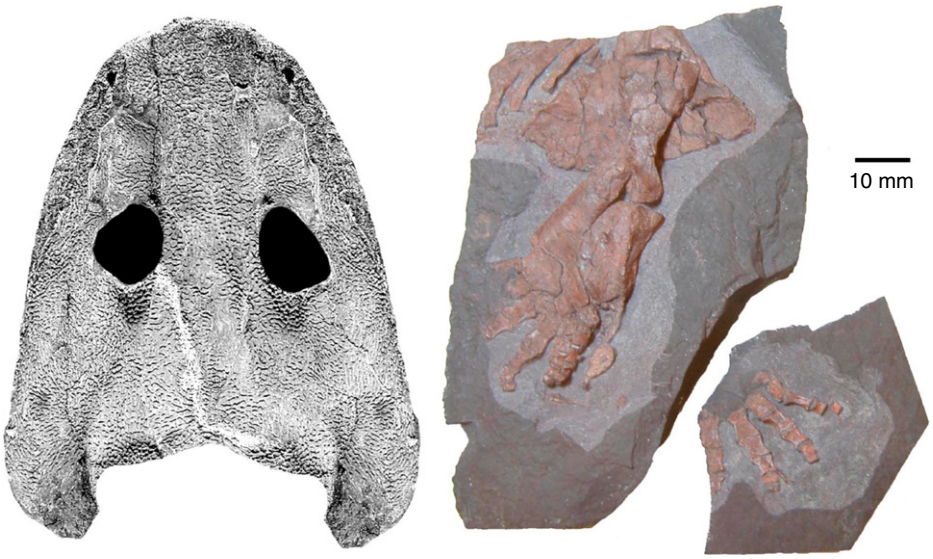

Figure 11 Photographs of the skull and hind limb fossil of *Ichthyostega stensioi* (photographs from UMZC archive).

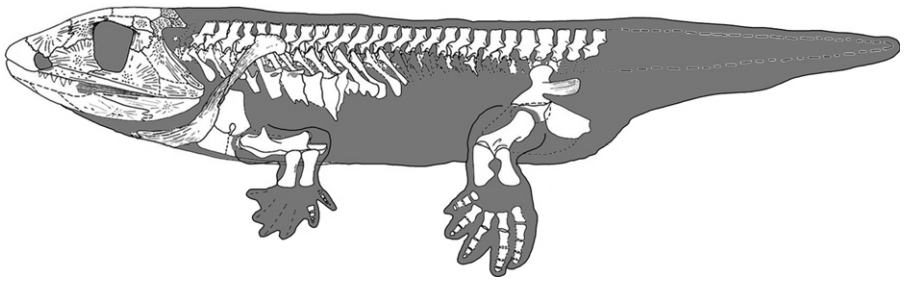

Figure 12 The Early Carboniferous tetrapod Pederpes. Reproduced from Clack, J.A., 2012. Gaining Ground: The Origin and Evolution of Tetrapods, second ed. Indiana: Indiana University Press. Material appears courtesy of Indiana University Press. All rights reserved.

earliest Carboniferous, the skeleton of the tetrapod *Pederpes* (Figure 12) had a pentadactyl hind limb with proportions and shape like that of later Carboniferous tetrapods (Clack, 2012). It had asymmetrical bones in its ankle that suggest a reorientation of the foot so that it pointed forwards rather than to the side as in the earlier forms. Nonetheless it still seemed to have had more than five digits on the forelimb (Clack, 2002).

Looking at the embryonic development of fore- versus hind limbs of modern animals, and combining this with what we see in fossil forms suggests that following the evolution of an enlarged hind limb and associated hip girdle, the hind limb 'took over,' developed ahead of the forelimb and began to provide the main propulsive force for walking and for raising the body off the ground (Coates *et al.*, 2008). However, the morphology of the humerus compared with the femur suggests that prior to that, it was the forelimb that was the major component in motion, raising the front of the body out of the water. The humerus is a much more complicated bone than the femur, and is much more comparable to that of the fish equivalent than is the femur. A gradual sequence of changes to the humerus can be traced across the transition, whereas the femur seems to have been a separate development. Evidence from embryonic development and from genetics supports the idea that fore- and hind limbs were not homologs, but have separate embryonic origins.

What we can say is that by the end of the earliest Carboniferous Tournaisian stage, diverse tetrapods were present. New fossils from the United Kingdom and Canada show a range of sizes and morphologies (Smithson *et al.*, 2012; Anderson *et al.*, 2015), and numerous trackways from Nova Scotia document diverse forms of locomotion from both very large (say 1–2 m length animals), to very small ones (say the size of a small lizard) (Figure 13).

As to 'why five' for the number of digits, the combined ability to have limbs that can bear weight with joints that allow the flexibility for walking may have restricted the possibilities for the form of the wrist or ankle around which five was the most comfortable fit.

Although it is clear that tetrapods could walk on land in a conventional way by the end of the Tournaisian stage, some may argue that full terrestriality was only achieved once the amniotic egg had been developed, allowing the animals to dissociate themselves from the need to reproduce in water. Unfortunately, it is very difficult to determine when this happened, or even what mode of reproduction these early tetrapods might have used.

Lichen-Forming Fungi, Diversification of

HT Lumbsch, Integrative Research Center, Science & Education, Chicago, IL, USA

Glossary

Ascoma A fruiting body bearing meiosporangia (sporangia in which meiosis occurs) known as asci.
Ascospore Meiospore of ascomycetes is called ascospore.
Columella Sterile tissue in the hymenium of some tropical crustose lichens.
Crustosen Crust-like growth form of the vegetative thallus in lichens.
Cupulate exciple It is a type of ascomatal margin forming a cupula.
Diaspore A vegetative propagule.
Endolichenic Growing inside a lichen.
Foliose Leaf-like growth form of the vegetative thallus in lichens.
Fruticose Growth form with pendulous or upright branches of the vegetative thallus in lichens.
Heterokont Having two morphologically different flagellae.
Hymenium A layer consisting of meiosporangia and sterile elements.
Isidium Corticated outgrowth of the thallus surface for vegetative dispersal of both partners in a lichen.
Lichenicolous Growing on a lichen.
Neoendemic A species that originated recently and is indigenous to a certain environment.
Periderm Cork-like outer layer of a plant stem.
Perithecium Pear-shaped ascoma opening with a small pore.
Photobiont Algal or cyanobacterial partner in a lichen symbiosis.
Soredium Powdery, non-corticated structures on the thallus surface for vegetative dispersal of both partners in a lichen.
Synapomorphy Shared derived character.
Thallus Plant-like vegetative body that lacks differentiation of stem, leaves, and roots.

Lichen-forming fungi form stable symbiotic associations with photosynthetic partners, such as algae and/or cyanobacteria. The fungi mostly belong to Ascomycota and to a lesser extent to Basidiomycota. Most algae in lichen symbioses belong to green algae, but heterokont (Stramenopiles) algae, such as brown algae or yellow-green algae, are also known to form stable associations with fungi. In addition, bacteria and additional fungi (endolichenic and lichenicolous) are found in the lichen symbiosis but their roles in the symbiosis are currently not fully understood. Lichen-forming fungi are a successful group, with almost 20% of all known fungi forming lichen associations, and they occur in all ecosystems: from the polar regions to the tropics. They are able to grow on all sorts of terrestrial substrates, including rocks, soil, wood, bark, and also living leaves. They are unusual for fungi in forming extensive vegetative structures, so-called thalli that have crustose, foliose, or fruticose growth forms (Figure 1). The vegetative structures provide space for the photosynthetic partners that provide nutrients in the form of sugar or sugar alcohols to the fungal partner.

Although some molecular clock-based studies suggested an origin of lichens (Heckman *et al.*, 2001) as early as the Precambrian, other studies suggest a later evolution (Lücking *et al.*, 2009; Beimforde *et al.*, 2014). Part of the problem is the uncertainty with interpreting the fossil species *Paleopyrenomycites devonicus*, which has been widely used to calibrate the fungal tree of life (Berbee and Taylor, 1993; Taylor *et al.*, 1999; Taylor and Berbee, 2006; Berbee and Taylor, 2010). The interpretation of the morphological structures has varied, with the ascoma-type and ascus interpreted differently, either as

Figure 1 Growth forms of lichens. (a) and (b). Crustose lichens ((a) – *Ochrolechia* on siliceous rocks, (b) – *Lecanora* on mosses and detritus). (c) and (d). Foliose lichens ((c) – *Menegazzia* on bark, (d) – *Hypogymnia* on twigs). (e). Fruticose lichen (*Cladia* on soil). Photos (c) and (d) by Todd Widhelm, photo (e) by Sittiporn Parnmen.

being a perithecium with unitunicate asci placing them in the derived Sordariomycetes (Taylor and Berbee, 2006) or as a perithecioid ascoma with operculate asci placing them in the early diverging Pezizomycetes (Lücking *et al.*, 2009). The earliest fossils of lichens are from the lower Devonian (Taylor *et al.*, 1997), which is consistent with a later evolution of this type of fungal symbiosis. In fact, there are no lichenized taxa in basal groups of Ascomycota or Basidiomycota (Lutzoni *et al.*, 2004; Schoch *et al.*, 2009; Prieto and Wedin, 2013), which together with the mostly mycorrhizal Glomeromycota (Redecker and Raab, 2006) form the crown group of fungi (**Figure 2**). The latter group and all other fungal phyla lack any lichenized species.

Within Ascomycota, stable, symbiotic relationships with algae and/or cyanobacteria evolved within the derived Leotiomyceta probably during the Carboniferous (Schwartzman, 2010; Prieto and Wedin, 2013). Although the major Ascomycota lineages with lichenized species originated then, successive waves of diversification in the Jurassic and Cretaceous created the diversity at higher phylogenetic levels (Amo de Paz *et al.*, 2011; Prieto and Wedin, 2013). This subsequently gave rise to the current species diversity that originated between the Eocene and Pleistocene (see below). The diversification of major clades in lichenized fungi, especially in Lecanoromycetidae and Ostropomycetidae, is probably correlated with the major diversification events in angiosperms (Prieto and Wedin, 2013). The angiosperms provided many new environments for epiphytic lichens. Three of the four most diverse families of lichenized fungi, Parmeliaceae (c. 2800 spp.), Graphidaceae (c. 2100 spp.), and Ramalinaceae (c. 800 spp.) are especially diverse on angiosperm bark (Jaklitsch *et al.*, 2015). Although substrate specificity is rare in lichens, a number of species are confined to similar substrates in terms of bark pH, water capacity, and bark hardness (Brodo, 1973). Recent estimates suggest the origin of angiosperms either in the lower Jurassic to lower Cretaceous (Bell *et al.*, 2005; Bell *et al.*, 2010) or in the Triassic to early Jurassic (Clarke *et al.*, 2011).

It is unclear whether lichenization within Leotiomyceta originated once (Lutzoni *et al.*, 2001) or several times (Gargas *et al.*, 1995; Schoch *et al.*, 2009). Experiments suggest that there is a latent capacity for mutualism in fungi and algae (Hom and Murray, 2014). In an experiment, obligate mutualism between the non-symbiotic model organisms *Saccharomyces cerevisiae* (yeast) and *Chlamydomonas reinhardtii* (alga) was induced in an environment requiring reciprocal carbon and nitrogen exchange. This capacity for mutualism was shown to be phylogenetically broad, including other *Chlamydomonas* and yeast species. These experiments showed that under specific conditions, environmental change induces free-living species to become mutualists. Also some fungi occurring in boreal ecosystems were shown to be facultatively lichenized

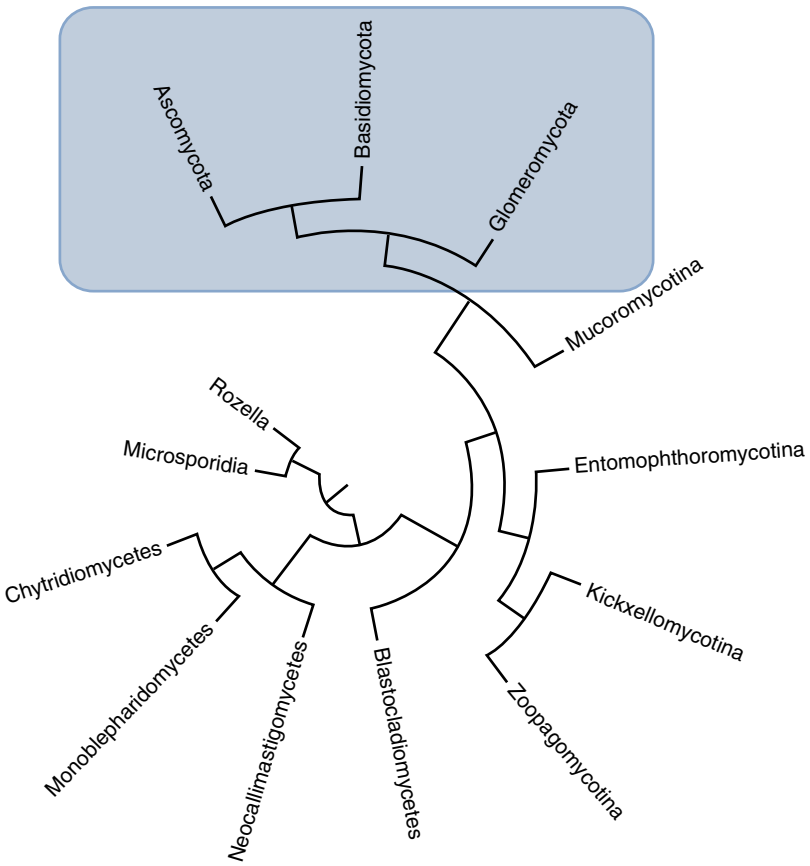

Figure 2 Cartoon tree of the phylogenetic relationships of phyla and other major clades within the fungal kingdom. The crown group of fungi indicated by a blue box.

(Wedin *et al.*, 2004). Phylogenetic analyses showed intermixed groups of lichenized and saprotrophic specimens, suggesting that these related species can undergo their sexual lifecycle either as lichens or as saprotrophs. The flexibility of nutritional modes allows separate individuals to exploit different niches during forest succession. These studies suggest that there is more plasticity in nutritional modes of fungi than previously thought. This is not surprising, given that nutritional modes (parasitism vs. mutualism) and interkingdom host switches have been demonstrated to be common at an evolutionary scale in fungi (Spatafora *et al.*, 2007; Arnold *et al.*, 2009). Some fungi growing on lichens, so-called lichenicolous fungi, have originated from lichenized ancestors, such as the genera *Nesolechia* and *Phacopsis*, which evolved during the Miocene (Divakar *et al.*, 2015). It was even hypothesized that lichenicolous fungi may represent a 'halfway house' to explain evolution of non-symbiotic fungi from lichenized ancestors (Lutzoni *et al.*, 2001; Arnold *et al.*, 2009).

The Evolution of Current Species Diversity in Space and Time

A number of studies have demonstrated that diversification events occurred during periods of climatic changes. For example, in the temperate to boreal crustose genus *Biatora*, the main diversification occurred during phases of climatic cooling when new types of forest vegetation and the arctic-alpine vegetation evolved (Printzen and Lumbsch, 2000). Likewise, the diversification of *Montanelia* was estimated to have occurred during a period of cooling and the development of marked thermal seasonality during the Miocene (Divakar *et al.*, 2012). In the genus *Melanohalea* it was shown that Pleistocene glaciations were not inherently unfavorable for some species and even indicated that some populations were able to expand during Pleistocene glacial cycles (Leavitt *et al.*, 2012a). Molecular data also suggest that closely related species may have experienced different demographic histories. In the genus *Xanthomendoza*, two closely related species with arctic-alpine to montane temperate distributions were studied (Leavitt *et al.*, 2013a). Whereas the data suggested a Late Pleistocene population expansion in *Xanthomendoza montana*, there was evidence for a long-term stability in the demographic history of the bipolar *Xanthomendoza borealis*, which suggests that the latter species was able to survive climatic oscillations without major contraction of its population size. In a study focusing on the phylogeography of *Ramalina menziesii*, a lichen occurring along the west coast of North America, from Baja California to Alaska, multiple lineages were found within the species (Sork and Werth, 2014). Localized lineages were found to be ancient, while some recent lineages were found to be widespread and some of the populations such as the ones in Baja California, were relatively isolated. This study provided evidence that both population persistence and dispersal contribute to the wide range of a genetically diverse species.

The fossil record for lichenized fungi is rather poor and largely restricted to Paleogene amber (Kaasalainen *et al.*, 2015). However, molecular clock approaches have been widely used to address the question of when the current diversity of species found in lichenized fungi evolved. An early study on *Biatora*, which occurs in temperate to boreal habitats mainly of the northern hemisphere, showed that species predominantly diversified during the Eocene and Oligocene (Printzen and Lumbsch, 2000). However, there is a growing body of evidence that a large portion of the current species diversity in lichen-forming fungi is much younger and most studies indicate major diversification happened during the Neogene. During the Neogene period the climate became cooler and drier and mountain systems developed with the uplift of the Himalayas, Alps, and Rocky Mountains, resulting in the alteration of air circulation and weather patterns. These processes likely had a major impact on diversification patterns. In the temperate-to-boreal genus *Melanelixia* (Leavitt *et al.*, 2012b) and the mostly Neotropical genus *Oropogon* (Leavitt *et al.*, 2012c) the main diversification was estimated to have occurred during the Miocene. Interestingly, in these two genera, cryptic species, which are delimited based on DNA sequence divergence, were detected that originated during the Miocene. This indicates that phenotypically cryptic species in lichenized fungi can be relatively ancient and do not necessarily represent recent divergence events. Diagnosable phenotypic differences may be absent even millions of years after their divergence, suggesting that our understanding of morphology and chemistry in these organisms is poor.

The main diversification during the Miocene and Pliocene was found in the genera *Flavoparmelia* (Del-Prado *et al.*, 2013), *Melanohalea* (Leavitt *et al.*, 2012a), *Montanelia* (Divakar *et al.*, 2012), the *Xanthoparmelia pulla* group (Amo de Paz *et al.*, 2012), and the Macaronesian species of *Nephroma* (Sérusiaux *et al.*, 2011). The former three genera all belong to the family Parmeliaceae, which is one of the largest families of lichen-forming fungi (Thell *et al.*, 2012; Kraichak *et al.*, 2015a). *Melanohalea* and *Montanelia* have their centers of diversity in temperate to arctic-alpine regions of the northern hemisphere, whereas *Flavoparmelia* – although being a cosmopolitan genus – has its center of diversity in Australasia. The latter genus occurs in temperate to subtropical areas mostly on tree bark. The *Xanthoparmelia pulla* group, which also belongs to Parmeliaceae, occurs worldwide in areas dominated by a Mediterranean (winter rain) climate. Traditionally, these species were distinguished using phenotypical characters and were assumed to have a subcosmopolitan distribution. However, molecular data, similar to results in the *Parmelina quercina* group (Arguello *et al.*, 2007), demonstrated that distinct lineages were correlated with geographical distributions (Amo de Paz *et al.*, 2012). Five major clades were found, two clades occurring in South Africa and one clade in the Mediterranean basin, Macaronesia, and California, whereas two clades had disjunct distributions, occurring in Australia and South America, and California and South America, respectively. These disjunctions were explained by long-distance dispersal (in the most recent California–South America disjunction it was estimated at 3.44 Ma). In a few genera of Parmeliaceae, molecular data suggest that the diversification predominantly occurred even more recently. In the fruticose genus *Letharia*, which occurs in temperate to boreal areas of western North America, continental parts of Eurasia, and montane areas of northern Africa, the major speciation was estimated to have occurred during the Pleistocene (Altermann *et al.*, 2014).

The genus *Xanthoparmelia* is the most speciose among lichenized fungi with over 800 species (Thell *et al.*, 2012). A clade of *Xanthoparmelia* species occurring in North America has been shown to have diversified mainly during the Pleistocene (Leavitt *et al.*, 2013b). Recently diverged lineages are generally more difficult to separate using molecular data due to incomplete lineage sorting, requiring a large sampling of markers (Leavitt *et al.*, 2013b; Altermann *et al.*, 2014). Whereas this has been a limiting factor examining these species complexes using Sanger sequencing, it is likely that next generation sequencing will allow more of these recently evolved complexes to be thoroughly studied.

The studies addressing diversification events of species complexes in lichens suggest that lichen-forming fungi are not unique, in that diversification is similar in land plants clades of similar age (Linder, 2008). However, lichenized fungi tend to have wider distributional ranges than land plants. This is true although molecular data have demonstrated that cryptic species are commonly found hidden within phenotypically circumscribed species (Crespo and Lumbsch, 2010; Lumbsch and Leavitt, 2011) and helped to revise species delimitation in these fungi. The wider distributional ranges are likely due to the higher distributional capacity of the relatively small ascospores or vegetative diaspores (soredia or isidia) that allow dispersal of the photosynthetic partner simultaneously with the fungal partner. Indeed, long-distance dispersal has been shown to have occurred commonly in lichenized fungi (Divakar *et al.*, 2010; Geml *et al.*, 2010; Otálora *et al.*, 2010; Amo de Paz *et al.*, 2011; Fernandez-Mendoza *et al.*, 2011; Amo de Paz *et al.*, 2012; Leavitt *et al.*, 2012a; Parnmen *et al.*, 2012).

Local diversification has been found in a clade of *Umbilicaria* species endemic to the central Andes (Hestmark *et al.*, 2011). All endemic species found in this region share a common ancestor in the *Umbilicaria vellea* group that has a worldwide distribution and contains several asexually reproducing species. The authors interpreted independent reversals to sexual reproduction as an explanation for different ascoma morphologies in this monophyletic endemic lineage. In a different study on the genus *Nephroma*, all species endemic to the north-west African archipelago of Macaronesia were shown to represent neoendemics that originated from a common ancestor shared with a widely distributed species (Sérusiaux *et al.*, 2011). The endemics are estimated to have reached the archipelago via long-distance dispersal.

Adaptive Radiation and Explosive Diversification

Across the entire tree of life, large disparities can be seen in species richness. Explosive diversification (Gittenberger, 1991; Givnish, 2015) or adaptive radiation (Osborn, 1902; Gavrilets and Losos, 2009; Rundell and Price, 2009) are well known to cause dramatic differences in species numbers among clades, and prominent examples of radiations include African cichlid fishes (Seehausen, 2006), Darwin finches (Grant, 1981; Lamichhaney *et al.*, 2015), or the Hawaiian silverswords (Baldwin and Sanderson, 1998). Adaptive radiation is usually explained as being driven by divergent selection caused by competition among closely related, ecologically similar species (Givnish, 1997). In lichenized fungi our understanding of the impact of trait evolution on diversification is not well understood and the few studies addressing this issue focus on specific genera. Despite the fact that some hyper-diverse families, such as Parmeliaceae, have distinct morphological synapomorphies, such as the cupulate exciple (Divakar *et al.*, 2013, 2015), the relationship of these traits and diversification are not well understood. However, the remarkable phenotypic disparity in the genus *Cladia* (including crustose, foliose, and fruticose species) has been explained by adaptive radiation (Lumbsch *et al.*, 2010) in temperate Australia. Explosive diversification has resulted in hyper-diverse groups, such as the genera *Ocellularia*, *Parmotrema*, *Usnea*, and *Xanthoparmelia* (Kraichak *et al.*, 2015a,b). The former genus belongs to a hyper-diverse family but even within the family, *Ocellularia* has a significantly accelerated rate of diversification (Kraichak *et al.*, 2015a,b). In this genus, the accelerated diversification rate was significantly associated with the presence of a unique sterile tissue in the hymenium (**Figure 3**) that often covers most parts of the ascomata, the so-called columella (Kraichak *et al.*, 2015b; Rivas Plata and Lumbsch, 2011). Hence the columella was interpreted as a key innovation, which is a trait that enabled a lineage to proliferate (Simpson, 1953). The function of the columella, however, is less clear and this underlines the poor state of knowledge of trait evolution in lichenized fungi. Hypotheses of its function include being a 'battering ram' to push through the outer periderm of these tropical epiphytic lichens (Redinger, 1936) or defense against fungivores, since the structure fills almost the entire hymenium and hence potentially protects the ascospores (Lücking and Bernecker-Lücking, 2000).

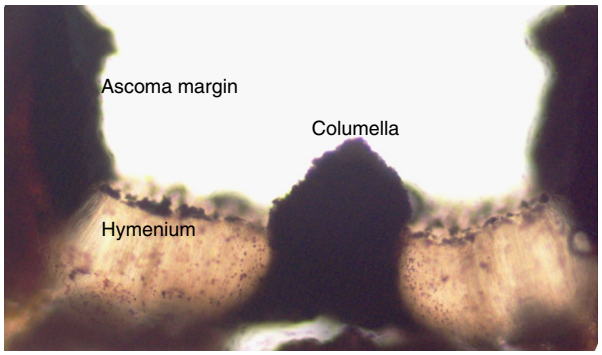

Figure 3 Cross section through an ascoma of the genus *Ocellularia* showing the columella, a sterile dark structure in the center of the hymenium.

Association of Rates of Diversification and Evolutionary Rates

Similar to the way rates of diversification fluctuate over time and among clades, differences in evolutionary rates have been shown to be common across the tree of life (Langley and Fitch, 1974; Britten, 1986; Arbogast *et al.*, 2002; Bromham and Penny, 2003). A number of causes have been invoked to explain the observed differences, most commonly body size and metabolic rate (Martin and Palumbi, 1993; Bromham, 2002), generation time (Gu and Li, 1992; Ohta, 1992), symbiotic association (Lutzoni and Pagel, 1997; Woolfit and Bromham,

2003), or environmental conditions (Bromham and Cardillo, 2003). Disparities of evolutionary rates have also been shown among lichen-forming fungi (Lumbsch *et al.*, 2008; Otálora *et al.*, 2013). In addition, theory also predicts a correlation between rates of substitution changes and diversification (Jobson and Albert, 2002). In the presence of a founder effect (Mayr, 1963), i.e., when speciation takes place in small, peripheral populations, genetic drift will cause rapid genetic change resulting in longer branches in phylogenetic trees (Pagel *et al.*, 2006). Evidence from various organismal groups support the correlation of evolutionary rates and rates of diversification (Barraclough *et al.*, 1996; Barraclough and Savolainen, 2001; Webster *et al.*, 2003) and has also been shown for Ascomycota (Wang *et al.*, 2010). Approximately a third of all Ascomycota species are lichen-forming. However, currently the frequency of speciation that experienced founder effects is poorly understood.

The Diversity of the Photobiont in the Lichen Symbiosis

Most studies to date have focused on the fungal partner in the lichen symbiosis. However, there is evidence for strong phylogenetic signals in the occurrence of photobionts in clades of lichenized fungi (Rambold *et al.*, 1998; Dahlkild *et al.*, 2001; Helms *et al.*, 2001; Persoh *et al.*, 2004; Buckley *et al.*, 2014; Lindgreen *et al.*, 2014; Leavitt *et al.*, 2015). At the same time, it was shown that some lichenized fungi are able to adapt to different habitats by forming symbiotic relationships with ecologically distinct photosynthetic partners (Del Campo *et al.*, 2010, 2013). It was hypothesized that ecological diversification and speciation of lichen symbionts in different habitats includes a transient phase consisting of associations with more than one photobiont in individual thalli (Del Campo *et al.*, 2013) and that such a diversification might be promoted by different physiological backgrounds. An alternative interpretation sees the ability to form association with ecologically different photobionts as an adaptive strategy to expand the potential geographical range of a species (Sadowska-Des *et al.*, 2014). Studies addressing photobiont diversity and selectivity of the fungal partner, however, are currently in their infancy and additional studies will undoubtedly shed more light in the complex interplay of partners in these fascinating symbiotic systems.

Glossary

Allometric relationship A linear relationship on the log–log scale between a life history trait and body mass. Across species, this corresponds to evolutionary allometry. The intercept is the allometric coefficient and varies a lot across taxons and life styles. The slope of the relationship is the allometric exponent and varies little across taxons or life styles, being mostly dependent on the dimension of the trait.

Biological (or physiological) time A measure of perceived time by a given species in opposition to the absolute time unit. Biological time is scaled to body mass. A given absolute time period (say a month) is perceived as being much longer in small species than in large ones.

Dimensional analysis A standardized analysis of the relationships between different biological traits. The standardization is based on three fundamental dimensions (length, volume, and time) and their associated measurement units (e.g., centimeter, kilogram, and years). The dimensional analysis tracks the dimensions and the measurement units when performing calculations or comparisons among traits.

Lifestyle A description of the way of life characterizing a species. This mostly includes the type of diet, the mating tactic, and the habitat features individuals within a species share.

Pace of life A synonymous term for slow–fast continuum. Often used in a broader perspective including not only life history traits, but also physiological and behavioral traits.

Variability is an essential property of living organisms. Both Darwin (1859) and Fisher (1930) understood that evolution required variation. Biologists have been assessing the causes and the consequences of the variability they observe at all stages of biological organization, from the cell to the ecosystem, since the very first studies of life history. The diversity of life history traits, defined here as any phenotypic trait that influences the trajectory of a given individual from birth to death, is one of the most striking and intensively studied topics in evolutionary biology. Let us consider mammals as an example of the wide range of variation. This vertebrate class, which includes about 4600 extant species (Wilson and Reeder, 2005), displays tremendous variation in life history traits. While the gigantic blue whale (*Balaenoptera musculus*), the largest animal to have ever existed on earth, weighs 172 t, the tiny shrew (*Suncus etruscus*) only weighs 1 g. In addition to large variation in body mass (Silva and Downing, 1995), mammals display a tremendous variation of life histories. For example, the gestation time of the African elephant (*Loxodonta africana*) is 660 days, while in voles (*Microtus* sp.) it can be as short as 20 days (Hayssen *et al.*, 1993). Bats (Chiroptera, Rhinolophidae family) give birth to offspring weighing almost one-third of the mother's weight, while in polar bears (*Ursus maritimus*), offspring at birth are only about one-thousandth of their mother's body mass (Hayssen *et al.*, 1993). The chimpanzee (*Pan troglodytes*) gives birth to a single offspring every 4 or 5 years while the tenrec (*Tenrec ecaudatus*) can produce up to 32 embryos within a single litter (Hayssen *et al.*, 1993). Also, small marsupial mice belonging to the genus *Antechinus* reproduce only once during their lifetime (semelparity), while a long-lived species like roe deer (*Capreolus capreolus*) can reproduce up to 15 times (iteroparity). Finally, the European water vole (*Arvicola terrestris*) lives for less than 6 months in the wild, whereas some individuals of Bowhead whale (*Balaena mysticetus*) can survive for more than a century. This extreme variability is highly structured across species with some strong associations with life history traits. This covariation corresponds to life-history strategies (Stearns, 1976, 1980), which are organized along major axes of life history variation. For example, within the mammals, the African elephant has a long gestation time (in fact the longest ever reported), large size, long inter-birth intervals (by giving birth only every 4 years on average), produces a large single offspring at each reproductive attempt, has a delayed age at first breeding and a long life. In contrast, voles have a short gestation time, produce several litters each year each consisting of several offspring, have an early age at first parturition and a short life. This type of covariance defines an axis of life history variation that is frequently defined as the slow–fast continuum of life histories, by far the most intensively studied axis of life history variation, especially in vertebrates (but not only; see also Blackburn, 1991 on Hymenoptera and Franco and Silvertown, 1996 on plants). What is the origin of the slow–fast continuum concept? What is the current empirical evidence supporting the existence of this axis of life history variation in vertebrates? What are the structuring factors shaping the slow–fast continuum of life histories? What are the ecological and evolutionary consequences of this continuum? Are there other axes of life history variation than the slow–fast continuum? From a selected review of the literature published over the past

 doi:10.1016/B978-0-12-800049-6.00085-8

50 years, we will try to provide answers to these questions. We will also identify gaps in our current understanding of life history variation.

A Brief History of the Origin of the Slow–Fast Continuum

Identifying the origin of a concept is difficult when several authors have contributed to our current understanding of it. This is exactly the case for the slow–fast continuum. The concept of the slow–fast continuum has no single, unique origin. As the main axis of life history variation, the slow–fast continuum is rooted in history of life history theory. In this respect, seminal work by Lack (1947) on clutch size in birds, Dobzhansky (1950) on latitudinal differences in the way natural selection operates in *Drosophila*, and Cole (1954) on the number of breeding attempts over the lifespan have all contributed to the emergence of the slow–fast continuum concept. However, the foundation of the slow–fast continuum is more precisely based on the concept of life history trade-offs and as such, is grounded in the principle of allocation proposed by Cody (1966) (itself partly inspired by Lack's works). This principle of allocation states that organisms have a limited amount of time or energy available for expenditure, so that allocating more to one biological function (e.g., growth, reproduction, or repair) should lead to the allocation of less energy to other functions. Thereby, the slow–fast continuum can be interpreted as the range of possible solutions to the trade-off between reproduction and survival.

In addition to these pillars of current life history theory, two important, but often overlooked papers, were published in 1962. First, Stahl (1962) called for more dimensional analyses (see **Box 1**) in biology when he stated "In order to define biological similarities in a meaningful way it is necessary to review the subject of dimensional analysis, which forms part of the basis for similarity theory" (p. 205). In particular, he identified that "two principles play a key role in biological analysis: conservation of volume and synchronism of times" (p. 209). Volume (like body mass or birth mass) and time (like age at first reproduction or lifespan) are the dimensions of traits most often included in empirical analyses of the slow–fast continuum. In the same year, MacArthur (1962) proposed a model extending Fisher's (1930) work to the density-dependent case, in which "the carrying capacity of the environment, K, replaces fitness as the agent controlling the action of natural selection" (p. 1897). This work set the basis for r-K selection (originally defined by MacArthur and Wilson (1967)) that led Pianka (1970) to launch his "r-K continuum" (p. 592). Pianka's r-K continuum provides the first axis of life-history variation with similarities and differences, to the slow–fast continuum (see below).

However, perhaps the easiest way to identify the origin of the slow–fast continuum is to simply identify the first use of this term. It was coined for the first time by Stearns (1983) in his pioneering comparative analysis of mammalian life histories when he wrote "This suggests that both size and phylogeny have significant independent effects on patterns of covariation in life-history traits, and that both effects contribute to the ordering of mammal species onto a "slow-fast" continuum" (p. 186). Regardless of when the term was born, or the historical contributions that led to our development of life history theory, empirical analyses of slow–fast continuum have accumulated over the last three decades.

Box 1 What is dimensional analysis?

Dimensional analysis was devised by physicists, but can be defined in an evolutionary biology context as a standardized analysis of the relationships between different biological traits. The standardization is based on three fundamental dimensions (length, volume, and time) and their associated measurement units (e.g., centimeters, kilograms, and years). The dimensional analysis tracks the dimensions and the measurement units when performing calculations or comparisons among traits. The problem of converting metrics from one dimensional unit to another is thus a main objective of dimensional analyses.

All life history traits can be related to a fundamental dimension, or derived units. For instance, gestation and incubation periods, weaning or hatchling periods, age at first reproduction, and lifespan are all measured in units of times (i.e., days, weeks, months, or years), antler size of deer is measured in units of length (centimeters or meters), and body mass has a dimension of volume measured in units of mass. Such an heterogeneity in dimension has obvious practical consequences. For instance, the dimensional analysis implies an allometric exponent to one-third (not 1) when regressing antler size against body mass (on a log–log scale) to assess the type of allometry (i.e., positive, negative, or isometry). Indeed, physical constraints lead us to expect isometric relationships among traits sharing the same dimension. The dimensional analysis thus provides the theoretical background for constructing dimensionless numbers (e.g., ratio between age at first reproduction and lifespan) that are expected to be size-independent (see Charnov, 1993).

Empirical Analyses of Life History Variation in Vertebrates

We will now review the evidence in support of this slow–fast continuum, the way the continuum is identified, and its biological meaning. We conducted a literature search in ISI Web of Knowledge using first the topic keywords 'slow–fast or fast–slow' and then 'pace of life' and, in both cases, refined the research domains to 'Zoology' and 'Evolutionary Biology.' We added the term 'pace of life' because it has become a general term for measuring the speed of a life cycle in ecological (e.g., Wiersma *et al.*, 2007) and physiological (Hille and Cooper, 2015) contexts. We identified 253 and 96 papers respectively and screened the summaries to select 29 studies of vertebrates in which at least one covariation among life history traits was tested (**Table 1**). We also identified 12 studies reporting analyses of a measure of species-specific positions on the slow–fast continuum in relation to other biological processes (**Table 2**). It is noteworthy that we did not identify any analysis in amphibians and that most studies focused on only one vertebrate class (only Herrando-Pérez *et al.*'s (2012) study encompassed a wide range of species including mammals, birds, reptiles, and fishes).

Table 1 Review of comparative analyses in which the slow–fast continuum of life histories across species has been investigated using only traits measuring biological times ('Time metrics') or both time metrics and traits measuring other dimensions ('Non-time metrics'). The taxonomic group analyzed (with its associated sample size in brackets), the method used to assess the slow–fast continuum, the support for the existence of a slow–fast continuum, and the reference, are provided. As traits measured as counts per unit of time (like annual fecundity) have the dimension of time, they are included as time metrics (see Allainé *et al.*, 1987 for further details). Corrections for allometric and/or phylogenetic constraints are displayed in italics. The studies are sorted in chronological order of publication

Time metrics	*Non-time metrics*	*Taxon/method*	*References*
Gestation time Age at eye opening Duration of lactation Inter-birth interval Number of litters per year Age at first reproduction Longevity	Offspring mass Number of offspring *Adult mass*	Mammals ($N=65$) PCA PC1 accounting for 68.1% of life history variation *Corrected for allometric constraints* *Replicated at different taxonomic levels* **Support**	Stearns (1983)
Gestation time Age at first reproduction Number of offspring per season	Neonatal mass Neonatal mass/Adult mass Litter size Litter size × Neonatal mass/Adult mass *Adult mass*	Lagomorphs ($N=22$) PCA PC2 accounting for 36.1% of life history variation **Support**	Swihart (1984)
Gestation time Age at weaning Estrous cycle length Age at first reproduction Age at maturity (both sexes) Lifespan Inter-birth interval	Adult mass (males) Neonatal mass Neonatal brain mass Adult brain mass *Adult mass*	Primates ($N=135$) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* *Analyzed at the taxonomic level of subfamily* **Support**	Harvey and Clutton-Brock (1985)
Gestation time Age at weaning Age at independence Lifespan Age at first reproduction Inter-birth interval	Litter size Birth mass Litter mass *Adult mass*	Carnivores ($N=112$) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* *Replicated at different taxonomic levels* **Support**	Gittleman (1986)
Incubation time (per egg) Time to fledging Age at first reproduction	Clutch size Egg mass *Adult mass*	European birds ($N=191$ genera) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* *Analyzed at the taxonomic level of genus* **Support**	Saether (1987)
Gestation time Inter-birth interval Age at first reproduction Lifespan r-max	Neonatal mass Litter size *Adult mass*	Primates ($N=58$) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* **Support**	Ross (1988)
Adult survival Age at first reproduction	Clutch size	European birds ($N=107$) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* *Replicated at different taxonomic levels* **Support**	Saether (1988)
Gestation time Age at weaning Period of maternal care	Adult brain mass Litter size Neonatal mass Neonatal brain mass	Mammals ($N=712$) Bivariate linear regressions (log–log scale) *Corrected for allometric constraints* *Replicated at different taxonomic levels*	Read and Harvey (1989)

To assess covariation among life-history traits, multivariate analyses are a reliable method. However, although the first analysis performed by Stearns (1983) relied on a Principal Component Analysis (PCA), subsequent works in the 1980s and 1990s typically used a series of bivariate linear regressions. The justification for not using multivariate analyses was generally based on two main arguments (see e.g., Harvey and Clutton-Brock, 1985): the necessity of having complete information for all traits in each species in the analysis, and the difficulty of interpreting a statistical combination of traits. Accumulation of life history data over the last 20 years has reduced the problem of missing data, as has the development of new methods for dealing with missing data in multivariate analyses (Josse and Husson, 2011). Problems of interpreting principal components of PCA in a biological context only occur when a heterogeneous set of traits in terms of dimension are included in analyses. These issues can easily be dealt with by accounting for the dimensionality of traits (see below). In recent years, as revealed by an examination of **Table 1**, PCA has become the rule when analyzing axes of life history variation, with all but two studies published since 2000 based on multivariate analyses. The move to PCA can even be detected within the work of the same group of researchers (e.g., Oli, 2004 vs. Dobson and Oli, 2007a,b, 2008).

Most of the available studies reported statistically significant covariation among life history traits and thereby supported the existence of a slow–fast continuum, providing clear evidence that it corresponds to the primary main axis of life history variation across species in mammals, birds, reptiles, and fishes (**Table 1**). The position of a species on the slow–fast continuum ranges from species with high adult survival and low reproductive output (the slow end of the continuum

Table 2 Studies reporting analyses of a measure of species-specific positions on the slow–fast continuum in relation to other biological processes. The metric used to assess the position of a given species on the continuum, the taxonomic group studied, the biological process analyzed, and the reference are all listed in the table. The studies are ordered chronologically. All metrics used but one (in italics) had a dimension of time

illustrated by Primates in mammals) to species with low adult survival and high reproductive output (the fast end of the continuum illustrated by lagomorphs in mammals). This axis of life history variation associates with principle of resource allocation (i.e., the Cody (1966) Principle of Allocation) supporting the hypothesis that a trade-off between survival and reproduction does shape the diversity of life histories across species within classes, and even orders, of vertebrates. In this narrow sense, it suggests that there is a universal slow–fast continuum of life history variation across vertebrates. Remarkably, in the most detailed analysis of the slow–fast continuum in vertebrates published to date ($N=46$ fish, 100 mammal, and 302 bird species), Jeschke and Kokko (2009) came to the opposite conclusion, writing "In other words, there is no universal fast-slow continuum" (p. 872). So, how can we reconcile what appears to be the contrasting conclusions of Jeschke and Kokko (2009) with our conclusions from a more up-to-date review of the literature? A likely explanation involves the variation among empirical studies in the approaches they use and subtle differences in the questions asked between early and current analyses. Different empirical analyses have corrected for different confounding factors and have worked with different life history traits, and these differences need to be taken into account before a clear take-home message of the existence of a slow–fast continuum within vertebrate lineages emerges.

Problems of Dimensionality When Assessing a Slow–Fast Continuum

Studies correcting for body mass and phylogeny have revealed allometric and evolutionary constraints, but even after having corrected for these processes, a slow–fast continuum of life histories still persists (**Table 1**). Body mass obviously has a major influence on all biological processes (Peters, 1983; Calder, 1984) and accounts for most of the variation observed in life history traits across species. Interestingly, while the slow–fast continuum shows up at both absolute and mass-dependent scales, the relative contribution of traits and the ranking of a given species along this continuum generally differ quite markedly. For instance, cetaceans obviously live in the slow line by displaying late age at first reproduction, low fecundity and long lifespan. However, for a given size, cetaceans rank among the fastest species in relation to the very large size they can reach in their marine habitat (Gaillard *et al.*, 1989). On the other hand, within a given lineage, the relative ranking of species on the continuum remains rather constant independent whether allometry is accounted for or not. The effects of phylogeny are also quite obvious, but often strongly covary with ecological factors. For instance, all bats belong to the order Chiroptera and share strong similarities including a remarkably long lifespan for their mass and their ability to fly. The phylogenetic inertia, which generates statistical problems of nonindependence among data points, has been increasingly accounted for (**Table 1**). However, the empirical evidence so far accumulated indicates that the phylogenetic inertia does not markedly influence the detection and the strength of the slow–fast continuum. The question of accounting for (or not) variation in body mass and phylogeny prior to analyse life history variation has focused most of the attention of evolutionary biologists (see, e.g., Jeschke and Kokko, 2009). However, the problem of dimensionality (**Box 1**) has been overlooked, even though it is likely a more crucial issue for interpreting life history variation from comparative analyses of life history traits.

Broadly speaking, Pianka's (1970) r-K continuum was the first formally proposed axis of life history variation. In addition to the trade-off between survival and reproduction, this continuum also includes in the covariation body mass, population size, climate, and intra- and interspecific competitions. In its original form it was a rather poor example of an axis of biological covariation in terms of dimensionality! Among other flaws not detailed here (see Stearns, 1977; Boyce, 1984 for further details), the r-K continuum of Pianka confuses the underlying pattern of life history variation with density-dependence, a process potentially involved to explain the pattern. Stearns (1976) was the first to start to separate the underlying pattern from the density-dependent component when he opposed the 'r-selection label' to the 'K-selection label,' which provides *sensu stricto*, the first slow–fast continuum. In the early 1980s, use of the concept of physiological time (that because "metabolic rate and longevity change with body size, time itself may be scaled", Lindstedt and Calder, 1976 (p. 91)) to life history analysis led some biologists to the view that observed covariation among traits measured in time units is an allometric consequence rather than a direct product of natural selection (Lindstedt and Calder, 1981; Calder, 1984). This explains why evolutionary biologists, starting with Stearns (1983), then searched for the existence of a slow–fast continuum of life histories after correcting for allometric constraints, providing unambiguous support for it (e.g., Harvey and Clutton-Brock, 1985; Gittleman, 1986; Saether, 1987; Gaillard *et al.*, 1989; Read and Harvey, 1989). A lively debate about whether allometric constraints or natural selection processes determine most of the observed life history covariation then took place in the late eighties (see, e.g., Read and Harvey, 1989). As allometric variation is itself under natural selection processes, such a separation between allometry and adaptation is highly disputable. Nowadays, it is widely accepted that both allometry and natural selection are acting to determine observed variation in life history. Thus, studying the slow–fast continuum requires consideration of the crucial problem of dimensionality (**Box 1**).

In all but three studies (Gaillard *et al.*, 1989; Dobson and Oli, 2007a,b), a mixture of traits with different dimensions were analyzed, leading researchers to question the interpretation of a slow–fast continuum, because common sense tells us that the slow–fast continuum is obviously based on the concept of time. As recognized in other research areas, including paleontology (see, e.g., Robson and Wood, 2008), life history traits can be classified into two broad categories: traits that describe the timing of life history events like age at first reproduction, gestation time, or longevity (corresponding to physiological times) and traits like mass, or growth rates, that are not biological times, but are correlated with biological times (as notably observed by Stahl (1962)). While the concept of biological similarity (Stahl, 1962) relies upon the use of time (e.g., gestation time, age at maturity, longevity) and time frequencies (e.g., heart beats/minute, annual fecundity, annual survival) to measure a time scale, it does not permit the inclusion of volume traits (like body, birth, or brain mass), nonstandardized number (like litter size or clutch size), or changes of volume over time (like growth rate). So far, most studies of the slow–fast continuum have included litter size or clutch size (**Table 1**) although these traits do not have the dimension of time. It was well established that litter size varies non-monotonously across mammalian species before any empirical analysis of slow–fast continuum was performed (Tuomi, 1980). The right metric for measuring the reproductive output in the context of a time scale is the fecundity per time unit (e.g., annual fecundity, Allainé *et al.*, 1987) because some small species produce several litters per reproductive season and some large species only reproduce every second, third, or fourth year. The use of clutch/litter size instead of annual fecundity in Jeschke and Kokko (2009) is likely to account for most of the differences they reported between analyses accounting for body mass or not. Moreover, among the common pitfalls, lots of analyses of the slow–fast continuum include redundancy in life history traits. Such nonindependence between traits is likely to alter both the assessment of relationships in bivariate analyses (as nicely pointed out almost 30 years ago by Sutherland *et al.*, 1986) and the relative contribution of life history traits to the slow–fast continuum by deviating the first major axis of the PCA towards redundant variables. Our literature survey thus points out that problems of dimensionality occur in most empirical studies (see **Table 1**), which likely explain differences of interpretation among studies and prevent a reliable understanding of the slow–fast continuum.

Importantly, when the dimensionality of all traits is restricted to physiological times and any trivial redundancy among traits is avoided or accounted for by using multivariate analyses, traits equally contribute to the slow–fast continuum, which supports the concept of biological similarities (Gaillard *et al.*, 1989; Dobson and Oli, 2007b). Only considering physiological times included in PCA performed so far also provides remarkable support for this remark (**Table 3**). Therefore, to answer clearly the question raised by Jeschke and Kokko (2009), body mass should not be included when assessing the slow–fast continuum of life history. We thus share their suggestion 'to reserve the term "fast–slow continuum' to the raw data,' but only when traits with a dimension of time are considered (p. 876).

What Shapes the Slow–Fast Continuum of Life Histories?

Three main factors have been identified that shape the slow–fast continuum: body mass, phylogeny, and ecology. Western (1979) was the first to recognize that life history variation can be partitioned into an allometric component, and one or several non-allometric components. All analyses have identified a major role of allometric relationships in generating variation in life history traits across species (e.g., Peters, 1983; McMahon and Bonner, 1983; Calder, 1984; Schmidt-Nielsen, 1984; Brown and West, 2000 for reviews). As a rule of thumb, about 50% of life history variation observed across species can be statistically explained by variation in body mass, as long as the range of body sizes included in analyses spans several orders of magnitude. The trade-off between reproduction and survival persists when body mass effects are accounted for in analyses, indicating that the diversity of life history strategy is not solely due to differences in size (Stearns (1983), Gaillard *et al.* (1989), and Read and Harvey (1989) on mammals,

Table 3 Loadings of the traits with a dimension of time on the axis of life history variation interpreted as a slow–fast continuum in a set of empirical PCA studies reporting the loadings of each trait on the slow–fast continuum. In virtually all instances (exceptions in bold), all traits positively covary (same sign for physiological times and opposite sign for time frequencies) and the loadings are remarkably similar, providing a clear support for the concept of biological similarities

[a]Presented as − 0.79 for annual mortality in the original paper.

Trait 1: Gestation (Stearns, 1983; Swihart, 1984; Bielby *et al.*, 2007; Catlett *et al.*, 2010; Swanson and Dantzer, 2014); Spawning duration (Juan-Jorda *et al.*, 2013).

Trait 2: Age at first reproduction (Stearns, 1983; Swihart, 1984; Clobert *et al.*, 1998; Jeschke and Kokko, 2009; Swanson and Dantzer, 2014); Age at 50% maturity (Juan-Jorda *et al.*, 2013).

Trait 3: Annual fecundity (Swihart, 1984; Clobert *et al.*, 1998); Number of litters per year (Stearns, 1983).

Trait 4: Annual survival (Clobert *et al.*, 1998); Age at weaning (Bielby *et al.*, 2007; Catlett *et al.*, 2010); Lifespan (Stearns, 1983; Jeschke and Kokko, 2009; Juan-Jorda *et al.*, 2013; Swanson and Dantzer, 2014).

Trait 5: Inter-birth interval (Stearns, 1983; Bielby *et al.*, 2007; Jeschke and Kokko, 2009; Catlett *et al.*, 2010; Juan-Jorda *et al.*, 2013; Lactation time (Swanson and Dantzer, 2014).

Swihart (1984) on lagomorphs, Harvey and Clutton-Brock (1985) on primates, Gittleman (1986) on carnivores, Saether (1987) on European birds, Saether and Gordon (1994) on ungulates).

Phylogeny also has an influence on the ranking of species on the slow–fast continuum. For instance, bats and primates in mammals, and Procellariiformes in birds, have much slower life histories than predicted by their size. While early studies accounted for the possible confounding effects of phylogeny by replicating the analyses at different taxonomic levels (e.g., Stearns, 1983) or performing analyses at a higher taxonomic level (like genera, e.g., Saether, 1987), methodological advances in phylogenetic methods have allowed phylogenetic inertia to be appropriately corrected for in life history analyses (Freckleton *et al.*, 2002), including PCA (e.g., Phylogenetic PCA, Revell, 2009, 2010).

The ecological factors shaping variation on the slow–fast continuum have not yet been clearly identified, which looks a bit paradoxical given that the original Pianka (1970) r-K continuum explicitly associated covariation among life history traits with ecological factors. According to Fisher *et al.* (2001), "most studies have failed to find robust ecological correlates of life history diversity in birds, mammals, and other taxa" (p. 3538). Some studies have identified habitat type (i.e., aerial, terrestrial, and marine, Gaillard *et al.*, 1989; Pontier *et al.*, 1990) or diet (Saether and Gordon, 1994; Fisher *et al.*, 2001) as structuring factors. Recently, stronger evidence that the lifestyle influences the pace of life of a species has been proposed. For example, evidence is accumulating that tropical birds have a slower life history than their temperate counterparts, likely as a function of lower basal metabolic rates (Wiersma *et al.*, 2007; Jimenez *et al.*, 2014) and smaller organ size (Wiersma *et al.*, 2012). For a given size, arboreal mammals live longer than those that live on the ground (Shattuck and Williams, 2010), and flying mammals outlive their nonflying relatives (Healy *et al.*, 2014). In addition, energy-saving strategies have been reported to shape species-specific pace of life. Thus, hibernation slows the pace of life in mammals (Turbill *et al.*, 2011). However, the current lack of evidence for strong structuring effects of ecological correlates might be explained by the simplicity of the metrics used to assess ecological correlates.

Evolutionary Consequences of the Slow–Fast Continuum

As rightly noted by Ricklefs (2000), analyses of life history variation have, for many years, contributed to "divorcing life-history from its environmental context" (p. 13). While the search for more refined ecological factors that likely shape the ranking of species on the slow–fast continuum has still to be performed, evidence is mounting concerning the evolutionary consequences of a given position on the slow–fast continuum. Indeed, several studies have assessed the effect of the species-specific position along the continuum on different biological processes like demography (Saether *et al.*, 2013), senescence (Jones *et al.*, 2008), or parent–offspring conflicts via placentation types (Garratt *et al.*, 2013). They clearly showed that slow- and fast-living species should markedly differ in demographic responses to human disturbance or climate change. Most of these studies ranked species on the continuum with an appropriate measure of time, with generation time, the weighted mean age of mothers in a stable population, being the most frequently used metric. In addition to closely matching a species position on the slow–fast continuum

identified through the use of the first component of a PCA conducted on time-related traits (correlation coefficients of 0.903 in mammals, Gaillard *et al.*, 2005), generation time is functionally the most relevant metric at the population level. Generation time proportionally decreases with increasing r-max (i.e., the maximum population growth rate a given species can reach in absence of any resource limitation, Caughley, 1977) across species, leading the product between r-max and generation time (i.e., the per-generation growth rate) to be a dimensionless number (*sensu* Charnov, 1993). Thus, within a lineage and in absence of specific adaptations, the per-generation growth rate is expected to be a constant independent of body mass. Moreover, generation time defines the scale at which genes pass from parents to offspring. It consequently obviously correlates with how quickly a lineage can evolve (Okie *et al.*, 2013) with species at the slow end of the continuum evolving at a slower rate than those at the fast end (Martin and Palumbi, 1993; Galtier *et al.*, 2009; Bromham, 2011). We could thus expect slow-living species to be more resistant to environmental perturbations but to be less able to respond to such perturbations (either by demographic or evolutionary changes) than fast-living species (Morris *et al.*, 2008; Gamelon *et al.*, 2014). Therefore, the position of the species along the slow–fast continuum of life history variation has important consequences from both ecological and evolutionary viewpoints.

Are There Other Axes of Life History Variation Than the Slow–Fast Continuum?

The slow–fast continuum identified from multivariate analyses only accounts for approximately half of the variation observed in life history traits, meaning that, for a given position on the slow–fast continuum, species are organized according to some other sources of covariation. This was recognized since Stearns (1983) identified a precociality–altriciality continuum after accounting for the slow–fast continuum. Subsequent analyses provided similar findings by identifying other axes of life history variation, involving covariations among some reproductive traits. For example, a gradient of allocation of reproductive effort over the lifetime going from semelparity to marked iteroparity accounted for about 10% of the demographic variation observed among mammalian species, once the effects of allometry and of the pace of life were accounted for (Gaillard *et al.*, 1989). On the other hand, Bielby *et al.* (2007) pointed out the existence of an offspring size–offspring number trade-off in mammals after accounting for the slow–fast continuum. These authors questioned the general relevance of the slow–fast continuum based on the argument that (1) there is more than one axis of variation in life histories across species, so that species can be fast or slow in different ways (Bielby *et al.*, 2007), and (2) strongly correlated traits in some taxonomic groups are poorly correlated in others. For example, the loadings of weaning age on the slow–fast continuum in Artiodactyls was only half those reported in other mammalian groups. While it is evident that the slow–fast continuum only corresponds to one axis of life history variation as demonstrated by our literature review (**Table 1**), the conclusion that the covariation of traits shaping the slow–fast continuum differs among groups does not hold. The detailed life history analysis performed by Bielby *et al.* (2007) involved traits with different dimension (e.g., time, volume, non-standardized number), and this heterogeneity in dimension among traits shaping the axes of life history variation prevents interpretation of axes of variation as corresponding to slow–fast continuums. As reported in the **Table 3**, when restricted to physiological times and frequencies, the slow–fast continuum is remarkably constant across taxonomic groups. Again, instead of mixing traits with different dimensions, we recommend looking for a series of axes of life history variation based on comparable traits (i.e., meeting the concept of biological similarity), which will be easy to interpret. For instance, performing a comparative analysis including a wide range of physiological times including developmental and demographic traits would offer a powerful way to assess the full complexity of life history variation.

Perspectives: Beyond Interspecific Analyses and Toward an Integrated Pace of Life Syndrome

The study of the axes of life history variation has primarily been performed at the interspecific level. However, these axes cannot account for all the variability of life history traits. For a given species, for a given ecological type, and for a given taxonomic position, variation in life history is still important. It is nowadays widely recognized that considerable variation in life history occurs among populations within a given species, and also among individuals within a population. Until now, whether the fundamental trade-off between survival and reproduction shapes a slow–fast continuum at these lower levels of biological organization has yet to be investigated. In roe deer, it has been shown that declining populations live at a slower pace of life than colonizing ones (Nilsen *et al.*, 2009). Similarly, heavily hunted wild boar (*Sus scrofa*) populations exhibited fastest life-history speed than lightly hunted ones (Servanty *et al.*, 2011). However, a recent comparative demographic analysis among eight contrasted populations of a lizard species (*Sceloporus grammicus*) did not find any evidence for a slow–fast continuum (Pérez-Mendoza *et al.*, 2013). Further work is clearly required to understand such patterns of variation.

While available analyses of life history variation have mostly been performed in an ecological context, a more holistic view is required, and this has started to emerge. For instance, a recent study aiming at understanding the life history differences between tropical and temperate birds, has suggested that a physiological slow–fast continuum is also existing (Hille and Cooper, 2015). In addition, the increasing popularity of personality analysis in ecology allows identification of behavioral syndromes (Sih *et al.*, 2004) that can be related to individual life history variation. The works of Careau *et al.* (2009) and Hua *et al.* (2013) relating the pace of life with exploratory behaviors of muroids and the perception of predation risk, respectively, and by Patrick and Weimerskirch (2014) on the links between personality and senescence rates among individuals provide insightful examples of what can be done in the next future. Finally, while available analyses of life history variation have mostly been performed in an ecological context, a more global view is required and has started to

emerge. The search for a better understanding of life history differences between tropical and temperate birds has led researchers to include physiological traits, suggesting that a physiological slow–fast continuum may also exist (Hille and Cooper, 2015). Therefore, we envisage a fully integrated view of life history variation including a covariation of axes of variation defined not only by times, volumes, and physiology as currently understood in the concept of pace of life syndrome (Hille and Cooper, 2015), but also by behavior and molecular evolution.

Life History: Age and Stage Structure

S Tuljapurkar, Stanford University, Stanford, CA, USA

Introduction

In biology, the principal use of demographic theory is to show how individual life histories (vital rates) determine fitness. As discussed in previous articles, when age alone determines survival and fertility, fitness is the stable population growth rate, r, that solves Lotka's equation. Broad understanding relies on the approximation $r \simeq (\log R_0/T_c)$ (Dublin and Lotka, 1925). Here R_0, the expected lifetime reproduction of an individual, measures the level of reproduction in a life history, whereas T_c, the average age at which an individual reproduces, measures the timing of reproduction. However, numerous traits other than age can influence survival and reproduction, for example, size in plants (Hoffmann, 1999), developmental/reproductive stages in insects or birds (Hu and Tessier, 1995; Steiner *et al.*, 2010), body mass in mammals (Coulson *et al.*, 2010), and body-mass index in humans (Preston *et al.*, 2012). Hence the need for, and importance of, a generalized demographic theory that incorporates stage in addition to age which we describe here.

In this generalization, the term 'stage' indicates virtually every kind of trait that can affect the components of a life history – quantitative or qualitative, for example, behavioral, physiological, developmental, morphological, (epi-)genetical, or geographical. For an individual, the theory tracks how stage changes with age (deterministically or stochastically) using functions that describe growth or development or plasticity; survival probability as a function of stage and age; and the total number of offspring as a function of stage and age. Offspring can be born in many stages, for example, different sizes, or different kinds as in seeds versus clones, or in different locations, so we need a transmission function that tells us what kinds of offspring are produced by parents in different stages and ages. When time is measured in discrete intervals, these elements (growth, survival, fertility, and transmission) can be combined to produce discrete-stage (matrix) or continuous-stage (integral) population models (Cochran and Ellner, 1992; Caswell, 2001; Ellner and Rees, 2007; Steiner *et al.*, 2010; Tuljapurkar *et al.*, 2012). These models provide a rich description of population dynamics and an especially valuable feature is that matrix methods are easily extended to compute the moments of age-at-death (lifetime), lifetime reproduction, and r and their sensitivity to model parameters (Coulson *et al.*, 2010; Steiner *et al.*, 2012; Steiner and Tuljapurkar, 2012).

Here we summarize the structure of age–stage models, their dynamics, and the macroscopic (summary) parameters that generalize quantities that are familiar in the age-only demography. These macroscopic parameters are useful, for instance, in showing how detailed life history components (stage-and-age dependent growth and development, survival, reproduction, and parent–offspring transmission) determine the speed of a life history, the level of reproduction, or both. Our description of vital rates and population growth follows mainly Coulson *et al.* (2010) but also depends on important earlier works (Le Bras, 1971; Rogers, 1975; Lebreton, 1996; Childs *et al.*, 2004; Ellner and Rees, 2006). Further results and mathematical details can be found in the cited references.

Individual Vital Rates

We work with discrete time, age, stage, and so with matrices; but note that these results apply to integral operators for continuous stages under the conditions given by Ellner and Rees (2006). At time t a census enumerates newborns (ages 0–1) in age-class 1, and individuals in all higher age-classes $a = 2, 3, \ldots$ (a terminal age is easily accommodated). We use 'age' and 'age-class' interchangeably: a newborn arrives at age $a = 1$, moves to age 2 after one time interval, and so on. An individual (we follow only females) of a given age a is in one of many discrete stages z (with integral models, our discrete intervals are bins on a continuous stage space). A population census at time t yields numbers $n_a(z,t)$ for all ages a and stages z. For example, the number of newborns in stage z at time t is $n_1(z,t)$. Stages are indicated by the symbols γ, z.

Stage–age structured vital rates comprise information about one or multiple traits and their influence on survival, reproduction, trait change (dynamic across life), and the transmission of the trait from parent to offspring which can be due to processes including genetic inheritance, epigenetics, and maternal effects. All of these influences can change with age, and are captured by four relationships (summarized in **Table 1**) that can be estimated directly from data, as explained by Coulson *et al.* (2010). To help fix ideas, think about that case where stage is just size. The theory works with two summary matrices for each age.

1. Fertility $\mathbf{F}_a$ at age a is the number of stage γ offspring of age 1 produced by a stage z parent of age a. This matrix (see **Table 1**) is determined by (1) the total number of offspring $M_a(z)$ produced by a stage z individual at age a, and (2) the stage-distribution of offspring: for a stage z individual at age a, $D_a(\gamma,z)$ is the fraction of this individual offspring that is born into newborn stage γ (clearly $\sum_\gamma D_a(\gamma,z) = 1$).
2. Survivorship $\mathbf{L}_a$ is a matrix of cumulative survival probabilities from birth (at age 1) to age a. The matrix element $L_a(\gamma,z)$ is the probability that an individual born in stage z is alive in stage γ at age a. An individual moves from stage z at age a to stage γ at age $(a+1)$ if (1) it survives with probability $S_a(z)$, and (2) changes stage from z to γ with probability $G_a(\gamma,z)$ (so that $\sum_\gamma G_a(\gamma,z) = 1$). The combined probabilities $P_a(\gamma,z) = G_a(\gamma,z)S_a(z)$ of surviving and moving from stage z at age a to stage γ at age $(a+1)$ are elements of a survival matrix $\mathbf{P}_a$. In the convention used here, individuals are born into age-class 1, which means that $\mathbf{L}_1$ is just the identity matrix (see **Table 1**). Then $\mathbf{L}_2 = \mathbf{P}_1\mathbf{L}_1$ and so on.

 doi:10.1016/B978-0-12-800049-6.00092-5

Table 1 Stage and age: vital rates

Quantity	*Equation*	*Notes*
Age	$a=1, 2,\ldots$ Newborns are in age-class 1	
Stage	y or $z=1, 2, \ldots$ An individual has both stage and age. Stage-and-age composition counted at a census	Stages may include several dimensions (e.g., size and developmental state)
Total recruitment	$M_a(z)$, number of offspring of age a, stage z individual that recruit as newborns in next census	
Inheritance	$D_a(y,z)$, fraction of $M_a(z)$ offspring that is born into newborn stage y	Parent–offspring transmission function $\sum_y D_a(yz)=1$
Fertility	$F_a(y,z)=D_a(y,z)M_a(z)$. Elements of matrix $\mathbf{F}_a$	Number of stage y recruits produced by a stage z parent of age a
Survival probability	$S_a(z)$, probability that individual in stage z at age a survives to $a+1$.	
Growth	$G_a(y,z)$, probability that individual in stage z at age a changes stage to y at $a+1$.	Conditional on survival, so $\sum_y G_a(yz)=1$
Stage transition matrix	$P_a(y,z)=G_a(y,z)S_a(z)$, probability that individual in stage z at age a is alive in stage y at $a+1$. Elements of matrix $\mathbf{P}_a$	Includes survival and stage change (e.g., growth).
Survivorship	$L_a(y,z)$, probability that newborn arriving in stage z is alive in stage y at age a. Elements of matrix $\mathbf{L}_a$. Here $L_1(y,z)=1$ if y=z and zero else	$\mathbf{L}_1=\mathbf{I}$=the identity matrix. $\mathbf{L_2}=\mathbf{P}_1\mathbf{L}_1$, $\mathbf{L}_3=\mathbf{P}_2\mathbf{L}_2$, etc.

Stable Cohorts

If age is all that matters, individuals born together are considered identical and make a birth cohort whose lifetime reproduction is readily described. But when stage also matters, individuals in the same birth cohort but different birth stages can differ in their future survival, growth, and reproduction. In other words, two cohorts with different stage compositions but equal total number will produce different numbers of offspring. What happens to such differences as we look forward in time?

Newborns in the first offspring generation go on to produce offspring over their lives; the latter is the second offspring generation, grand-offspring of our original cohort. The number of individuals in successive offspring is determined by a 'generation' matrix

$$\mathbf{A}_0=\sum_{a\geq 1}\mathbf{F}_a\mathbf{L}_a \qquad [1]$$

This matrix $\mathbf{A}_0$ has a dominant eigenvalue R_0. The total number of individuals in successive offspring generations will eventually change at the geometric growth rate R_0. There is a corresponding right eigenvector $\mathbf{c}$ that describes the stage-structure of offspring generations. In the long run, this unique stage-structure defines a 'stable cohort.' Such a cohort and only such a cohort produces offspring generations that grow at exactly the rate R_0. A corresponding left eigenvector $\mathbf{d}$ that describes the generational reproductive value. For an age-only model, $\mathbf{A_0}$ reduces to the number $\sum_a f_a l_a = R_0$, and the vectors $\mathbf{c,d}$ are each replaced by the single number unity.

At age a a stable cohort produces a fraction ϕ_a of its total reproduction:

$$\phi_a=\frac{(\mathbf{d}^T\mathbf{F}_a\mathbf{L}_a\mathbf{c})}{R_0} \qquad [2]$$

Here the superscript T indicates a transpose. The fractions ϕ_a sum to 1. This equation generalizes the simple product of survivorship and fertility for an age-only life history.

Using ϕ_a, we compute the average age of reproduction

$$T_c=\sum_a a\phi_a$$

The quantity

$$\mu_2=\sum_a a^2\phi_a$$

is the mean-square age of reproduction, and the age-dispersion $V_a=\left(\mu_2-T_c^2\right)$ describes how much reproduction occurs earlier or later than the mean age T_c.

Population Structure and Growth

In stage-and-age demography, the population at age a has components $n(a,t,z)$ at each discrete stage z. Letting $\mathbf{n}(t)$ be a vector with component $n(a=1,t,z)$, $n(a=2,t,z),\ldots$, the population's dynamics can be written in matrix form as

$$\mathbf{n}(t+1)=\mathbf{X}\mathbf{n}(t) \qquad [3]$$

where

$$\mathbf{X}=\begin{pmatrix}\mathbf{F}_1 & \mathbf{F}_2 & \cdots & \mathbf{F}_A\\ \mathbf{P}_1 & 0 & \cdots & 0\\ \vdots & \vdots & \vdots & \vdots\\ 0 & \cdots & \mathbf{P}_{A-1} & 0\end{pmatrix} \qquad [4]$$

An equivalent renewal equation can also be written for newborns (Le Bras, 1971; Rogers, 1975; Lebreton, 1996)

$$\mathbf{n}(1,t)=\sum_a \mathbf{F}_a\mathbf{L}_a\mathbf{n}(1,t-a)$$

Stable Population

Assuming demographic ergodicity (Keyfitz and Caswell, 2005), the dominant eigenvalue of $\mathbf{X}$ is $\lambda=e^r$ and is the

Table 2 Stage and age: cohorts to fitness

Struture of stable cohort	Normalized so that $(\mathbf{d}, \mathbf{c})=1$	Generational reproductive value of stages in a cohort
Level of reproduction by stable cohort	R_0	Net reproductive rate
Age-distribution of stable cohort reproduction	$\phi_a=(\mathbf{d}^T \mathbf{F}_a \mathbf{L}_a \mathbf{c})/R_0$, superscript indicates transposed vector	Fraction of stable cohort's reproduction that occurs at age a.
Mean age of reproduction by a cohort	$T_c=\sum_a a\phi_a$	Also called cohort generation time
Mean square age of reproduction	$\mu_2=\sum_a a^2\phi_a$	
Age-dispersion of reproduction	$V_a=(\mu_2-T_c^2)$	
Stage-dispersion of reproduction	$V_s=\xi_1-T_c^2$ $\mathbf{B}_1=(1/R_0)\sum_a a\mathbf{F}_a\mathbf{L}_a$ $\mathbf{Z}=\mathbf{c}\mathbf{d}^T$ $\mathbf{H}=\{\mathbf{I}-([\mathbf{A}_0/R_0]-\mathbf{Z})\}^{-1}$ $\xi_1=(\mathbf{d}^T\mathbf{B}_1\mathbf{H}\mathbf{B}_1\mathbf{c})$	
Simple stage–age structured approximation	$r_1=(\log R_0)/T_c$	R_0 and T_c differ compared to Dublin–Lotka approximation
Better stage–age structured approximation	$r_2=r_1+[V_a+2V_s](\log R_0)^2/2T_c^3$	Takes age- and stage-dispersion of reproduction into account

long-run growth rate in a constant environment. When the population becomes stable, write the stable stage-structure of newborns as $\mathbf{u}=\mathbf{U}_1$. For every other age a (from eqn [4]), the stable structure

$$\mathbf{U}_a=e^{-r(a-1)}\mathbf{L}_a\mathbf{u},\ \text{for}\ a\geq 1 \qquad [5]$$

Similarly, write $\mathbf{v}=\mathbf{V}_1$ for the reproductive value of newborns. Then for all ages a

$$\mathbf{V}_a^T=\mathbf{v}^T\sum_{b=a}^{b=A}e^{-r(b-a+1)}\mathbf{F}_b\mathbf{L}_{b|a},\ \text{for}\ a\geq 1 \qquad [6]$$

The always alert reader will note the strong similarity between these equations and the usual scalar versions of these that apply for age-structured demography.

The renewal equation shows that

$$\mathbf{u}_1=\left\{\sum_a \mathbf{F}_a\mathbf{L}_a m e^{-ra}\right\}\mathbf{u}_1=\mathbf{A}(r)\mathbf{u}_1 \qquad [7]$$

Here $\mathbf{A}(r)$ is the population 'renewal matrix'; its dominant eigenvalue is 1; the corresponding right eigenvector is the vector $\mathbf{u}$; and the corresponding left eigenvector is $\mathbf{v}$. The elements $v(i)$ are the relative reproductive values of individuals born in stage i. The stage-distribution of newborns and the stage dependence of reproductive value are fundamental distinctions between stage–age models and age-only models. The elements $u(i)$ are the fractions of newborns entering a stable population in stage i.

From Vital Rates to r: Levels and Timing

For general stage–age models, the stable population growth rate is given (Steiner *et al.*, 2014) by the approximation,

$$r=\frac{\log R_0}{T_c}+\frac{[V_a+2V_s](\log R_0)^2}{2T_c^3}+O\left(\frac{(\log R_0)^3}{T_c^3}\right) \qquad [8]$$

This precise mathematical relationship identifies measures that can be computed directly from the stage–age structured life history and predict r (see Table 2). The two explicit terms in eqn [8] predict r well so long as R_0 is close to 1. This equation is a direct generalization of the corresponding result in age-only structured demography, and can be extended to higher order in $\log R_0$ if desired.

The first two parameters describe the amount and average timing of a stable cohort's reproduction, as described above. The second term on the right of eqn [8] describes two kinds of reproductive dispersion.

1. Age-dispersion. Individuals of age a produce (a weighted) total of ϕ_a offspring, and the variance $V_a=(\mu_2-T_c^2)$ measures the age-dispersion of reproduction around the mean age of reproduction T_c. Larger age-dispersion of reproduction increases r, because early (relative to T_c) reproduction increases growth rate more than later reproduction reduces it.
2. Stage-dispersion. Suppose now that reproductive individuals produce the same stage-distribution of offspring at every age; in this case, there can only be age-dispersion of reproduction. But what if parents of different ages produce distinct distributions of offspring? Then the stage-distribution of the total number of offspring changes with age, producing a new kind of reproductive dispersion that can only happen in stage–age structured populations.

Discussion

We have summarized the demographic theory of stage-and-age structured population models. We have not presented here results on the mean and variance (and higher moments) of age-at-death and lifetime reproductive success; these and related work on dynamic heterogeneity are given by Tuljapurkar *et al.* (2009), Tuljapurkar and Steiner (2010), and Steiner and Tuljapurkar (2012). What about density-dependence? At a density-regulated equilibrium, the population's growth rate is zero, which means that the net reproductive rate R_0 must be 1, but T_c can vary. Our definitions of R_0 and T_c still apply of course, which means that we can examine how specific kinds

of density-dependence (e.g., predation, cannibalism, and resource competition) constrain different components (growth, survival, recruitment, parent–offspring correlation, or dispersal among locations of a meta population) of a life history at equilibrium. We can examine variation in T_c which still measures the speed of a life history and its response to environmental signals.

The results described here contribute to a powerful framework of stage–age structured models that is being applied in evolutionary and ecological population biology. In many populations, demographic dynamics, life histories, and quantitative variation can only be accurately predicted by these kinds of models. In particular, such models are needed to understand the consequences of variation in development, physiology, migration, behavior, or plasticity.

Glossary

Demographic transition The change from high birth and death rates to low ones as a country develops from a preindustrial to an industrialized economic system.
Genome-wide association study (GWAS) A study determining the genomic regions underlying traits of interest by assessing statistical associations between traits and the genotypes of many individuals at many thousands of loci across the genome.
Heritability The additive genetic variance in a trait, divided by the total phenotypic variance in that trait: $h^2 = V_A/V_P$. The additive genetic variance is the variance accounted for by additive effects on that trait that is due to the alleles an individual possesses.
Life-history theory A branch of evolutionary theory that explains aspects of anatomy and behavior by determining how patterns of development, growth, reproductive schedule, and lifespan have been shaped by natural selection.
Pleistocene period The geological epoch spanning approximately 2.5 million to 11 700 years before the present, when modern humans evolved.
Quantitative genetics The branch of genetics which studies how genes contribute to variation in complex traits determined by many genetic loci, such as size or fecundity.
Quantitative trait loci (QTLs) Regions of the genome that are linked to, or contain, genes which explain a part of the genetic variation in a complex trait.
Single nucleotide polymorphism (SNP) A DNA sequence in which a single nucleotide (A, C, T, G) differs between members of a species or between paired chromosomes.

Then and Now: The Unusual Life History of Humans

The human life history is characterized by several puzzling aspects. Compared to our closest relatives, the other great apes, humans have a delayed onset of reproduction; a short birth interval between each offspring; a complete cessation of reproductive capacity in females (menopause); and a long post-reproductive lifespan (Mace, 2000; Hawkes and Paine, 2006). Evolutionary biologists use 'life-history theory' to determine how these unusual patterns have evolved. Traditionally, studies on human life-history evolution have focused on the past, attempting to determine what genetic and environmental factors favored the evolution of these unusual life-history characteristics. Consequently, most studies on human life-histories have focused on contemporary 'traditional' societies, such as extant hunter-gatherer groups (see Hawkes *et al.*, 1997), whose lifestyle is thought to resemble that during the 'Pleistocene period' when many key human characteristics evolved.

This focus on a limited subset of human societies may hinder our attempts to determine how human life-histories evolved, since there is remarkable variation across cultural and ecological contexts. For example, average age at first reproduction can differ by 10 years even between populations with no access to medical care and contraception (Walker *et al.*, 2006); average family size ranges from little over one in contemporary Europe to around ten in the Hutterites, an Anabaptist group who practice communal living and shun birth control (Tietze, 1957); and the age when women have their last child differs by several years between populations. An increasing number of researchers have therefore begun to determine how this variation arises, including asking to what extent human life-history traits are still evolving in contemporary populations. This is particularly significant in the wake of the recent transition of many contemporary populations to dramatically reduced mortality and fertility rates (the 'demographic transition'), associated with industrialization and the introduction of effective contraception and medicine ('industrialized populations'). Determining how such rapid environmental changes may have altered selection on life-history traits and associations between them will be important for predicting how human life-histories may evolve in the future and the epidemiology of health and disease.

The question of whether or not contemporary human populations are undergoing evolutionary change has been a subject of debate in many disciplines. The major argument against the continuing evolution of human life-histories has been that, thanks to modern medicine and improved nutrition, nearly all children survive to adulthood in industrialized countries, which starkly contrasts with child mortality rates in preindustrial populations (Gagnon *et al.*, 2009; Rickard *et al.*, 2010; Gillespie *et al.*, 2013). Thus, natural selection through survival is weak in industrialized populations, but survival alone does not guarantee descendants in future generations. Only individuals that reproduce gain fitness, and while survival is a prerequisite to reproduce, natural selection ultimately acts on variation in reproductive success. Therefore, even if a set of individuals all survive to reproductive age, they may vary substantially in their ability to find a mate and produce and raise children, and this indeed is the case in industrialized populations (Byars *et al.*, 2010; Stearns *et al.*, 2010). This observation is crucial to the study of human life-history evolution, since any trait associated with variation in lifetime fitness can be under natural selection.

Phenotypic Correlations between Human Life-History Traits and Fitness

The traditional approach to studying life-history evolution has been to quantify phenotypic correlations between life-history traits and fitness. This approach has revealed that both the opportunity for selection (variation between individuals in fitness) and strength of selection on life-history traits, such as age at first and last reproduction, can be substantial in industrialized populations (Stearns *et al.*, 2010) and that selection pressures can change rapidly over time (Moorad, 2013). For example, in a contemporary Gambian population going through the 'demographic transition,' selection reversed from favoring decreased height and increased BMI before the transition to favoring increased height and decreased BMI after the transition, over a period of less than 60 years (Courtiol *et al.*, 2013). This change probably arose at least partially from improvements in the predictability of food supplies, which led to reduced need to carry energy reserves that allowed girls and women to survive past the annual hungry season.

A Crash Course in Quantitative Genetics

Although studies of phenotypic selection on human life-history traits are informative, selection on phenotype alone does not lead to evolution. The 'breeder's equation' (**Box 1**) shows that only traits that have 'heritable' genetic variation can show an evolutionary response to selection (Falconer and Mackay, 1996). Only recently have studies on humans followed the lead of studies of natural populations of animals (Kruuk, 2004; Wilson *et al.*, 2010; Charmantier *et al.*, 2014) in applying methods that estimate selection, heritability, and evolutionary responses. Applying these methods would allow us to predict how traits under selection can evolve over time, which is entirely feasible, given recent evidence for phenotypic selection operating in modern societies (Byars *et al.*, 2010; Stearns *et al.*, 2010; Courtiol *et al.*, 2013; Moorad, 2013), and evidence that many of these traits are heritable (de Bruin *et al.*, 2001; Kirk *et al.*, 2001; Pettay *et al.*, 2005; Milot *et al.*, 2011; Vink *et al.*, 2012; Bolund *et al.*, 2015). Life-history traits show considerable among-individual variation, which may be driven in part by social (e.g., age at marriage) or cultural factors (e.g., contraception), but each trait also has a complex genetic basis and is influenced by many genetic loci. For example, age at first birth depends on social practices, but has a substantial genetic basis in modern populations, with an individual's genes explaining ~11% of the total phenotypic variation (Stearns *et al.*, 2010). These genes may influence characteristics underpinning an individual's age at first reproduction, such as behavior, personality, appearance, and reproductive physiology. The study of such complex quantitative traits is the subject of quantitative genetics.

Quantitative genetics is based on estimating the genetic contribution to phenotypic similarities between relatives. By measuring the phenotypes of many individuals and coupling this with their relatedness information, the phenotypic variation in traits can be divided into contributions from genetic and environmental factors (**Figure 1**). A traditional approach has been to compare sets of relatives, such as parents and their offspring, or different types of siblings. Based on information about the 'average' relatedness of these sets of relatives, the proportion of variation in a trait due to genetics can be

Box 1 Predicting Evolution: The Breeder's Equation

$$R = h^2 S$$

This simple equation states that the evolutionary response (R) to selection of a trait is a product of the selection differential S (the difference in mean trait value between individuals that reproduce and the mean trait value of the population), and the heritability h^2 of the trait. This univariate Breeder's equation was developed for predicting a response to artificial selection by animal breeders. However, in wild populations, where selection acts on many correlated traits simultaneously, the multivariate form of this equation is more effective:

$$\Delta \mathbf{z} = \mathbf{G}\beta$$

The multivariate breeder's equation calculates the expected change in several traits at once: the vector of changes of mean trait values Δz is the product of the genetic variance-covariance matrix G (the diagonal elements $\sigma^2_{1,1}$ and $\sigma^2_{2,2}$ are the genetic variances for traits 1 and 2, and the off-diagonal element $\sigma_{1,2}$ is the genetic covariance between the traits) and the vector of selection gradients β:

$$\begin{pmatrix} \Delta z_1 \\ \Delta z_2 \end{pmatrix} = \begin{pmatrix} \sigma^2_{11} & \sigma_{12} \\ \sigma_{12} & \sigma^2_{11} \end{pmatrix} x \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix}$$

Here, the response of traits 1 and 2 to selection additionally depends on the genetic covariance between the traits and the strength of selection on the other trait:

$$\Delta z_1 = \sigma^2_{11}\beta_1 + \sigma_{12}\beta_2$$
$$\Delta z_2 = \sigma^2_{22}\beta_2 + \sigma^2_{12}\beta_1$$

Thus, the response to selection on one trait depends on the degree to which genes associated with that trait are also associated with related traits under selection. However, the Breeder's equation assumes that any association between a trait and fitness are causal, and that there are no unmeasured traits. This assumption may be unlikely to be met (Hadfield, 2008; Morrissey *et al.*, 2010), and so an alternative model has recently been advocated for the study of natural populations (Morrissey *et al.*, 2012). This model is known as the Robertson–Price identity, or Robertson's secondary theorem of natural selection (Robertson, 1966; Price, 1970), and states that evolutionary change can be calculated as the additive genetic covariance between a trait and fitness:

$$\Delta \bar{z} = \sigma_a(z, w)$$

This equation does not assume causality between trait and fitness: evolution is predicted by directly estimating the genetic aspect of the trait–fitness association. This change may be due to selection on an unmeasured, genetically correlated trait and so the equation does not identify the true form of selection, but unlike the breeder's equation it does provide a direct prediction of evolutionary change. These methods are vital for determining how life-history traits have evolved and how they may respond to selection in the future.

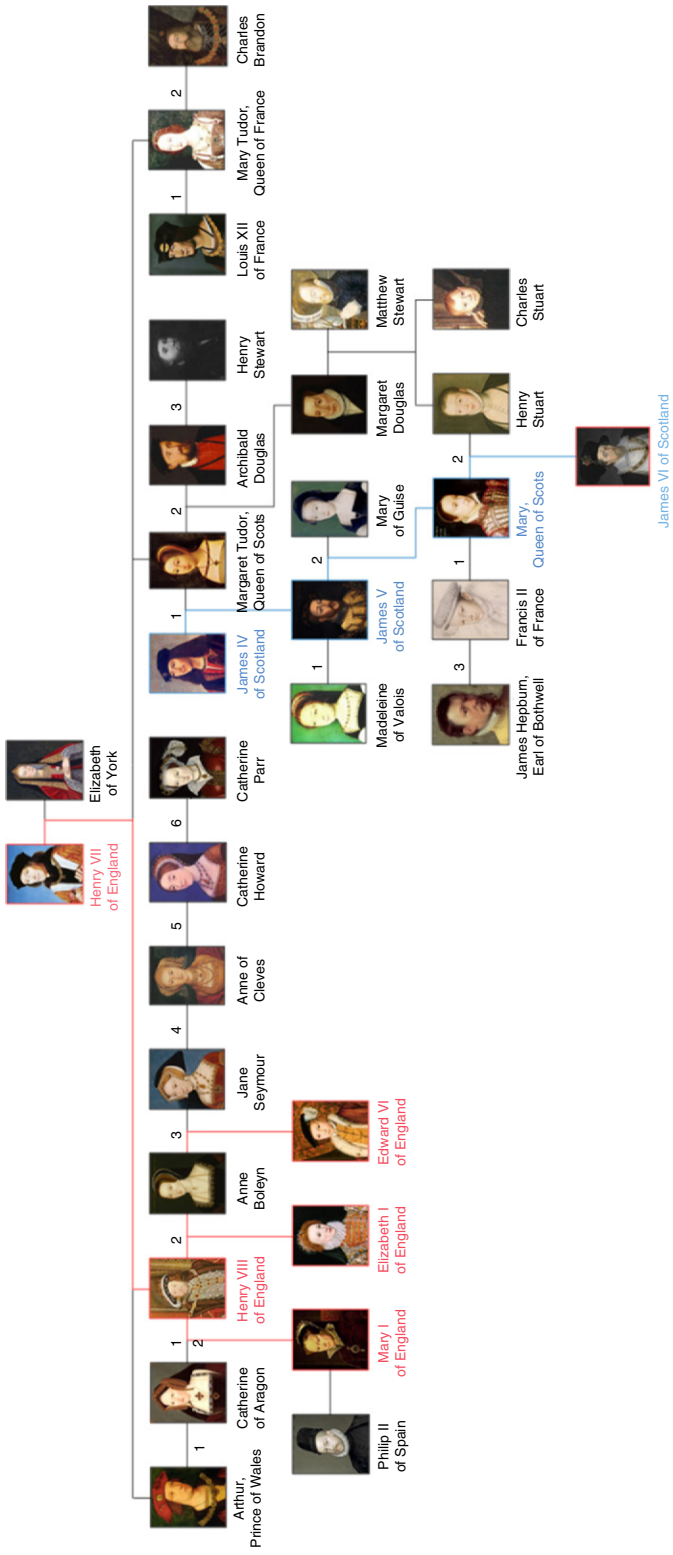

Figure 1 A pedigree showing the Tudor family tree, the dynasty of English monarchs, 1485–1603. Simple quantitative genetic analyses might calculate genetic parameters using trait values from parents and offspring (e.g., Henry VII and Henry VIII), or half-siblings (e.g., Mary I and Elizabeth I). The 'animal model' (see text) accounts for phenotypic information from all relatives: for example, James VI has 18 relatives in the pedigree depicted.

calculated: for example, monozygotic twins, full siblings and half-siblings share 100%, 50%, and 25% of their genes on average.

A drawback of this approach is that relatives share environments as well as genes: an individual's early puberty may arise because of genes inherited from their parents, or because they received a similarly good diet as their parents. In laboratory studies, this can be addressed by using breeding designs to accurately quantify genetic and environmental effects on specific traits (Falconer and Mackay, 1996; Lynch and Walsh, 1998). Such manipulations are usually not possible in studies of wild populations, which must rely on the often incomplete and unbalanced data that are available. The same is true of human populations: close relatives commonly share environments and many traits are affected by cultural transmission, which upwardly biases heritability estimates calculated using traditional methods.

Another nonexperimental situation is in populations of domesticated animals, which include many different levels of relatives, some of which share genes but not environments. A statistical approach to estimate heritability of traits in such situations, the 'animal model,' was developed over 50 years ago (Henderson, 1950, 1975). It estimates the heritability of quantitative traits by using pedigrees (**Figure 1**), and has been successfully applied to answer a wide range of evolutionary questions in wild animal populations (Kruuk, 2004; Kruuk and Hill, 2008; Wilson *et al.*, 2010; Charmantier *et al.*, 2014). The animal model is able to adjust for confounding factors, and therefore can account for aspects of cultural transmission measured in pedigreed humans, such as socioeconomic status, in the model structure. The heritability estimate from such a model quantifies the genetic contribution to phenotypic variance, accounting for the fact that individuals within one socioeconomic group are likely to be more similar to each other than to individuals from other socioeconomic groups.

Several multigenerational pedigree datasets, collected for clinical, medical, or demographic reasons, but also suitable for quantitative genetic analyses are now available. Historic pedigree data on humans use social information to determine parentage, though this should not be a limitation given the low extra-pair paternity (EPP) rates in humans (Anderson, 2006) and the robustness of quantitative genetic models to low EPP rates (Charmantier and Reale, 2005; Firth *et al.*, 2015). The availability of such pedigree datasets and statistical methods means that an evolutionary perspective on human life-histories is gaining momentum.

Case Studies on Using Quantitative Genetics to Understand Life-History Evolution in Humans

Life-History Traits are Heritable

A system of data collection originally designed to enforce stringent tax collection may seem an unlikely source of data on human life-history evolution, yet a system of Finnish church records dating back to the seventeenth century has increased our understanding of human life-history evolution (**Box 2**). This dataset and others like it, comprising information on relatedness, survival, reproduction, and socioeconomic standing, have been used to determine the genetic basis of key life-history traits and how selection acts upon them. A landmark study using the Finnish dataset estimated heritabilities and genetic correlations of several important life-history traits (Pettay *et al.*, 2005). Heritabilities of female life-history traits were largely significant (estimates ranged 0.18–0.47 for number of children, number of surviving children, the time interval between births, age at last reproduction, and lifespan). Interestingly, bivariate models also revealed evidence for genetic trade-offs: a genetic correlation between inter-birth interval and lifespan suggested that genes associated with producing children rapidly were associated with a shorter lifespan. These results showed that selection could have shifted the average birth interval over time, due to the additive genetic basis of this trait, but that a response to selection could have been constrained because of genetic correlations between traits (Pettay *et al.*, 2005). In this case, selection for faster birth rate

Box 2 The Finnish tax system during the eighteenth century, and how it unexpectedly aided the study of human life-history evolution

The King of Sweden, of which Finland was formerly a province, decreed in 1749 that the Lutheran church was obliged to document all births, marriages, deaths, and movements in the whole population for tax purposes. At the time, the Finns mostly depended on farming for their livelihood, supplemented with fishing and hunting. The standard of living was low with famine and disease being common, and with the main causes of death being infectious diseases associated with malnourishment (Turpeinen, 1978; Hayward *et al.*, 2012). Genealogists have used such records to compile multigenerational datasets with accurate information on individual survival, reproduction, family configuration, and dispersal for up to 15 generations. Industrialization began relatively late in Finland, and fertility and mortality rates were high until this occurred in the early twentieth century (Liu *et al.*, 2012). This dataset offers rare opportunities to follow the same genetic lineages from 'natural' mortality and fertility periods through the different phases of the demographic transition until the modern day. Finnish church records also provide information on occupations of adult men, allowing classification of individuals into different socioeconomic groups. Distinguishing different levels of resource availability is important as it is often associated with survival, reproductive success, and selection on different life-history traits (Pettay *et al.*, 2007; Courtiol *et al.*, 2012). Similar datasets on historical human populations are also available for many other countries, and they are increasingly used in evolutionary research.

An example of a church record page (left) detailing life-events of historical Finnish families (on the right).

would also lead to indirect selection for shorter lifespan, with the likely overall outcome of selection being a compromise between such alternative outcomes. Such trade-offs are one of the forces maintaining genetic variation in key life-history traits (Stearns, 1992).

Genetics of Life-History Traits in the Two Sexes – an Arena for Conflict

Genetic correlations between traits can constrain independent evolution in the two sexes because, while the sexes share much of their genome, their evolutionary interests are often not aligned (Parker, 1979). If the sexes have different phenotypic optima for a trait, different selection pressures act in the two sexes. Coupled with a shared genetic basis of the trait (a high cross-sex genetic correlation, r_{MF}), this leads to conflict over optimal trait expression, or intra-locus sexual conflict (Lande, 1980; Bonduriansky and Chenoweth, 2009). Studies on the Finnish population have revealed that age at first and last reproduction, reproductive timing and reproductive rate were all strongly genetically correlated with fitness in both sexes, and thus under selection (Bolund *et al.*, 2013). Further, there were no differences between the sexes in these genetic correlations between life-history traits and fitness. The genetic correlations between the sexes (r_{MF}) were also high, suggesting that, for example, genes associated with an early age at first reproduction in women are also associated with an early age at first reproduction in men. This indicates that the sexes cannot reach their sex-specific optima of trait expression even if selection pressures are different between males and females, as was indeed the case. These results likely reflect the strictly monogamous mating system in preindustrial Finland, which meant that an individual's reproduction was severely constrained by that of their partner. Thus, the sexes constrained each other's independent evolution. Given that humans exhibit many different mating systems (monogamy, polygyny, polyandry, polygynadry), they offer the opportunity to investigate how changes in mating systems affect selection pressures and genetic correlations. For example, over the reproductive lifetimes of Utahans born between 1830 and 1894, socially induced reductions in the rate and degree of polygamy corresponded to a 58% reduction in the strength of sexual selection (Moorad *et al.*, 2011). This illustrates the potency of sexual selection in polygynous human populations and the dramatic influence that societal changes can have on evolutionary processes. Intra-locus sexual conflict can also have important implications for health in modern populations, as shown by recent work using the ongoing Framingham Heart Study in the USA, which showed that evolution of a contemporary population may be constrained by genetic conflict between the sexes (Stearns *et al.*, 2012). In this population, selection favored shorter women and taller men, but female height was negatively genetically correlated with male cholesterol. Thus, selection for shorter women could lead to higher cholesterol levels in men. The possibility that complex traits associated with diseases can have a sexually dimorphic genetic basis which is maintained by disparate selection pressures in the sexes is an exciting emerging area of study.

Genetics of Life-History Traits over the Lifetime

As well as differing between the sexes, the expression of additive genetic variance is often observed to increase with age in diverse taxa (Réale *et al.*, 1999; Charmantier *et al.*, 2006; Von Hardenberg *et al.*, 2007; Wilson *et al.*, 2007, but see Brommer *et al.*, 2007). Evolutionary theories of senescence predict this is due to the accumulation of late-acting deleterious mutations, which are not selected against due to the declining force of selection with age (the mutation accumulation theory of ageing; Medawar, 1952). Senescence may also have evolved through antagonistic pleiotropy (Williams, 1957), or the effects of genes promoting fitness in early life at the expense of fitness in later life, a scenario which would lead to antagonistic genetic correlations between early- and later-life fitness. Quantifying age-specific changes in additive genetic variance is thus crucial if we are to determine the evolutionary mechanisms for senescence (Wilson *et al.*, 2008). In the preindustrial Finnish population, the additive genetic variance for female fecundity increased with age (Pettay *et al.*, 2008), due to changes in maternal and genetic variance for fecundity. Before age 31, maternal identity explained 25% of the variance in fecundity, and the additive genetic effect only 13%; after the age of 31, the maternal effect accounted for only 2% of the variance in fecundity, and the additive genetic effect increased to 25%. This suggests that early in reproductive life, mothers may have played a substantial role in enhancing their daughters' fecundity, perhaps by proving childcare through a 'grandmother effect' (Hawkes and Coxworth, 2013; Lahdenperä *et al.*, 2004). However, the Finnish study found no evidence for a negative genetic correlation between fecundity at early and later ages, and thus no evidence for the antagonistic pleiotropy theory of ageing. Further research using these approaches could determine whether the trade-off between fecundity and survival changes with age, testing the prediction that the menopause could have evolved as a result of diminishing benefits and increasing costs of reproduction with increasing female age (Williams, 1957; Hawkes and Coxworth, 2013).

Genetics of Life-History Traits Over Time and Across Environments

A major goal of evolutionary quantitative genetics is to predict evolutionary change over several generations: given current selection pressures and patterns of genetic (co)variance, how will traits respond to selection and be expressed in the future? To this end, the Framingham heart study measured the strength of selection, estimated genetic (co)variation, and predicted gradual evolutionary change in several life-history and health traits in the contemporary USA. The descendants of the study women were predicted to become on average slightly shorter and stouter; have lower total cholesterol levels and systolic blood pressure; have their first child earlier and reach menopause later than they would in the absence of selection (Byars *et al.*, 2010). Two important caveats to these predictions are that both the selection pressures and the genetic (co)variance may change rapidly. Changes in climate have been shown to affect selection and patterns of genetic (co)variation in wild animals (Garant *et al.*, 2008; Björklund *et al.*, 2013) and could

have profound effects on human populations, particularly with regard to changing patterns of disease spread (Lafferty, 2009; McMichael, 2014). Generally, the genetic (co)variance of traits (conceptualized as **G**, **Box 1**) are predicted to change over time and across environments (Roff, 2000) but little is known about how rapidly this happens (Steppan *et al.*, 2002; Arnold *et al.*, 2008). This has important implications for predicting evolutionary change, because such predictions rely on stability of **G** and β (**Box 1**). Thus, it is important to reveal how rapid changes in culture and technology are changing human biology. A study on the Finnish dataset found that the **G**-matrix of four key life-history traits (age at first and last reproduction, lifespan and lifetime reproductive success) remained largely stable over the demographic transition in Finland, but showed a trend for increased additive genetic variance (increased evolutionary potential of the population) after the demographic transition (Bolund *et al.*, 2015). Similarly, recent studies of other populations found changes in the additive genetic variance of age at first reproduction over a 140-year period (Milot *et al.*, 2011) and female fecundity over a 100-year period (Kohler *et al.*, 2002). Such changes in patterns of genetic (co)variance mean that projections of evolutionary change over more than a few generations are likely to be unreliable.

Studying Human Life-History Evolution in the Genomics Era

The last 20 years have seen rapid progress in genomic technologies. A major aim of medical genetics is to identify 'quantitative trait loci' (QTLs) associated with risk of developing diseases including cancer, heart disease, and mental illness (Plomin *et al.*, 2009; Visscher *et al.*, 2012). Sequencing the human genome has enabled the development of 'genome-wide association studies (GWAS),' which assess an individual's genotype at many thousands of 'single nucleotide polymorphisms (SNPs)' across the genome (Donnelly, 2008; Hindorff *et al.*, 2009). GWAS can also provide insight into the genetics underpinning life-history traits, as has been demonstrated in wild populations (Slate *et al.*, 2010; Jensen *et al.*, 2014). Combining genome sequence data with pedigree and life-history data could determine how individual genetic loci underlie important associations between life-history and health traits. A recent study found a negative genetic correlation between the lifetime number of children born to women and their lifespan, and then identified five SNPs that were associated with this relationship (Wang *et al.*, 2013). However, this result was not robust to changes in the sample, illustrating the difficulty in identifying QTLs that underlie variation in quantitative traits that are likely to be influenced by hundreds or even thousands of loci.

In summary, application of quantitative genetic techniques can help us to determine how cultural and environmental changes have led to new selection pressures and, importantly, what the evolutionary consequences of these changes could be. The observation that our biological nature continues to evolve has important implications for public health and demographic forecasts because it will allow us to predict human evolutionary responses to a rapidly changing world.

Glossary

Adaptive landscape Relationship between fitness and trait(s) under selection (= fitness landscape).

Fitness Individual contribution to the genetic pool of the next generation (= relative reproductive success).

Response to selection Change in mean trait value(s) in a population due to selection. Response to selection operates through the transmission of heritable information (nucleic acids, hormones, knowledge...) from one generation to the next.

Selection The process through which environmental conditions generate fitness variation among individuals. Selection operates on different units of selection corresponding to the different levels of biological organization (genes, cells, individuals…).

Introduction

The expansion of agriculture about 10 000 years ago allowed the settlement and growth of human populations, and from there the development of cities and of a social organization (civilization) that promoted technological innovations. Together, the human demographic expansion and technological improvements are the main drivers of so-called 'anthropogenic changes,' the perturbations brought about by human activities on natural systems.

Fundamentally, anthropogenic perturbations on natural systems simply arise from resource consumption by humans. However, its manifestations are multiple and interconnected, among which are often reported landscape alterations, soil deterioration, disruption of geochemical cycles, climate warming, or over-harvesting. All of these perturbations almost inevitably alter, directly or indirectly, the selective pressures acting on organisms.

Impacted populations must respond to these anthropogenic selective pressures by evolving life histories that are more fit to the newly selected, composite adaptive landscape that results from the combination of natural and anthropogenic selection. This response is the subject of the present article. If the response is too slow to track changes in the selective pressures, the population goes instinct. This failure to adapt is the underlying cause of the global biodiversity loss currently experienced by the earth ecosystems.

First, in this article, basic theory of selection and response to selection is recalled, then a specific focus on three major sources of anthropogenic selection (harvesting, habitat fragmentation, and temperature increase) is provided, and finally it is examined how rapid life-history evolution may change natural selection acting back on life histories, the so-called eco-evolutionary feedback loop.

Selection and Response to Selection

Natural and Anthropogenic Sources of Selection

In this article only selection acting on individuals transmitting genes to their offspring will be considered, because the individual is the level of selection having received the most thorough treatment in the literature (for a broader perspective see Wilson and Sober, 1994), and because genes represent the most widespread 70 support of heredity (for non-genetic inheritance, see Danchin, 2013). Selection of individuals may be 'natural' or 'artificial' depending on whether it results from nonhuman or from anthropogenic factors, respectively. To illustrate this, let me consider the case of pike *(Esox lucius)* in Windermere, the largest natural lake in England.

In Windermere, scientists have conducted long-term mark-recapture experiments on pike (Le Cren, 2001). The resultant data has allowed the computation of a component of natural selection, namely the form of the relationship between survival and body size (Haugen *et al.*, 2007; Carlson *et al.*, 2007; Vindenes *et al.*, 2014). This relationship shows that natural selection favors large-sized pike up to a body length of about 60 cm (blue solid line in **Figure 1**), after which survival is likely to remain constant (Vindenes *et al.*, 2014). A larger size likely provides pike with access to more resources, increased protection against cannibals and other predators, and increased energy stores to survive to winter fasting (Edeline *et al.*, 2007; Vindenes *et al.*, 2014). From this relationship, we may predict that there is a *directional natural selection* for rapidly reaching a body length of about 60 cm in Windermere pike.

In parallel with mark-recapture experiments, scientists have also submitted pike to gillnet fishing since the early 1940s (Le Cren, 2001). All pike captured in the gillnet fishery are killed, measured for several biological variables, and their opercular bones are removed. These bones record the age of each fish in the form of annuli (like in a tree trunk), and the radius of these annuli are proportional to individual body length, thus allowing the back calculation of length-at-age. From this information, it was possible to model the link between body length and the probability for a fish to be captured in the fishery. This relationship is depicted in **Figure 1** (red dashed line), which shows that the probability for a pike to be caught in the gillnet fishery suddenly increases after a body length of 50 cm. Hence, we predict that there is a *directional anthropogenic selection* for growing slowly so as to remain smaller than about 50 cm in Windermere pike.

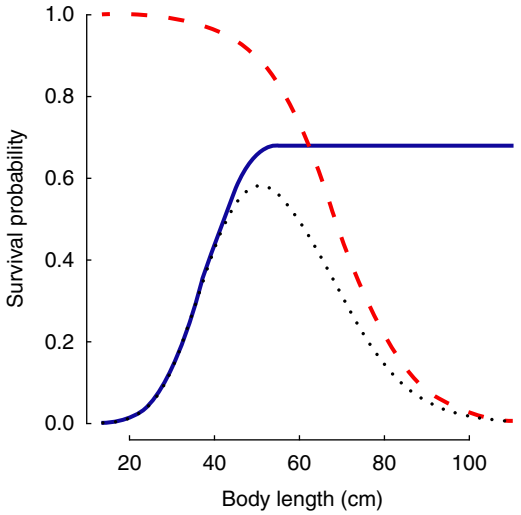

Figure 1 Size-dependent survival probability of Windermere pike (*Esox lucius*) through the directional components of natural selection (blue solid line) and the gillnet fishery (red dashed line). The resultant composite survival curve (the product of the two functions) is represented with the black dotted line and shows stabilizing selection around an adaptive peak at about 50 cm. The natural survival function was computed following Vindenes *et al.* (2014).

Combining these two (natural and anthropogenic) sources of selection acting on the body size of Windermere pike reveals the composite adaptive landscape, which reflects the truly experienced selective regime (black dotted line in **Figure 1**). We see that this composite landscape is very different from the naturally selected landscape. Anthropogenic selection decreases the overall area below the curves, i.e., it decreased overall survival probability of pike. This is predicted to induce an evolutionary response toward faster life histories in the pike population (see section Non-phenotypically Selective Harvesting of this article).

However, this increase in mortality is nonrandom, but instead biased toward large-sized pike, thus further reinforcing directional selection toward smaller sizes and faster life histories (see section Phenotypically selective harvesting of this article). This biased mortality is visible in that anthropogenic selection generates an adaptive peak (i.e., stabilizing selection) around a body length of 50 cm. Let us now more closely examine how response to these sources of selection may be qualitatively predicted.

Response to Directional Selection

Predicting response to selection is the central purpose of quantitative genetics theory (Lynch and Walsh, 1998). This theory predicts that dynamic response to selection of a single trait having negligible genetic covariance with other fitness traits obeys the equation:

$$\overline{\chi}_{t+1} = \overline{\chi}_t + R_\chi \qquad [1a]$$

where $\overline{\chi}_{t+1}$ = mean value of trait x in the population at generation $t+1$, $\overline{\chi}_t$ = mean value of trait x in the population at generation t, and R_χ = response to selection in trait χ, that may be recast as:

$$R_\chi = H_\chi S_\chi = \frac{Va_\chi}{Vp_\chi} S_\chi = Va_\chi \frac{\partial w_\chi}{\partial_\chi} \qquad [1b]$$

where $H_\chi = Va_\chi/Vp_\chi$ = narrow-sense heritability for the trait where Va_χ = additive genetic variance and Vp_χ = phenotypic variance (with $Vp_\chi \geq Va_\chi$), and $S_\chi = \overline{\chi}_a - \overline{\chi}_b = net$ directional selection differential where $\overline{\chi}_a$ = mean trait value in the population after selection and $\overline{\chi}_b$ = mean trait value in the population before selection. Here, following Lande and Arnold (1983) the equation is rearranged to obtain the directional selection gradient $(\overline{\chi}_a - \overline{\chi}_b)/Vp_\chi = \partial w_\chi/\partial_\chi$, where w_χ = relative fitness of an individual with trait x.

Note that eqn [1b] makes the assumption that Va_χ is independent of S_χ, which is not true if directional selection drives allelic frequencies toward 0 or 1 in the population (see section Evolvability of this article). In such a case, eqn [1b] can be used only to predict short-term response to selection. Additionally, eqn [1b] is often used by considering S_χ as a constant, which may be true when one considers artificial selection only, but which is wrong when trait change alters natural selection acting on that trait – the so-called eco-evolutionary feedback loop (see section Change in the naturally selected adaptive landscape of this article).

However, despite these shortcomings, eqn [1b] remains conceptually very useful in that it clearly shows that evolution of a life-history trait requires that both $Va_\chi > 0$ and $\delta w_\chi/\delta_\chi \neq 0$, and that the speed of evolution is proportional to the values of these two components. Generally, $Va_\chi > 0$ for life-history and morphological traits (Mousseau and Roff, 1987), which are thus highly susceptible to respond to anthropogenic directional selection. Let us now concentrate on reviewing some of the current knowledge on such responses.

Evolutionary Response to Harvesting

Humans have harvested wild plant and animal species since they appeared on earth. Hunting by human populations is thought to have played a role in the late Pleistocene (15 000 years ago) extinctions of large terrestrial mammals in Australia, North America, and South America (Barnosky *et al.*, 2004). The development of agriculture has made humans less dependent upon wild plant and animal resources, but the parallel rise in the human population and progress in harvesting technologies has also tremendously increased the pressure on those populations that remain exploited. The overexploitation problem is mostly documented in fish and mammals, but it may arise in any animal or plant population. Here, we will consider separately the effects of non-phenotypically selective and phenotypically selective harvesting.

Non-Phenotypically Selective Harvesting

Non-phenotypically selective harvesting adds a mortality component to the natural mortality background uniformly in all age or size classes, and thus provides a gain in relative fitness to early-maturing individuals which have a higher

probability to reproduce before being killed (Abrams and Rowe, 1996).

If maturation (and reproductive allocation) conflicts with somatic growth due to physiological or ecological trade-offs, then harvesting also induces a decrease in somatic growth rates. Similarly, trade-offs may occur between reproduction and somatic maintenance, so that we may expect to also observe increased senescence in exploited populations. Accordingly, a number of studies have demonstrated that reproduction incurs a cost in terms of somatic growth (Roff, 1992), predation risk (Magnhagen, 1991), or immune capacity (Zuk and Stoehr, 2002). A cost of reproduction in terms of senescence (Williams, 1957) has received more contrasted support (Reznick *et al.*, 2004).

Phenotypically Selective Harvesting

Harvesting is almost always phenotypically selective. Harvesters often target larger and older individuals due to their higher market or trophy values, and/or due to regulatory rules that impose a minimum size limit to the catch. Compared to non-size-selective harvesting, this biased mortality further strengthens the relative advantage for an early maturation, and also directly selects for slower somatic growth because larger individuals are often faster growers (Biro and Post, 2008). In line with this theoretical prediction, earlier maturation and/or smaller body size in response to harvesting have been documented in a variety of wild, exploited populations.

Size-related trait change in exploited populations are on average 3 times faster than in unexploited populations, and results in 20% smaller traits on average (Darimont *et al.*, 2009). For instance, in the snow lotus *(Saussurea laniceps)*, plant cropping for medicine has induced a decrease in mean plant size from about 30 cm in 1900 to about 20 cm in the 2000s (Law and Salick, 2005). In the bighorn sheep (*Ovis canadensis*), mean body weight of rams has declined from 85 to 65 kg from 1975 to 2005 due to trophy hunting, while mean horn sizes have decreased from about 70 to 50 cm (Coltman *et al.*, 2003). In the pink salmon (*Oncorhynchus gorbuscha*), weight at spawning (age 2) has decreased by up to 34% from the 1950s to the 1990s (McAllister *et al.*, 1992). In the Canadian Altlantic cod, female length at 50% maturation probability dwindled from about 65 cm (and 7 years of age) in the early 1950s to about 40 cm (and 4.5 years of age) in the early 1990s, and remained at this low level up to the early 2000s (Olsen *et al.*, 2004; Swain, 2011). On longer time scales, decrease in mean body size may be even larger. Archeological records of skeletal parts suggest that mean body size of cod in the Gulf of Maine (USA) has decreased from 100 to 30 cm due to overfishing (Jackson *et al.*, 2001).

Harvest-induced evolution is sometimes (maybe abusively) termed 'maladaptive,' because it may drive the population far from its naturally selected adaptive peak (i.e., evolution is maladaptive relative to natural selection acting alone). This 'maladaptive' evolution simply reflects a severe reduction in fitness due to anthropogenic selection. For instance, in Atlantic cod (*Gadus morhua*), earlier maturation at a smaller size in response to fishing is expected to increase the mortality cost of reproduction. A reduction of age at maturity from 6 to 4 years projects into a 25–30% decrease in population growth rate (Hutchings, 2005). This decrease in fitness may be linked to increased reproductive mortality (Hutchings, 2005; Swain, 2011), as well as changes in traits correlated with body size. For instance, selection against a large body size in Atlantic silverside (*Menidia menidia*) depresses fecundity, egg volume, larval size at hatch, larval viability, larval growth rates, food consumption rate, and conversion efficiency (Walsh *et al.*, 2006).

Evolutionary Response to Habitat Loss and Fragmentation

Habitat loss and fragmentation often result from 'modern' agricultural practices, road building or, more dramatically, from urbanization. Habitat loss is a primary cause of species extinction, indicating that the generated selective pressures are so strong that many populations can simply not adapt. Habitat fragmentation, in contrast, may allow species to persist, but tend to change large homogeneous populations into metapopulations, i.e., a population of populations between which individuals may disperse (Levins, 1969; Pulliam, 1988). Here, I consider how anthropogenic habitat fragmentation may affect life histories through selection acting on body size and on dispersal ability.

Size-Dependent Selection

Although many studies have linked a large body size with an increased extinction risk in response to anthropogenic perturbations (Purvis *et al.*, 2000; Cardillo *et al.*, 2005; Van Allen *et al.*, 2012), the link between body size and sensitivity to habitat perturbation is not clear (Henle *et al.*, 2004). This lack of evidence for size-dependent selection might come from conflicting selective pressures.

Large animals have large home ranges (Peters, 1983; Jetz *et al.*, 2004), and are thus more likely to be impacted by the fragmentation and loss of their vital habitat. For instance, carnivores in protected areas primarily die from 'edge effects,' i.e., due to conflicts with humans on reserve borders (Woodroffe and Ginsberg, 1998). In the Amazonian forest, fragmentation-induced edge effects magnify the negative impact of hunting on medium-sized and large vertebrates (Peres, 2001). Additionally, a large body size is associated with small population sizes (Woodward *et al.*, 2005). Hence, in a context of reduced habitat availability, large-bodied species may rapidly reach population sizes at which demographic stochasticity elevates extinction risk. Finally, because habitat perturbation imposes so strong selective pressures, population persistence critically depends on the capacity of the population to adapt (or disperse, see below). However, a large body size requires a long development time (i.e., long generation time), and thus imposes slow life histories and slow rates of adaptive evolution. In parallel with selection against a large body size, habitat perturbation may also select against a *small* body size. A small size is associated with a narrower range of prey sizes, reduced trophic generalism (Woodward *et al.*, 2005), and possibly also with an increased habitat specialization.

Accordingly, this link between a small body size, habitat specialization, and increased sensitivity to habitat loss was found in birds (Owens and Bennett, 2000) and freshwater fish (Olden *et al.*, 2007), but the underlying drivers remain unclear. Therefore, the net overall effect of habitat fragmentation might be to select against both small and large body sizes, ultimately favoring medium-sized individuals and species. More research is needed to test this hypothesis.

Dispersal-Dependent Selection

Dispersal generally brings a selective advantage in heterogeneous environments, where the environment is understood in terms of the ecological niche (Hutchinson, 1957). Hence, anthropogenic selection for increased dispersal propensity occurs when habitat fragmentation increases habitat heterogeneity in space and time. In particular, smaller patch sizes are likely to amplify population fluctuations due to increased demographic stochasticity (from smaller population sizes), elevate the temporal heterogeneity of the environment, and ultimately result in increased selection for dispersal (Parvinen *et al.*, 2004).

In turn, dispersal-dependent selection may induce the evolution of life-history traits correlated with dispersal (Roff and Fairbairn, 2001). For instance, the sand cricket (*Gryllus firmus*) shows a genetically based trade off between flight allocation and reproductive allocation (King *et al.*, 2011), indicating that selection for dispersal will also induce evolution towards reduced reproductive investment. In insects and fish, an increased ability for long-distance dispersal is often positively associated with a large body size, because a larger size increases the energetic efficiency of movement (Roff, 1991). Hence, anthropogenic selection for increased long-distance dispersal may indirectly select for a large body size, and is thus expected to interact with direct size-dependent selection (see previous section).

However, anthropogenic habitat fragmentation may also increase dispersal mortality and select against dispersal traits. Hence, the counteracting effects of landscape fragmentation on the evolution of dispersal and life histories may give rise to complex evolutionary dynamics when realistic ecological complexity is accounted for (Parvinen *et al.*, 2004). This complexity might be responsible for an often reported absence of a link between dispersal-dependent selection and life-history evolution (Ronce and Clobert, 2012).

Evolutionary Response to Climate Warming

Temperature determines the rate of metabolic reactions and is a key driver of individual physiology (Brown *et al.*, 2004). Warmer ambient temperatures have been repeatedly reported to favor smaller body sizes and faster life histories in both endotherms and ectotherms (Angilletta, 2009), a phenomenon dubbed 'Bergmann's Rule' (BR) in endotherms and temperature-size rule (TSR) in ectotherms (Atkinson, 1994).

BR posits that heat loss of an endotherm organism is proportional to its body surface-to-volume ratio. Because body volume increases faster than body surface area with increasing body size, there is a selective advantage to a small body size (higher body surface-to-volume ratio and easy heat loss) in warm areas, and conversely to a large body size in colder climates (lower body surface-to-volume ratio and reduced heat loss).

The thermodynamic argument proposed by Bergmann for endotherms does not hold for ectotherms, and the underlying drivers of the TSR remain far from clear (Angilletta, 2009). Proximate mechanisms so far proposed to explain the TSR include a higher thermal sensitivity of gonad growth rate than body growth rate, resulting in an increased fraction of energy allocated to gonads under warmer temperatures (Van der Have and de Jong, 1996; Zuo *et al.*, 2011), and/or smaller sizes of cells and genome at higher temperature (Partridge *et al.*, 1994; Hessen *et al.*, 2013), and/or limitation of oxygen path length at higher body sizes (Pörtner and Knust, 2007; Forster *et al.*, 2012). Ultimate (adaptive) mechanisms include increased mortality and/or higher population rate of increase at higher temperatures (Sibly and Atkinson, 1994).

However, none of these mechanisms has yet been shown to be universal. Recently, however, there has emerged the idea that different thermal sensitivities of ingestion and maintenance rates may drive a competition-mediated selective advantage for small-bodied individuals under warm conditions (Ohlberger *et al.*, 2011; Reuman *et al.*, 2014; Edeline *et al.*, 2013). To understand the arguments it is necessary to start from the R^* theory of exploitative competition (Tilman, 1982), adapted to account for the size-dependency of resource consumption and metabolic rates (Persson *et al.*, 1998; De Roos *et al.*, 2003).

In this framework, resource-dependent variations in individual body mass dB/dt are given by:

$$\frac{dB}{dt} = Fr(R) - m = aR - m \qquad [2]$$

where dB/dt is also equivalent to individual fitness since mass gain can be invested in reproduction, a = attack or intake rate in a Holling's type I functional response, and m = maintenance metabolic rate. Equilibrium, i.e., null fitness, occurs at $R = R^*$ such that $R^* = m/a$, i.e., where resource density makes aR^* equal to m (**Figure 2**). Just as in Tilman's (1982) theory, the individual having the lowest R^* wins the competition and excludes the others that starve to death (Persson *et al.*, 1998).

Biological rates usually follow power allometric exponents (Peters, 1983; Brown *et al.*, 2004), such that the relationship between R^* and body size can be written:

$$R^* = \frac{m}{a} = \frac{\mu B^{\gamma}}{\alpha B^{\delta}} = \frac{\mu}{\alpha} B^{\gamma-\delta} \qquad [3]$$

where μ, α, γ, and δ are positive constants. Equation [3] shows that whether R^* increases or decreases with an increasing body mass, B depends on the sign of the $\gamma - \delta$ difference. If maintenance metabolic rate increases faster with increasing body mass than intake rate, i.e., if $\gamma > \delta$, then R^* increases with increasing body mass, small individuals dominate large individuals in exploitative competition (Persson *et al.*, 1998; De Roos *et al.*, 2003; Persson and De Roos, 2006), and low resources select for smaller body sizes. Resource-poor environments select for reduced somatic growth rates (i.e., select for smaller body sizes) in a variety of taxa (Arendt, 1997), suggesting that an increase of R^* with body size is common.

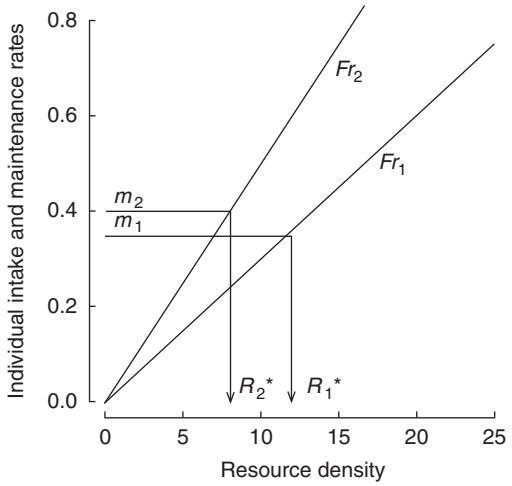

Figure 2 The R^* rule for two individual consumers competing for the same resource R. Resource intake rate is represented by a Holling's type I functional response Fr, while maintenance rate m is resource-independent. Zero growth (equivalent to null fitness in eqn 2) occurs where $R=R^*$. The individual having the lowest R^* (here individual 2) wins the competition. Reproduced from Tilman, D., 1982. Resource Competition and Community Structure. Princeton, NJ: Princeton University Press.

However, R^* *decreases* with body size in waterflies *Daphnia* sp. (Gliwicz, 1990), suggesting that filter-feeding organisms – and maybe generally organisms having a Holling's type I functional response – might constitute an exception. More research is needed to clarify this question.

Biological rates are in fact not just size- but also temperature-dependent (Gillooly *et al.*, 2001). The effects of temperature on intake and maintenance rates included in eqn [3], and thus on and its size dependency, are poorly understood. It was shown in a physiologically-structured model tailored for Eurasian perch Perca fluviatilis that higher temperatures may increase the advantage of small against large individuals in exploitative competition (Ohlberger *et al.*, 2011). Hence, climate warming seems to increase in large individuals relative to small individuals. Reuman *et al.* (2014) and Edeline *et al.* (2013) came to a similar conclusion in unicellular phytoplankton and river fish communities (52 species), respectively. Finally, Vindenes *et al.* (2014) showed in Windermere pike that this temperature-dependent R^* selection translated into accelerated juvenile growth and decreased survival of large individuals, such that the proportion of medium-sized individuals increased in the population. More details about warming-induced selective pressures acting on life-history traits may be found in the chapter An Age- and Length-Structured Life History Model for Pike, a Top Predator in Freshwater Ecosystems (00094) by Yngvild Vindenes. Taken together, these results call for an increased focus on size-dependent exploitative competition in climate-warming research.

Reversibility of Trait Changes and Population Recovery

A natural management response to human-induced ecological problems is to relax the source of perturbation, so that the ecosystem may return to its initial state. However, not all sources of perturbation are easily relaxed. In case of habitat loss and fragmentation, backward re-naturalization of urbanized or agricultural habitats requires will power and investments that often go beyond the capacities of local managers. This problem is even more insurmountable when it comes to reversing the global trend toward increased production of greenhouse gas and the parallel global warming.

Hence, most examples of relaxed anthropogenic forcing on life histories come from harvested systems. In particular, fisheries provide us with reassuring examples of systems that return to their initial state (rebound) after fishery relaxation or closure, but also with the worrying cases of systems that do not recover (stasis). Let us here concentrate on the possible causes of stasis (for rebounds, see Edeline *et al.*, 2007; Edeline *et al.*, 2009; Conover *et al.*, 2009 and Frank *et al.*, 2011). Evolutionary stasis has two possible sources: a loss of evolvability for life-history traits and/or a change in the natural selective pressures acting on life histories.

Evolvability

Equation [1b] assumes for simplicity that additive genetic variance (evolvability) and selection differentials are independent, such that the trait can endlessly evolve. However, in theory evolvability and selection are not independent because intense directional selection should exhaust additive genetic variance and impair reversibility of trait changes, unless genetic variation is constantly renewed (Crow, 2008). This gave rise to concern about a potential loss of evolvability in heavily exploited populations (Hutchings and Fraser, 2008), and might explain why some fish stocks have problems to recover even after the relaxation of exploitation rates (Hutchings and Reynolds, 2004; Frank *et al.*, 2005; Swain, 2011). In these stocks, relaxation of fishing would reestablish the naturally selected phenotypic optimum (i.e., $\delta w_x/\delta_x \neq 0$ in eqn [1b]), but traits could not follow due to lack of genetic variability (i.e., $Va_x \to 0$ in eqn [1b]). Is this a credible hypothesis?

The tremendous phenotypic diversity of formerly wild, now domestic animals (e.g., dogs, pigeons, chicken, …) or plants (roses, cereals, …) suggests that genetic diversity hardly limits the range of possible phenotypes under captive conditions. For instance, maize (*Zea mays*) still responds to strong bidirectional selection on oil and protein concentration in grains since more than 100 generations (Moose *et al.*, 2004). Similarly, white Plymouth Rock chickens continued to respond to bidirectional selection on body weight at 8 weeks of age since 54 generations (Dunnington *et al.*, 2013). At generation 54, males weighted on average 2 kg in the high-selected lines versus 0.173 kg in the low-selected lines, respectively (1.380 vs. 0.129 kg in females). These examples from domestic populations suggest that additive genetic variance often persists, even under severe directional selection (Crow, 2008). But what about wild populations?

A fundamental difference between captive and wild conditions is natural selection. If anthropogenic and natural selection act in opposition (**Figure 1**), then overall selective pressures are no longer directional but stabilizing, and stabilizing selection may erode trait genetic variance even more

rapidly than directional selection. However, in Windermere pike, the overall form of fishing-induced selection was in fact not directional (as presented for simplicity in **Figure 1**) but disruptive (Carlson *et al.*, 2007), which is typical for gillnets (Lagler, 1968). Consequently, scientific gillnet fishing for pike in Windermere, whose intensity was mild (mean exploitation rate was 6.5% per year $\pm$4.7 SD (Langangen *et al.*, 2011)), was associated with an increased variability for length-at-age in the population, and thus presumably increased genetic variance for body size in the pike population (Edeline *et al.*, 2009).

In contrast with scientific fishing, commercial fishing may impose very high exploitation rates (Hutchings (2000) reports reductions of 45–99% in reproductive biomass), in which case medium-sized individuals probably have no chance to reach a large size, even if harvest-induced selection is disruptive. Hence, in many situations anthropogenic selection likely generates strong directional selection acting in opposition with natural selection (**Figure 1**), and resulting in magnified stabilizing selection with a great potential for eroded genetic variance in body size and associated traits. To date, no empirical study has specifically explored the effects of commercial harvest on the genetic variability of fitness-related traits (for neutral genetic markers see for instance Allendorf *et al.*, 2008; Pinsky and Palumbi, 2014), and this obviously represents an important gap in our knowledge.

Change in the Naturally Selected Adaptive Landscape

If a loss of adaptive genetic variability for body size and correlated traits is not involved (i.e., $Va_x > 0$ in eqn [1b]), impediment to the recovery of exploited populations necessarily results from a change in natural selection (i.e., $\delta w_x/\delta_x \to 0$ in eqn [1b]). It has been argued that natural selection toward the phenotypic optimum is likely to be much weaker than harvest-induced selection away from it (Law, 2000; Enberg *et al.*, 2009). However, weak natural selection is incompatible with the fact that harvest-induced evolution incurs severe fitness costs (see above). Instead, as a population phenotype evolves away from the naturally selected optimum, the strength of natural selection toward the optimum should increase. A more likely hypothesis to explain impediment to recovery involves a fishing-induced change in the naturally selected optimum itself.

This idea is well illustrated by a study by Douglas Swain on cod (*Gadus Morhua*) in the southern Gulf of Saint Lawrence (Swain, 2011). This cod stock, like several other Canadian cod stocks, has collapsed during the early 1990s in parallel with a rapid decrease in age and size at maturity, which presumably represented a response to fishing-induced selection (Olsen *et al.*, 2004). However, despite severe reductions in the fishing pressure, age and size at maturity remained low in this stock and apparently did so because of an increase in natural mortality (Swain, 2011). Hence, the fishery seems to have changed the ecological conditions, shifting the naturally selected adaptive landscape of cod such that a faster life history is now the new adaptive optimum. This important result requires that we now examine what ecological changes may cause this shift in the naturally selected adaptive landscape.

Swain (2011) points to potential candidate mechanisms for increased natural mortality in southern Gulf of St. Lawrence cod. First, increased reproductive investment (as initially favoured by a high fishing mortality), together with low food conditions (Shelton *et al.*, 2006), might have caused an increase in reproductive mortality. This hypothesis is supported by the fact that post-fishery increase in natural mortality mainly affected cod older than 5 years, i.e., reproductively active cod (Swain, 2011). Second, cod collapse was paralleled by an increase in the number of gray seals (*Halichoerus grypus*), which are predators for cod. However, seals tend to prey on juvenile cod, while the increased natural mortality effectively affected mainly adult cod (Chouinard *et al.*, 2005), suggesting that predation from seals might not be a major cause of the now high natural mortality in adult cod.

We may propose additional mechanisms for increased mortality in adult cod. Cod and seals might in fact interact through intraguild predation (IGP), a type of interaction in which predators and prey also compete for common food sources (Holt and Polis, 1997). Hence, increased seal numbers might thus participate in depleting food resources for adult cod, and thus favor starvation during energy-demanding reproductive periods. Other species probably interact with cod through IGP. For instance, in the North Sea, herring (*Clupea harengus*) – a prey for cod – inhibits cod recruitment through competition with juvenile cod for zooplankton, but also through predation on cod eggs and larvae (Fauchald, 2010). In the southern Gulf of St. Lawrence cod, increased adult cod mortality possibly operated through exploitative competition from smaller-sized (i.e., lower *R*-starred) fish species that may also be prey for cod. Hence fishing for cod might have pushed an initially cod-abundant system to a new, stable but cod-sparse system in which selection favors smaller-sized cod (Abrams, 2011).

The cod example highlights the potential for eco-evolutionary feedback loops in human-perturbed ecosystems (**Figure 3**). These feedback loops act through density- or frequency-dependent natural selection, and are of crucial importance if one wants to correctly manage natural populations

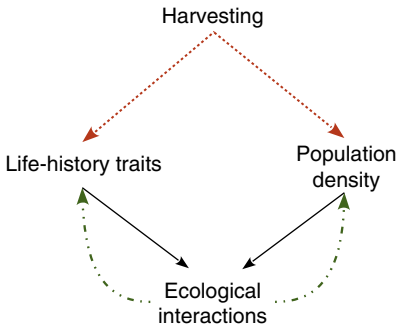

Figure 3 Density-dependent feedback loops arising from harvesting wild populations. Harvest-induced selection (dashed red arrows) favor in parallel faster life histories and reduced population density, which both potentially alter the strength or even nature of intra- and interspecific interactions (solid black arrows). Ultimately, natural selection acting through these ecological interactions (dotted and dashed green arrows) may feedback on life histories and population densities to either oppose (stabilizing eco-evolutionary feedback loop) or reinforce (runaway eco-evolutionary feedback loop) the effects of anthropogenic selection.

(Dieckmann and Ferriere, 2004). A natural selection opposing the effects of anthropogenic selection results in a stabilizing feedback loop, helps in maintaining the system under control, and fosters recovery when the perturbation has ceased. However, in some cases (e.g., cod) natural selection may instead reinforce anthropogenic selection, accelerate change to a new population or ecosystem state, and impede reversal to the initial state. Hence, eco-evolutionary feedback loops stress the need to fully integrate food–web interactions and life-history theory in the next generation conservation plans.

Life History Evolution in Guppies, Experimental Studies of

D Reznick, University of California, Riverside, CA, USA

Glossary

Costs of reproduction Costs refer to any loss of fitness, either in the form of increased risk of mortality or decreased potential for future reproduction, associated with current investment in reproduction. Examples of costs include the risk that parents take when caring for young, the increased susceptibility of females to any mortality risk when pregnant, or any consequences of the resources parents invest in their offspring. For example, the energy and nutrients that a mother invests in producing offspring restrict their availability for other functions, such as growth, storage, or maintenance.

Demographic theory This is a diverse body of theory that models the evolution of populations with age structure, including nonreproducing juveniles and reproducing adults. Each age class can be characterized by its probability of survival to the next age class and the average number of offspring each individual produces. This body of theory models how the life history is predicted to evolve as a function of the risk of mortality of the different age groups. The predicted outcome can vary, for example, if mortality rates are higher in juveniles, adults, or are uniform across all age classes. The predicted outcome can also be modified by whether or not the populations experience density regulation. The sorts of evolution that are predicted are the timing of reproduction (when to begin, how often to reproduce) and the quantity of resources that are devoted to reproduction, as opposed to growth, maintenance, or storage.

Eco–evo dynamics Such dynamics occur when an organism evolves in response to some type of selection and, as a consequence, alters its environment and in turn alters the kind of selection it experiences, causing an ongoing feedback between ecology and evolution. Density regulation represents one possible forum for such dynamics. As an organism increases in abundance, its impact on its natural community may also increase, causing it to experience some change in the selection it experiences. For example, increased abundance of a predator could cause a decline in abundance of some categories of prey which in turn can select for changes in the predator's feeding strategies or perhaps its metabolism and life history if food is less abundant.

Integral projection model (IPM) IPMs produce an estimate of the growth rate of a population in a given set of circumstances. In our case, each of our artificial stream experiments gave us an estimate of the growth rate and risk of mortality for each size class of fish. We were able to preserve and dissect all females at the end of the experiment to get an estimate of size-specific fecundity. These data are then combined to yield an estimate of the population growth rate. Since there were different populations represented and different experimental treatments, the population growth rate represents a point estimate of relative fitness – faster population growth rates mean that a population/treatment group has higher fitness in the context of the experiment.

Mark-release-recapture A powerful tool for studying evolution in action is to mark individuals so that they can be recognized when seen again. If marking is associated with regular formal censuses of the population, then it is possible to estimate mortality rates from the probability of recapture of marked individuals. If such studies are combined with pedigrees, such as by marking juveniles when they are still under the care of their parents or by determining who the parents are from tissue samples collected from each individual when it is marked, then it is possible to determine how many offspring each individual contributes to the next generation. If we also characterize the phenotype of each individual then it is possible to estimate the genetic contribution to the phenotype from phenotypic similarities among relatives. It is also possible to determine whether or not differences among individuals in phenotype contribute to reproductive success.

Purifying selection Selection that 'weeds out' deleterious mutations. This type of selection is also often referred to as 'negative Darwinian selection.' The alternative of 'positive Darwinian selection' refers to natural selection, or selection that results in increased fitness via improved adaptation to the organism's environment. Note that 'environment' refers to the physical environment and biotic interactions, or interactions with other organisms.

Senescence Age-related decline in performance or fitness, with the latter being estimated from the mortality rate and rate of reproduction.

William's generalization of Lack's Principle David Lack postulated that the number of eggs that a bird laid would evolve to be that number that resulted in the maximum number of offspring. This became known as the Lack Optimal clutch size, but practice showed that the most common clutch size tended to be smaller than the optimal clutch size. George Williams postulated that this was because of a trade off between reproductive value, the return on current investment in reproduction, and residual reproductive value, or the expected return from future reproductive investment. Birds, and other organisms, invest less now to save for the future.

The Evolution of Life Histories in Guppies

My associates and I have been studying the evolution of life histories in guppies since 1978. A consequence of persisting for so long is that there has been a maturation of the way we think about the evolution of life histories and the methods we use to study them. I will present key results of this research program in a chronological fashion so that I can simultaneously highlight the main accomplishments of the research program alongside the growth of the discipline.

Life History Evolution in the 1970s

At the outset of my work, the theory of life history evolution was dominated by the concept of r- and K-selection (MacArthur and Wilson, 1967; Pianka, 1970), George Williams' generalization of Lack's principle (Williams, 1966), and evolution in age-structured populations (Charlesworth, 1980; Charlesworth and Leon, 1976; Law, 1979; Michod, 1979). Empirical research had progressed to the point of producing some synthetic overviews of life history variation, such as on the evolution of clutch size or nestling development rate in birds (Cody, 1966; Ricklefs, 1969, 1970), and comparative analyses of a broader array of life history traits in reptiles (Tinkle, 1969; Tinkle *et al.*, 1970; Vitt and Congdon, 1978). The field had some diversity in both theory and empirical research, but was small enough to be covered well in two review articles (Stearns, 1976, 1977).

I chose to study differences in life histories among populations within a species because I wanted to couple life history variation with other features of the environment. Such correlations help establish the causes of life history evolution. I was also most impressed with demographic theory because it explicitly incorporated the details of age-specific survival and reproduction and generated testable predictions. I wanted to add some form of genetic analysis of any interpopulation differences in life history that I discovered. Prior work on diverse organisms often revealed that species or populations had different life history phenotypes but did not give us a measure of the extent to which these differences were attributable to genes or the environment.

Guppies and Trinidad

Guppies are small (1.5–3 cm as adults), have rapid development (as little as 10 weeks between the birth of a female and the birth to her first litter of babies) and are easy to maintain and breed in the laboratory. The diversity of habitats guppies occupy in the Northern Range Mountains of Trinidad was already known to be associated with significant differences among populations in local adaptation (Endler, 1978).

The Northern Range Mountains are a seasonal, tropical rainforest that receive from 3–4 m of rain per year. The slopes have many small streams that flow through steep ravines before emptying into larger streams in the more level lowlands. The streams are punctuated by waterfalls that often serve as barriers to the upstream dispersal of some fish species. Guppies range from the mouths of the largest rivers up into the smallest headwater streams. They co-occur with a diversity of larger fish species in the lower elevation streams; some of these larger fish frequently prey on guppies. Above barrier waterfalls, guppies can often be found in streams where the killifish *Rivulus hartii* is the only other resident fish species. *Rivulus* will occasionally eat guppies, but is more inclined to eat insects. These contrasting communities are found in close proximity to one another, above and below a barrier waterfall on the same stream that excludes the larger predatory fish but not guppies and *Rivulus*.

John Endler established that guppies that lived with predators downstream were less brightly colored than those that lived upstream with *Rivulus* (Endler, 1978). Females prefer to mate with brightly colored males, but brightly colored males also attract the unwanted attention of predators. When predators are absent, females are free to choose to mate with more brightly colored males. When predators are present, brightly colored males suffer higher mortality, causing the average male to be less brightly colored than when predators are absent. Endler then did two remarkable things (Endler, 1980). He found a tributary to the Aripo River that had a dramatic waterfall that stopped all species of fish save *Rivulus*. He transplanted guppies from a high predation locality downstream into this previously guppy-free low predation locality. This new population became more brightly colored than their ancestors after only 2 years. He also built artificial streams in a greenhouse and populated them with either *Rivulus* or the pike cichlid *Crenicichla alta*, one of the guppy predators from downstream communities. He introduced a genetically diverse population of guppies. He found that the guppies kept with *Rivulus* became significantly more brightly colored than those with *Crenicichla*, again within around 2 years.

Comparative Life Histories

Endler's results provide an important clue about how *Rivulus* and *Crenicichla* differ as predators. *Crenicichla*, and other predators that co-occur with *Crenicichla*, must eat adult male guppies much more frequently than do *Rivulus* for them to be able to shape the evolution of male coloration. This pattern suggests that adult guppies have a higher risk of mortality in the downstream fish communities (hereafter referred to as high predation, or HP, localities) than they do in communities where *Rivulus* is the only other fish species present (hereafter referred to as low predation, or LP, localities). The demographic theory of the 1970s predicted that this higher adult mortality risk should select for an earlier age at maturity and a greater investment in reproduction than seen in fish that live in low predation environments (Law, 1979; Michod, 1979; Charlesworth, 1994; Gadgil and Bossert, 1970). I set out to test these predictions.

I quantified guppy life histories first by comparing the phenotypes of wild-caught fish. I preserved guppies from a series of high and low predation localities then performed dissections to characterize the size at maturity, number of offspring, size of offspring, and reproductive allocation (RA) (Reznick and Endler, 1982). RA is the proportion of female body weight that consisted of developing offspring. I then performed laboratory experiments in which I quantified the life histories of the grandchildren of wild-caught fish (Reznick, 1982). Phenotypic

differences in life histories of HP and LP fish that persisted after two generations in a common laboratory environment are likely to have a genetic basis. I was also able to quantify additional aspects of the life history, including age at maturity, frequency of reproduction and the proportion of consumed food that was devoted to reproduction versus growth and maintenance.

The field and laboratory work produced consistent results. Guppies from HP environments were smaller and younger at sexual maturity than their counterparts from LP environments. They also devoted more resources to reproduction. They did so by beginning to reproduce when they were younger, reproducing more frequently and, in most comparisons, by devoting more resources to each litter of offspring (Figure 1). All of these results were as predicted by theory. In addition, the HP guppies produced more offspring in each litter and each baby was smaller, on average, than the babies produced by LP guppies.

This work presented two forms of progress in the study of life history evolution. First, the association between predation and life histories was replicated in different rivers that represent independent instances in which guppies had adapted to life with and without predators, so life history evolution is

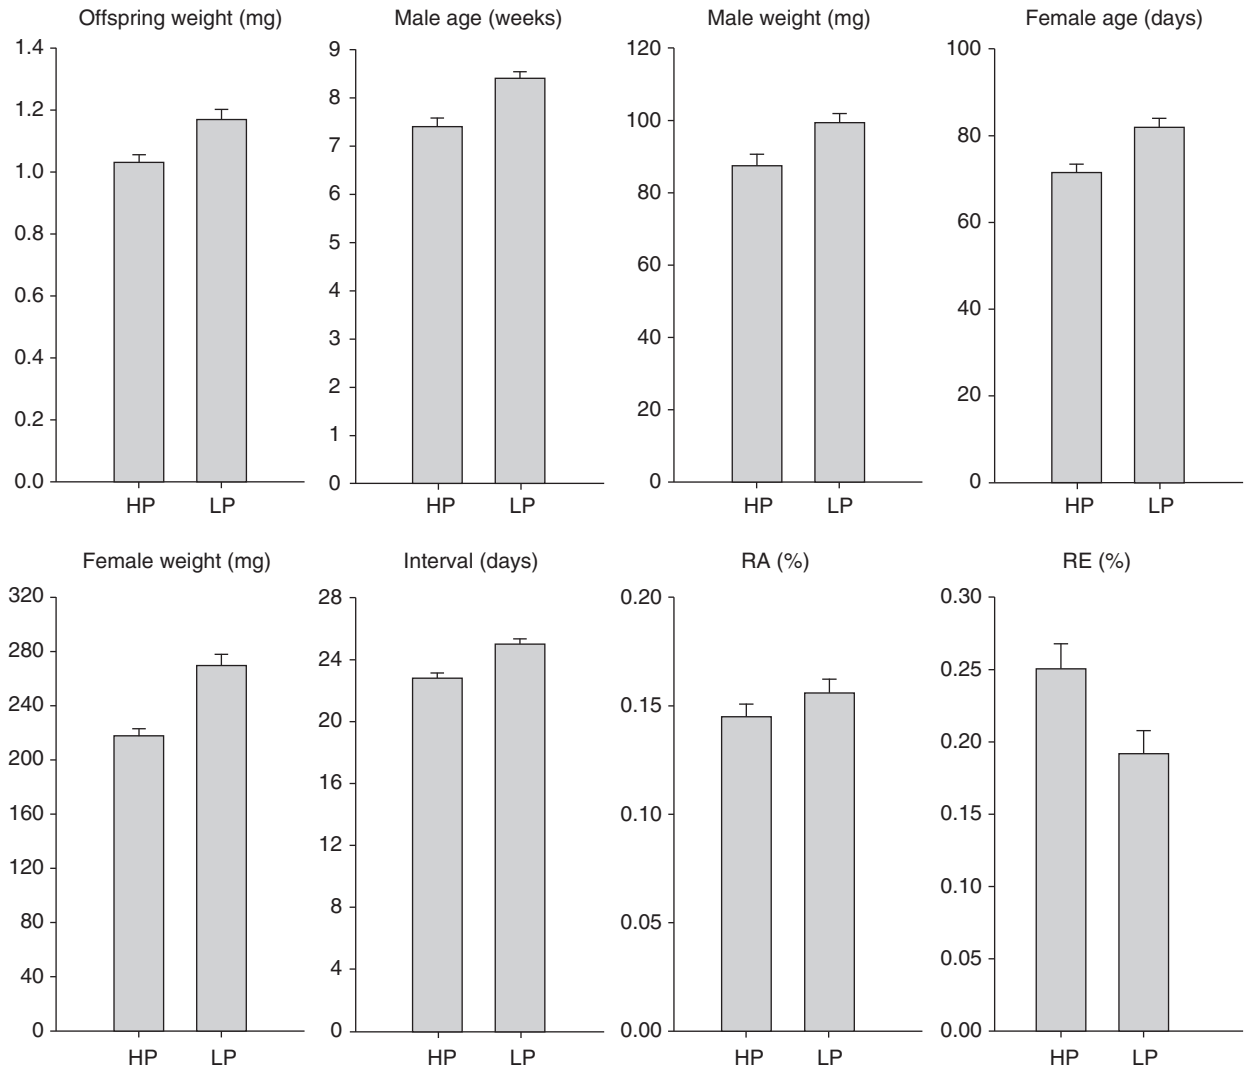

Figure 1 Results of the laboratory assay of life histories of guppies from two high and two low predation environments. Reproduced from Reznick, D.N., 1982. The impact of predation on life history evolution in *Trinidadian guppies*: The genetic components of observed life history differences. Evolution **36**, 1236–1250. Reported here are means and one standard error. 'Offspring weight (mg)'=the mean dry mass of offspring at birth. In wild-caught fish, the difference in mean mass is much larger. 'Male age (weeks)'=mean male age at maturity. 'Male weight (mg)'=mean male wet mass at maturity. 'Female age (days)'=mean female age at first parturition. 'Female weight (mg)'=female mean wet mass at first parturition. 'Interval (days)'=the mean interval between the birth of successive litters. 'RA (%)'=mean reproductive allocation, which is the percent of total female dry mass that consists of developing embryos. RA is higher for HP guppies in all large-scale field comparisons and all other lab studies. 'RE (%)'=reproductive effort, or the cumulative percent consumed resources devoted to the production of offspring in the first three litters. RE is higher in high predation guppies because they began to produce offspring at an earlier age and reproduced more often. Redrawn from Reznick, D.N., 1982. The impact of predation on life history evolution in *Trinidadian guppies*: The genetic components of observed life history differences. Evolution 36, 1236–1250.

repeatable. Second, there is a genetic basis to the differences in life histories among guppies from high and low predation environments.

Experimental Evolution

We followed John Endler's lead of treating streams as if they were giant test tubes. We transplanted guppies from high predation sites below a barrier waterfall into previously guppy-free low predation sites above a waterfall. We also added predators to a section of stream above a fall that excluded predators but not guppies. These two manipulations caused either a decrease or increase in guppy mortality risk, respectively. The two guppy introduction experiments included the one initiated by John Endler in 1976 and a second initiated by me in 1981. In both we observed significant life history evolution in as little as 4 years (Reznick *et al.*, 1990, 1997; Reznick and Bryga, 1987). The life histories of the introduced HP guppies evolved to become more similar to what is typical of LP environments; they were older at maturity, produced fewer, larger babies and invested less in reproduction in comparison to the ancestral HP guppies found below the barrier waterfall (Figure 2). All of these conclusions are derived from the same combination of field and laboratory results as the original comparative studies. Our introduction of predators to what had been a low predation locality caused the resident guppies to evolve smaller sizes and earlier ages at maturity in comparison to guppies found above a barrier waterfall that excluded the predators (Reznick, 1997).

Life History Evolution in the 1990s – Awkward Adolescence

Mortality Rate Estimates

Progress in science can be driven as much by methods as ideas. Theory predicts how organisms would evolve in response to age-specific mortality risk, so one must quantify mortality risk. I had assumed that guppies that lived with predators had higher adult mortality risks, but I did not actually know that this was true. I developed a way to mark individual guppies in the late 1980s and was able to measure comparative mortality risk by the early 1990s. My colleagues and I also discovered that it was easy to apply mark-recapture methods in smaller

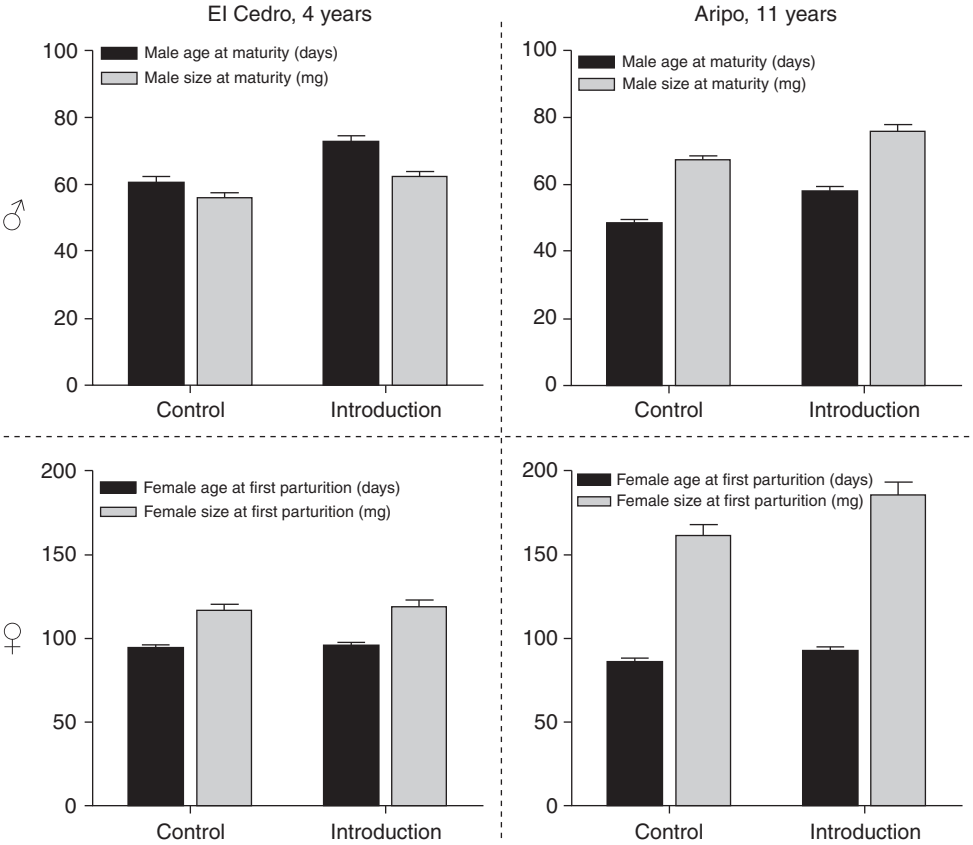

Figure 2 Mean (1 standard error) age and size at maturity in males and females from two experiments in which guppies were transplanted from a high predation site downstream (the control) into a previously guppy-free low predation site upstream (the introduction). Data are derived from a laboratory study of the grandchildren of wild-caught fish. Male age and size at maturity were significantly later/larger in the introduction site only 4 years after the introduction on the El Cedro River and 11 years after the introduction on the Aripo River (we first looked for evolution after 11 years). Females showed no response after 4 years on the El Cedro, but were significantly older and larger at maturity in the introduction site after 11 years in the Aripo. Redrawn from Reznick, D.A., Bryga, H., Endler, J.A., 1990. Experimentally induced life-history evolution in a natural population. Nature 346, 357–359.

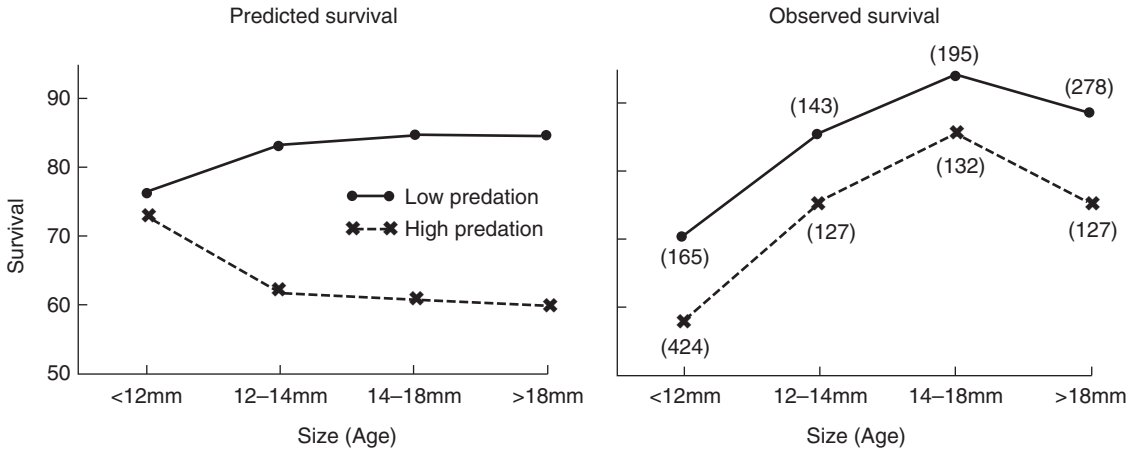

Figure 3 Predicted and observed differences in mortality risk in guppies from high and low predation environments. Data are derived from 14 mark-recapture studies, seven each in high and low predation environments. The observed data represent recapture probability after 12 days. *X*-axis = size class of fish, with <12 and 12–14 mm fish being immature. 14–18 mm fish includes mature males and females that have just matured and are producing their first litters of babies. >18 mm are adult females only. The theory that provided the initial predictions for how guppies should evolve in response to predator-induced mortality also assumed that there would be a proportionately higher risk of mortality in adult fish, hence the nonparallel lines in the curves that predict the relationship between size and survival. Redrawn from Reznick, D.N., Butler, M.J., Helen Rodd, F., Ross, P.,1996. Life history evolution in guppies (*Poecilia reticulata*). 6. Differential mortality as a mechanism for natural selection. Evolution 50, 1651–1660.

streams that had a pool-riffle structure. Such streams are like a string of beads, where each bead is a pool. Each pool is separated from its neighbor by a steeper, shallower portion of stream, a riffle, where the water flowed more rapidly to the next pool. We found that guppies cluster in pools and are disinclined to migrate among pools.

Two things had to be true about the comparative mortality risks of guppies from high and low predation environments for there to be a good match with demographic theory. First, HP guppies must have higher mortality risks. Second, these higher mortality rates must fall more heavily on the adult age classes (Figure 3). Guppies from HP localities clearly experienced higher risks of mortality, but the difference is not magnified in adults. We instead found that there was an approximately equal increase in risk across all age/size classes (Reznick *et al.*, 1996). This may seem like a small difference, but it creates a mismatch between theory and reality. The theory I had been using had shown that an increase in mortality risk spread equally across all age classes would result in no evolution, yet I had already seen guppies evolve in the context of introduction experiments and had comparative data that suggested evolution.

This result became an invitation to think more carefully about how the theory was constructed and about all of the alternative models that had been proposed. I had derived predictions from a model that only included the effects of predators on guppy mortality rates, but otherwise allowed the guppy populations to grow without limit. An alternative model that is perhaps more realistic is to assume that guppies are also resource limited so that, even in the absence of predators, their populations will be regulated because of limited resource availability (Figure 4). There are actually diverse models that include such added ecological complexity. With such added complexity it becomes possible for the sort of mortality differences we found between high and low predation environments to cause the sort of life history evolution we had observed. Our result thus suggested that such added ecological complexity might be playing an important role in shaping guppy life history evolution.

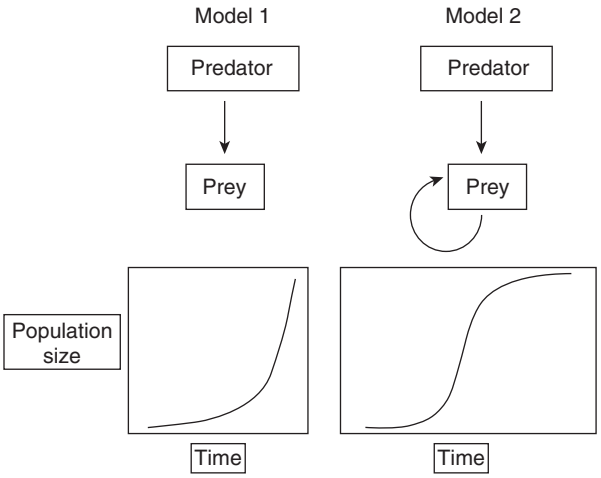

Figure 4 Two schematic models of life history evolution: Model 1 = density independent (exponential population growth in the lower panel). Here, all that is modeled is the increased risk of mortality caused by predators. Model 2 = density dependent (logistic population growth in lower panel). Here, the prey population is regulated by both predation and by its own density.

Comparative Ecology

We quantified features of the ecology of HP and LP environments at the same time that we estimated mortality risk. We wanted to know if there were any predictable ecological differences in HP and LP environments.

LP environments have higher population densities of guppies, lower light level and lower primary productivity. Individual guppies have slower growth rates. The lower growth rates of LP guppies could be a simple consequence of lower light levels, but they could also be an indirect consequence of predation. When predators are present, they trim guppy populations and the survivors have more food resources. Conversely, when they are absent, guppy populations expand and per capita resource availability declines (Reznick *et al.*, 2001).

Evolution of Senescence

A corollary of the sort of life history theory we were testing pertains to the evolution of the aging process. Guppies adapted to life with predators are predicted to age more quickly and hence have shorter life spans than those from low predation environments, for two reasons. One is a by-product of costs of reproduction. HP guppies begin to reproduce at an earlier age and devote more resources to reproduction. It is predicted that there is a price to be paid for this because it means having less to devote to growth and maintenance. The second reason is a by-product of 'purifying' or 'negative Darwinian' selection. Mutations of diverse sorts are a predictable occurrence of cell division. Most are deleterious. These are either removed or kept rare by purifying selection. Some of these mutations are age-specific in when their damaging effects occur. If their deleterious effects are felt early in life, they are more likely to be eliminated by selection because they will have a large impact on an individual's ability to contribute offspring to the next generation. If the mutations instead affect only older individuals, their impact on fitness will be smaller and they will be subject to weaker selection. Because guppies from HP environments are much less likely to live to advanced ages, they are more likely to accumulate deleterious mutations that only affect older individuals. It is the accumulation of these late-acting mutations that is proposed to cause accelerated aging.

We tested these predictions by quantifying lifetime reproductive success and lifespan in a laboratory experiment on the grandchildren of wild-caught guppies (Reznick *et al.*, 2004). When guppies are reared in the laboratory they are free of extrinsic sources of mortality, like predation. We can then ask if there are differences in intrinsic mortality rates. We performed this experiment on guppies from two rivers, each represented by fish derived from a high and low predation site. The guppies in these rivers (the Yarra and the Oropuche) are genetically distinct and represent independent instances in which guppies have adapted to life with and without predators. Our results were the opposite of predictions. HP guppies had lower probabilities of mortality throughout their lives and longer life spans in spite of their investing more in reproduction early in life. Furthermore, they continued to produce offspring at a higher rate throughout their lives and were substantially older when they ceased reproduction.

These results raise two issues. First, was the underlying theory appropriate? Our estimates of mortality rates provided indirect evidence that ecological interactions were playing an important role in shaping the evolution of the early life history. There has been the parallel development of theory for the evolution of senescence that also argues that such ecological interactions (e.g., density regulation) can play a role in shaping the evolution of senescence. In some cases, this added complexity could cause the sorts of results we had observed. Second, if these data alone define the relative fitness of HP and LP guppies in nature, then they tell us that HP guppies are unconditionally superior to LP guppies and that the LP life history should never evolve. But the LP phenotype does evolve and does so repeatedly which tells us that it is likely to be adaptive in some circumstances. The key is figuring out what it is about the natural HP and LP environments that could cause the LP phenotype to have superior fitness. If this second explanation applies, then it says that the apparent superiority of HP guppies is only realized in some environments.

Summary

The results of our mortality rate estimations suggest that resource limitation and density regulation are likely to play a critical role in shaping the way guppies adapt to life without predators. The results of the comparative study of senescence might also be explained by density and resource limitation. They at least suggest that ecological context should affect the relative fitness of HP and LP guppies. The comparative ecology study suggests that the indirect effects of predators may also play a role in shaping guppy evolution. When predators are present, guppy population densities are low and food is more abundant. When they are absent guppy population densities increase and food resources are limiting.

Life History Evolution in the Twenty-First Century

The way we study guppy life histories has been refined by the advent of a different theoretical framework, new methods, and new statistical tools. The new theoretical framework is eco–evo dynamics, or the idea that ecology and evolution are contemporary processes that feedback on one another in real time. Eco–evo dynamics emerged as a distinct facet of evolutionary ecology in the 1960s but has now gained prominence (Pimentel, 1961, 1968; Yoshida *et al.*, 2003). The connection between this concept and guppies lies in the implied importance of density regulation and indirect effects of predators. Both processes suggest that the high density of guppies in LP environments plays a role in shaping the evolution of the LP phenotype. If so, then this means that the way guppies are evolving is determined at least in part by how a high density of guppies reshapes their ecosystem. We are characterizing this aspect of guppy life history evolution by integrating studies of the feedback between guppies and their ecosystem into our life history work.

We also have new methods for studying guppy evolution. We can now individually mark and track thousands of guppies in experimental populations. We can also genotype all of the marked fish. When we mark them, we save two or three scales from each individual and use them as a source of DNA.

We have initiated four replicate introduction experiments in which guppies from a single HP population were introduced into four small, guppy-free headwater streams. Each

founder was marked, photographed, and scales were saved for DNA. We exhaustively census each population once per month, mark all new recruits and collect scales from them. At the same time, we are assessing how components of the ecosystem are changing in response to guppy occupancy. We have also created replicate artificial streams in which we can conduct short-term, multi-factor experiments to quantify how guppies affect their environment and how the fitness of HP and LP guppies depends upon the environment.

Our new methods are matched by new statistical approaches for quantifying evolution in action. We can now reconstruct the pedigrees of our evolving populations based on the genetic fingerprints of the founders and all of the new recruits.

This enables us to study evolution in the traditional way, as a change in the average attributes of a population over time, but also as variation in individual reproductive success, which is the root of changes in population means. We can quantify how attributes of individuals contribute to this variation. We have deployed the newly developed integral projection models to estimate relative fitness of HP and LP guppies in our experimental streams to gain a better understanding of the factors that have shaped the evolution of these alternative phenotypes.

Here we offer some examples of recent progress that illustrate how we have combined the new theoretical framework, methods, and statistics to address some of the problems suggested by the results of the '1990s.'

Density Regulation

We have now proven that guppies are density regulated in LP environments and that LP guppies have adapted to living at high population densities (Reznick *et al.*, 2012). We performed field experiments in natural LP streams that had a pool-riffle structure. We either increased or decreased density in natural pools while leaving other pools unmanipulated to serve as controls. Increased density causes a decline in population growth rate and reduced density causes an increase in population growth rate relative to the controls. This combination of responses tells us that resources are limiting at ambient population densities.

We then performed experiments in our artificial streams in which we stocked streams with either HP or LP guppies at either high or low population densities (**Figure 5**; Bassar *et al.*, 2013). HP guppies had higher population growth rates and hence higher fitness than LP guppies (as estimated with the application of IPMs) at low population densities. HP and LP guppies had equal fitness at high population densities, suggesting that adaptation to density at least partially explains how the LP phenotype has evolved. However, this result also says that adaptation to density alone is not a complete explanation for the evolution of the LP phenotype. LP guppies must have higher fitness than HP guppies for the LP phenotype to evolve.

Guppy–*Rivulus* Interactions and the Demise of the Superguppy

In a separate series of experiments in the artificial streams, we reared HP and LP guppies in the presence of *Rivulus*. Since guppies and *Rivulus* live together at high densities in LP streams, we reasoned that coadaptation between guppies and *Rivulus* could also play a role in shaping the evolution of the LP phenotype. LP guppies have higher fitness than HP guppies when both are kept with *Rivulus* (**Figure 6**). Furthermore, the fitness advantage of LP guppies is even greater when they are kept with *Rivulus* derived from a site where they co-occur with guppies than if they are derived from a site where *Rivulus* is the only fish species present. This result suggests that there has been some form of coadaptation between guppies and *Rivulus*. While this result resolves the dilemma posed by our

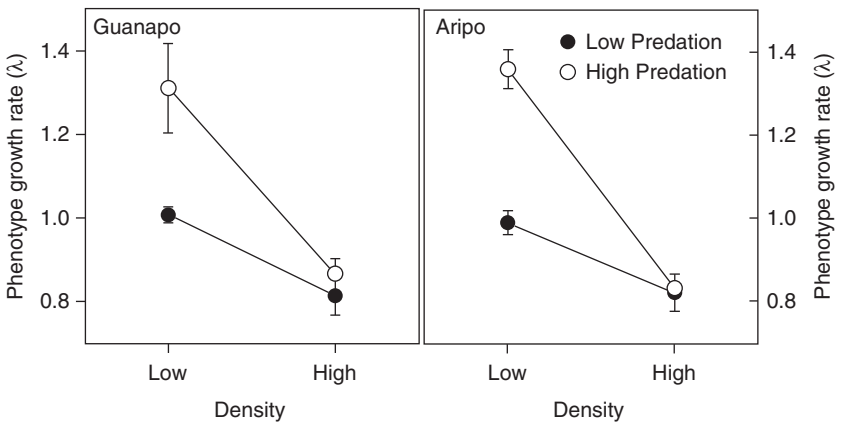

Figure 5 Replicate experiments in artificial streams that document the potential role of density-dependent evolution in shaping guppy life histories. This experiment was done twice. We compared the response of guppies from high and low predation environments, first with fish derived from such sites in the Guanapo River, then with fish derived from such localities in the Aripo River. The high and low density treatments were parameterized from our comparative studies of natural populations in low and high predation communities, respectively. *Y*-axis (phenotypic growth rate) is the estimated population growth rate of the guppies in each of the four treatment groups derived from an integral projection model. These models combine the survival, growth and reproduction data from each treatment group into a life-table estimate of population growth rate. Redrawn from Bassar, R.D., López-Sepulcre, A., Reznick, D.N. Travis, J., 2013. Experimental evidence for density-dependent regulation and selection on Trinidadian guppy life histories. American Naturalist 181(1), 25–38.

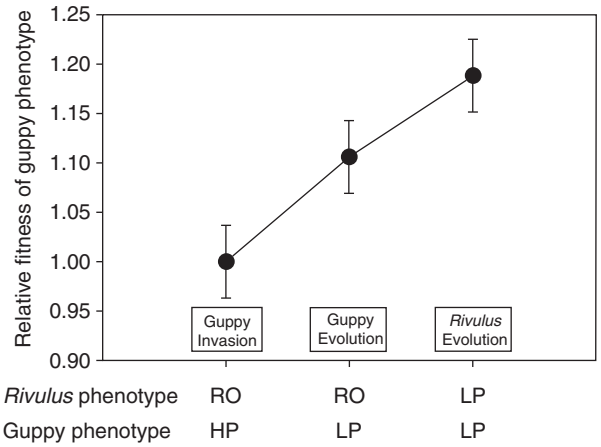

Figure 6 Estimated population growth rate of guppies when interacting with *Rivulus* in experiments conducted in artificial streams. *Y*-axis = estimated population growth rate in each treatment group, derived from an integral projection model. 'Guppy Invasion' = a recreation of the invasion of a previously guppy-free stream, with *Rivulus* only (RO), by guppies from a high predation site below the barrier. 'Guppy Evolution' = a combination of locally adapted, low predation guppies with *Rivulus* from a natural RO site. '*Rivulus* evolution' = pairing of guppies from a LP locality with *Rivulus* from an LP locality, or *Rivulus* that have coadapted to life with guppies.

senescence results, which suggested that HP guppies are unconditionally superior to LP guppies, it also begs a question. Why do LP guppies have higher fitness than HP guppies in these headwater streams? We are now addressing this question. We know that one big factor is that LP guppies have higher growth rates than HP guppies when kept with *Rivulus*. Faster growth affects age at maturity and how many babies they produce. It can also be a factor of traits other than the life history, like foraging behavior or foraging efficiency.

Experimental Evolution II

Our new series of four introduction experiments is yielding a picture of the dynamics of guppy evolution and the associated dynamics of ecosystem change. We have seen an impact of the introduced guppies on the resident *Rivulus* populations in all four streams. Up to this point, we had thought of guppies as the victims who evolve in response to predation. Now we know that they are also the aggressors because adult guppies prey on newborn *Rivulus* and compete with adolescent *Rivulus*. When guppies invade, the abundance of *Rivulus* declines and their size distributions shift to larger sizes because guppies are choking off the recruitment of young *Rivulus*. Guppies also sometimes cause a reduction in the abundance of invertebrates. In artificial streams, guppies clearly reduce the abundance of algae, but that signal is less apparent in the natural streams. We have also begun to apply our pedigrees to the estimation of individual reproductive success and the evolution of male size at maturity and male coloration. The pieces are in place to study the feedback between ecology and evolution.

Our research began with the narrow focus of life history evolution. This approach was practical but it also made sense because the different components of the life history (age at maturity, age-specific allocation of resources to reproduction) could represent an integrated package of attributes that could be treated as an independent feature of the phenotype. One consequence of our new perspective is that the life history ceases to be the sole focus of research. The life history is instead absorbed into the background of other features of the organism that are evolving. We knew at the outset that the HP and LP phenotypes differed in male coloration, courtship behavior, and schooling behavior. Now we know that they differ in shape, jaw morphology, diet, and other aspects of behavior. Studying the life history in isolation of other traits and thinking about how the different components of the life history traded off with one another was a logical place to start. What we know now suggests that we need to think more broadly and to integrate life history evolution with these other components of the phenotype.

Life-History Evolution in Island Populations of Birds

R Covas, CIBIO-InBio, University of Porto, Campus Agrário de Vairão, Vairão, Portugal

Islands are unique ecosystems sharing a distinctive set of characteristics that make them particularly interesting to study adaptation by organisms. The isolation and reduced area of islands result in simplified ecosystems with an impoverished fauna – including reduced number of predators and parasites. In addition, being surrounded by ocean, islands benefit from a generally milder climate, with less extreme fluctuations than similar mainland areas at the same latitude (Weigelt *et al.*, 2013). All these biotic and abiotic features have predictable effects on several characteristics of organisms and are expected to lead to convergent patterns of adaptation, the oft-called 'insularity syndrome' (Blondel, 2000; Clegg and Owens, 2002; Covas, 2012; Grant, 1998; Losos and Ricklefs, 2009; McNab, 1994; Whittaker and Fernández-Palacios, 2007).

The effects of the island environment on life histories provide an excellent illustration of the factors affecting life-history evolution. Island populations have long been thought to have reduced fecundity, increased survival, and increased investment in young. These ideas on island evolution were triggered by observations of extreme island forms, and birds played a prominent role in building the stereotype of what island forms tend to become. Well-known examples of morphological evolution such as the gigantism and loss of flight in species like the dodo *Raphus cucullatus* or moas (Dinornithiformes) and reproductive adaptations such as the extremely large eggs and slow development of kiwis (*Apteryx* spp) promoted a general view of a slow pace of life on islands. In brief, the absence or low numbers of predators on islands and a generally benign climate would promote loss, or reduction, of flight capacity and dispersal and a generally slower rhythm of life, with increased longevity, reduced fecundity, and slower development, but greater investment per young (reviewed in Whittaker and Fernández-Palacios, 2007; Blondel, 2000). Some of these ideas gained theoretical support through the works of Cody (1966) and MacArthur and Wilson (1967) and the model became a popular paradigm. However, it lacked formal testing until recently (Blondel, 2000; Clegg and Owens, 2002; Covas, 2012). Whether there is or not a set of convergent adaptations on island, and hence whether there is or not an 'island syndrome' can only be established if it is shown that there is repeated convergent evolution by distinct island animals living on different islands. Additionally, several factors need to be taken into account when attempting to make generalizations about adaptations on islands. In particular, closely related species share a common evolutionary past that will constrain their evolutionary trajectories after colonizing an island. Furthermore, life-history characteristics are known to be influenced by several ecological factors, in addition to those that might or not change on islands. A particularly prominent one is the positive effect of latitude on body size (Olson *et al.*, 2009) and fecundity, while adult survival decreases with increasing latitude (Lack, 1968). Establishing whether there are patterns of life-history evolution specific to islands therefore requires carefully controlling for latitude. In recent years, several studies have tackled these tasks and a more precise picture of patterns of evolution in island birds (and other groups) is now starting to emerge. These studies confirm several previous expectations which concur with life-history theory, but also reveal some unexpected trends that offer interesting new insights.

Body Size and Shape

Efforts to establish patterns and processes of morphological evolution in island animals are hindered by the number of extinctions among island forms (Steadman, 2006). Islands experience extremely high levels of extinction compared to mainland areas (e.g., ca. 90% of bird species known to have become extinct in historical times were island species; Johnson and Stattersfield, 1990). Among the most severely affected are large flightless species which forage and breed on the ground and hence are interesting targets for humans and easy prey for human-introduced predators (rats, cats, dogs, etc.). These species may also suffer disproportionately from the rapid habitat changes that follow island colonization by humans. Recent analyses have therefore focused mostly on extant faunas (but see Boyer and Jetz, 2010; Steadman, 2006). These analyses have nonetheless confirmed evolutionary trends on islands which set them apart from their mainland counterparts.

Morphological evolution of island organisms is thought to follow the 'island rule' according to which small-bodied organisms evolve toward a larger size and large bodied organisms evolve toward a smaller size (Lomolino, 1985, 2005; Price and Phillimore, 2007; Van Valen, 1973). In birds, the most well-known examples are the large flightless birds from several Pacific and Indian Ocean islands, most of which are now extinct (e.g., Boyer and Jetz, 2010; Steadman, 2006) and the insular ducks, which are usually smaller than mainland ducks (Lack, 1970). Whether or not the island rule is valid has been strongly debated, given the several exceptions that have been found for different taxonomic groups (e.g., Meiri *et al.*, 2008; Meiri *et al.*, 2006). In addition, an important difficulty is to determine that the giants or dwarfs that appear on islands are the results of evolution taking place in response to insularity and not simply a bias in colonization success (e.g., Raia, 2009). However, it has been argued that there is some general support in favor of the island rule (Price and Phillimore, 2007). Specifically for birds, support for the island rule has been found for extant faunas from islands around the world (Clegg and Owens, 2002). This pattern would be most likely stronger if extinct large flightless forms were included in the analyses, as illustrated by a recent analysis of body size trends in relation to island area in Pacific birds (Boyer and Jetz, 2010). In this study, which included both extant and extinct faunas, support for the island rule was stronger when extinct and flightless species were included (**Figure 1**).

 doi:10.1016/B978-0-12-800049-6.00099-8

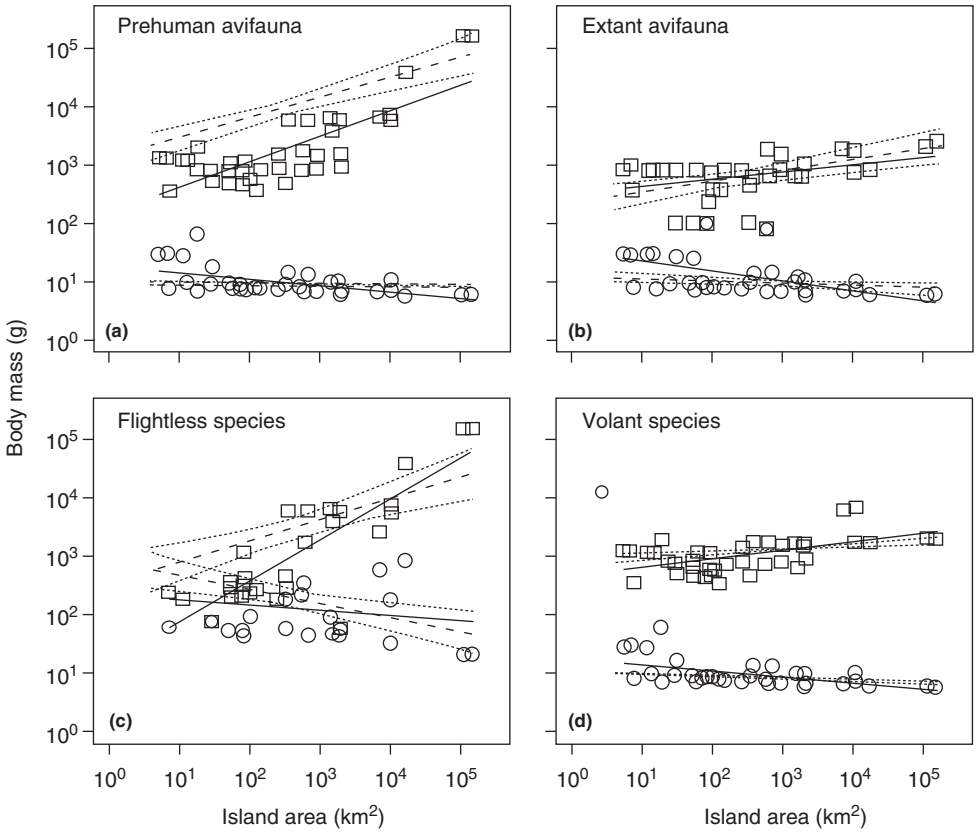

Figure 1 Boyer and Jetz (2010) investigated the relationship between island area and body size for non-predatory birds in 48 Pacific islands. The figure illustrates the scaling of body size extremes with island area for non-predatory birds. The squares indicate maximum and the circles minimum body mass values. Solid lines are the result of a linear regression and dashed lines indicate the predictions of a null model. The four graphs illustrate these relationships separately for: (a) the prehuman avifauna; (b) extant birds; (c) flightless; and (d) volant species on each island.

However, it remains unclear which factors may underlie these changes in body size on islands. Lomolino (2005) suggested that under a release from predators and competitors, island forms evolve toward a size that optimizes their use of the available food resources, i.e., as opposed to a body size that is affected by a combination of energetic, predator avoidance, and inter-specific competition constraints. However, both dwarfism and gigantism are likely to be influenced by a combination of other factors associated with island life and no consensus has emerged on which factors play a predominant role (see also reviews in Meiri and Raia, 2009; Raia, 2009; Meiri, 2009).

First, as a general pattern, large animals may become smaller on islands since the limited island size may not be able to provide the large amount of food required for large species. This mechanism may explain several striking cases, such as the dwarf extinct faunas of elephants and hippopotamuses that are known from several Mediterranean and Indonesian islands (e.g., Lomolino, 2005; but see Meiri and Raia, 2009). In addition, however, several other mechanisms may favor dwarfism on islands, although these mechanisms are likely to arise from a combination of specific characteristics of the island and former mainland habitat experienced. For example, a decrease in size may be beneficial if it allows specialization for a niche which was not available on the mainland (see also review in Whittaker and Fernández-Palacios, 2007). A remarkable example is the Inaccessible rail *Atlantisia rogersi*, the smallest flightless bird in the world (**Figure 2**), which is confined to the tiny and remote Inaccessible island in the south Atlantic where it appears to occupy the ecological niche of a mouse (Del Hoyo *et al.*, 1996). In addition, a release from predators may also favor a smaller size if, in the ancestral mainland form, a larger body allowed escaping from local predators, an advantage that becomes unimportant in the island environment (e.g., Heaney, 1978). Analyses in birds suggested additionally that thermal ecology may play a role as evolution toward a smaller size should facilitate heat dissipation at lower latitudes (Clegg and Owens, 2002). However, this mechanism may be equally important in mainland areas (Olson *et al.*, 2009). Climatic variables have been repeatedly associated with changes in size in island birds and mammals (Boyer and Jetz, 2010; Clegg and Owens, 2002; McClain *et al.*, 2013), but given the correlation between variables such as precipitation, temperature, and productivity it remains unclear how they influence body size evolution and further study is currently needed.

Second, the benefits of evolving toward a larger body size after island colonization are also presumably linked to energy use optimization under a release from predation pressure and inter-specific competition, but acting in the opposite direction for smaller species. Specifically, given the reduced number of species on islands, some niches will be vacant, and island

Figure 2 The Inaccessible rail *Atlantisia rogersi* – here showing its stubby wings while sunning – is the smallest flightless bird in the world. It is confined to the tiny and remote Inaccessible Island (Tristan da Cunha archipelago) in the south Atlantic, where it appears to occupy the ecological niche of a mouse (Photo Peter G Ryan).

Figure 3 Two sunbirds (Nectarinidae) endemic to the island of São Tomé (São Tomé and Principe, Gulf of Guinea, West Africa). The São Tomé sunbird *Dreptes thomensis* (right) is the largest of all sunbirds. It lives in primary and secondary forest and in addition to nectar it feeds also on fruit pulp and on arthropods that it obtains from leaves and by probing the bark of trees in a way similar to the typical feeding habits of woodhoepoes or scimitarbills (Phoeniculidae), which it resembles in size. The co-occurring Newton's sunbird *Anabathmis newtonii* is one of the smallest species in the family.

species may take advantage of these situation and use an enlarged niche, thereby gaining access to more food (Heaney, 1978; Lomolino, 1985). However, this idea has been criticized since there is no solid association between body size and niche breadth (Palkovacs, 2003). In addition, the tendency to increase body size is likely to be favored by the crowded island environments, with higher population densities than what is usually found on the mainland (Lomolino, 2005). This peculiarity of islands is the result of ecological niche widening (in the absence of several species that are present on the mainland) and higher survival (a process known as 'density compensation'; see MacArthur *et al.*, 1972). Under these crowded conditions, intra-specific competition is stronger and there is selection to increase body sizes, as this increases competitive capacity; this was demonstrated by an impressive experiment on Caribbean *Anolis* lizards where island and predator densities were manipulated (Calsbeek and Cox, 2010). The same mechanism has been suggested to be particularly important to explain and increase in size in island birds. Clegg and Owens (2002) found a relationship between increased body size of small birds and intra-specific competition as indicated by territoriality or group foraging. Finally, as with the tendency for dwarfism discussed above, gigantism may be favored in specific situation where a larger size on the new island habitat allows to exploit a new niche. For example, the São Tomé sunbird *Dreptes thomensis* (**Figure 3**) is the largest of all sunbirds (Nectarinidae). It lives in the forests of São Tomé island (Gulf of Guinea, West Africa) feeding partly on nectar, as other members of its family, but also on fruit pulp and on arthropods that it obtains from leaves and by probing the bark of trees in a way similar to the typical feeding habits of woodhoepoes or scimitarbills (Phoeniculidae) (Christy and Clarke, 1998). Finally, and specifically for birds, gigantism may be associated with reduced tendency for dispersal on islands and associated loss of flight (e.g., Steadman, 2006; Boyer and Jetz, 2010). Given that flight is highly costly, reduced need of dispersal and escape from predators should promote the evolution of flightlessness and gigantism could appear as a side effect, since there would no longer be a strong constraint on maximum body size (Raia, 2009).

In addition to the island rule and loss of flight in birds, other patterns of morphological change have been observed, most prominently a tendency for increase in beak and tarsus size (Grant, 1965). Changes in beak size are interesting as they may reflect switches in ecology, and particularly a tendency for species to become ecological generalists on islands (Grant, 1965). However, this trend may be only valid for passerines; subsequent analyses based on a larger number of passerine and non-passerine birds found that instead of a general increase, bill length either followed the island rule (i.e., longer bills decreased an shorter bills increased on islands; (Clegg and Owens, 2002) or did not follow any specific trends. On the other hand, the trend for longer tarsus on islands seems to be a robust one (Grant, 1965) and likely reflects an adaptation to increased time spent walking, which is presumably made possible under decreased predator pressure on islands.

Reproductive Behavior and Life-History

Reproductive strategies in island animals are believed to follow a shift toward 'slower' (or 'K-selected') life histories (Cody, 1966; Blondel, 2000; Grant, 1998; MacArthur and Wilson, 1967). The specific characteristics of islands, with milder climates and less predators and parasites are expected to lead to improved adult survival on islands which, according to life-history theory, should favor reduced fecundity as part of a strategy to allocate more resources into self-maintenance, since maximizing survival is key to maximizing lifetime reproductive success (Barbraud and Weimerskirch, 2001; Charlesworth, 1994; Clutton-Brock, 1988; Goodman, 1974).

Furthermore, since island populations usually live at higher densities than their mainland counterparts (Blondel, 2000; Crowell, 1962; MacArthur and Wilson, 1967; MacArthur *et al.*, 1972), greater competition for food (at the intra-specific level) is expected, which may further favor reduced fecundity (Ashmole, 1963; McNab, 1994; Ricklefs, 1980). Broad-scale analyses in birds based on a large number of islands around the world have now confirmed this tendency for reduced fecundity on islands (Jetz *et al.*, 2008; Covas, 2012). A parallel analysis in lizards has produced a similar result (Novosolov *et al.*, 2013).

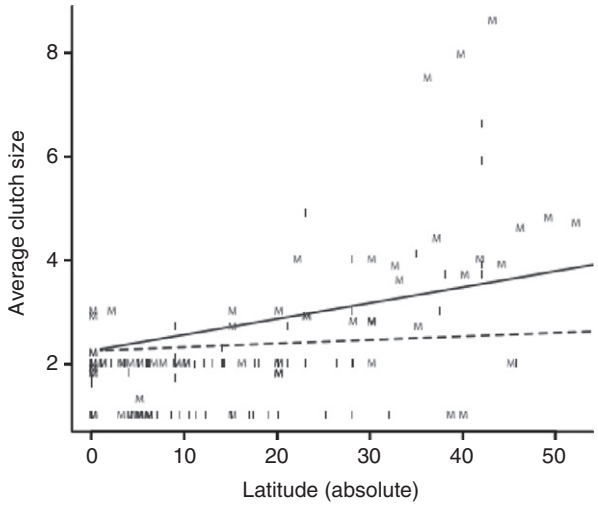

Figure 4 Island birds generally have lower fecundity than their mainland counterparts, but this effect of insularity is strongly influenced by latitude. In a study that compared clutch sizes of 148 island endemics with their close mainland relatives, clutch size increased with latitude at a pace that was ca. 4.5 times faster on the mainland (solid line) than on the island (dashed line). The letters 'M' and 'I' correspond to the data points from the mainland and island species (Covas, 2012).

Fecundity in birds is additionally influenced by an interesting interaction of insularity and latitude. Clutch size in birds is known to be strongly influenced by latitude, being generally lower in the tropics and increasing toward the high-latitude temperate regions (Lack, 1948). This effect of latitude strongly influences the response to insularity, making the differences in clutch size between the island and mainland species much stronger at higher latitudes (Covas, 2012; **Figure 4**). This mechanism probably has a stronger effect on temperate islands because climatic fluctuation is more markedly reduced when compared to the mainland (MacArthur and Wilson, 1967; Whittaker and Fernández-Palacios, 2007). In the tropical mainland regions, climatic conditions are already fairly benign and resource levels less fluctuating, which promotes survival, and hence island-mainland differences are less pronounced. This result thereby further supports that improved adult survival is one of the main factors driving life-history change and reduced fecundity on islands (Ashmole, 1963; Cody, 1966; MacArthur and Wilson, 1967; Blondel, 2000; Jetz *et al.*, 2008). Nonetheless, increased intra-specific competition on islands should favor reduced clutch size regardless of latitude (Ashmole, 1963; MacArthur *et al.*, 1972; Blondel *et al.*, 1988; Blondel, 2000; McNab and Ellis, 2006). However, mainland tropical species already have small clutches (often two and, occasionally, even a single egg, as is the case of some sunbirds; Del Hoyo *et al.*, 2008). Hence, it may be difficult for selection to reduce clutch size further after island colonization by these species.

While fecundity generally decreases on islands, investment per young increases. Specifically, and echoing the example of the kiwi, island birds usually lay larger eggs (**Figure 5**) and have extended developmental periods (Covas, 2012). Under

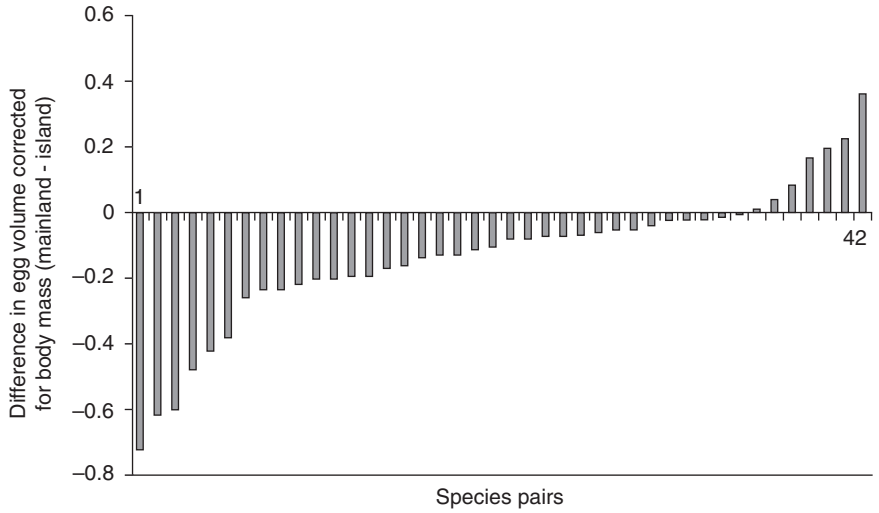

Figure 5 Islands species generally produce larger eggs, in relation to their body size, than do their close mainland relatives. This figure illustrates the difference between the mainland and island egg size for 84 species (an island endemic and its close mainland relative); negative values indicate larger egg volume on the island. The figure accounts for egg size by using the residuals of a regression of egg volume against body mass (Covas, 2012).

lower pressure from predators, juvenile survival should be higher and hence it should be advantageous for parents to increase their investment per young in order to improve offspring quality and competitiveness (Cody, 1966; MacArthur and Wilson, 1967).

In birds, given the external development of young, this can be achieved through larger eggs (see Styrsky *et al.*, 2000; Christians, 2002) and extended developmental periods (if the latter are beneficial for the development of young, which remains debated; Martin, 2002; Ricklefs, 2006; Martin *et al.*, 2007). In addition, extended developmental periods may be more common on islands since nest predation is reduced (and hence the pressure to quickly take offspring off the nest is released). This is advantageous for parents as it allows them to decrease their investment in incubation and nestling feeding in a short time period, allowing them to save energy through lower incubation effort and reduced feeding rates (reviewed in Dmitriew, 2011; see also Ricklefs, 1992; Martin *et al.*, 2011).

Other interesting, but poorly explored characteristics of reproductive strategies on islands relate to mating and parental care. First, the frequency of extra-pair paternity (EPP) appears to be lower on islands (Griffith, 2000). EPP is known to be common in birds and provides an indication of the strength of sexual selection in a given species or population (Petrie and Kempenaers, 1998). Females engaging in EPP are believed to be searching primarily 'good genes' for their offspring, though other direct benefits may be involved, for example, if females gain increasing foraging opportunities at other males' territories (Petrie and Kempenaers, 1998; Petrie *et al.*, 1998). On islands, populations are mostly derived from a small founding group. This leads both to lower levels of genetic diversity and higher relatedness levels (Frankham, 1998). Hence, the advantages brought by EPP are reduced in this genetic setting. Under this scenario, males have higher certainty of paternity, which is expected to increase reproductive investment by males, further reinforcing the shift toward greater investment in young as described above (see also Bennet and Owens, 2002).

The decrease in sexual selection implied in this hypothesis is further corroborated by yet another evolutionary pattern observed in birds: island populations would be less colorful than their mainland counterparts (Grant, 1968; Fitzpatrick, 1998; Figuerola and Green, 2000). This pattern was supported by a recent broad-scale study based on spectrophotometric measurements which found that island birds have a reduced diversity of colors and plumage brightness and well as reduced number of plumage patches (**Figure 6**). These changes, however, may be partly explained by a decrease in the need for species recognition on islands (Figuerola and Green, 2000; Grant, 1968). Plumage color and patches are used in mate choice, but also in species recognition and as such have important consequences for the fitness of individuals since attempting to mate with individuals from the wrong species would represent a significant cost. The impoverished diversity of species on islands translates in reduced number of closely related species living in sympatry, and hence in reduced risks of attempting to mate with heterospecifics. Under this condition, the complexity of signals (here plumage pattern and coloration) is expected to decrease, as observed for bird coloration islands (see also Morinay *et al.* (2013) for a similar result on bird song).

Figure 6 Island birds tend to have duller plumage, reduced number of colors and less colored patches than their mainland counterparts. This is illustrated here by specimens of fruit dove (*Ptilinopus* spp) held at the British Museum of Natural History. The species on the left is *Ptilinopus purpuratus* from Tahiti Island and on the right is *Ptilinopus regina* from mainland Australia (Photo C Doutrelant).

Finally, islands hold strikingly high numbers of cooperatively breeding species (Covas, 2012). Cooperative breeding is an interesting behavior where nonbreeding sexually mature birds assist with raising the offspring of others. These 'helpers' are often (though not always) offspring of the breeding pair that delay dispersal and stay in the parental territory forming family groups (Brown, 1987). While this type of parental care is known from ca. 9% of all birds species (Cockburn, 2006), on islands, one study found cooperative breeding to occur in 33% of the islands species surveyed (Covas, 2012). Why some species breed cooperatively and others do not remain actively debated (e.g., Andrew Cockburn and Russell, 2011)? One view that has received some support is based on the observations that cooperatively breeding species tend to have high survival (Arnold and Owens, 1998; Cockburn, 2003; Covas and Griesser, 2007). Increased survival may favor cooperative breeding since long-lived species often start to breed later in life (Covas and Griesser, 2007). Long-term occupancy of breeding territories by long-lived residents should decrease the opportunities for independent breeding by younger birds (Emlen, 1982; Arnold and Owens, 1998). Hence, the demography of these species may frequently lead to a situation where individuals do not attempt to breed in their early years but remain in the natal territory, where they are exposed to the subsequent breeding attempts, which they will assist. This route to cooperative breeding is consistent with the demographic shift observed on islands (Blondel, 2000; Covas, 2012; MacArthur *et al.*, 1972; see also Cockburn, 2003). However, additional more in-depth study is needed to test the links between island life and the different steps leading to cooperative breeding and hence to fully understand this change.

The islands around the world continue to fulfill the role of natural laboratories of ecology and evolution. The simplicity of island ecosystems serve as a magnifying glass to examine some of the most important drivers of evolution, while the number of islands around the world – with their varieties of faunas, geographic and climatic conditions – provide natural replicates which offer unique opportunities to test

evolutionary mechanisms. The examples above illustrate how islands have contributed to our understanding of several factors affecting life-history evolution, including body size and several reproductive and behavioral traits. Global patterns of adaptation on islands are beginning to emerge and some of the key factors underlying change are beginning to be understood. Reduced species diversity (including the reduced number of predators and parasites) and the milder climates appear to play a prominent role for life-history change on islands through ecological release and enhanced survival. However, even on simplified island environment several factors may interact and more detailed work remains to be done to conclusively assess several of the hypotheses advanced here.

Life History Evolution, Plants

CJE Metcalf, Guyot Hall Princeton University, Princeton, NJ, USA

Glossary

Integral projection model (IPM) A demographic model that reflects size-dependent demographic rates (i.e., survival, fertility vary as a function of the size of the individual) and from which classic fitness measures can be extracted.

Monocarpic A plant for which reproduction is fatal.

Background

In previous articles we have seen how fitness can be defined as the asymptotic population growth rate in deterministic models, as the long-run stochastic growth rate in stochastic models and, for some density-dependent models, as carrying capacity. However, in many cases, the frequency or density of different classes of individuals can impact the fitness of other classes. In these cases, fitness cannot be universally estimated as a single quantity, and the researcher needs to rely upon simulation approaches where different strategies are competed against one another. These techniques, referred to as evolutionary game theory or adaptive dynamics, are a powerful approach to identify the eventual outcome of evolution. However, in order for the approach to be tractable, one or two key assumptions are required. The most important one is the way that strategies are passed from parents to their offspring; the approaches assume near perfect fidelity. A second requirement is that trade-offs exist between different components of the life history. Without a trade-off, Darwinian demons evolve. One trade-off that is often incorporated into approaches to identify Evolutionarily Stable Strategy (ESS) in frequency dependent environments is one between offspring number and offspring size. In this article, the author gives a brief overview of life history approaches and their application, primarily to plants that can live for a variable number of years, but which flower only once – monocarpic perennials.

Using Evolutionarily Stable Strategy Methods to Understand Evolution in Perennial Plants

An ESS is a life history strategy (i.e., a time of flowering, or a seed size) that cannot be invaded by any other strategy. A mutation that results in a phenotype that is not at the ESS (a smaller or larger flowering size, or a larger or smaller seed size) will not be able to invade a population where the ESS is present at high frequencies.

Interactions between individuals are central to the ESS concept. As well as its own strategy (genotype), the strategies (genotypes) of other individuals within the population affect a focal individual's survival or fertility, and thus fitness. The centrality of interactions between individuals implies that either density or frequency dependence is operating within the population. Density dependence might result from a restriction of the total number of seeds recruiting, or adults surviving, or reproducing due to resource limitation (e.g., microsites for recruitment, nutrients, or water for growth and survival). Positive frequency dependence occurs when a particular strategy is disproportionately represented in subsequent generations when it is rare – self incompatibility alleles are a classic example in plants. As a consequence of either density or frequency dependence, the success of a strategy will depend on what other individuals in the population are doing. Therefore, both an individual's strategy and the strategies of individuals around them will shape evolutionary outcomes.

This inherent nonlinearity can result in evolutionarily singular strategies that are not, in fact, convergent stable. Although such strategies can invade every other possible strategy (e.g., every possible flowering size), they are themselves invasible – their dominance within a population results in a density or frequency dependent environment that is more favorable to strategies other than themselves. However, once these strategies establish, the ESS will in turn invade their replacements successfully. Complex evolutionary cycles and branching points may result (Geritz *et al.*, 1999).

ESS theory has been successfully deployed to understand evolution of timing of flowering in monocarpic perennials. For these plants, reproduction is fatal, and therefore timing of flowering is the outcome of a relatively simple trade-off. Plants should wait as long as possible before flowering, since the longer they wait, the larger they grow, and the larger they grow, the more seeds they produce. However, if they wait too long, they risk dying without ever reproducing (Metcalf *et al.*, 2003). The ESS balances these two forces. Further, given the simplicity of the monocarpic life history (in particular, the lack of complex costs of reproduction requiring parameterization) the ESS can be predicted using integral projection models parametrized from field data (Rees and Rose, 2002; Rees *et al.*, 2006; Metcalf *et al.*, 2003). Since density dependence appears to act mostly on seedling establishment within these systems (Metcalf *et al.*, 2003), complex feedbacks are not expected (Mylius and Diekmann, 1995); and the result is a convergent stable strategy (CSS), which is often found to be a close match to observed flowering sizes. Stochasticity plays a major role in determining the convergent stable flowering size, as timing of flowering is inherently a bet-hedging trait. Longer delays before flowering act to distribute flowering over more years, allowing for a spread of seed recruitment across conditions. This spread acts to reduce variance in the population growth rate (Childs *et al.*, 2010), increasing fitness and invasion rates in a stochastic environment, even though the mean one time-step growth rate is likely to be reduced, as delayed reproduction allows more time for extra mortality. Similar

analyses have been used to predict optimal rates of germination from the seedbank (Rees *et al.*, 2006), again with strong matching of predictions with observations.

ESS theory has also been deployed to address the question of the evolution of seed size. This is usually framed in the context of a trade-off between seed size and seed number (plants may either produce many small seeds, or a few large ones, with larger seeds having higher competitive ability, or survival). A range of theoretical outcomes have been described (Geritz *et al.*, 1999). It has proved more difficult to test this theory in natural systems, given complexity in parametrizing the range of underlying trade-offs, particularly in the face of resource heterogeneity.

Summary

ESS methods are the appropriate method to identify the optimal life history strategy when frequency or density dependence is operating. They make the assumption that strategies are passed from parent to offspring with near perfect fidelity, consequently ignoring genetic mechanisms. They have been applied across a number of animal and plant systems, with a large body of work on monocarpic perennial plants.

Life History Evolution: The Role of Mating Systems

S Schindler, University of Oxford, Oxford, UK

Why Mating and Life History Have to be Associated?

Evolution results in strategies that maximize fitness. A life history strategy is determined by life history traits, which include those listed in Table 1. Many of these traits are associated with, or are a consequence of, decisions regarding reproduction.

A part of reproduction is mating itself, a process that includes searching for a mate, mate choice, mating system, mating tactic, and behavior. Some mating decisions are made at the individual level, for example, the choice of whom to mate with. Others, like the mating system, are population-level descriptors. Finally others, including generation length, are genetically and phylogenetically constrained.

Life history traits can directly be aspects of mating. For instance, the tactics that individuals use to successfully mate can directly drive life history evolution. However, mating traits can also limit the evolution of alternative life history traits: for example, hermaphroditic (monoecious) plants are unlikely to evolve into dioecious plants. The next section discusses how mating influences life history as well as how mating is influenced by life history. A later section highlights sex allocation and sexual conflict. This article primarily focuses on the animal kingdom although it includes a discussion on plant mating systems. Finally, a population model that allows a whole range of questions on how life history and mating interact is presented.

Table 1 Non-exhaustive list of life history traits

Gestation length
Body weight at birth, seed size and mass
Developmental state after birth (altricial and precocial)
Length of growth period, growth pattern, germination
Optimal body size
Dormancy
Allometry
Age and weight at maturation
Distribution of resources to maintenance, growth, and reproduction
Reproductive strategy, reproductive morph
Reproductive timespan
Period between litters or reproductive events
Mating preference
Litter size, seed number
Pollen–ovule ratio
Sex ratio of offspring
Parental care, length of care
Sociality
Age of dispersal
Timing of sex reversal for hermaphrodites
Number of reproductive events (Semelparity and iteroparity)
Mortality rates, life expectancy

The Role of Mating on Life History Evolution

Timing, Behavior, and Mating Preference

Mate choice evolved because specific mate combinations have higher fertility and produce fitter offspring than alternative combinations. Mating preferences can consequently influence population growth rate by impacting the fertility rate, but also by impacting the distribution of fitness-related traits in the offspring generation (Schindler *et al.*, 2013).

The timing of mating can affect lifetime reproductive output via routes beyond an earlier age of sexual maturity being expected to result in a longer reproductively active life. Trade-offs between reproduction and mortality or between reproduction at different ages mean that reproducing at as young an age as possible is not the fittest life history strategy (Stearns, 1992). However, delaying mating can also carry a cost: in butterflies *(Bicyclus anyana)* late reproduction increases life span but reduces fertility at the first reproductive attempt (Zijlstra *et al.*, 2000).

Decisions on when to mate, and with whom, can consequently influence not only individual offspring number and offspring phenotype, but also population-level survival and reproductive rates.

Mating System

Mating system classification differs between plants and animals. In animals, the classification is based on how many mates can be monopolized, how mates are acquired, characteristics of a pair bond, and patterns of parental care (**Table 2**; Emlen and Oring, 1977). In plants, the classification of the mating system is based on the amount of selfing and inbreeding depression (**Table 3**; Sakai and Westneat, 2001).

Table 2 Animal mating systems

Parthenogenesis	Reproduction without fertilization
Monogamy	Pair bond between one female and one male for the reproductive season, often shared parental care
Polygyny	Several females mate exclusively with one male
Polyandry	Several males mate exclusively with one female
Polygynandry	Both sexes mate exclusively with a small set of members of the other sex
Promiscuity	Short-term association between any female and male
Polybrachygyny	Absence of pair bonds, no parental care by males, males are constantly seeking mating opportunities
Lekking	Males aggregate in a display area where they defend small territories, females arrive at display area to find a mate

For both plants and animals, ecology influences the evolution of the mating system (Lloyd, 1980; Emlen and Oring, 1977). A change in the mating system in turn drives life history adaptation. In plants, for example, the transition from outcrossing to selfing causes selection for a lower pollen–ovule ratio (Dudley *et al.*, 2007), a younger age at maturity (Dudley *et al.*, 2007), and from a perennial to an annual life cycle (Zhang, 2000). In animals the transition from monogamy to promiscuity has two implications. First, if females mate

Table 3 Plant mating systems

Selfing	Self-fertilization
Outcrossing	Fertilization with unrelated pollen
Apomixis	Vegetative propagation or seeds with complete maternal genome
Dichogamy	Flowers have female and male function at different times
Gender change	Change in sex-expression or sequential hermaphroditism
Heterostyly	Two to three different reproductive flower morphs, self-incompatibility, mechanism for outcrossing
Dioecy	Variance in sex-expression at individual level, for example, female or male flowers or plants, or at population level

polyandrously then increased longevity is selected for in males. For example, in two butterfly species from the genus *Yponomeuta* (Lepidoptera: Yponomeutidae), *Y. cagnagellus* and *Y. padellus*, male life span increases with the level of polyandry and becomes better matched to female reproductive life span (Bakker *et al.*, 2011). Second, the mate of a promiscuous individual that provides parental care will be uncertain as to whether it is the parent of an offspring or not. As the certainty of parentage declines, the lower the expected contribution of the sex that cannot determine whether it is a parent or not to offspring care. For example, when females provide care, male promiscuity evolves and male reproductive success increases with the number of mates he acquires (Sæther, 1986). However, the increase in male reproductive success is counterbalanced by a reduction in reproductive life span as male–male competition for mates increases (Lukas and Clutton-Brock, 2014). The higher female promiscuity, the lower the probability of finding the same paternal genes in litter mates and future siblings and the greater mother–offspring conflict over resource provisioning. Offspring of promiscuous mothers demand more resources, which in turn increases her costs of reproduction (Garratt *et al.*, 2014). Female promiscuity consequently selects for a reduced reproductive life span. In summary, while a female balances a shorter reproductive life span with increased genetic variation in her offspring, a male balances a shorter reproductive life span with the benefits of potentially producing more offspring. For both sexes, a change in the mating system toward higher promiscuity alters life history.

Ways Life History Can Influence Mating

Phylogenetic studies suggest that evolution from one mating system to another cannot always be reversed. For instance, selfing in plants has evolved several times from outcrossing, but not vice versa (Barrett *et al.*, 1997). Similarly, polygyny in animals has evolved several times from monogamy but there are no examples of evolution in the reverse direction (Lukas and Clutton-Brock, 2013). The lack of these reversals suggest that life history adaptations to the mating system (see Section Mating System) can generate evolutionary constraints.

Although life history constrains the evolution of the mating system, life history can select for a change in mating system because it determines optimal mating behavior. For example, studies of seed beetles (*Callosobruchus maculatu*) where lines are selected for either reproduction at young or old ages revealed that mating frequency at early ages can evolve quickly (Maklakov *et al.*, 2010).

In addition, juvenile mortality can impact the benefits of polygynous or monogamous mating in males. Under the assumption that monogamous males invest more into paternal care than polygynous ones, polygyny is expected to evolve when the fitness reduction for males due to reduced parental care for each of its offspring is compensated by more offspring resulting from more matings (Sæther, 1986). In other words, the benefits of monogamy increases with juvenile survival, or the ratio of juvenile survival to adult survival (Sæther, 1986). In plants, longevity correlates negatively with inbreeding depression independently of whether mating is random (outcrossing) or mixed (some self-fertilization) (Morgan, 2001), which further supports the hypothesis that the evolution of annual life cycles preceded the evolution of selfing (Barrett *et al.*, 1997).

In the following sections further examples of life history effects on mating focusing on survival rates, fertility rates, and reproductive morphs are given.

Survival

Survival rates usually – but not always – decrease in older age (Jones *et al.*, 2013). If survival rates decrease with increasing age beyond some age, then life history theory predicts that mate choice should decline and mating effort should increase with age. There are various lines of evidence in support of this. First, both female and male mate choice in the fruit fly (*Drosophila melanogaster*) decreases with age (Edward and Chapman, 2013). Second, young male scorpionflies give more valuable nuptial gifts to high-quality females than to low-quality ones. In contrast, old males are less discriminative (Engqvist and Sauer, 2002). Third, female mate choice in cockroaches declines with age as does her fecundity (Moore and Moore, 2001). Fourth, adult survival rate determines reproductive effort at early ages in many species including alpine ibex (*Capra ibex*), while male reproductive effort at young ages decreases with survival rates across species (Willisch *et al.*, 2012). Sex-differences in mortality also impact the operational sex ratio and consequently the variance in mating success (Partridge and Endler, 1987). In addition, sex-differences in survival and other demographic rates enhance the effect that mate preferences have on the population growth rate (Schindler *et al.*, 2013).

Finally, vital rates limit the extent of sexually selected traits (Partridge and Endler, 1987) as the prevalence of such traits correlates negatively with survival rates (e.g., red deer *Cervus elaphus*, Clutton-Brock *et al.*, 1985).

Fertility

Females and males can adjust their reproductive investment as a function of the quality or behavior of their mate. A meta-analysis of dragonflies, for example, has shown that tandem

species (males of tandem species remain in physical contact and guard females they have mated with until she oviposits) lay larger eggs and produce faster growing larvae (Koch and Suhling, 2005).

Males can adjust the amount and quality of sperm ejaculate as a function of the mating status and fecundity of their mate. For example, some male insects adjust sperm number on whether their mate has previously been mated (Wedell *et al.*, 2002) and male sailfin and Amazon mollies (*Poecilia latipinna* and *Poecilia formosa)* transmit less sperm to unisexual females than to those that are bisexuals (Riesch *et al.*, 2012). In addition, sperm quality can be adjusted to the attractiveness of females. For example, male fowl transmit faster sperm to mates with larger combs (Cornwallis and O'Connor, 2009). Females can adjust offspring number to the quality of the male. For example, in cichlid fish, females lay smaller clutch sizes to a male that has been more helpful in its juvenile state (Schürch and Heg, 2010).

Reproductive Morphs

Within a species there can be alternative life histories that are manifest in different morphs. This occurs primarily in males, with mating behavior often differing between morphs. A common set of alternative mating tactics is the sneaking (cuckoder) morph that either disguises itself using female mimicry or hides and tries to sneak matings and avoids aggression from the other morph that is usually bigger, has weapons, or provides paternal care (e.g., lampreys *Petromyzontiformes*, Hume *et al.* (2013); sand-bubbler crab *Scopimera globosa*, Koga and Murai (1997); Alpine ibex *Capra ibex*, Willisch *et al.* (2012)). Some crabs (*S. globosa*) that grow throughout their life apply a size-dependent mating strategy of either underground copulation or surface copulation which is less costly but involves lower reproductive success (Koga and Murai, 1997). Alternative life histories are maintained in a population via disruptive selection such that intermediate morphs produce less offspring than either sneaker or the big morph (e.g., coho salmon *Oncorhynchus kisutch*, Gross, 1985). The expression of one of two alternative life histories is almost always due to a conditional strategy and arises via frequency- and status-dependent selection (Gross, 1996). Examples for the status of an individual include quality, competitive ability, or condition (Gross, 1996).

Although alternative reproductive strategies are most common with two alternatives, there are species with three or more alternative reproductive strategies (e.g., side-blotched lizard *Uta stansburiana*, Sinervo and Lively (1996); Mediterranean wrasse *Symphodus ocellatus*, Alonzo *et al.* (2000)). The maintenance of more than two strategies is not yet fully understood and might be species-specific (Sinervo and Lively, 1996; Alonzo and Calsbeek, 2010).

Sex Allocation and Sexual Conflict

Sex Allocation

Life history affects sex allocation because mating patterns and parental care determine the optimal offspring sex (Stearns, 1992). Sex allocation can also be explained as a response to ecological or environmental conditions: for example, parents in some species can alter the amount of energy invested in sons and daughters, often investing more in the rarer sex or the frailer sex (Fisher, 1930), the sex that disperses more (local resource competition, West, 2009) or the sex that is likely to face the strongest competition later in life (local mate competition, Hamilton, 1967). Individual mating status and condition can also influence offspring sex ratio. For example, previously mated female spider mites (*Tetranychus urticae*) produce fewer offspring, but more daughters (Macke *et al.*, 2012), while sexually exhausted male rats *(Rattus norvegicus)* sire more female-biased litters (Bartos and Trojan, 1988; Hornig and McClintock, 1996). Trivers and Willard (1973) predicted that good-condition mothers of polygynous and sexually dimorphic species should produce the sex with highest variation in the reproductive value (Trivers and Willard, 1973; Leimar, 1996). In spite of more than 40 years of tests of the Trivers–Willard theory, empirical evidence is rather inconclusive (Hewison and Gaillard, 1999; Sheldon and West, 2004), which is due to a failure to account for sex-differences in demographic rates (Schindler *et al.*, 2015).

Sexual Conflict

Sexual conflict (the focus is on interlocus sexual conflict as opposed to intralocus conflict which arises via sex-specific gene expression (Arnqvist and Rowe, 2005)) arises when females and males have different life histories. Sexual conflict – like life history – shapes the mating system, and the mating system can lead to sexual conflict (King *et al.*, 2013). For example, male ungulates can induce estrus in females and reduced male presence can consequently increase female breeding age (Mysterud *et al.*, 2002). Additionally, young female seed beetles (*Canthoscelides obtectus*) can reduce their resistance to male mating attempts but pay a reduction in lifetime fecundity (Maklakov *et al.*, 2007).

Modeling Framework

Often it is not possible to identify the causal sequence of effects in the feedback loop between life history and mating in a real system. Models are therefore a useful tool to study the effect of mating on life history evolution and the effect of life history traits on mating probabilities. A recent model combines the major demographic rates – survival, ontological growth, and fertility rates which represent a specific life history strategy – with explicit age and phenotype-based mating preferences (Schindler *et al.*, 2013; Traill *et al.*, 2014) and thus allows the study of the link between life history and mating in detail. The model is a two-sex integral projection model (IPM) which projects into the future a population that is structured by age and a continuous trait, for example body size. The two-sex IPM has been proven useful to show how mating preferences affect population growth rate (Schindler *et al.*, 2013), how trophy hunting affects the demography of the trophy-bearing species when hunters target a sexually selected trait (Traill *et al.*, 2014), and how optimal sex allocation

depends on the interaction between the mating system and sex-differences in life history strategies (Schindler *et al.*, 2015). This model allows the study of a range of questions, for example, how changes in the demographic rates affect mating chances and reproduction, or how demographic rates adapt to the mating system.

Conclusion

This article provided a non-exhaustive overview about studies that investigated the link between mating traits and life history traits. It becomes clear that our understanding of this link is very limited. Besides having identified a handful of trade-offs between both sets of traits, the mechanism or precise nature of these trade-offs still have to be revealed. The use of models – such as the two-sex IPM described – can help to investigate hypothesis on the interface of mating dynamics and life history evolution.

Life History Patterns

OR Jones, University of Southern Denmark, Odense, Denmark

Glossary

Determinate growth Growth that is terminated once a predetermined size or structure has been reached, often at around the age of sexual maturity in many animals.

Germ line The germ line is composed of the sex cells (giving rise to the gametes, sperm, and eggs) that pass on genetic information between generations in sexually reproducing organisms.

Indeterminate growth Growth that continues over an organism's life course is not terminated once a predetermined size or structure has been reached.

Senescence A decline in the age-specific probability of survival, or age-specific reproductive output with age.

Soma/somatic cells Somatic cells (collectively known as the 'soma') give rise to all cells of the body except reproductive cells (sperm and eggs). Mutations in somatic cells are not passed on to offspring.

Survivorship The proportion of a population cohort surviving to a given age.

Background

Survivorship is defined as the proportion of a cohort that survives to a given age, and survivorship curves represent this quantity over age. Three archetypes of these curves were described by Deevey (1947), after Pearl and Miner (1935): type I, II, and III. Naturally, these curves are intimately related to age-specific mortality trajectories, with constant mortality with age resulting in a type II curve, while increasing or decreasing mortality with age result in type I and type III curves, respectively (**Figure 1**). Thus, trajectories of survivorship are tightly bound together with life span, trajectories of mortality, and the evolutionary theories of senescence.

The classical evolutionary theories of aging, 'mutation accumulation' and 'antagonistic pleiotropy' (Medawar, 1952; Hamilton, 1966; Williams, 1957), rely on the observation that there is a decline in the force of natural selection with increasing age. A third theory (Kirkwood, 1977), now known as the 'disposable soma theory,' argues that senescence is the result of balancing trade-offs between maintenance of the precious and immortal germ line (i.e., sex cells) and maintenance of the body (soma), which is viewed as merely a disposable vessel for transmitting genes. Together these theories imply that senescence, an increase in age-specific mortality rate over the life course (a decline in age-specific survival) is inevitable in organisms that separate germ line and soma, 'even in the farthest reaches of almost any bizarre universe' (Hamilton, 1998). Hamilton (1966) noted that reproductive senescence is a more complex trait than mortality senescence, and much less theoretical work has been carried out on it, but it follows that one would expect a decline in fertility with age to be concurrent with the increase in mortality.

Senescence in Humans

From maturity, human mortality rates, like those of many other animals, approximate a Gompertz (positive exponential function) or Gompertz–Makeham function (Ricklefs, 1998; Finch and Pike, 1996; Finch *et al.*, 1990), at least until very advanced ages (Vaupel, 1997). Considering the entire life course though, mortality rates are usually J- or U-shaped. For example, in historic human populations, and in modern hunter-gatherers, mortality is characterized by a U-shaped trajectory where infant mortality rates are high, and decline with age. Mortality rates then remain low for a period before increasing rapidly at older ages. The initial decline, dubbed ontogenescence, is a common feature across a wide range of taxa (Levitis, 2011) and has variously been hypothesized to be an adaptive quality control mechanism to remove defective individuals and increase the viability of their more robust kin (Hamilton, 1966), a result of trade-offs among growth processes, maintenance, and reproduction (Chu *et al.*, 2008), a heterogeneity effect whereby the frailest die first causing robustness to increase with age at the population level (Vaupel and Yashin, 1985), and a result of genetic or developmental malfunctions during transition points during development, concentrated in early life, when mechanisms are first expressed and tested (Levitis, 2011).

With the advantages brought by medical and public health advances, infant mortality has been reduced in most modern human populations, while the onset of senescence has been delayed (**Figure 2**) (also see Burger *et al.*, 2012), resulting in a transition from a U- to a J-shaped mortality trajectory. In some populations, declines in the rate of increase in mortality and even mortality plateaus at very advanced ages have been recorded (Vaupel, 1997). This is a puzzling phenomenon that usually requires immense amounts of data to detect, but that has also been observed in non-human taxa (e.g., Curtsinger *et al.* (1992) and Carey *et al.* (1992) in fruit flies, and Chen *et al.* (2013) in nematodes). Fertility in humans is hump-shaped, and there is an extended period of post-reproductive survival in women (**Figure 2**). But how do these trajectories compare to other animals?

Senescence in Non-Human Vertebrates

Until recently it was often argued that senescence would not be an important feature of the demography of wild animal

 doi:10.1016/B978-0-12-800049-6.00090-1

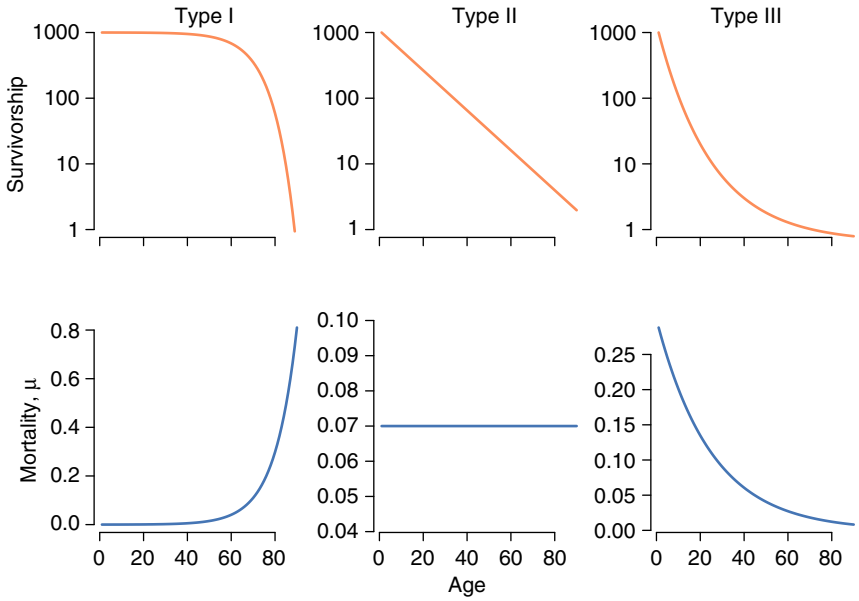

Figure 1 Type I, Type II, and Type III survivorship curves on a logarithmic scale (top row, orange lines) arise from increasing, constant, and declining mortality trajectories (bottom row, blue lines).

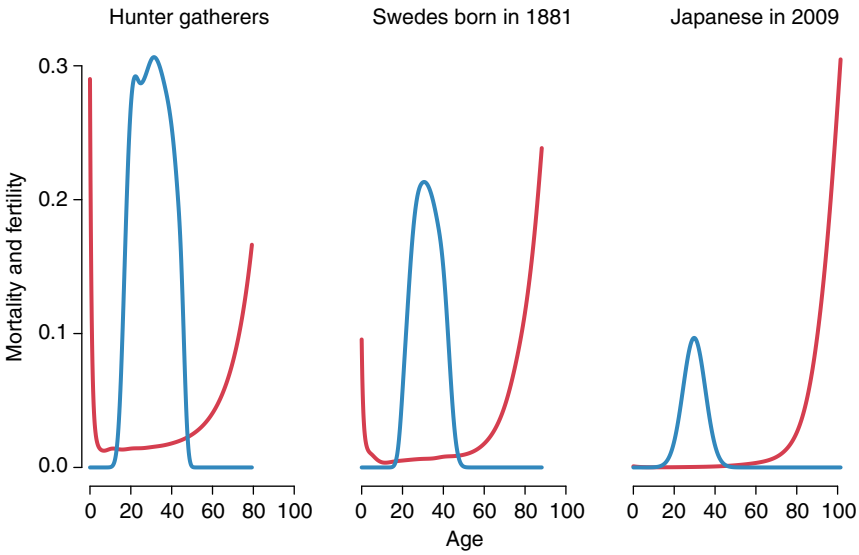

Figure 2 Mortality (red) and fertility (blue) trajectories in humans. From left to right, a hunter-gatherer population (the pre-contact Ache of Paraguay), a historic human population (Swedes from the nineteenth century), and modern humans, exemplified by the Japanese in 2009. Each curve ends as proportion surviving from a synthetic cohort reaches 0.05. Note how, with medical and public health advances, infant mortality has declined and the length of the life course has increased. At the same time, fertility has declined and occupies a smaller proportion of the life course. Data obtained from the Human Mortality Database (Human Mortality Database, 2013) and Hill and Hurtado (1996).

populations because individuals would 'die before they got old' from environmentally driven mortality like predation (Lack, 1943; Medawar, 1952; Comfort, 1956; Kirkwood and Austad, 2000). However, in recent decades there has been a growth in the availability of longitudinal datasets of intensely monitored mammal and bird populations (Nussey *et al.*, 2008, 2013), complemented by the development of sophisticated statistical methods such as capture-mark-recapture (Lebreton *et al.*, 1992; Gimenez *et al.*, 2008; Colchero *et al.*, 2012). Together these advances have brought ample evidence that actuarial senescence is a common feature of mammalian and avian life histories (e.g., Jones *et al.* (2008), Jones *et al.* (2014), Nussey *et al.* (2013) and references therein). Collectively the weight of evidence suggests that, in these groups, senescence is inevitable with U-shaped mortality trajectories, confirming the early comparative demographic work of Caughley (1966) on a small subset of mammals.

Evidence for reproductive senescence is a little more equivocal, perhaps because measuring fertility in the wild can be challenging and, although it is certainly detectable as a

hump-shaped fertility trajectory in many species (e.g., Jones *et al.* (2008), Jones *et al.* (2014), Nussey *et al.* (2013) and references therein), in others there is no hint of a decline after maturity with rates remaining constant well into advanced age (Jones *et al.*, 2008). Detailed studies of pregnancy rates in roe deer (Hewison and Gaillard, 2001) show that rates remain constant through most of the adult life course, but decline sharply at advanced age suggesting that in many cases the lack of detection could simply be an artifact of data quality and/or quantity for older individuals. In other species though rates decline with age directly from maturity (e.g., in olive baboons (*Papio anubis*) and lions (*Panthera leo*) (Packer *et al.*, 1998), and in red deer (*Cervus elaphus*) (Nussey *et al.*, 2009)). Senescence in the demographic traits of mortality and fertility are concurrent with changes in physiology (e.g., Catry *et al.*, 2006; MacNulty *et al.*, 2009), immune function (Palacios *et al.*, 2011), and body mass (e.g., Mysterud *et al.*, 2001; Nussey *et al.*, 2011), which represent more proximate causes for the observed population-level demographic trends.

There appears to be a degree of predictability in both the rate and timing of senescence. Closely related species tend to share similar life spans and qualitative trajectories (Healy *et al.*, 2014; Jones *et al.*, 2014). In birds and mammals, life spans increase and senescence rates decrease as the pace of life, measured by generation time, increases (Jones *et al.*, 2008; Peron *et al.*, 2010; Ricklefs, 2010; de Magalhaes *et al.*, 2007). In addition, protected populations – those that in some way avoid predation or other causes of mortality – tend to have lower rates of senescence and consequently longer life spans. This includes captive populations (Lemaître *et al.*, 2013), island populations (Austad, 1993), and species who's particular life history renders them less vulnerable to predation (e.g., bats (Healy *et al.*, 2014; Wilkinson and South, 2002; Munshi-South and Wilkinson, 2010)). Other factors that may shape senescence in these groups include the social system, with the expectation that the observation that males tend to have short lives compared to females being due to intra-sexual competition (Clutton-Brock and Isvaran, 2007). Studies that have examined the timing of senescence (e.g., Jones *et al.*, 2008; Loison *et al.*, 1999; Peron *et al.*, 2010) have demonstrated that, contrary to Hamilton's (1966) prediction that senescence should begin at maturity, senescence usually begins well after this point. But how do these patterns manifest outside the commonly studied groups of mammals and birds?

Beyond Mammals and Birds

Mammals and birds are all determinate growers, but there are many animal species that have very different architecture. For example, some species are clonal (e.g., coral), while others are indeterminate growers whose vulnerability to predation declines, and whose fertility increases with size and age (e.g., many fish, reptiles, and mollusks). In fact there are many species, especially indeterminate growers where size may be a more relevant predictor of demographic state than age (Sauer and Slade, 1987; Kirkpatrick,1984). Furthermore, since Vaupel *et al.* (2004) have shown mathematically that senescence may be avoided in indeterminate growers if small decreases in reproduction now can increase survival and reproduction later, it is of particular importance to study senescence in species with a wider range life histories – including indeterminate growth.

Jones *et al.* (2014) used data from a wide taxonomic scope of animals and plants and examined the shape of mortality and fertility trajectories (*sensu* Baudisch, 2011) over a typical life course from maturity. Their study revealed the existence of a great diversity of demographic trajectories: mortality trajectories can increase, decrease, or remain constant, while fertility trajectories can be hump-shaped, increase or decrease. Only one species, the nematode worm *Caenorhabditis elegans*, showed both mortality and fertility trajectories that conformed to the expectation of a consistent decline in fertility and an increase in mortality with age from maturity. Some species showed no, or negligible, increases in mortality. For example, the study confirmed the work of Martínez (1998) showing that the cnidarian *Hydra*, which reproduces clonally, has extremely low and unchanging mortality rates, and constant fertility rates. Other species like the desert tortoise (*Gopherus agassizii*), an indeterminate grower, exhibited declining mortality and increasing fertility with age – presumably related to increases in body size. Other chelonians are reported to show negligible changes in mortality (Hayflick, 1998; Congdon *et al.*, 2003). Studies on other reptiles have shown increasing mortality, despite their indeterminate growth patterns (Massot *et al.*, 2011; Bronikowski, 2008; Sparkman *et al.*, 2007), although at the same time fertility rates in some species increased with age (and size) (Sparkman *et al.*, 2007; Paitz *et al.*, 2007). Insects like *Drosophila* and medfly (*Ceratitis capitata*) have trajectories that are qualitatively similar to those of humans (Snoke and Promisiow, 2003; Vaupel *et al.*, 1998; Khazaeli and Curtsinger, 2013) – albeit with considerably shorter life spans.

Although the life spans of most insect species are undoubtedly short, the life spans (and presumably mortality trajectories) of some insects can be considerably longer. In eusocial insects (e.g., many Hymenoptera), although the worker castes have fairly short life spans, the adult queens, although genetically identical, enjoy life spans that are 100 times greater than those of solitary species (Keller and Genoud, 1997). This stark difference has been attributed as an evolutionary consequence of the extremely low mortality of the queens which reside in heavily defended nests and are usually virtually immune to predation (Keller and Genoud, 1997) – a hypothesis supported by the observation that species with larger colonies tend to have a larger life span differential between worker and queens than smaller ones (Kramer and Schaible, 2013).

The Plant Kingdom

The plant kingdom also shows great diversity in its demographic trajectories. This is reflected in the huge variation in maximum recorded life spans from short-lived annual species like corn, wheat, and rice, to incredibly long-lived tree species like the bristlecone pine (*Pinus longaeva*) with maximum recorded life spans of 4600 years, and the almost unbelievable life spans of clonal species like King's lomatia (*Lomatia tasmanica*) (>43 000 years) (Thomas, 2012).

The most important demographic factor that would help a plant attain a long life span is a low and flat, or even declining

mortality trajectory. Demographic trajectories can be derived from matrix population models (Caswell, 2001). The first major comparative study on plant senescence, by Silvertown *et al.* (2001), used this approach and showed that although many plants senesce, others have the declining rates of senescence necessary for extreme life spans. Additional work using a similar approach, but on a larger sample of species has confirmed that mortality rates in plants can increase, decrease, or remain approximately constant over the life course of a plant, but that the majority of Angiosperm species have declining mortality over most of their life course (Baudisch *et al.*, 2013; Jones *et al.*, 2014). Using individual-based data, other workers have shown both negative senescence (improvement with age) (Garcia *et al.*, 2011) and senescence (Roach, 1993). This great diversity of plant demographic trajectories likely stems from the great variety of architectures employed across the plant kingdom (Munné-Bosch, 2007; Thomas, 2012; Noodén, 2013).

All vascular plants have a modular architecture – they develop by the repetitive construction of similar units – and can replace and renew damaged modules. In addition, the totipotency of plant cells allows great flexibility in resource allocation in the face of changing environmental conditions. During times of hardship, many plant species can therefore allow tissue to die back (i.e., shrinkage – Salguero-Gomez and Casper, 2010), or undergo vegetative dormancy (Garcia *et al.*, 2011), and can then continue to grow when conditions improve. Finally, all plants grow indeterminately, and their increasing size is a key factor in reducing vulnerability to the ravages of the weather, and to herbivores. Thus, although the history of aging research on plants is shorter than that on animals, great strides have been made in understanding the driving factors, and there is much that animal-focused researchers can learn from it.

Conclusions

It is interesting to consider that the mechanisms of senescence escape noted above for plants are not restricted to the plant kingdom. There are representatives in the animal kingdom that exhibit clonal reproduction, modular architecture (e.g., corals), dormancy, and varying degrees of tissue regeneration. Other evolutionary innovations such as sociality, flight, and fossoriality are also likely to have strong influences on aging patterns but have, with some notable exceptions (e.g., Healy *et al.*, 2014; Buffenstein, 2007; Holmes and Austad, 1994), been somewhat neglected. The underlying framework that can explain these observations is life history theory, which in part studies the compromises made in resource allocation among processes of growth, reproduction, and maintenance, which vary among species and environment (Baudisch and Vaupel, 2012; Stearns, 1992). It is clear that across the tree of life, evolution has generated a dazzling array of life history strategies giving rise to a diversity of demographic trajectories, and resulting in life spans that range from days to millennia. Several taxonomic groups remain demographically unexplored and it is certain that aging research will benefit from widening its taxonomic scope.

Life History: Pike

Y Vindenes, University of Oslo, Oslo, Norway

Introduction

The Goal of This Section

A key step toward understanding life history evolution is to find out how survival and reproduction vary with age and size (Stearns, 2000), as these patterns create different selection pressures throughout the life cycle. As in many fish species, the vital rates of pike (*Esox lucius*) are largely size-dependent, but other state variables such as age, as well as external factors like temperature and resource availability, may also be important factors shaping the population dynamics and life history. To understand the joint effect of different vital rates in the life cycle on fitness (long-term population growth rate) and other life history quantities, we need a population model including the effects of individual state variables as well as external drivers. Integral projection models (IPM) fulfill these requirements, allowing both continuous and discrete state variables (Easterling *et al.*, 2000; Ellner and Rees, 2006; Coulson, 2012). Having discrete time steps, IPMs are especially suited to studies with empirical data from natural populations that are often gathered at discrete time intervals. Because continuous state variables like body size are often quantitative traits, IPMs represent a promising framework to study eco evolutionary dynamics, i.e., changes in both ecological and evolutionary quantities on a contemporary scale (Smallegange and Coulson, 2013; Vindenes and Langangen, 2015). This section presents an example of an age- and length-structured IPM for pike (*Esox lucius*) from Windermere, UK, demonstrating (1) how to estimate and derive the main vital rate functions defining the model, and (2) how to derive key life history quantities from analysis of the model (fitness, net reproductive rate, generation time).

Some Aspects of Pike Ecology and Life History

Pike is a top predator occurring in freshwaters around the Northern hemisphere and the most widespread species of the esocid taxa (Diana, 1996; Craig, 2008). They live under a wide range of climatic and ecological conditions, but generally prefer shallow waters and depend on vegetation for spawning and throughout early life (Bry, 1996; Craig, 2008). Pike hunt by visual cues and stalk their prey, remaining still for long periods of time. This is largely reflected in their morphology, with an elongated body shape and cryptic coloring providing camouflage in the vegetation. Pike are also highly plastic in choice of prey type, prey size, and prey behavior, and can easily adapt to new prey species (Craig, 2008). This opportunistic behavior, and the fact that pike is a cannibalistic species, may explain the rather low variation in recruitment (i.e., the number of offspring produced) found in pike compared to many other fish species (Craig, 1996b).

As for many species with indeterminate growth, body size is an important predictor of vital rates like survival, somatic growth rate, and fecundity in pike (Craig, 1996a). The vital rates are also influenced by other extrinsic and intrinsic factors, such as temperature and water levels (Craig, 1996b). Temperature is one of the most important environmental factors affecting several physiological and behavioral processes and thereby the vital rates (Casselman, 1996; Diana, 1996; Winfield *et al.*, 2008).

Depending on location, pike can mature at an early age and continue to grow after maturation. Maturation is largely determined by body size, and differences in age at maturity mainly arise because of differences in growth rate (Frost and Kipling, 1967; Billard, 1996). Females produce a large number of eggs, which increases with body size (Frost and Kipling, 1967; Vindenes *et al.*, 2014). Spawning occurs in spring, providing the offspring a long season to grow before next winter. The egg development in the female occurs throughout the autumn and winter preceding spawning (Frost and Kipling, 1967; Billard, 1996).

Pike survival depends on body size via different mechanisms, in particular predation (Craig, 1996b). Small individuals experience much higher risk of predation (also from cannibalism) than larger ones, and very few survive to maturity. In the early life stages individuals also undergo important processes of physiological development and are more vulnerable to environmental stresses such as food limitation or extreme temperatures (Kamler, 1992). One such critical period for fish is the phase where the larvae has absorbed the egg yolk and starts external feeding (Kamler, 1992). Large fish also have a higher capacity to store energy, allowing them to survive longer periods of low food availability (even though their overall energy requirements are higher). However, large fish are also more susceptible to fishing mortality (in areas where fishing occurs), which might represent an opposing selection pressure to the natural selection (Carlson *et al.*, 2007; Edeline *et al.*, 2007).

Pike can potentially grow to a large size and are relatively long-lived. The somatic growth rate is size- and age-dependent, and generally declines with size (individuals grow toward an asymptotic length over life). There is a high selection pressure for rapid early growth, as that increases the chances of survival during the first critical period in life (reducing the time spent in the size range of high mortality). As a top predator pike can play an important role in ecological communities (Craig, 2008). Changes in a pike population, for instance due to climate warming, can potentially cascade down to affect other species in the ecosystem (Estes *et al.*, 2011).

Methods

Study System and Data

The model presented here is based on data collected from the glacial lake of Windermere, UK (54°22′ N, 2°56′ W; altitude 39 m). Data on pike and other fish species as well as biotic and

 doi:10.1016/B978-0-12-800049-6.00094-9

abiotic variables have been collected since the 1940s (see review of the history of the data collection by Le Cren, 2001). The annual mean air temperature of the study area is predicted to increase over the next century (Jenkins *et al.*, 2009), and the observed surface temperature of Windermere (**Figure 1**) has shown a marked increase over the recent decades (Winfield *et al.*, 2008).

The four data sets used in this model are available online (see URL for each data set in the references), and include information on (1) fecundity (Winfield *et al.*, 2013a), (2) somatic growth (Winfield *et al.*, 2013b), (3) survival (Winfield *et al.*, 2013c), and (4) the annual mean surface temperature (Winfield and Fletcher, 2013). These data sets were used by Vindenes *et al.* (2014) to construct and parameterize a length-based IPM to investigate population dynamical consequences of climate warming. The model presented here is largely building upon this model, but also includes age as a state variable affecting somatic growth and reproduction. In addition, a reaction norm for size at maturity is also included, instead of having a fixed size at maturation.

The pike data for growth and fecundity were collected in a winter sampling period (October–February) where pike were captured using 64 mm mesh gillnets. The survival data are derived from a separate capture mark recapture (CMR) study, where sampling was also done in spring. In the winter sampling captured pike were measured for body length (in centimeters, measured as fork length), weighed (in kilograms), and sexed, and opercular bones were removed for age and length back-calculation, following a method validated for Windermere pike by Frost and Kipling (1959). The growth data set (Winfield *et al.*, 2013b) contains measured and back-calculated lengths from 1944 to 1995 (7939 females). Since 1963, data on female reproductive investment (gonad weight, egg number, and egg weight) have also been collected (Frost and Kipling, 1967). The fecundity data set (Winfield *et al.*, 2013a) contains fecundity data (egg number) from the period 1963–2002 (3634 females).

The survival data set (Winfield *et al.*, 2013c) contains survival data from 1953 to 1990, for both males and females (3992 individuals), based on the CMR study (for details on this sampling see Kipling and Le Cren, 1984; Haugen *et al.*, 2007). There is no age information in these data, so survival probability is assumed to depend on length only. Analysis of this data set is complicated by the fact that for individuals who were never recaptured, the time of death and size at death are unknown (but Windermere is a closed system so individuals do not leave, see Carlson *et al.*, 2007). To improve the survival estimates Vindenes *et al.* (2014) used a Monte Carlo resampling method to correct for this bias, using the somatic growth model to predict size at death for the unobserved individuals. The survival function used in this model is the same as in that study.

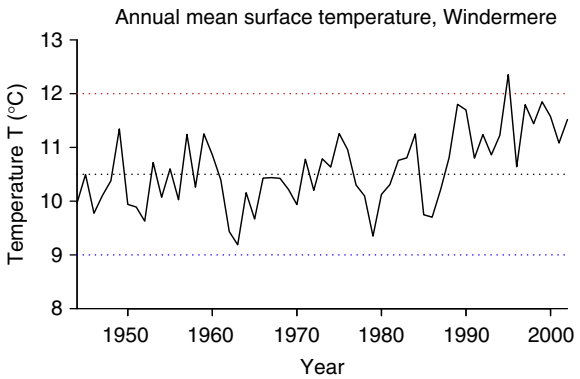

Figure 1 Observed annual mean surface temperatures in Windermere, 1944–2002. The dashed lines represent the three values of temperature used in other plots of this study (red corresponding to a warm conditions, 12 °C; blue corresponding to cold conditions, 9 °C; and black corresponding to 10.5 °C, close to the observed average over the time period.

Estimation of Vital Rates

Estimation of the vital rate functions was done using the software R (R Development Core Team, 2013), with the package 'nlme' (Pinheiro *et al.*, 2013). Mixed effects modeling is only one of many methods available, and the preferred method may depend on the vital rate function, the data, and the general questions of the study (Rees *et al.*, 2014). Vindenes *et al.* (2014) included year as a random effect in order to estimate environmental variance and covariance among the vital rates. This article focuses on the deterministic dynamics (dynamics of the expected population size), but given that the annual variance and covariance of vital rates are already estimated in the regressions, the model can easily be extended to also consider stochastic dynamics (Vindenes *et al.*, 2014).

Over the long study period changes have occurred in the abiotic and biotic environment, the level of fishing pressure, and also the sampling techniques (Paxton and Winfield, 2000; Le Cren, 2001). Such changes are reflected in the data as some of the vital rates show a trend (sometimes non-linear) over time, also when other effects are accounted for. To account for (and measure) the temporal trends due factors that are not of direct interest to the study, year effects were included in the regression models (Vindenes *et al.*, 2014).

There are often several candidate models for each of the vital rates. When the goal is to understand the effect of a particular variable (e.g., temperature), this variable was always included in the model (if it has small or insignificant effects the resulting effect on the model outputs will also be small). Interactions were only considered if they were expected for biological reasons. For instance, an interaction between temperature and body length on the vital rates is expected, because large and small individuals typically respond differently to temperature (Pörtner and Farrell, 2008). Model selection was based on the Akaike information criterion (AIC) (Zuur *et al.*, 2009). Here, the fixed effects structure was evaluated by fitting different candidate models with a procedure maximizing the log-likelihood (not the restricted log-likelihood). The final model was then refitted to maximize the restricted log-likelihood (Zuur *et al.*, 2009).

After the regression analysis is conducted, even though the estimated vital rate models may show good statistical fits, this does not necessarily mean they are biologically reasonable across the entire state space of the IPM (Merow *et al.*, 2014). For instance, it is common that data are scarce for parts of the state space (e.g., for the largest or smallest individuals).

Depending on the statistical regression model used, the data-heavy parts of the state space may have a large influence on the regression fit in other parts of the state space.

Even though back-calculated lengths are available for early ages in the Windermere pike, these are based on the subsample of individuals that have survived long enough to be captured. Pike are not susceptible to the sampling until they are large enough to be captured by the gillnets (usually around 3 years of age), so that for age 1 (and largely also age 2) only the back-calculated length estimates are available. The description of the growth model below includes an explanation of how this may lead to a bias in the estimated growth rate of small individuals, and how this can be adjusted in the final IPM. It is important to use knowledge of the species and system in question to evaluate whether the estimated vital rate functions are biologically reasonable, and perhaps make some adjustments before using them to construct the projection kernel (Merow *et al.*, 2014).

Model Description

Pike life cycle of the model

Figure 2 shows an overview of the life cycle for this model, with six age classes and length structure within each age class. The model is female-based and density-independent, assuming a pre-reproductive census so that offspring are counted as 1-year olds (offspring number includes offspring survival over the first year). The individual state variables are current length x (cm, $0<x<\infty$) and age class j ($j=1,\ldots,6$, where the last age class represents ages $\geq$ 6 years). The environmental state variable is the annual mean surface temperature T (for simplicity referred to as 'temperature'). For a year with temperature T, an individual of age j and length x survives to next year with a probability $s(x,T)$ (independent of age). If the individual survives, it grows to reach a new length y next year, according to a probability density function $g_j(y;x,T)$. It is assumed that no growth or mortality occurs over the winter before spawning. The individual can also produce a number of female offspring $b(x,T)$ that enter the population next year. The offspring length distribution $f(y,T)$ describes the initial lengths of offspring at age 1.

Vital rate functions

In this subsection, each of the four main vital rate functions that determine the IPM is presented in more detail including underlying functions. An overview of the model parameters and variables is given in Table 1, while values of the estimated effects and their standard errors are given in Table 2.

Offspring number

Offspring number is defined as the number of 1-year-old female offspring produced by a female of length x in age class j, at the temperature T, and is given by

$$b_j(x,T) = 0.5 p_j(x) m(x,T) s_O$$

where $p_j(x,T)$ is the probability of maturity given age j and size x, $m(x,T)$ is the fecundity (number of eggs produced) given size x, and $s_O(T)$ is the survival probability from egg to 1-year old. The factor 0.5 enters because only females are counted (assuming equal sex ratio among fertilized eggs). The function $m(x,T)$ describing egg numbers was estimated by Vindenes *et al.* (2014), and is given by

$$\sqrt{m(x,T)} = \beta_{m0} + \beta_{mx}x + \beta_{mT}T + \beta_{mxT}Tx$$

Offspring survival s_O (from egg to age 1) cannot be directly estimated from data, because the pike are not susceptible to the gillnet sampling until about 3 years of age. However, based on a model for the age-specific population densities estimated by Langangen *et al.* (2011), and using the estimated vital rate models for survival, fecundity, and growth, it is possible to obtain a prediction of the annual offspring survival probability over the study period (53 years, not shown). The mean offspring survival based on these predicted values is 0.00028, in line with estimates from other studies (on the order of 10^{-4}; Kipling and Frost, 1970; Wright, 1990; Craig and Kipling, 1983). Here, it is assumed that offspring survival is independent of maternal size or age, but a positive effect of temperature is included, as indicated by this analysis and other studies (Craig and Kipling, 1983; Paxton *et al.*, 2009), and which is also consistent with the estimated survival function with a positive effect of temperature for small pike (Vindenes *et al.*, 2014). Offspring survival is modeled on the logit scale, as

$$\text{logit}\, s_O(T) = \beta_{se0} + \beta_{seT}T$$

The probability of maturity, $p_j(x,T)$, could not be estimated from the winter sampling data because few pike are caught until they reach a length of $\sim$55 cm, at around 3 years of age (Frost and Kipling, 1967). Instead this function was determined to fit the results reported by Frost and Kipling (1967), based on data that also included smaller pike. According to this study most female pike in Windermere become mature at age 2, at a mean length of $\sim$41.5 cm (ranging from 31 cm to 49.8 cm). The study also noted that maturity is determined by size rather than age, and that differences in age at maturity largely arise from differences in somatic growth rate. Here, the probability of maturity, $p_j(x)$, is modeled on the logit scale,

$$\text{logit}\, p_j(x,T) = \begin{cases} \beta_{p0} + \beta_{px}x, & j \geq j_{\min} \\ -\infty, & j<2 \end{cases}$$

so that the minimum age of maturity is 2. The values of β_{po} and β_{px} are chosen to fit the results of Frost and Kipling (1967).

Figures 3(a)–3(d) show all the underlying functions determining fecundity, as well as the resulting total fecundity $b_j(x,T)$ (number of 1-year-old female offspring produced). The shape of the total fecundity is determined largely by the egg number function $m(x,T)$. Note that even though many females are mature at a length around 40 cm, they produce much fewer eggs compared to larger females.

Offspring length distribution

Vindenes *et al.* (2014) estimated the offspring length distribution $f(y;T)$ from the back-calculated data, and used a log-normal distribution where the mean $\mu_{L1}(T)$ depends on temperature but where the variance σ^2_{L1} is constant. The mean (on absolute scale) is given by

$$\mu_{L1}(T) = \beta_{L10} + \beta_{L1T}T$$

Figure 3(e) shows a histogram of the data together with the distribution $f(y;T)$ at different temperatures.

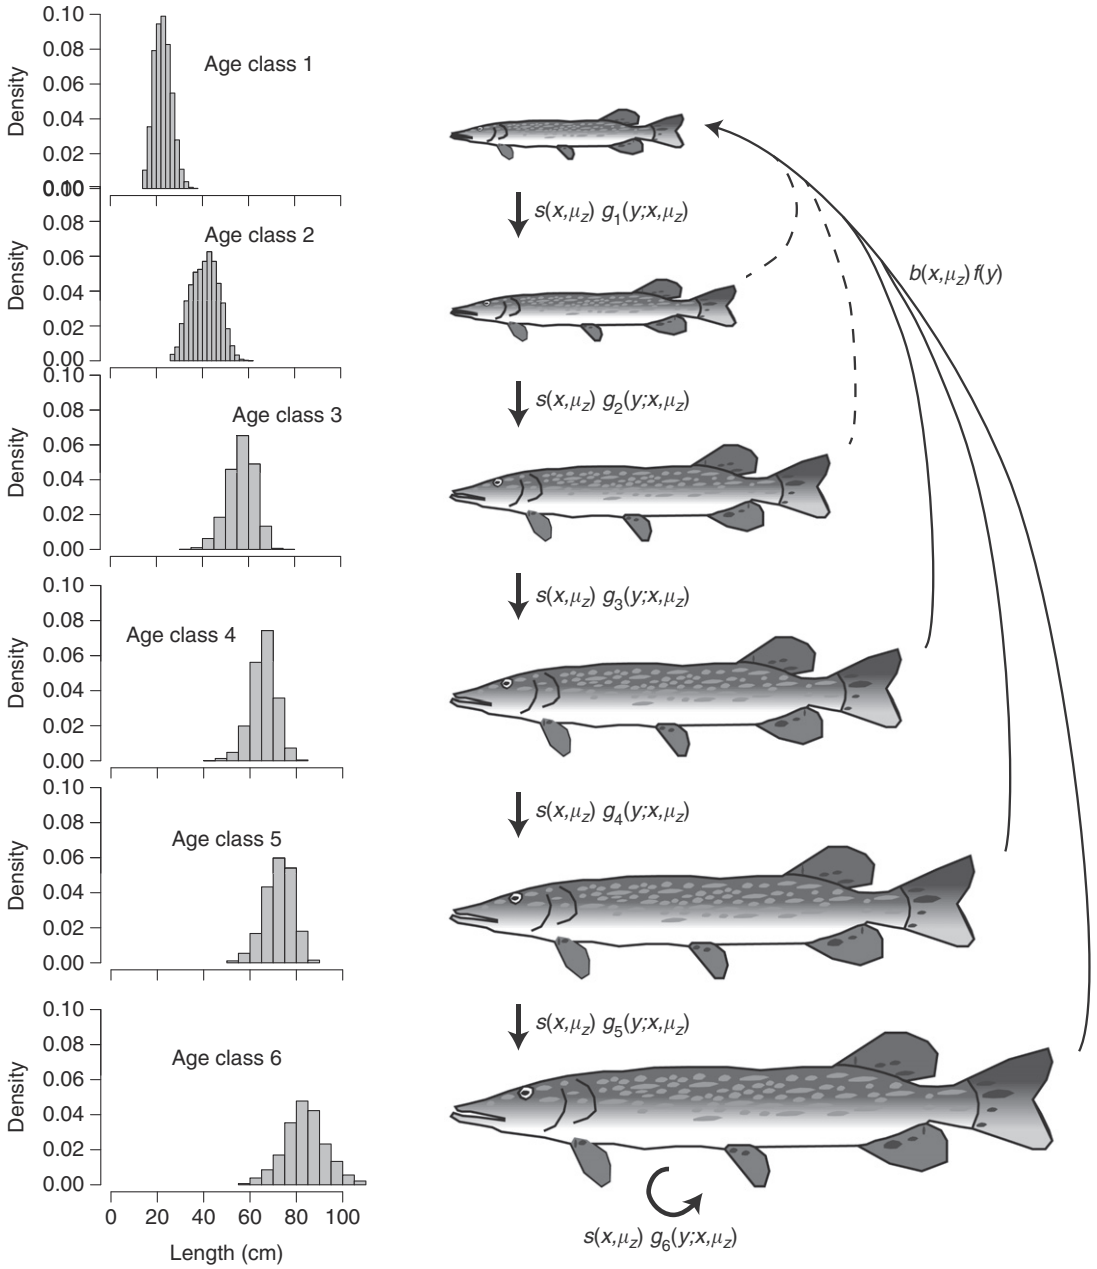

Figure 2 An illustration of the pike life cycle used in the model, with the observed size distributions at different ages. Age class 6 contains all individuals of age 6 and older. The model assumes a pre-reproductive census, and is defined by the vital rates describing survival probability $s(x,T)$, somatic growth $g_j(y;x,T)$, reproduction $bj(x,T)$ (number of age 1 offspring), and the offspring length distribution $f(y;T)$.

For this analysis, it is assumed that there is no correlation between parental and offspring size at age, because data on maternal identity are not available. Such a correlation could arise from genetic inheritance or from maternal effects. It could have been included in the model by letting the offspring size distribution depend on parental size x and age j.

Survival probability

The survival probability was estimated as a function of length and temperature by Vindenes *et al.* (2014). The survival data do not include age, but there are also good reasons to assume that survival is primarily determined by size rather than by age (as many mortality processes are closely related to size, e.g., predation risk). There could be some age effects as well, for instance through senescence at old ages. For population growth, however, senescence is probably not so important (at least in this particular case) because the older and larger individuals constitute a very small proportion of the population. Because data on the largest individuals are scarce, and because the capture probability may be lower for these, the estimated survival probability is uncertain for large lengths. Vindenes *et al.* (2014) therefore imposed a constant survival after the maximum is reached, although there is a possibility that it is declining with size for the largest individuals. This function is

Table 1 Overview of main variables and parameters in the IPM

Variable/parameter	*Signification*
x	Current body length (cm)
y	Next year's body length (cm)
j	Age index ($j = 1, ..., 6$, final class contains all ages >5 years)
T	Annual mean surface temperature (°C)
$s(x,T)$	Survival probability
$b_j(x,T)$	Offspring number (number of 1-year-old female offspring)
$g_j(y,x,T)$	Distribution of next year's length (growth)
$f(y,T)$	Offspring length distribution
$\mathbf{K}(T)$	Projection kernel at temperature T
$K_{ij}(x,y)$	Contribution from age j and length x to age i and length y (for $j\leq5$, $i=j+1$ and for $j>5$, $i=j$).
$\mathbf{S}(T)$	Survival/growth kernel at temperature T
$\mathbf{B}(T)$	Reproduction kernel at temperature T
$\mathbf{R}(T)$	Net reproduction kernel at temperature T
$n_j(x,T)$	Joint density distribution of age and length
$\lambda(T)$	Long-term population growth rate/expected fitness
$u_j(x,T)$	Joint stable distribution of age and length
$v_j(x,T)$	Reproductive value of individual with age j and length x
$R_0(T)$	Net reproductive rate at temperature T
T_0	Generation time defined as $\frac{\ln R_0}{\ln\lambda}$
T_M	Generation time defined as $\frac{\lambda}{\sqrt{Bu}}$

shown in Figure 3(f). The survival probability function is given by

$$\text{logit } s(x,T) = \beta_{0s} + \beta_{xs}x + \beta_{Ts}T + \beta_{Txs}Tx$$

restricted to its maximum for x above this size.

Somatic growth rate

Vindenes *et al.* (2014) estimated the somatic growth rate as a function of length and temperature, however the data indicate that there are clear age patterns as well. Because of a high correlation between age and body size in the data (0.91), including both in the same model would likely lead to problems of multicolinearity. Instead, a separate growth model is estimated for each age class. The cost is a reduced sample size, in particular for the older ages where there are fewer data points. Because of this, and because there is no evidence of large changes with age in the older age classes, all individuals of age 6 and above are lumped together in the final age class. The variance in growth rate was approximately constant within each age class. Thus, there are six age classes, and the final growth models are given by

$$\mu_{G1}(x,T) = \beta_{0G1} + \beta_{xG1}x + \beta_{x2G1}x^2 + \beta_{Tg1}T + \beta_{xTg1}xT,$$
$$\mu_{G2}(x,T) = \beta_{0g2} + \beta_{xg2}x + \beta_{x2g2}x^2 + \beta_{Tg2}T,$$
$$\mu_{Gj}(x,T) = \beta_{0gj} + \beta_{xgj}x + \beta_{Tgj}T (j>2)$$

Thus, in the first two age classes there is a second order effect of length, while in the older age classes this effect is not present. The variable $\mu_{Gj}(x,T)$ defines the mean of the growth distribution $g_j(y; x,T)$ from age class j to $j+1$. This is defined as a truncated normal distribution, truncated at x as individuals are not allowed (or expected) to shrink in length. The variance in growth σ^2_{Gj} is assumed to be constant within each age class.

A source of bias in the growth model is that the back-calculated length data represent a conditional sample of the underlying population, conditional on survival until capture (due to size-dependent gill netting most individuals avoid sampling until they are 3 years old). Because survival increases with size, this means that the growth model tends to overestimate size at age compared to the underlying population, as well as underestimate the variance in growth. Using the IPM (where survival is included) we can compare the mean size at age (at stable distribution) with the values from the growth model (where survival is not included), to get some idea of the magnitude of the bias (about 4 cm at the maximum bias in age 1). Here, the value is adjusted for this bias by reducing the growth rate at each age (more in the earlier ages) so that the mean size at age in the model matches the mean size at age in the data. Values reported in Table 2 are the adjusted values.

Figure 3(g) shows the mean length next year, $\mu_{ga}(x,T)$, as a function of current age class a and length x, for three different temperatures. In age 1 the largest individuals grow faster relative to their size than in older classes. This pattern can be explained by underlying heterogeneity among individuals in the growth rates (Vindenes and Langangen, 2015), which is not included here. Individuals who are relatively large when young tend to remain larger for a long time, but may also experience a slightly higher mortality (Vindenes and Langangen, 2015). Temperature has a positive effect on growth in all age classes, but the effect is strongest in ages 1 and 2. Figure 3(h) shows the resulting length at age from the unadjusted growth model, for three different temperatures.

In the growth model of Vindenes *et al.* (2014) that did not include age, there was an interaction with temperature and length so that temperature had a negative effect on growth for the largest individuals. This is not the case in the current

Table 2 Values of underlying parameters in the vital rate functions. The survival and fecundity models were calculated by Vindenes *et al.* (2014). Values given in parentheses are standard errors (where applicable)

model, as temperature was found to have a positive effect on growth for all sizes and ages, although the effects are very small for older ages (**Figure 3**). The model is still largely in agreement with that of Vindenes *et al.* (2014), where the temperature effects were also very small for the largest individuals.

Projection Kernel and Population Dynamics

While the vital rate functions alone contain much information about the life history, understanding their combined effect on fitness and other life history variables requires a population model, like an IPM. A key element of an IPM is the projection kernel (analogue to projection matrix in matrix models), which is a function of all the vital rates. The projection kernel describes how the population density distribution (in this case, the age/size distribution) changes from one time step to the next.

Letting $n_j(x)$ represent the number (density) of individuals in age class j within a small length interval $[x, x+\mathrm{d}x]$, the size of age class j is given by $N_j = \int_0^\infty n_j(x)\mathrm{d}x$, and the total population size is given by $N = \sum_{i=1}^{6} \int_0^\infty n_j(x)\mathrm{d}x$ (Ellner and Rees, 2006). The population growth from year t to $t+1$ is described by the projection kernel $K_{ij}(x,y)$, giving the contribution from individuals in age j with length in the interval $[x, x+dx]$ to age class i and length interval $[y, y+dy]$ (unless $i=j+1$ this contribution is zero). Transitions between ages is a purely deterministic process, as individuals are always one year older the next ear. Growth transitions, on the other hand, are characterized by the variation around the mean growth (note that the model is still deterministic, this variation just describes the spread of individuals across length within each age class). For this model, the projection function is given by

$$\mathrm{K}_{ij,t}(x,\,y) = \begin{cases} s(x,T)g_j(y;x,T), & i=j+1 \text{ and } 1\le j\le 5, \text{ or } i=j=6 \\ b_j(x,T)f(y;T), & i=1, \\ 0, & \text{otherwise} \end{cases} \quad [1]$$

Figure 4 shows the projection kernel calculated at the mean temperature $T=10.5\,^{\circ}\mathrm{C}$. Notice that the projection kernel shows values for the growth and reproduction of individuals for the entire size range within each class (due to extrapolation of the vital rate models), however no individual will actually reach the larger sizes in the young classes.

Net Reproductive Rate and Generation Time

The net reproductive rate R_0 describes the generation-to-generation population growth rate, and if offspring are all born into the same state it also describes the expected lifetime reproduction of an individual (Caswell, 2001). In this model, offspring have different sizes, so the expected lifetime reproduction of an individual is conditional on its size at age 1. The generation-to-generation population growth is described by a matrix (kernel) $\mathbf{R}=\mathbf{B}(\mathbf{I}-\mathbf{S})^{-1}$ (Ellner and Rees, 2006). Additional requirements need to be fulfilled for the existence of a unique dominant eigenvalue R_0, the net reproductive rate for the population (Section 5.3.4 in Caswell, 2001).

Generation time is another important life history characteristic, intuitively defined as the time between subsequent generations. However, when the generations are overlapping different generation time measures exist. A commonly used measure is the time it takes for the population to increase by a factor R_0, $T_0 = \frac{\ln R_0}{\ln \lambda}$ (Caswell, 2001). Another measure is the cohort generation time T_c, that is the mean age of parents of offspring produced by a cohort over its lifetime (for a definition for IPMs, see Ellner and Rees, 2006). A third measure is the mean age of

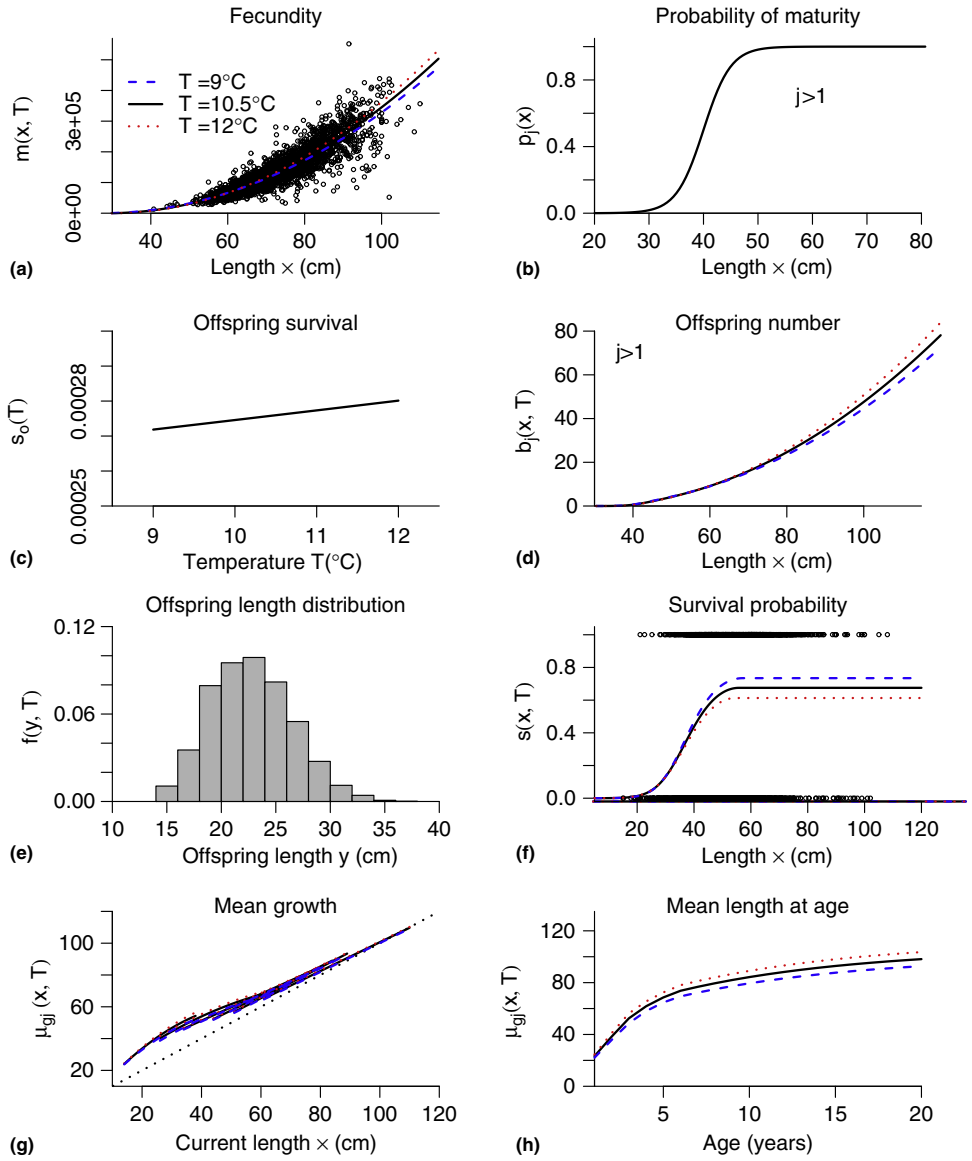

Figure 3 The vital rate functions defining the integral projection model (IPM). (a) Egg number $m(x,T)$ as a function of female length x, shown for three values of the temperature T. (b) Probability of maturity $p_j(x)$ as a function of female length x, for age $j>1$. (c) Offspring survival probability $s_O(T)$ as a function of temperature T. (d) Offspring number, $b_j(x,T)=0.5p_j(x)s_O(T)m(x,T)$ (number of 1-year-old female offspring produced) as a function of female length x, shown for three different temperatures. (e) Length distribution of offspring (at age 1), shown for three different temperatures. (f) Survival probability as a function of female length x, shown for three different temperatures. (g) Mean length next year $\mu_{gj}(x,T)$ as a function of current length x, shown for three different temperatures. The six clusters of lines correspond to the age classes, where the leftmost represents growth from age 1–2, the second leftmost from age 2–3, etc. (h) Mean length at age predicted from the growth model, shown for three different temperatures.

parents in a population at the stable age/size distribution, T_M (Caswell, 2001). Using a Markov chain definition of the population dynamics in a general stage structured population, Bienvenu and Legendre (2015) demonstrated that this value can be calculated as $T_M = \frac{\lambda}{\mathbf{vBu}}$ (adapting their formula to the scaling of the eigenvectors used here, $\mathbf{vu}=1$).

Discretization of the Model for Numerical Calculations

IPMs are typically discretized to a (large) matrix model before model calculations are done, so that the continuous projection kernel surface becomes a large projection matrix. The number of mesh points determines the accuracy of the model calculations, and should be chosen to obtain the desired level of accuracy. Many techniques are available for this numerical integration (e.g., using the midpoint rule; Easterling *et al.*, 2000; Ellner and Rees, 2006; Merow *et al.*, 2014; Rees *et al.*, 2014). Importantly, the discretization of an IPM is done after the vital rates are estimated, and only represents a method for numerical calculation of the model outputs (Ellner and Rees, 2006).

The discretized version of the projection kernel is the matrix $\mathbf{K}$, with 6 age classes and k size classes within each age class (each of width dx). Thus, the dimension of $\mathbf{K}$ is $6k \times 6k$.

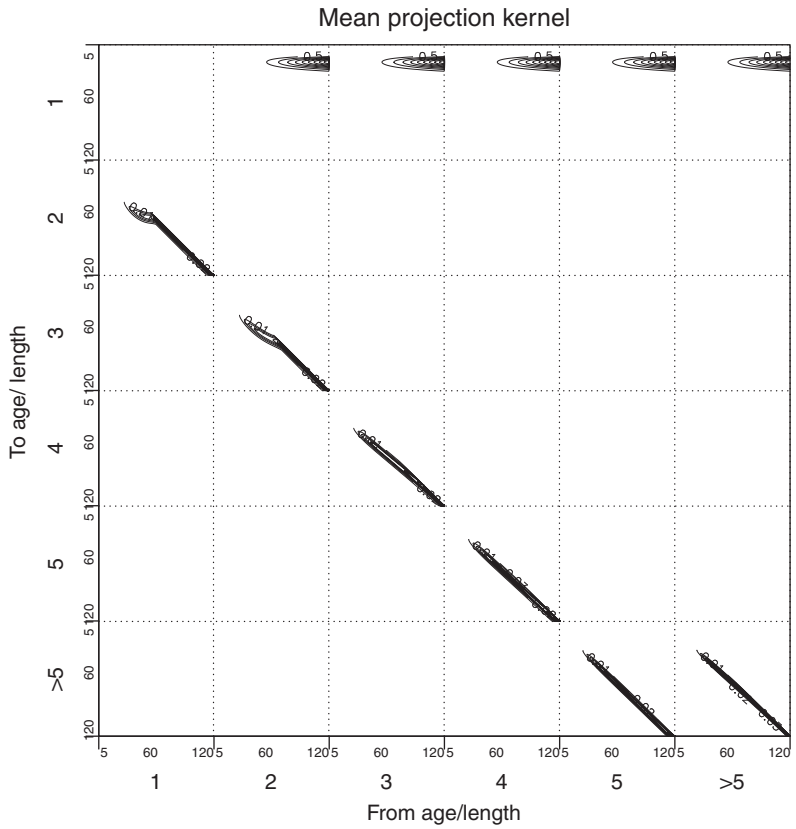

Figure 4 Mean projection kernel K for the temperature $T = 10.5\ ^{\circ}\mathrm{C}$ (note that the size values on the axes are approximate).

Results

Mean Growth Rate (fitness), Stable Structure, and Reproductive Value

An eigen analysis of the discretized matrix **K** yields three populaton parameters that describe the long-term asymptotic behavior of the population: the average population growth rate, the stable structure, and the reproductive value (Caswell, 2001). The long-term growth rate λ, which also measures the fitness of the life history in constant environments, is given by the dominant eigenvalue of **K**. The corresponding right and left eigenvectors provide the stable age/size structure $u_j(x)$ and the reproductive value function $v_j(x)$. Here, these are scaled so that

$$\sum_{j=1}^{6} \int_0^{\infty} u_j(x)\mathrm{d}x = 1$$

and

$$\sum_{j=1}^{6} \int_0^{\infty} u_j(x)v_j(x)\mathrm{d}x = 1$$

Figure 5(a) shows how λ changes with temperature in this model. As in the model of Vindenes *et al.* (2014) the effect is positive. Figure 6 shows the stable age and length distribution calculated for three different temperatures. This analysis suggests that the proportion of large and old individuals in the population will decline with warming (from age 5 and above), while the proportion of small and intermediate-sized individuals will increase, in particular for ages 2–4. The proportion of offspring (age 1) does not change much with temperature, but there are slightly fewer (and larger) individuals under warm conditions. Figure 7 shows the reproductive value as a function of age and length, calculated for three different temperatures. In all age classes and for all temperatures, the reproductive value increases with length, as is expected when neither survival nor offspring number declines with length.

Net Reproductive Rate and Generation Time

Figure 8 shows the kernel **R** for this model, calculated at the mean temperature $T = 10.5\ ^{\circ}\mathrm{C}$. It is equal to zero for all elements corresponding to sizes outside of the offspring size range, and for all elements corresponding to contributions to ages other than 1. Each value $R_{1j}(y, x)$ represents the expected lifetime number of size y offspring for an individual who has reached age j and size x.

Figure 5(a) shows how R_0 varies with temperature in this model. It is equal to λ when $\lambda = R_0 = 1$ (as it should be). As the temperature increases R_0 increases at a rate higher than λ. At warm temperatures individuals have reduced expected lifetimes, but leave a higher number of offspring on average. This is a good example that R_0 and λ are not equivalent and that R_0 is not, in general, a good measure of fitness (Caswell, 2001).

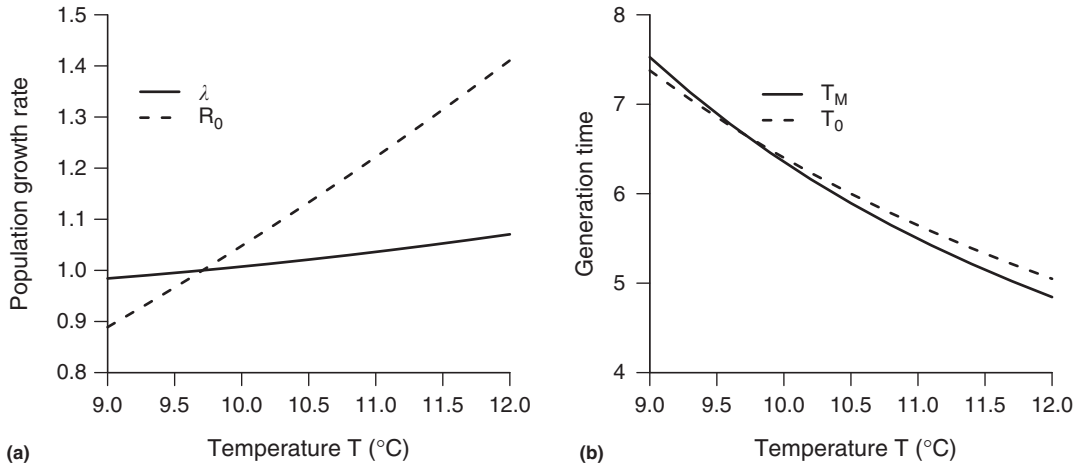

Figure 5 Some model outputs from analysis of the integral projection model (IPM) in different temperatures. (a) The expected population growth rate λ and the net reproductive rate R_0. (b) The two measures of generation time. T_m is the mean age of mothers in the stable population, whereas T_0 is the time for the population to grow by a factor R_0.

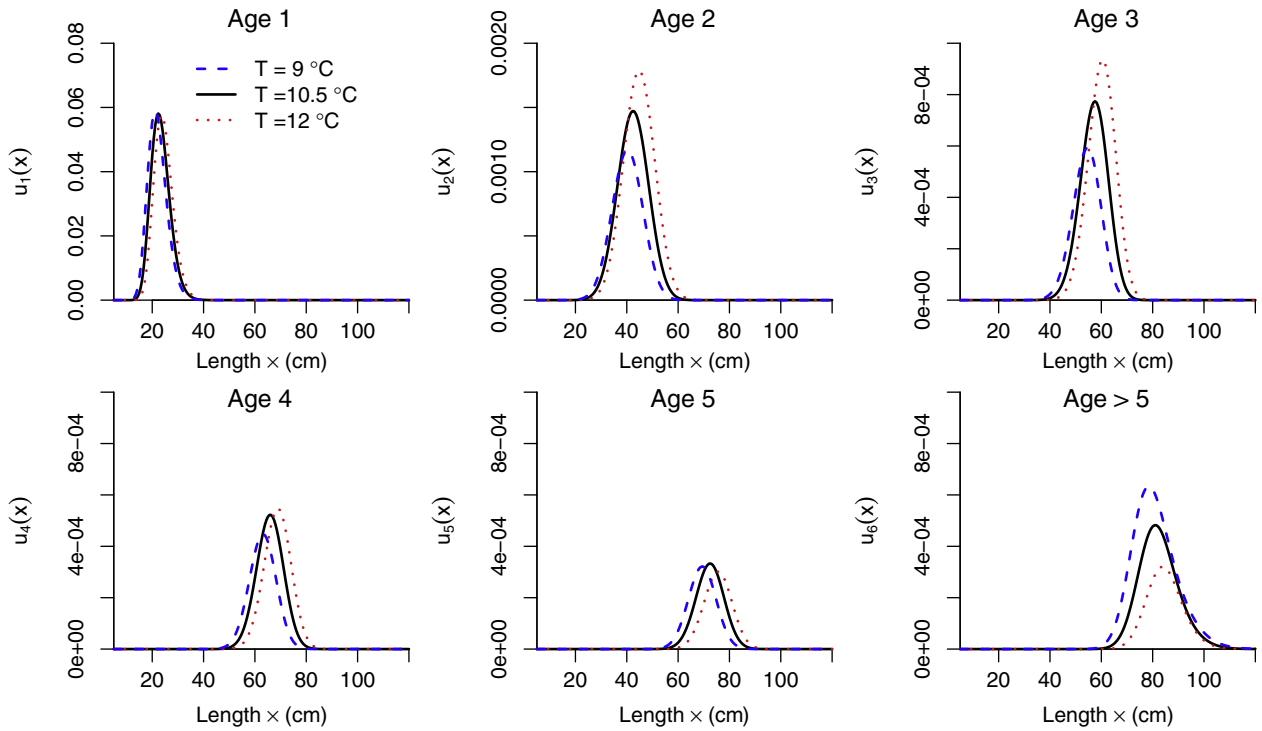

Figure 6 Stable age and size distribution calculated from the projection kernel, for three different temperatures.

The net reproductive rate R_0 is an important life history characteristic and a component to fitness, but it does not account for changes in generation time.

Figure 5(b) shows T_M and T_0 calculated for this model, as functions of temperature. The two measures are similar and both decline with temperature, but T_M declines a bit more rapidly. The figure also confirms that $T_M = T_0$ for $\lambda = R_0 = 1$, as expected.

Conclusions

This article has shown how the vital rates of female pike from Windermere depend on size, age, and temperature (Figure 3), and how these vital rates in turn affect population growth rate and other demographic outputs (net reproductive value and generation time; Figure 5). Temperature is a key environmental driver affecting many aspects of the life history of pike,

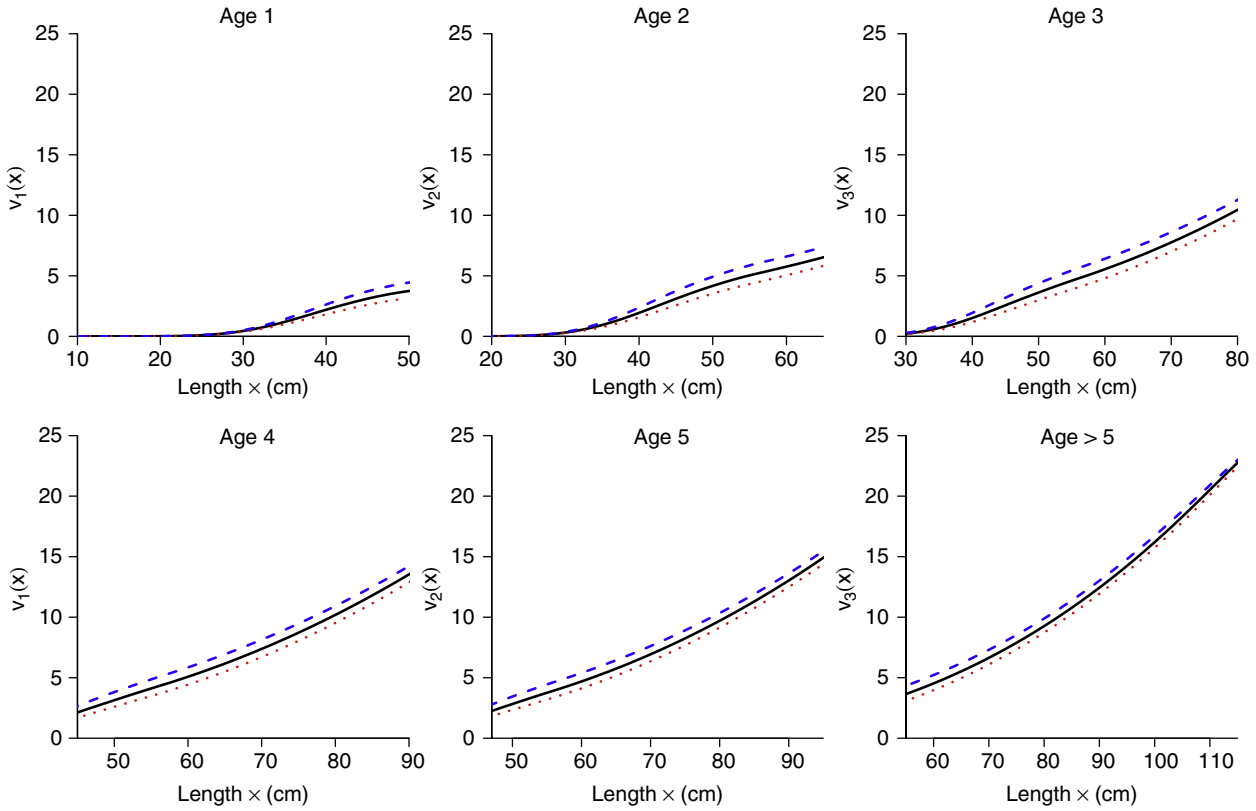

Figure 7 Reproductive value as a function of length x for each age class, calculated from the projection kernel at three different temperatures (see legend in **Figure 6**).

but is particularly important in the early life stages when individuals are small. Overall, these results indicate that warming may 'speed up' the life history of pike, as the net reproductive rate R_0 increases but the generation time decreases with temperature (**Figure 5**). Moreover, warming may shift the stable age/size distribution toward younger individuals, but larger individuals within each age class (**Figure 6**).

The underlying mechanisms of the thermal responses of vital rates are complex, and likely reflect both indirect and direct responses. Direct responses include physiological mechanisms (e.g., increasing metabolic rate) and behavioral mechanisms (e.g., increased aggression or feeding activity), while indirect mechanisms include responses mediated by effects on other species in the ecosystem (Winfield *et al.*, 2008). Some of the observed vital rate responses to temperature are also likely due to trade-offs in the life history. More research is needed to reveal the underlying mechanisms for these vital rate responses of Windermere pike.

Estimating vital rates for a demographic model can be challenging as it generally requires detailed individual-based data, preferably across the entire life cycle and over a long time period (especially for long-lived species), that captures a sufficiently large range of the environmental variability experienced by the population (Clutton-Brock and Sheldon, 2010). Unfortunately, such data are unavailable for most species. When some aspect of the life cycle is unobserved, such as the offspring survival probability in this model, available prior information from other studies can be used. Sometimes, as in this study, the missing parameter can be predicted or inferred.

Pike are relatively long-lived with a high fecundity, and the vital rates largely reflect this general life history. The high mortality of young and small pike leads to a strong selection pressure for rapid early growth. In a largely unpredictable environment where the average offspring survival is very low (only about 3 in 10000 pike survive the first year), having a long life with many reproductive events, and where many offspring (eggs) are produced in each event can be a good life history strategy (Roff, 1992). Having many reproductive years increases the probability that at least some will be favorable to the offspring, where potentially a much higher proportion survives than in the average year. This strategy is reflected in the high survival probability and fecundity of large pike.

Life History Theory: Basics

CC Horvitz, University of Miami, Coral Gables, FL, USA

Connection between Population Dynamics and Life History

There is a deep connection between population dynamics and life history, not surprisingly, since populations are comprised of individuals. "Population dynamics" refers to a time series of population size (and structure). At any one point in time, a population may be comprised of individuals of different ages or life stages. Individuals of different age or 'stage' may do different things; they may make different kinds of contributions to the size of future population and to the relative numbers of each age and stage in the next time period. Examples of 'stage' include: ontogenetic stage (immature vs. mature, larva vs. pupa, …), size (biomass, height, …), breeding status (nesting currently, prior mating experience, …), type of recruit (vegetative vs. sexual, …), or essentially any characteristic of an individual that can be measured at a point in time. Individuals can be represented in the future by themselves or their offspring, or both. Population dynamics thus depend upon the collective contributions of all the individuals of all ages and stages at each point in time. We model population dynamics by matrix projection methods and analyses (Caswell, 2001). The main variable of interest is the population size (and structure) at a given time and their dynamics. Time is measured from some initial point to some future point, not constrained by the lifetimes of individuals. The time line of the population intercepts individuals at different points of their lives and individuals come and go from the population.

'Life history,' in contrast, refers to the timing of 'key events' across the life cycle of individuals. Key events include death as well as milestones such as maturity, starting to reproduce, ceasing to reproduce, reproducing by different amounts, and may include changing form or location like entering and exiting dormant periods or migrating. Some events are of special interest for particular organisms. For trees in forests, for example, achieving canopy height (and thereby accessing constant high light) is a milestone. Folded into the idea of life history is that the occurrence of these key events is accompanied by changes in allocation of energy and time to different functions. Patterns of life history are diverse. Differences in timing of key activities is thought to be adaptive as it is thought to be related to expected differences in how environment varies over the life course of individuals. In this context variables of interest include the 'status' and 'activity' of the individual at a certain point in its life and the time (age) at which particular events occur. 'Status' refers to whether a particular 'event' has or has not yet occurred (or recurred) during the lifetime of the individual. Time for each individual is measured from birth. We model the process of individuals undergoing events and traversing life stages as a Markov chain process (Cochran and Ellner, 1992; Caswell, 2001). Each individual's life is a trajectory across time or a realization of the process, also called a sample path. Consideration of the trajectories of many individuals (or many sample paths) gives rise to the estimation of many different kinds of parameters.

Here how the same basic empirical data form the core quantitative basis for estimating both population dynamics and life history parameters is shown. Both realms of interest are grounded in having estimates for probabilities of 'status' change (e.g., from live to dead) and of 'stage' change (e.g., change in size) over a time step. The connection between the two realms can be established by clarifying the meaning of the time step and identifying a birth stage. To do this, matrix models have been used (both projection models and Markov chains) that classify individuals by age or stage and treat time as discrete, noting that discrete time formulations are relevant for a wide array of organisms. For organisms where birth and death occur at particular seasons, it is natural to model population and life history processes in discrete time. However, even when birth and death occur continuously over the year, census data are taken at discrete times; thus modeling population and life history processes from discrete time data are of interest for them as well.

Population Projection Structured by Discrete Age or Stage Classes

Populations are said to be structured when birth, death, and growth rates depend upon some trait(s) that characterize the individuals in a population. Commonly, populations are structured by age or stage which can be either continuous or discrete. Populations structured by discrete age classes are modeled by Leslie matrices (Leslie, 1945), whereas those structured only by discrete stage classes are modeled by Lefkovitch matrices (Lefkovitch, 1965). Some populations are structured by a combination of age and stage (Steiner *et al.*, 2014). This article focuses on populations structured by either discrete age categories or discrete stages. In either case, the matrix $\mathbf{A}$ has entries a_{ij} (j=column, i=row). Most entries provide the probability that individuals in the jth age (or stage) at time t survive and become individuals in ith age (or stage) at $t+1$. Some entries provide the number of individuals in the ith age (or stage) produced at time $t+1$ by individuals who were counted in the jth age (or stage) at time t. All matrix entries are average rates for individuals in a particular stage, they are expressed per capita per time step, i.e., survival rate, recruitment rate, etc. The matrix is used to project a population vector $\boldsymbol{n}(t)$ forward through time from any initial population vector,

$$\boldsymbol{n}(t+1) = \boldsymbol{A}\boldsymbol{n}(t) \qquad [1]$$

The vector has structure; it is the number of individuals in each age- (or stage-) class at a given time. The dimension of the matrix is the number of age- (or stage-) classes. Given certain characteristics of the matrix $\boldsymbol{A}$ (non-negative, irreducible,

 doi:10.1016/B978-0-12-800049-6.00091-3

primitive), there will be convergence asymptotically to a constant per capita growth rate (per time step) λ with a stable stage distribution $\boldsymbol{u}^*$ and a vector of reproductive values $\boldsymbol{v}^*$, given, respectively, by the dominant eigenvalue of the matrix with its corresponding right and left eigenvectors (Cohen, 1979).

Both kinds of matrices can be decomposed into a sum of two matrices, one that includes only the single time-step fates of already existing individuals $\boldsymbol{Q}$ (with entries q_{ij}) and another that includes only the single time-step production of new individuals $\boldsymbol{F}$ (with entries f_{ij}),

$$\boldsymbol{A} = \boldsymbol{Q} + \boldsymbol{F} \qquad [2]$$

The column sums of $\boldsymbol{Q}$ provide the probability of survival over one time step for each age (or stage), constituting the entries p_j of the vector $\boldsymbol{p}$. The corresponding entries $m_j = 1 - p_j$ in the vector $\mathbf{m}$ provide the probability of death for each age (or stage). The matrix $\boldsymbol{T}$ (with entries $t_{ij} = q_{ij}/p_j$) provides the probabilities of transitioning from age (or stage) j to age (or stage) i during the time interval t to $t+1$, conditional on surviving the time interval. The column sums of $\boldsymbol{T}$ are all 1s for any ages (or stages) that have nonzero survival.

The difference between Leslie and Lefkovitch matrices is structural, i.e., the permissible locations for nonzero entries. In Leslie matrices the only nonzero entries are just below the diagonal in the first sub-diagonal (all survivors advance by one age class) and in the top row (newborns are all produced into the first age class) (**Figure 1(a)**). In Lefkovitch matrices, any entry can be nonzero (**Figure 1(b)**). Survivors can potentially be in any stage at the next time step (stay the same, advance or regress when they survive); newborns may occur as different sizes or types. Consequently, for a Leslie matrix $\boldsymbol{A}$, the corresponding $\boldsymbol{F}$ has zeros everywhere except the top row (**Figure 1(c)**), $\boldsymbol{Q}$ has zeros everywhere except the first sub-diagonal (**Figure 1(e)**), and $\boldsymbol{T}$ has zeros everywhere except the first sub-diagonal which are all 1s (**Figure 1(g)**). While for a Lefkovitch matrix **A**, there are no such structural restrictions for the corresponding $\boldsymbol{F}$, $\boldsymbol{Q}$, and $\boldsymbol{T}$ (**Figures 1(d), 1(f),1(h)**), some populations are structured by continuous state variables in which case an integral linear operator rather than a matrix $\boldsymbol{A}$ is used to project the population forward in time (Easterling *et al.*, 2000; Ellner and Rees, 2006). There are analagous quantities to λ_{dom}, $\boldsymbol{u}^*$, $\boldsymbol{v}^*$, $\boldsymbol{F}$, $\boldsymbol{Q}$, $\boldsymbol{T}$, $\boldsymbol{p}$, and $\boldsymbol{m}$ in that context.

Markov Chains for Individuals Traversing the Life Cycle

The central idea: given the current state of an individual entity, there are probability rules that govern its state at the next point in time. These probability rules are contained in a matrix that governs/constitutes the Markovian process. When these rules are applied repeatedly over time to an individual entity, a sequence of states over time is experienced by each individual. The sequence of states for an individual is *a* 'sample path' or *a* 'realization of the process.' For some states, there is zero probability of exiting that state; these are called 'absorbing' states. The other states are called transient states. For example, in our application to demographic analysis, death is an absorbing state while particular ages or stages are not absorbing states; they are transient states. In the Markov chain literature (Iosfescu, 1980; Kemeny and Snell, 1976), the transition matrix is written so that the row state at t determines the column state at $t+1$, but here we follow Caswell (2001) and Keyfitz and Caswell (2005) in writing the transition from column state at t to row state at $t+1$, since here we are interested in drawing the connection to population projection matrices which are structured this way.

The Markov chain model for individual trajectories across the life span for the populations structured by either age or stage is

$$\boldsymbol{P} = \begin{bmatrix} \boldsymbol{Q} & 0 \\ \boldsymbol{m} & 1 \end{bmatrix} \quad [3]$$

where $\boldsymbol{Q}$ is the matrix of transient state transitions and $\boldsymbol{m}$ is the vector of transitions into death, the absorbing state. There is one absorbing state, death. The transient states are ages (or stages). This $\boldsymbol{Q}$ and $\boldsymbol{m}$ used in the Markov chain is the link from one realm of analysis to another since they are the ones described above, calculated from population projection matrices.

Age-Patterns of Survivorship and Fertility in Age-Structured Populations

Death – Consider the significant event of death. It happens to all living things and it happens once in a lifetime. Of interest for the individual at a given age is its 'status' (dead or alive). Considering a collection of individual life trajectories from a cohort point of view, where time starts at birth for each individual (age = 0), the collection of individual trajectories can be used to calculate the proportion still alive at age x ('survivorship' to age x, or l_x) which estimates the 'probability' that newborn individuals will survive to age x. Since life trajectories track individuals from one age to the next (= one time to the next), they also contain information on the probability that individuals of given age survive for one time step (p_x). Information about the 'probability of surviving' from one age to the next is also information about the 'probability of dying' ($m_x = 1 - p_x$) during the interval. Identified with each individual trajectory is the age of death. The mean or expected age of death for the collection of individual trajectories is also known as the 'life expectancy' from birth (e_0).

Reproduction – Consider the significant lifetime events of starting and stopping reproduction. Not all individuals reproduce during their lifetime. Some die before they reproduce. Of interest for the individual who is still alive at age x is not only its 'reproductive status' (reproducing or not), but also 'how many offspring' it will make during the age interval x to $x+1$ (the 'fertility at age x, or f_x). Each individual trajectory shows whether or not an individual reproduced before dying, as well as the ages of first reproduction and last reproduction for that individual. Considering a collection of individual life trajectories, the average contribution of each individual of the initial cohort to the production of offspring at that age is estimated by the probability that an individual is still alive weighted by the per capita fertility at that age, $l_x f_x$. Summing over all ages provides a measure of the expected number of offspring in the next generation for each individual of the initial cohort; it estimates 'population growth rate per generation' and it is known as the 'net reproductive rate,'

$$R_0 = \sum_x l_x f_x \quad [4]$$

'Generation' is a unit of time, but how long is a generation, how many time steps constitute a generation? Conceptually, the idea of generation time is the average separation in time between the birth of a mother and the birth of her children. Coale (1972) presented three distinct metrics, fully discussed by Keyfitz and Caswell (2005). The measure that focuses on what a cohort does over its lifetime, call it T_μ, weights the $l_x f_x$ by how many years have passed since the mother's birth (i.e., the mother's age), sums over all ages, and divides by R_0,

$$T_\mu = \frac{\sum_x l_x f_x}{\sum l_x f_x} \quad [5]$$

Later the focus will be on the one that relies on the relationship between per capita population growth rate per time step (λ) (obtained from the matrix analysis above) and per capita population growth rate per generation, $\lambda^T = R_0$. Then solve for T,

$$T = \frac{\log\ R_0}{\log\ \lambda} \quad [6]$$

Connecting life table parameters to Leslie matrix parameters – The life table schedule of age-specific survivorship l_x, the probability of surviving from birth to age x, for all ages after 0 ($l_0 = 1$ by definition), can be calculated as a product of annual survivals,

$$\begin{aligned} l_1 &= p_0 \\ l_2 &= p_1 p_2 \\ l_x &= p_{x-1} \ldots p_2 p_1 p_0 \end{aligned} \quad [7]$$

These annual survivals p_x (re-indexed to match matrix subscripts such that they start at p_1 rather than p_0) are found on the sub-diagonal matrix entries of the Leslie matrix **A** and its corresponding **Q**. The life table schedule of age-specific fertilities f_x (re-indexed to match matrix subscripts such that they start at f_1 rather than f_0) are essentially (we will assume they are) found in the top row of the Leslie matrix and its corresponding **F**. Depending upon the timing of reproduction with respect to the census interval, the actual matrix entries may be products of survivals of adults or juveniles with these

fertilities (see discussion of how birth pulse vs. birth flow, pre-breeding vs. post-breeding censuses affect the entries in the top row in Caswell (2001)).

Age-Patterns of Survivorship and Fertility in Stage-Structured Populations

Even when demographic rates are structured strictly by stage, individuals do have ages at particular times and cohorts have emergent age-patterns of survivorship and fertility. However, the probabilities of death and the probabilities and amounts of reproduction at each age are determined purely by the stage structure at that age.

Death – For purely stage-structured populations, the probability of death depends solely upon stage; for stage j this probability is $m_j = 1 - p_j$, where p_j is the annual probability of survival for a given stage given by the sum of the jth column of $\mathbf{Q}$. For a cohort then, the probability of survival at a given age p_x depends solely upon its stage structure at that age. The survival probability is essentially a weighted average of the p_js, where the weights are determined by what proportion of the cohort is in each stage. Imagine starting a cohort in a particular stage (or distribution of stages) at birth (age = 0), then use the $\mathbf{Q}$ matrix to project the cohort forward. The $\mathbf{Q}$ matrix acts on the stage structure of the cohort, transforming it at each age. As some individuals of each stage die, the cohort decreases in size at each age. Reshuffling of the survivors among stages is also governed by this matrix. Over the long term (at late ages), if there are any individuals remaining in the cohort, the stage distribution will reach a quasi-equilibrium, age-specific survival l_x will become stabilized (Steinsaltz and Evans, 2004) and instantaneous mortality rate ($\mu_x = \log(l_x) - \log(l_{x+1})$) will reach a plateau (Horvitz and Tuljapurkar, 2008) (**Figure 2**).

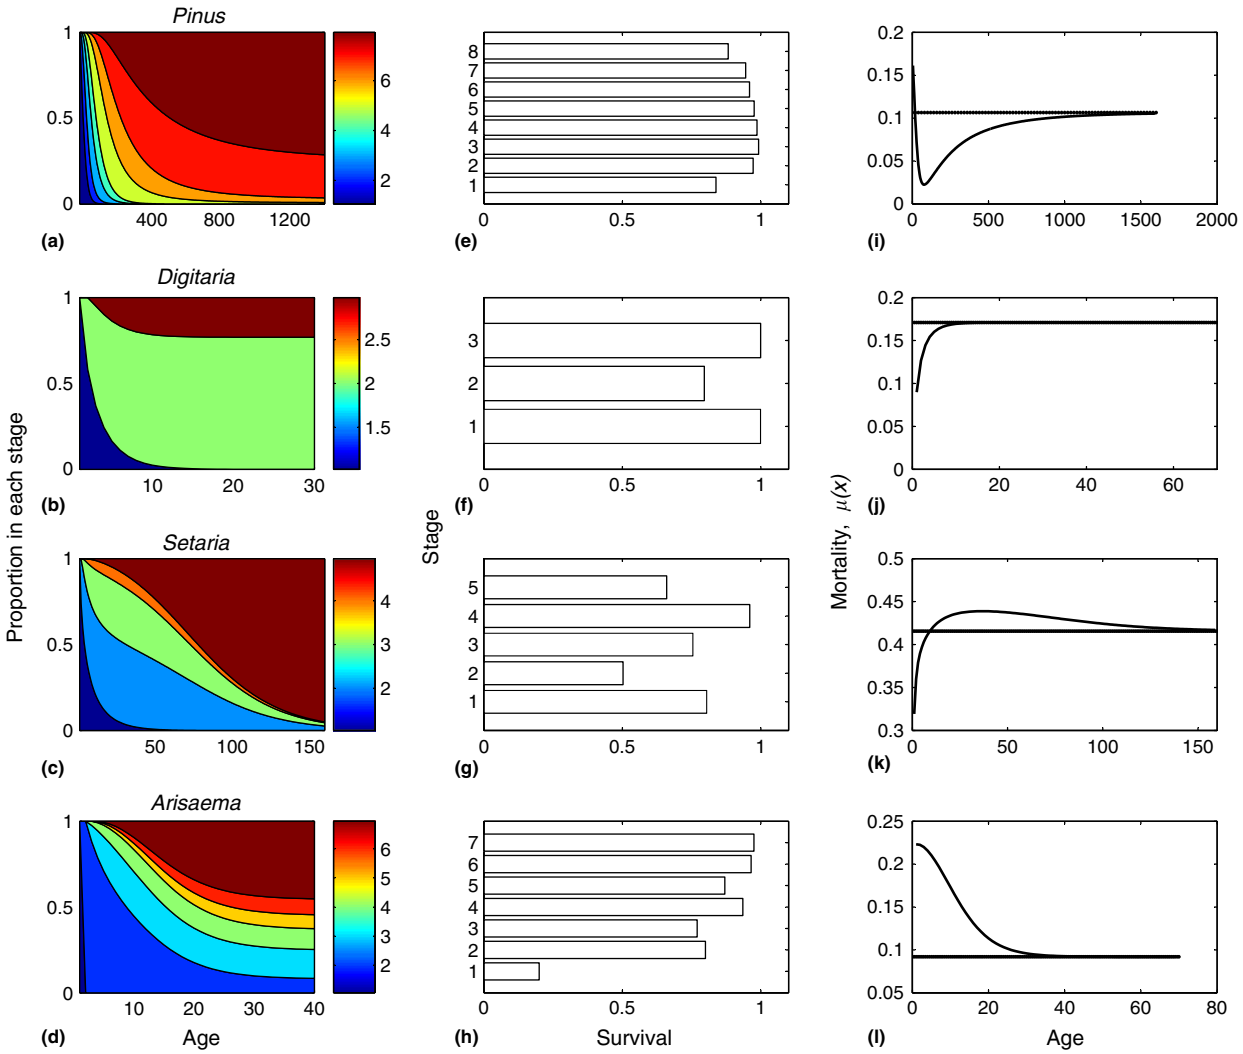

Figure 2 Stage distribution at each age for each of four plant species (*Pinus*, *Digitaria*, *Setaria*, and *Arisaema*) with stage-structured demographic rates (in (a)–(d)). One-period stage survival p_j for each species (in (e)–(h)). Age-specific instantaneous mortality μ_x (calculated from age-specific survivorship l_x as follows: $\mu_x = \log(l_x) - \log(l_{x+1})$) and the mortality plateau (dotted lines) for each species (in (i)–(l)). Reprinted from Horvitz, C. C., Tuljapurkar, S., 2008. Stage dynamics, period survival and mortality plateaus. American Naturalist 172, 203–215, with permission from ©2008 by C. C. Horvitz.

Survivorship to each age l_x, is the product of the prior age-specific survivals as in the age-structured case. Of course, underlying these cohort patterns are collections of individual trajectories. The Markov chain analysis below will provide further insights and a mechanism for calculating life expectancy, the average age at death.

Reproduction – For purely stage-structured populations, the probability of reproducing and the amount of reproduction depends solely upon stage; for stage j this is f_j the annual amount of offspring made by a given stage, it is an entry in **F**. For a cohort, the number of offspring expected to be produced at age x f_x depends solely upon its stage structure at that age and a kind of weighted average of the f_js across stages provides this metric. The Markov chain analysis below will provide further insights and a mechanism for calculating net reproductive rate and generation time.

Markov Chain Analysis for Stage-Structured Populations

Markov chain analysis is concerned in general with how long individual entities spend, on average, in different states before being absorbed and on first passage times to absorbing states. The examples presented here focus on death as the absorbing state, but other events of interest (like reaching a critical threshold size) can also be analyzed in the same framework. The framework is stochastic, so analytical methods provide not only means, but variances. Here the focus is on means only. More details and applications can be found in Caswell (2001) and Keyfitz and Caswell (2005). The general context is that the sequence of states experienced by individuals is governed by the state they start in and the process encapsulated in the matrix. Thus Markov chain analysis is ideal for providing insights on life history or anything related to timing. These include age-specific patterns of survivorship and fertility and life expectancy and similar life history parameters for stage-structured populations. One underlying feature of this analysis is that survival and transitions among stages at each time step are summarized in the $\boldsymbol{Q}$ matrix (the matrix of transient state transitions). Each year transitions are independent of previous years. The process is multiplicative over time.

Age-specific survivorship – Raising $\boldsymbol{Q}$ to the power x provides the probability that individuals from an initial cohort will be alive and be in a particular stage at age x, in other words, after x years. Therefore, to find out the total number still alive at age x, sum over all stages, meaning sum over the column. Considering each of the column sums of $\boldsymbol{Q}^x$, the sum of the first column provides the 'age-specific survivorship l_x' for individuals who were in stage 1 (that is to say, who were newborns) initially.

Life expectancy – The fundamental matrix in Markov chain analysis provides a measure of expected time in each state before being absorbed. It is defined as the summation of a series starting with the identity matrix and then having terms that are subsequently higher powers of $\boldsymbol{Q}$ and it is calculated as follows:

$$N = I + Q + Q^2 + Q^3 + \ldots$$
$$= (I - Q)^{-1} \qquad [8]$$

The entries in column 1 of this matrix are the number of years that an individual who was in stage 1 initially (a newborn) will spend in each stage before it dies. The summation over the whole column is the 'life expectancy of newborns,' e_0. The summation over each of the other columns is the 'remaining' life expectancy for individuals that start in each of the other stages.

Age-specific fertility – A matrix can be calculated from the **Q** and the $\boldsymbol{F}$ matrices that will provide the mean number of offspring of stage i produced at age x by an individual who began in stage j at age 0 (i.e., as a newborn). Start with $\boldsymbol{Q}^x$ and find all its column sums. Then normalize by dividing each matrix entry by its own corresponding column sum. So each resulting column is a measure of stage structure at age x for those who started in the stage of that column. Call that normalized matrix of stage structures $\mathbb{Q}(x)$ and multiply it on the left by the **F** matrix, essentially weighting fertilities by stage structure as follows,

$$\phi(x) = F\mathbb{Q}(x) \qquad [9]$$

The matrix entry $\phi(x)_{11}$ is the fertility for age x. Repeating this procedure for each age and harvesting the single entry of interest, obtain age-specific fertilities for the stage-based model (Caswell, 2001; Keyfitz and Caswell, 2005).

Net reproductive rate – A matrix $\boldsymbol{R}$ can be calculated from the fundamental matrix $\boldsymbol{N}$ and the $\boldsymbol{F}$ matrix. The entries r_{ij} provide the expected lifetime production of type i offspring by an individual who starts life in stage j,

$$R = FN \qquad [10]$$

$\boldsymbol{R}$ can incorporate reproduction by more than one means, for example seeds and vegetative offshoots. The dominant eigenvalue of $\boldsymbol{R}$ provides a measure of R_0, the net reproductive rate for the stage-structured population, since $\boldsymbol{R}$ projects the population from one generation to the next (Caswell, 2001; Keyfitz and Caswell, 2005).

Generation time – There are at least three measures of generation time for age-structured models. The one that most readily lends itself to stage-structured models is the one that relies on the relationship between per capita population growth rate per time step (λ) (obtained from the projection matrix analysis above) and per capita population growth rate per generation, $\lambda^T = R_0$, which was calculated in the previous paragraph. Then solve for T exactly as before in eqn [6],

$$T = \frac{\log R_0}{\log \lambda} \qquad [11]$$

Conclusion

Population projection matrices are clearly related to age-specific survivorship and fertility schedules of life tables, directly for age-structured populations and through Markov chain analysis for stage-structured populations. Connecting population projection matrices, life histories, life tables, and Markov chains for age- and stage-structured populations provides insight that populations are collections of individuals of different ages (or stages) at any given (externally defined) time, individuals each of whom has a particular life path. As key life

history events may occur at different ages for different individuals, this connection requires that we specify the relationship among age, stage, and (externally defined) time. Also revealed is the multiplicative nature across the lifetime of annual demographic rates for a cohort of newborns. Furthermore, elucidating these links in age-only or stage-only models (as done here) provides a context for further examination in greater depth of the joint effects of stage and age as well as for a definition of generation time that takes such joint effects into account (Steiner *et al.*, 2014).

Life History Trade-offs

IM Smallegange, University of Amsterdam, Amsterdam, The Netherlands

What Are Trade-offs and Why Do They Exist?

Trade-offs play a central role in life history theory and occur when a beneficial change in one trait comes at a (fitness) cost through a concurrent detrimental change in another trait. In life history terms, this entails that selection will act to simultaneously maximize the $l(x)$ and $m(x)$ schedules, which are, respectively, the probability of surviving from birth to the start of age class x and the expected number of offspring for a female in age class x (see 'What is a life history' in this article). However, selection is prevented from achieving this because of direct trade-offs between the $l(x)$ and $m(x)$ schedules, or because an indirect trade-off exists with a third trait. If there were no trade-offs, then selection would drive all traits correlated with fitness, and thereby the $l(x)$ and $m(x)$ schedules, to limits imposed by history and design (Stearns, 1989), resulting in so-called Darwinian demons that reproduce directly after being born, produce an infinite number of offspring and live forever. However, many, if not all, traits are well within these limits, which means that trade-offs must exist.

Trade-offs occur at both the phenotypic and genetic level, but can also be shaped by mechanisms that connect the latter two levels (e.g., physiological mechanisms that determine resource allocation to growth, survival, maintenance, and reproduction) (Stearns, 1989). Trade-offs can be divided into two groups: the first group comprises direct trade-offs between the $l(x)$ and $m(x)$ schedules, which arise through physiological constraints as energy is a limiting resource and allocation to one trait means deprivation of another. van Noordwijk and de Jong (1986) summarized this concept in their acquisition-allocation model (also called Y-model), which was first formulated by James (1974). Roff (2002) refers to this as the partitioning of resources model (after James (1974) and Riska (1986), who derived this model independently), as the variable-proportion model. The second group comprises indirect trade-offs, which occur when the trade-off between the $l(x)$ and $m(x)$ schedules is mediated by separate relationships that each schedule has with, for example, body size. For example, a positive correlation between offspring production and body size and a negative correlation between survival and body size will necessarily lead to a negative correlation between the $l(x)$ and $m(x)$ schedules.

Examples of Important Life History Trade-offs

The trade-off between 'current reproduction and survival' was the first trade-off to be analyzed (Williams, 1966). This trade-off is easy to visualize: reproductive individuals might be more vulnerable to predation as they are more visible, slower moving or less maneuverable. In addition, the energy diverted into reproduction might increase the risk of death, for example, through reduced immunocompetence. The empirical evidence for the existence of this trade-off, however, is mixed. In arthropods and nematodes, virgins and individuals that mate less live longer, but, in rats and mice, only one of four studies found that virgins live longer (Bell and Koufopanoum, 1986). Results from other taxonomic groups, including birds and insects, also give mixed results (reviewed in Stearns, 1989). Evidence for genetic trade-offs between survival and reproduction have also failed to reveal a general pattern. Results from breeding experiments also do not support the existence of this trade-off, while those from selection experiments do (Stearns, 1989).

Just as important a determinant of fitness as the effect of reproduction on survival is the direct effect of 'current reproduction on future reproduction.' Again, however, empirical studies investigating the existence of this trade-off show mixed results. In their overview of 11 laboratory studies (eight species) investigating the phenotypic correlation between current and future reproduction, Bell and Koufopanou (1986) listed only one study that found evidence for a negative correlation between the two traits. Field studies, mainly on birds, have been more successful in finding evidence for a negative relationship between current and future reproduction (Warner, 1984; Bell and Koufopanou, 1986). Gustafsson and Pärt (1990), for example, manipulated clutch sizes of one-year-old collared flycatchers (*Ficedula albicollis*) and monitored their reproductive output in the following 3 years. They found a negative correlation between current and future reproduction as bird pairs whose clutches were enlarged had smaller clutches over the next 3 years than control pairs. Breeding experiments have rarely found evidence of a negative correlation whereas selection experiments have been far more successful (Bell and Koufopanou, 1986).

The final example concerns the trade-off between 'offspring size and offspring number.' If we look across species, we find that some species produce thousands of small offspring (e.g., marine invertebrates such as bivalves and crustaceans), tens to hundreds of intermediate sizes offspring (e.g. most plants and insects), or only a few large offspring per reproductive event (e.g., most birds and mammals). The trade-off between offspring size and number plays an important role in explaining these differences in offspring size. This trade-off has been detected in many semelparous species (which reproduce only once in their lifetime) but has been detected less frequently in iteroparous species (e.g., many vertebrates and perennial plants that have multiple reproductive events) or in species with parental care (reviews in Roff, 1992; Fox and Czesak, 2000). Messina and Fox (2001) argue that one important reason for this discrepancy is that a negative relationship between offspring size and number is only expected to occur if the amount of resources available to invest into reproduction is fixed. However, in nature, this amount is often variable, for example, because individuals differ in their juvenile growth rate as a result of which they mature at different sizes, which in turn influences individual reproductive effort.

 doi:10.1016/B978-0-12-800049-6.00084-6

In summary, there is no general pattern of negative genetic or phenotypic correlations for the major life history trade-offs described here. It is therefore imperative to investigate whether a trade-off exists and not simply assume that it does.

Measuring Trade-offs

Trade-offs have been measured through field observations (e.g., Clutton-Brock *et al.*, 1982, 1983), in experiments conducted in the laboratory (e.g., Partridge and Farquhar, 1981) and in the field (e.g., Askenmo, 1979), through phenotypic correlations in the laboratory (e.g., Bell, 1984a,b), and through genetic correlations (e.g., Rose and Charlesworth, 1981a,b). Reznick (1985) divides these different methods into four categories (Reznick, 1985):

1. Phenotypic correlations: A correlation is measured between two traits at the level of the phenotype but there is no manipulation of the organism or of its environment.
2. Experimental manipulations: A single factor is manipulated in an experiment and all else is kept constant (or randomly assigned).
3. Genetic correlations from sib analysis: The genetic correlation between two traits is estimated using covariation between individuals within or between families, or using covariation between clones or inbred lines.
4. Genetic correlations from selection experiments: The genetic correlation between two traits is estimated from correlated changes in one trait in response to selection on another.

These different methods of measuring trade-offs have received criticism (Tuomi *et al.*, 1983; Partridge, 1987) and controversy (Bell, 1984a,b; Reznick *et al.*, 1986). Reznick (1985) argues that categories 1 and 2 are flawed because causation is inferred from observed correlations and because there is no demonstration that the trade-offs are under genetic control. Stearns (1992), in turn, classifies categories 2 and 4 as the most reliable and informative methods for measuring trade-offs. Roff (2002) argues that both phenotypic and genetic correlations are important in shaping the evolution of two traits in a trade-off if each trait is subject to selection. His argument is that, if we take a phenotypic correlation to be a component of the set of trade-offs that together determine fitness, then there is no problem with either category, although it is preferable to investigate a possible trade-off by manipulating the traits in question. Roff (2002) warns, however, that problems can arise if potentially confounding third variables are ignored, as this could lead one to infer an incorrect causal mechanism determining the trade-off. Finally, it is important to realize that trade-offs are contingent on conditions. If no evidence is found for a trade-off between two traits in a particular environment and at a particular time, this does not necessarily mean that the trade-off does not exist in general. First, trade-offs are often the result of physiological or ecological factors; and second, trade-offs may manifest themselves differently in different organisms, or differently across different environments within the same organism. This means that a life history trade-off is likely only apparent in an organism under a particular set of circumstances, for example, under conditions of stress (Reznick, 1985).

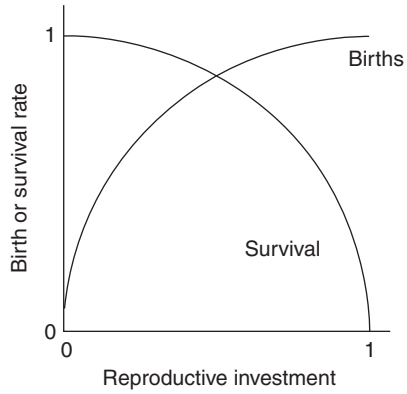

Figure 1 A schematic illustration of one of Schaffer's model of reproductive trade-offs. Reproductive investment varies from 0 to 1, at which point the individual produces the maximum possible number of offspring (birth rate equals 1) and the individual dies (survival rate equals 0). Other shapes are possible which affects reproductive investment. Modified from Schaffer, W.M., 1974. Selection for optimal life histories: The effects of age structure. Ecology 55, 291–303.

It is furthermore important to note that, when measuring trade-offs, one should not only focus on identifying the sign of the correlation between two life history traits – i.e., is there a negative correlation (in which case a trade-off is inferred), no correlation, or a positive one – but also on the shape of the correlation. The simplest shapes that a negative relationship between two traits can have include linear, concave, or convex (concave up) associations. Schaffer (1974) demonstrated theoretically that such differences in shape can critically influence predicted evolutionary responses. In his model of reproductive trade-offs, Schaffer (1974) plots reproductive investment at the current age against the probability of surviving to the next age (an example is shown in **Figure 1**). Which reproductive strategy is predicted to be optimal (e.g., semelparity or iteroparity) and what the optimal age for reproduction is, depends on the shape of the reproduction and survival curves. Werner and Anholt (1993) developed a model to investigate how the optimal foraging activity in the presence of predators depends on the shape of the trade-off between current and future reproduction. They found that, depending on whether the trade-off is of a concave or convex shape, the optimum allocation to current reproduction may stay the same, increase or decrease in response to the presence of predators. Hence any prediction on optimal life history strategies is possible but meaningless in explaining responses to perturbations unless the trade-off relationship can be specified.

Why Do We Observe a Positive Correlation Where We Expect a Negative One Between Traits?

Life history theory predicts negative correlations between traits such as survival and reproduction. However, observations often indicate that these traits are positively correlated, particularly when these are observations obtained from different

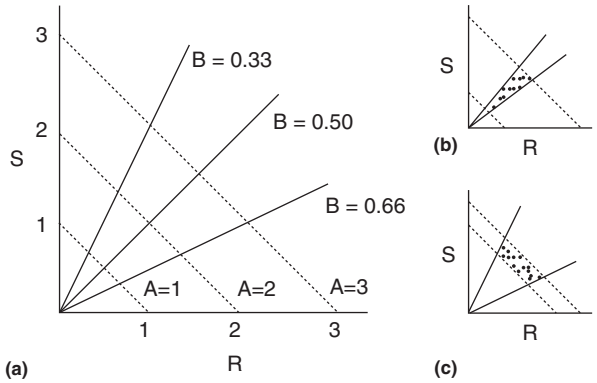

Figure 2 A schematic illustration of the partition of resources or acquisition-allocation model. The total amount of energy A that an organism can allocate to reproduction, R, and survival, S, is $A = R + S$. An individual i allocates a fraction B_i of energy A_i to reproduction: $R_i = B_i A_i$. Panel (a) shows different scenarios for different values of B (solid lines) and A (dashed lines). Panel (b) shows a scenario where variation in A is large between individuals and variation in B small; as a result there is a positive correlation between reproduction and survival. Panel (c) shows a scenario where variation in A is small between individuals and variation in B large, which results in a negative correlation between reproduction and survival. Modified from van Noordwijk, A.J., de Jong, G., 1986. Acquisition and allocation of resources: Their influence on variation in life history tactics. American Naturalist 128, 137–142 and Stearns, S. C., 1989. Trade-offs in life-history evolution. Functional Ecology 3, 259–268.

individuals within a population (Bell and Koufopanou, 1986). van Noordwijk and de Jong (1986) have shown how variation between individuals can lead to a positive, zero, or negative correlation between two traits. Their premise is based on their acquisition-allocation model (see above) in which each individual has a certain amount A of food available that can only be allocated to either reproduction, R, or survival, S (Levins, 1968; Sibly and Calow, 1986):

$$A = R + S$$

This model implies that all individuals allocate energy to R and S in the same manner. However, individuals typically differ in the amount of energy that they are able to acquire as well as in the fraction of the energy acquired that they allocate to reproduction, B, in which case we have:

$$R_i = B_i A_i, \text{ and}$$

$$S_i = (1 - B_i) A_i$$

where the subscript i indicates each individual. The sign of the correlation between the traits R and S depends on the relative degree to which each trait varies between individuals (van Noordwijk and de Jong, 1986) as is illustrated graphically in **Figure 2**. This illustration highlights the importance of asking critical questions when theory predicts a correlation between two traits to be negative and instead a positive correlation is observed. For example, how does variation in A and B change with changing environmental conditions in nature? Is between-individual variation in A higher than between-individual variation in B and vice versa? Answers to these questions are necessary to decide whether the trade-off in question plays an important role in the functioning of natural populations (Stearns, 1989).

Evolution of Life History Trade-offs

Although no one doubts the existence of trade-offs and the central role they play in the evolution of life history strategies, there is little understanding of how such trade-offs evolve (Chippendale *et al.*, 1996; Reznick *et al.*, 2000; Roff and DeRose, 2001; Roff, 2002). Roff and Fairbairn (2007) identified four issues that contribute to the lack of progress in understanding the evolution of trade-offs. The first issue is one of semantics: what exactly do evolutionary biologists mean by the term 'constraint'? Roff and Fairbairn (2007) suggest clearly distinguishing between using the term to denote a bias or to denote combinations of traits that are biologically not possible (e.g., unavailable to selection). The second issue concerns a misunderstanding of the central equation of the acquisition-allocation model (van Noordwijk and de Jong, 1986; **Figure 2**), which has led to incorrect predictions and invalid tests. That is, Roff and Fairbairn (2007) mathematically showed that the sign of the correlation between reproduction and survival (e.g., **Figures 2(b)** and **2(c)**) depends on more than only the relative variances in energy acquisition and allocation. The latter, however, is what authors commonly infer from the acquisition-allocation model (e.g., Brown, 2003; Ernande *et al.*, 2004). The third issue focuses on the difficulty of deriving accurate predictions on the evolution of trade-offs and the precise testing of these predictions, whereas the fourth issue deals with an essential ingredient for the evolution of trade-offs to occur: there has to be variation in a trade-off upon which selection can act. The latter raises the crucial question of what maintains variation in a trade-off. Roff and Fairbairn (2007) identify four candidate mechanisms for this (mutation-selection balance, antagonistic pleiotropy, correlated selection, and spatio-temporal heterogeneity in genetic variation), but, again there are few empirical studies to determine which mechanisms may be at play in nature. Addressing the four issues identified by Roff and Fairbairn (2007) is imperative to further progress in the study of life history trade-offs.

Life History and Life History Traits

The Atlantic salmon (*Salmo salar*) inhabits rivers and streams that flow into the northern Atlantic Ocean in Europe and enter the sea on the east coast of North America. Salmon spend part of their life-cycle feeding in the ocean but return to the streams where they hatched to spawn. They can live up to 11 years, with longer living individuals spawning several times during their lifetimes. In contrast, the Pacific salmons (*Oncorhynchus* spp.) occur in streams and rivers in North America and Asia that drain into the Pacific Ocean. Like the Atlantic salmon, Pacific salmons migrate to the ocean to feed and grow, and return to the streams where they hatched when they are 5–7-years-old; however, they spawn just once and then die.

The flatfish (*Hippoglossoides platessoides*) in the Grand Banks of New Foundland, Canada, grow slowly and reach an adult length of 60 cm, mature at about 14 years of age, can live for 30 years and have low reproductive rates. The same species of fish inhabiting waters off the coast of Scotland grow faster and mature earlier (3 yrs), have smaller body sizes (30 cm), live for 6 years, and have much higher reproductive rates compared to the flatfish inhabiting the Grand Banks (Roff, 2002).

The Asian elephant (*Elaphus maximus*) female is reproductively mature at 14 years of age, produces a single calf that weighs nearly 100 kg every seven years, and can live for a century. Under favorable environmental conditions, some species of vole (*Microtus* spp.) can attain reproductive maturity soon after they are weaned (about 1 month of age) and can produce litters of up to 12 small, altricial pups.

Why don't elephants produce four calves at each breeding attempt with each weighing 25 kg? Why don't voles produce fewer, larger and better-developed pups that may have better prospects of surviving to adulthood? How could a seemingly counter-productive strategy of dying after a single reproductive event have evolved in the Pacific salmons? Why do flatfish in the Grand Banks live for five times as long than those off the coast of Scotland? These are just a few examples of questions biologists ask about the diversity of life history patterns. Each species seems to do its own thing, and sometimes even individuals of the same species do different things depending upon the environment in which they find themselves. Understanding the causes and consequences of the mind-boggling diversity of life history patterns has long been a major focus of ecology and evolutionary biology.

So, how to define life history? A life history is the schedule of key events in an organism's life cycle, and is usually defined in terms of life history traits calculated across individuals within a population. Life history traits (also called *fitness traits*) are phenotypic characters that affect fitness, and include size at birth, age or size at maturity, and the sex ratio of offspring, and age- or stage-specific rates of growth, reproduction, survival, and investment in offspring (Stearns, 1992, 2000; Roff, 2002; Braendle *et al.*, 2011). Life history theory is a collection of ideas proposed to explain both the diversity of life history patterns, and the mechanisms by which natural selection has shaped life history traits. It is generally accepted that life histories are shaped by complex interactions between extrinsic ecological factors like species interactions and intrinsic factors that include trade-offs among life history traits and design and phylogenetic constraints. Because the currency of natural selection is fitness, and the focus of life history theory is traits that are directly related to fitness, life history theory has grown to provide an explicit link between ecology, genetics, and natural selection. Examples of questions life history theorists attempt to answer include (Stearns, 1992, 2000): Why are organisms small or large? Why do they grow slowly or rapidly? Why do they mature early or late? Why do they reproduce only once or many times during their lifetimes? Why do they produce small or large offspring? Why do they produce few or many offspring per reproductive attempt? Why do they have short or long life spans? Why must organisms get old, and ultimately die? And what are the fitness consequences of variation in life history patterns within a population?

Life Tables and Euler–Lotka Equation

Consider a hypothetical age-structured population in which survival and reproduction is dependent upon age. The hypothetical organism attains reproductive maturity at some age α (age at first reproduction), and continues to reproduce until some age ω (age of last reproduction). They may reproduce at some interval Υ (inter-birth interval), and at each reproductive attempt, produce ψ offspring (litter or clutch size). The life history of such an organism can be compactly summarized in a life table, which provide tabular summaries of age-specific survivorship and reproduction (Caughley, 1977; Stearns, 1992; Roff, 2002).

In its basic form, a life table consists of three columns: age (x), age-specific survivorship (probability at birth or hatching of surviving to age x, l_x), and age-specific fecundity (the average number of daughters born to a female of age x, m_x). Most vertebrate life tables tend to focus on fecundity of the female segment of the population, primarily because male reproductive output is difficult to measure. In cases where reproductive output of males can be accurately quantified, there is no reason why life tables cannot be compiled for males.

How does one go about compiling a life table? One can use any reasonable data and statistical approach that permits unbiased age-specific estimates of survivorship and fecundity. Caughley (1977) provides a thorough discussion of methods that can be used to derive l_x. The best approach is to capture, individually mark and follow a cohort from birth until death. One can then record the number of individuals alive at each successive age (n_x). Then l_x is obtained by dividing the number of individuals alive at age x by the original size of the cohort,

 doi:10.1016/B978-0-12-800049-6.00083-4

n_0 (i.e., $l_x = n_x/n_0$). Alternatively, but equivalently, one can record the number of individuals that die during each age interval (d_x). This information can then be used to calculate survivorship along with various other measures of age-specific survival (or its compliment, mortality) including age-specific survival (P_x) and mortality (q_x) rates. These quantities are related to each other as follows (Caughley, 1977):

$$l_x = \frac{n_x}{n_0} = \prod_{i=0}^{x} P_i$$

$$d_x = n_x - n_{x+1}$$

$$q_x = \frac{d_x}{n_x} = 1 - P_x$$

$$P_x = \frac{n_{x+1}}{n_x} = 1 - q_x.$$

Given any one of these variable, all others can be calculated as shown in **Table 1**.

Life tables compiled by following a cohort from birth until all members have died are called 'cohort life tables.' However, compiling cohort life tables can be very challenging, especially for long-lived organisms. Most ecological field studies last only a few years, yet many organisms live for tens or hundreds of years. Catching, marking and following members of a cohort can be logistically difficult and expensive. Because of these difficulties, most life tables for long-lived species are 'static life tables.' Static life tables are compiled from a snap-shot of the population, based on either the standing age distribution or age at death data. Static life tables assume a static (or stable) age structure of the population, and require that the population growth rate is known. The age-structure assumption is rarely met in free-living populations and the population growth rate can be challenging to measure (Caughley, 1977), and these constraints make static life tables of limited value for life history studies. For the remainder of this article we focus on cohort life tables.

The method of compiling cohort life tables discussed above assumes perfect detectability – that is, all individuals alive at a given point in time are detected and their identity accurately recorded. When the detectability is <1.0 (which is often the case in field studies), statistical estimation approaches that allow explicit consideration of imperfect detection, such as capture-mark-recapture (CMR) or live recapture – dead recovery methods should be employed to estimate survivorship (Lebreton *et al.*, 1992; Williams *et al.*, 2001). Life tables compiled using CMR-type approaches can be described as 'pseudo-cohort' life tables because they are often not compiled by following a real cohort, but are based upon individual-based data collected across multiple cohorts. For all practical purposes, pseudo-cohort life tables are just as good as cohort life tables, and do not require the stringent assumptions inherent in static life tables (Caughley, 1977).

Table 1 Calculation of survival (l_x and P_x) and mortality parameters (q_x and d_x) based on information collected by following a cohort of song sparrow chicks. See text for details

Age (x)	n_x	$l_x = n_x/n_0$	$d_x = n_x - n_{x+1}$	$q_x = d_x/n_x$
0	115	115/115 = 1	115 − 25 = 90	90/115 = 0.783
1	25	0.217	6	0.24
2	19	0.165	7	0.36
3	12	0.104	10	0.83
4	2	0.017	1	0.5
5	1	0.009	1	1
6	0	0	0	–

Source: Smith, J.N.M., 1988. Determinants of lifetime reproductive success in the song sparrow. In: Clutton-Brock, T.H. (Ed.), Reproductive Success. Chicago: University of Chicago Press, pp. 154–172.

Methods of estimating age-specific fecundity rates (m_x) also vary widely depending on the study species, methods of tracking or monitoring study organisms, and time and resources at one's disposal. For example, age-specific fecundity rates for black bears (*Ursus americanus*) can be estimated by radio-tracking a large number of females of known age, following them to their winter dens where they give birth, and counting the number of cubs (McLean and Pelton, 1994; Garrison *et al.*, 2007). Reproductive rates of yellow-bellied marmots (*Marmota flaviventris*) can be determined by following individually marked females as they emerge from natal burrow with pups (Schwartz *et al.*, 1998). In contrast, reproductive rates of Soay sheep (*Ovis aries*) can be estimated by recording reproductive output of individually marked females during the birth-pulse (Clutton-Brock and Pemberton, 2004). Fecundity for some birds has been estimated by recording reproductive output of individually marked birds in artificial nest boxes or natural nesting sites. More invasive methods (e.g., based on shot samples) can be used for some harvested species (e.g., Caughley, 1970).

Regardless of the field or estimation methods employed, what is really needed is an estimate of the average number of daughters produced by a female of age x, m_x. Once the m_x are estimated, this information is combined with the table of age-specific survivorship l_x to construct a life table.

Nothing in nature remains constant in time for very long, but for the sake of simplicity, let's assume that l_x and m_x are constant with time. This implies that the environment is constant and that population is sufficiently large such that demographic stochasticity has no discernable effects. Under this assumption, the population will ultimately converge to a stable age distribution (SAD) – that is, the proportion of organisms of different ages remains constant over time, and the number of individuals of each age class as well as the entire population grow (or decline) at a constant rate, r. Under these conditions, l_x and m_x are related to the per capita or instantaneous growth rate r via the Euler–Lotka equation:

$$1 = \int_{\alpha}^{\omega} l_x m_x e^{-rx} dx$$

In practice, the discrete time version of the equation is often used:

$$1 = \sum_{\alpha}^{\omega} l_x m_x e^{-rx}$$

The Euler–Lotka equation, also called the characteristic equation or the basic equation, derived in a population context by Lotka (1924, 1956), links r to its determinants (l_x and m_x), and forms the foundation of the stable age theory that underlies much of modern plant, animal and human demography.

Under the assumptions of large population size and constant l_x and m_x, the 'per capita' population growth rate r (also called the instantaneous population growth rate and the Malthusian parameter) can be calculated iteratively as the solution to the Euler–Lotka equation (i.e., the value of r that makes the equality true); $r<0$ implies a declining population, whereas $r>0$ implies an increasing population. Note that r is asymptotic population growth rate assuming the population is at equilibrium and that l_x and m_x are constants. The Euler–Lotka equation also permits calculation or approximation of several biologically important quantities including the net reproductive rate, generation time, the SAD, reproductive value and age-specific life expectancies (Stearns, 1992; Charlesworth, 1994; Caswell, 2001; **Box 1**).

The net reproductive rate (R_0) is the average number of daughters produced by a female over her lifetime and is given by:

$$R_0 = \sum l_x m_x$$

Thus, R_0 is the sum of age-specific fecundity 'weighted' by the probability at birth of surviving to that age. $R_0>1$ implies that, on average, each female more than replaces herself with female offspring, and $R_0<1$ implies she does not; these correspond respectively to increasing ($r>0$) or declining ($r<0$) population size. R_0 is consequently a measure of the 'per generation' population growth rate. This definition of R_0 implies that a 'generation' can be defined as the time required for a population to grow by a factor of R_0, and can be characterized with the relationship

$$R_0 = e^{rG}, \text{ or } G = \frac{\ln R_0}{r}$$

Another commonly used measure of generation time, referred to as the 'cohort generation time,' is defined as the mean age at reproduction of a cohort of females, and is calculated as (Charlesworth, 1994):

$$T_0 = \frac{\sum x l_x m_x}{\sum l_x m_x} = \frac{\sum x l_x m_x}{R_0}$$

Finally, the generation time is also defined as mean age of the mothers of a new-born cohort at SAD. This measure of generation time can be calculated as:

$$T = \sum x l_x m_x e^{-rx}$$

Charlesworth (1994) notes that T arises naturally in different contexts, and argues that it provides the most appropriate measure of generation time. T has also been used to quantify the relative 'tempo' of life history along a fast–slow continuum (e.g., Jones *et al.*, 2008). Species that have short generation lengths tend to live fast lives and die young, while those characterized by long generation lengths live slow lives and reach older ages.

Once at the SAD, the proportion of individuals in different age classes will not change over time. This distribution is given by:

$$c_x = \frac{e^{-rx} l_x}{\sum_x e^{-rx} l_x}$$

Box 1 Example calculation of *per capita* population growth rate (or Malthusian parameter) and related quantities using the life table method

Barkalow *et al.* (1970) compiled age-specific survivorship (l_x) and fecundity (m_x) for a Gray squirrel (*Sciurus carolinensis*) population (reproduced below). We use these data to illustrate calculation of various life history quantities.

Life table data for a gray squirrel population in North Carolina, USA

Age (x)	l_x	m_x	l_x*m_x	l_x*m_x*x
0.0	1.000	0.000	0.000	0.000
1.0	0.253	1.280	0.324	0.324
2.0	0.116	2.280	0.264	0.529
3.0	0.089	2.280	0.203	0.609
4.0	0.058	2.280	0.132	0.529
5.0	0.039	2.280	0.089	0.445
6.0	0.025	2.280	0.057	0.342
7.0	0.022	2.280	0.050	0.351
Sum			1.120	3.128

As described in the text, the net reproductive rate is calculated as $R_0 = \sum l_x m_x$; we need only to multiply l_x and m_x columns, and add them up! For this squirrel population, $R_0=1.12$. So, on average, each female produces 1.12 daughters during her lifetime, implying that the population is increasing at the rate of 12% per generation. But how long is a generation? We find answer to this question by calculating the generation time for this population. There are several measures of generation time (see text); for this example, we will use a simple measure that is easy to calculate: $T_0 = \frac{\sum x l_x m_x}{R_0}$. All we have to do is to multiply x, l_x, and m_x columns together, and divide the sum by R_0 which we have calculated already. From the table above, $T_0=3.128/1.120=2.79$ years. So, we know that the population is increasing approximately 12% every generation (=2.79 years), which allows us to calculate the approximate value of *per capita* population growth rate: $r \approx \ln(R_0)/G = \ln(1.12)/2.79 = 0.040$.

Calculation of other quantities discussed in the text (e.g., stable age distribution, reproductive values) requires the exact value of r, which in turn can be found by solving the Euler–Lotka equation: $1 = \sum_\alpha^\omega l_x m_x e^{-rx}$ This can be easily accomplished by using software packages such as R or MATLAB; one should obtain identical results regardless of the software used. Using the example R code, we find the exact value of r to be 0.041 – the approximate value was very close indeed! The following R script can be used to solve the Euler–Lotka to find the exact value of r.

```
#Define the Euler-Lotka equation:
lotka=function(lx, mx, x, r) {y=(1 - sum
(lx*mx*exp(-r*x))) return(y)}
#Call R function "uniroot" to find the
root; r_approx is the approximate #value of r
as calculated #above
interval=c(r_approx - 0.5, r_approx+0.5)
r_exact=uniroot(lotka, interval=interval,
lx=lx, mx=mx, x=x)$root
```

Age-specific reproductive value v_x quantifies the relative contribution of females of different ages to population growth. It can be calculated as:

$$v_x = \frac{e^{r(x-1)}}{l_x} \sum_{y=x}^{\infty} e^{-ry} l_y m_y$$

In many applications, the –1 is omitted from the first exponent; this causes reproductive value for each age class to be off by a factor of e^r (Roff, 2002). This omission makes no difference because v_x is often expressed relative to the reproductive value of youngest age class such that $v_0 = 1$. Reproductive value can also be written as the sum of current reproduction and expected future (or residual) reproductive value (Williams, 1966; Stearns 1992). This decomposition can be useful in the context of costs of reproduction, especially those pertaining to the trade-off between current reproduction and future reproductive potential.

Finally, given l_x, one can calculate the age-specific life expectancy, E_x, which is an estimate of how much longer an individual of age x is expected to live given that it has already survived to age x (Charlesworth, 1994):

$$E_x = \frac{\sum_{y=x}^{\infty} l_y}{l_x}$$

A slightly different measure of life expectancy considers survivorship to the mid-point between age x and $x+1$ in the numerator (as opposed to survivorship to age x):

$$E'_x = \frac{\sum_{y=x}^{\infty} L_x}{l_x}$$

where

$$L_x = (l_x + l_{x+1})/2$$

Much demographic theory has been developed to study dynamics and persistence of populations of specific species. This means all of the quantities that can be calculated based on the stable age theory have a natural population ecological interpretation. For example, r quantifies instantaneous asymptotic growth of the whole population, while c_x gives the proportion of organisms at age x at the SAD, and R_0 measures per generation finite population growth. Much of the same theory applies to life history studies as well as to population growth studies; however, the quantities can have different interpretations. When applied in the life history context, they no longer refer to populations of a species, but instead are often applied to specific genotypes and strategies (Stearns, 1992). For an allele to spread through a population, individuals with genotypes that includes that allele must survive and reproduce more than competitor genotypes without the allele. Similarly, the fittest strategy will have highest value of r. The same theory can be applied in both population dynamic and life history contexts, but the results must be interpreted with respect to the group of organisms under focus.

Second, the stable age theory based on the life table approach is, in the strict sense, only appropriate for age-structured populations where survival and fecundity rates depend upon age. However, in many biological populations survival and reproductive rates are affected more strongly by something other than chronological age (Caswell, 2001). For example, some species are naturally structured by discrete life history stages (e.g., eggs, larvae, pupae, and adults in insects). Some plants and invertebrates have complex life histories, produce multiple types of offspring and the progression of life does not proceed deterministically as is observed in age-structured populations of birds and mammals. In other species, survival and reproductive rates may be strongly influenced not only by chronological age but also by some quantitative character like body mass, body size or stem diameter. For populations structured by discrete stages, or those exhibiting complex life histories, matrix population models provide a flexible and powerful framework for population modeling and estimating r (or its discrete time analogue, $\lambda = e^r$) and R_0 (Caswell, 2001). For populations in which rates are influenced by quantitative characters (e.g., body mass, body length, diameter), integral projection models (IPMs) offer similar tools (Easterling *et al.*, 2000; Ellner and Rees, 2006; Coulson, 2012). In later chapters we cover both classes of model, and provide examples of their application.

Third, much of the stable age theory – whether based on life tables, matrix models or IPMs – is applicable to populations inhabiting constant, unlimited environments. All quantities calculated from these analyses are 'asymptotic' measures and assume that (e.g., Roff, 2007, 2010): (1) survival and reproductive rates (or more generally, vital demographic rates) are constant over time, such that the population ultimately converges to a stable age, stage, or mass distribution. Both the entire population, and the size of each age or stage class, will grow at the same rate r (or it discrete time equivalent $\lambda = e^r$); (2) there are no stochastic, density-dependent or frequency-dependent effects on vital rates; and (3) the population is sufficiently large so that demographic stochasticity can be ignored. When these assumptions are violated, demographic or evolutionary quantities calculated based on stable age theory (e.g., r, R_0, E_x) should be interpreted with caution.

Many plants and animals occur in small numbers, so 'demographic stochasticity' may not always be ignored. Most natural populations are subject to the vagaries of nature, with components of the environment varying unpredictably with time, space or both ('environmental stochasticity'). Most living organisms inhabit finite environments and their growth will ultimately cease as the resource needs of the population exceed what the environment can provide; populations must cease to grow when that happens ('density-dependence'). Finally, the contribution of a character (genotype or phenotype) to the next generation often depends upon the frequency of that character in the population ('frequency-dependence') (Ayala and Campbell, 1974). Despite these restrictive assumptions, analyses based on stable age (stage, or mass) theory have provided the foundation of much of life history theory. Nonetheless, theoretical advances have been made that permit comparable analyses in the presence of demographic and environmental stochasticity, and density- and frequency-dependence (Tuljapurkar, 1990; Caswell, 2001; Rees and Ellner, 2009; Coulson *et al.*, 2010; Roff, 2010; Coulson, 2012). However, the complexity of models increases rapidly as new processes are included, and results obtained from them can be more challenging to interpret when compared to

those obtained from stable age (stage, or mass) theory-based analyses.

The Fitness Concept

Much of life history theory is concerned with identifying the fittest life history for a particular situation. For example, under what circumstance will a slow life history strategy outcompete a fast one? The answer to this question depends upon the relative fitnesses of the competing strategies. The fittest life history will always win. Unfortunately, there is no single measure of fitness that will always identify the fittest life history. Under the assumptions of stable age theory, and the absence of density- or frequency dependence, the Malthusian parameter r (or $\lambda = e^r$) is the appropriate measure of fitness. However, quantifying fitness in the presence of environmental stochasticitcty, and density- or frequency dependence is rather challenging. Fitness measures appropriate under such circumstances vary widely, and have been thoroughly discussed in the literature (e.g., Jong, 1994; Brommer, 2000; Roff, 2002, 2007, 2010; Metcalf and Pavard, 2006).

Trade-Offs and Constraints

Individuals are not always able to simultaneously maximize all components of fitness. If they could, we would see Darwinian demons – species with infinite lifespans producing infinite numbers of offspring starting immediately after birth (Law, 1979). However, such evolutionarily 'ideal' organisms do not exist because individuals are unable to simultaneously maximise all components of fitness. Individuals consequently trade-off different elements of their life history, within developmental or genetic constraints underpinning life history traits. The fittest life history is the point along this trade-off where fitness is maximized (Partridge and Harvey, 1988; Stearns, 1989, 1992).

Smallegange, later in this volume, provides an in-depth treatment of trade-offs.

Analytical Framework

Classical life history theory treats evolution of life history traits as an optimization problem (Stearns 1992, 2000; Roff, 2002). It assumes that life history patterns are determined by an interaction between extrinsic environmental (ecological) factors and intrinsic trade-offs and constraints including design and lineage-specific constraints. Extrinsic environmental factors are thought to shape life histories through their effects on age- or stage-specific survival, reproduction, and growth rates, subject to trade-offs and constraints. The 'Evolutionarily Stable Life History Strategy' (ESS) is the strategy that maximizes fitness. This approach to modeling life history evolution typically necessitates (1) an unambiguous definition of fitness; (2) a model that connects life history traits to fitness; (3) functional (or otherwise explicit) relationship among life history traits that represent trade-offs; (4) boundary conditions, representing developmental, design or lineage-specific constraints; and (5) optionally, relationships between intrinsic and/or extrinsic factors and life history traits. Each of these aspects is covered in chapters later within this section.

Linkage Disequilibrium: Population Genetics of Multiple Loci

RM Single, University of Vermont, Burlington, VT, USA
G Thomson, University of California, Berkeley, CA, USA

Glossary

Disease association A genetic locus shows an association with a disease when there is a difference in allele or genotype frequencies between an ethnically matched set of patient and control samples.

Hitchhiking The 'hitchhiking effect' refers to genetic changes at 'neutral' loci which are not directly subject to selection, but can exhibit changes in allele frequencies and linkage disequilibrium due to their close physical presence to a selected locus. As an approximate generality, significant effects at a neutral locus are seen if the recombination fraction between the neutral and selected loci is smaller than the order of magnitude of the selected differences at the selected locus (Thomson, 1977).

Permutation test A permutation test is a type of statistical randomization test where the distribution of the test statistic under the null hypothesis is obtained by calculating all possible values of the test statistic (or a random subset thereof) based on shuffling the labels of the observed data. For LD studies, this is accomplished by randomly permuting the allele names at one locus, thus imposing the null hypothesis of no association, and recalculating the measure of LD for each rearrangement.

Recombination fraction Recombination refers to the shuffling of genetic material between pairs of homologous paternal and maternal chromosomes. The recombination fraction θ is calculated as the proportion of combinations of alleles in the offspring not seen in the parents. For loci which are very closely physically linked θ is very close to zero, while the maximum value of θ is 0.5 (50%).

Stratified or conditional analyses When two or more loci in a genetic region show an association with a disease, conditional analyses may indicate the primary effect. If the two loci are not 100% correlated, it is possible to stratify analyses on variation at one locus (performing a separate analysis for each subset at the conditioned upon locus) in order to help distinguish which locus is more likely to be directly involved in disease risk.

Causes of Linkage Disequilibriuim

Linkage disequilibrium (LD), also known as gametic disequilibrium, is the nonrandom association of alleles at two or more loci (see e.g., Slatkin, 2008). Patterns of LD are important to consider in evolutionary biology as well as medical genetic studies. LD can be created by various evolutionary factors: selection (including disease) either directly on one or both loci, or indirectly via a hitchhiking event, migration and admixture, inbreeding, or genetic drift. The most likely cause though is historical – when a new mutation arises there is a nonrandom association created with respect to variation at other polymorphic loci. This association is broken down over time by recombination, at a rate per generation of $(1-\theta)$ for neutral loci, where θ is the recombination fraction. The relationship between LD and the recombination fraction has been used to develop methods for dating mutations based on allele frequencies (Slatkin and Rannala, 2000). LD can remain for a very long time between loci which are physically very close (closely linked loci). This fact is used for mapping mutations related to disease associations and was part of the impetus for the International HapMap Project. This project revealed the block-like structure of LD across the genome. Note, however, that although rare, unlinked markers may show significant LD; also very closely linked loci may be in linkage equilibrium.

The original models of population genetics dealt chiefly with single loci, so that the genome was regarded as a collection of individual independent loci each undergoing its separate evolution. Theoretical and simulation studies of selection and of two- and three-locus systems demonstrated that LD of alleles could be maintained in a stable polymorphism (see Feldman *et al.*, 1974 for references). Simulations were made of multi-locus systems involving more loci and of simple selection schemes (Lewontin, 1964; Franklin and Lewontin, 1970) and it was thought that LD might be quite ubiquitous across the genome, but this turns out not to be the case.

The hitchhiking effects produced on the allele frequencies and LD of linked neutral loci as a selected locus evolves toward its equilibrium value were also studied (Smith and Haigh, 1974; Thomson, 1977; Stephan *et al.*, 2006). As an approximate generality, significant effects on the neutral locus were seen if the recombination fraction between the neutral and selected loci is smaller than the order of magnitude of the selected differences at the selected locus. Further, significant LD could be generated between neutral loci that initially showed no LD (Thomson, 1977).

Migration and admixture of populations with different genetic profiles can create transient LD. Again, this will be maintained for a longer time the more closely linked the loci are. The human leukocyte antigen (HLA) system in the human immune system is known for its strong and extensive LD. Distinguishing among demographic and selective explanations for patterns of variation observed with HLA genes is a challenge (Meyer and Thomson, 2001; Meyer *et al.*, 2006; Single *et al.*, 2007a). However, many features of HLA LD patterns and allelic and amino acid variability implicate selection acting on the classical HLA class I and II loci (summarized in Meyer and Thomson, 2001).

Measures of Linkage Disequilibrium Strength

The definition of the LD parameter D_{ij} (also written as $D_{A_iB_j}$) of nonrandom association between a pair of alleles A_i and B_j at two loci (A and B) is the difference between the observed (or estimated) haplotype frequency ($f_{ij} = f(A_iB_j)$) and that expected under random association of the two alleles (linkage equilibrium). If the allele frequencies are given by p_{A_i} and p_{B_j}, then $D_{ij} = f_{ij} - p_{A_i}p_{B_j}$ (see **Table 1**, line 1). While this is the base of all measures of LD, defining the 'strength' of any observed nonrandom association is complicated by the fact that the maximum value D_{ij} can take is a function of the observed allele frequencies. In the bi-allelic case, the constraints based on allele and haplotype frequencies (see **Table 1**, footnote b) make it possible to characterize LD with a single disequilibrium parameter D, having an arbitrary sign depending on which are the focal alleles, since $D_{11} = -D_{12} = -D_{21} = D_{22}$.

There are several normalized measures of the strength of LD for 'bi-' and 'multi-allelic data' (Hedrick, 1987; Lewontin, 1988). Each of these statistics represents a single summary of multidimensional data, capturing different aspects of the underlying LD, and has different strengths and weaknesses for addressing specific research questions. The two most common measures of the strength of LD are: (1) the normalized measure of the individual LD values (Lewontin, 1964), $D_{ij}' = D_{ij}/D_{\max}$ (**Table 1**, line 2 for details); and (2) the correlation coefficient r for 'bi-allelic' data, often reported as $r^2 = D_{ij^2}/(p_{A_1}p_{A_2}p_{B_1}p_{B_2})$.

For bi-allelic data, $D' = 1$ whenever one or more of the four possible haplotypes are 'not' observed, irrespective of the expected frequencies. In contrast, r directly measures the correlation coefficient of the bi-allelic variation at two loci. Specifically, $r = 1$ only when the allelic variations at the two loci show 100% correlation, i.e., when both loci have equal allele frequencies and only two complementary haplotypes are observed. This correlation property is of interest to many research questions. For example, if two loci show associations with a disease but r is close or equal to one, then there is little or no variation between them that can distinguish which is more likely to be directly associated with disease risk. In other situations stratification or conditional analyses may allow testing for risk heterogeneity between two potentially disease predisposing genetic variants. For illustration, consider an example with $f_{11} = 0.2$, $f_{12} = 0.3$, $f_{21} = 0$, $f_{22} = 0.5$ for the A_1B_1, A_1B_2, A_2B_1, A_2B_2 haplotypes, respectively. $D' = 1$, since not all haplotypes are observed. However, the value of $r = 0.5$ reflects the variation at the B locus on haplotypes carrying A_1, and variation at the A locus on haplotypes carrying B_2.

Hedrick (1987) extended the D' measure for multi-allelic data as a weighted average over all alleles at each locus of the individual normalized LD values (see **Table 1**, line 4). The multi-allelic extension of the r^2 measure is denoted W_n^2 (see **Table 1**, line 5). In the statistics literature it is known as Cramer's V statistic (Cramer, 1946), defined on the contingency table relating two categorical variables and is a reexpression of the Chi-square statistic, normalized to be between zero and one (Hill, 1975; Hedrick, 1987; Single *et al.*, 2007b).

When there are 'different numbers of alleles' at the two loci, the direct correlation property mentioned above for the r measure is not retained by its multi-allelic extension W_n. The complementary pair of conditional 'asymmetric' LD (ALD) measures, $W_{A/B}$ and $W_{B/A}$ (see **Table 1**, line 6) was developed to extend the W_n measure, and is especially useful when there are 'different' numbers of alleles at the two loci (Thomson and Single, 2014). This leads to cases where W_n may equal or be close to one while one of the two ALD measures is substantially less than one. For example, consider a scenario with two and three alleles at the first and second loci, with $f_{11} = 0.3$, $f_{22} = 0.5$, $f_{23} = 0.2$ for A_1B_1, A_2B_2, and A_2B_3 haplotypes. $W_n = 1$, however there is variation at the B locus on haplotypes containing the A_2 allele. The correlation cannot be 100% when the number of alleles at the two loci differs. In this example, the two ALD measures reflect that while there is no variation of A locus alleles on any of the haplotypes conditioned on the B locus alleles ($W_{A/B} = 1$), there is variation at the B locus on haplotypes carrying A_2 ($W_{B/A} = 0.73$). The ALD measures show that with appropriate sample size, stratification analyses could

Table 1 Linkage disequilibrium and genetic diversity measures

Description	*Definition of measures*[a]
1. Pairwise multi-allelic LD[b]	$D_{ij} = f_{ij} - p_{A_i}p_{B_j}$
2. Individual normalized LD[c]	$D_{ij}' = D_{ij}/D_{max}$
3. r^2 (bi-allelic)	$r^2 = D_{ij}^2/(p_{A1}p_{A2}p_{B1}p_{B2})$
4. Multi-allelic D' extension	$D' = \sum_i\sum_j p_{A_i}p_{B_j}\lvert D_{ij}'\rvert$
5. Multi-allelic r^2 extension[d] (overall LD squared)	$W_n^2 = \left[\sum_i\sum_j D_{ij}^2/\left(p_{A_i}p_{B_j}\right)\right]/\min(k_A-1,\ k_B-1) = [X_{LD}^2/2N]/\min(k_A-1, k_B-1)$
6. Multi-allelic squared ALD[e] (overall asymmetric LD squared)	$W_{A/B}^2 = \left[\sum_i\sum_j\left(D_{ij}^2/p_{B_j}\right)\right]/(1-F_A)$
	$W_{B/A}^2 = \left[\sum_i\sum_j\left(D_{ij}^2/p_{A_i}\right)\right]/(1-F_B)$

[a] Summation is over all i=1, 2, …, k_A and j=1, 2, …, k_B, where k_A and k_B are the number of alleles respectively at the A and B loci. The observed sample size is denoted by N individuals ($2N$ alleles/haplotypes).

[b] $\sum_j D_{ij} = 0,\ \sum_i D_{ij} = 0,\ \sum_j f_{ij} = p_{Ai},\ \sum_i\sum_j f_{ij} = 1$

[c] $D_{\max} = \min\left[p_{Ai}(1-p_{Bj}), (1-p_{Ai})p_{Bj}\right]$ if $D_{ij} > 0$

$D_{\max} = \min\left[p_{Ai}p_{Bj}(1-p_{Ai})(1-p_{Bj})\right]$ if $D_{ij} < 0$. The range of D_{ij}' is (–1, 1).

[d] The range of W_n^2 is (0, 1).

[e] F_A and F_B are expected homozygosity values under Hardy–Weinberg proportions: $F_A = \sum_i p_{A_i}^2$ $F_B = \sum_j p_{B_j}^2$.

be carried out for specific comparisons. An appealing property of the ALD measures is that $W_{A/B} = W_{B/A} = W_n$ when there is symmetry in the observed data and thus for bi-allelic single nucleotide polymorphisms (SNPs).

Several conditional LD measures have been proposed for mapping disease predisposing genes via the association of marker genes near the putative disease predisposing locus (Nei and Li, 1980; Chakravarti *et al.*, 1984; Hudson, 1985; Guo, 1997). The difference in proportions statistic, $d_* = (f_{A_2B_1}/p_{A_2} - f_{A_1B_1}/p_{A_1})$, of Nei and Li (1980) measures the association between alleles at a marker locus (B) and a disease locus (A). It is applicable to study designs of rare diseases where individuals are not randomly sampled from a single population, but sampling intensity varies within disease categories (Kaplan and Weir, 1992; Maiste and Weir, 1992). Other conditional measures have been applied related to the presence and strength of disease risk in a genetic region (Levin and Bertell, 1978; Bengtsson and Thomson, 1981). Devlin and Risch (1995) summarize these and other measures used in LD mapping.

Multi-Locus Linkage Disequilibrium Measures

When a large number of loci are involved, it is common to use graphical techniques to explore patterns of LD based on all pairwise combinations among loci (e.g., Abecasis and Cookson, 2000; Barrett *et al.*, 2005). The measures described below can be used in the two-locus case and easily extend to more than two loci. Nothnagel *et al.* (2002) proposed a multi-locus LD measure based on the degree of structure in a set of haplotypes as measured by entropy. Entropy measures the disorder or lack of predictability in a system and is thus maximal when all haplotypes are equally likely and zero when there is only one haplotype (i.e., complete predictability). For a set of observed haplotype frequencies, f_i, the entropy, S_{obs}, is defined as $-\Sigma_i\, f_i\, \log(f_i)$. The normalized entropy difference is defined as $(S_{eq} - S_{obs})/S_{eq}$, where S_{eq} is the entropy based on haplotype frequencies expected under linkage equilibrium. Sabatti and Risch (2002) describe the use of haplotype homozygosity, $\Sigma_i \Sigma_j f_{ij}^2$, as a measure of LD. This measure works equally well with bi-allelic and highly polymorphic data as its definition does not depend on the number of alleles at either locus. Another measure of overall multi-locus LD is based on the observed likelihood-ratio statistic, S_{obs}, for testing LD significance. The standardized statistic is defined as $\xi = \left(\sqrt{2df}/N\right)([S_{obs} - \mu_S]/\sigma_S)$, where μ_s and σ_s are the mean and standard deviation of the permutation distribution for S (Zhao *et al.*, 1999). Details of the permutation distribution are provided in the next section on significance testing.

Linkage Disequilibrium Significance

The statistical significance of individual LD coefficients, D_{ij}, can be tested using $X_{ij}^2 = (2N)D_{ij}^2/p_i(1-p_i)q_j(1-q_j)$ (Slatkin and Excoffier, 1996; Weir, 1996), which is the number of haplotypes times the r^2 measure in the SNP setting with two alleles at each locus. For multi-allelic loci, the X_{LD}^2 statistic, listed in the alternate definition for W_n, in Table 1 (line 5) can be used to test the significance of overall LD. However, for highly polymorphic data a permutation test is recommended (Slatkin and Excoffier, 1996).

Likelihood-ratio tests relate the likelihood of the observed data with no constraints (L_1), to the likelihood of the data under the null hypothesis of linkage equilibrium (L_0), where haplotype frequencies are computed as the product of allele frequencies. The likelihood-ratio statistic, $S = 2\log(L_1/L_0)$, has an asymptotic Chi-square distribution with $(k_A - 1) \times (k_B - 1)$ *df*. The Chi-square approximation for S and X_{LD}^2 can be poor for highly polymorphic loci. A better approximation for the distribution of S under the null hypothesis of no LD can be generated by first permuting phenotypes at each locus between individuals, thus imposing equilibrium. In the second step, the likelihood of the permuted data, L_1, and a corresponding new value of S is computed for the permuted sample. These two steps are repeated a large number of times to give the permutation distribution of S, which can be used to compute a p-value for the test of no LD.

Linkage Disequilibrium and Natural Selection

The homozygosity F statistic ($F = \Sigma_i f_i^2$) can be used to detect selection at a single locus (Ewens, 1972; Watterson, 1978; Slatkin, 1994, 1996). The Ewens–Watterson test compares the observed sample homozygosity to the distribution of values expected under a null hypothesis of no selection. Haplotype homozygosity was described above as one measure of multi-locus LD. Sabeti *et al.* (2002) defined the extended haplotype homozygosity (EHH) in order to examine signatures of recent positive selection using a collection of SNPs. A stepwise approach was used to study the breakdown of LD over increasing distances from a 'core' region by including an increasing number of SNPs at each step. The haplotype homozygosity is computed for each of the core SNP-defined haplotypes. At each step of the EHH computation, additional SNPs are considered with the effect of smoothing the results compared with considering the markers individually. While this is a good approach for neighboring SNPs, it is not practical for more broadly spaced polymorphic markers such as microsatellites or HLA. The conditional ALD measures described above were originally derived as a weighted average of haplotype specific homozygosity values and are informative for detecting selection acting independently on loci in high LD (Thomson and Single, 2014).

The 'disequilibrium pattern analysis' (DPA) (Klitz and Thomson, 1987; Thomson and Klitz, 1987) and 'constrained disequilibrium values' (CDV) (Robinson *et al.*, 1991a) methods are two complementary approaches that have been used to detect selection acting on sets of HLA loci. These methods also apply to other closely linked loci; the DPA method requires more than bi-allelic variation. Results from the two methods have identified specific HLA haplotypes that show signs of past selection in specific populations.

The DPA method identifies patterns of pairwise LD that are consistent with present or recently past selective events in the genetic region. Suppose that selection was acting directly on the A_1B_1 haplotype. Related haplotypes which share an allele with a selected haplotype (i.e., A_1B_j $j \neq 1$ and A_iB_1 $i \neq 1$) then have an expected value of pairwise LD that is proportional to

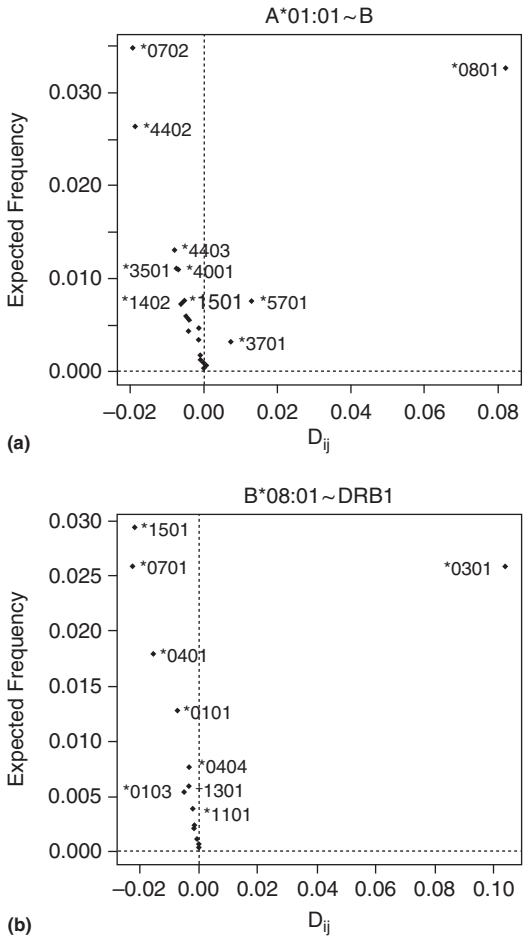

Figure 1 DPA analysis for pairwise combinations of the class I HLA-A and B loci, and the class II DRB1 locus with the alleles A*01:01, B*08:01, and DRB1*03:01 constituting the putative selected haplotype. The allele in the figure title is the one that is conditioned on (e.g., A*01:01 in (a)) with frequencies and LD values plotted for each allele at the second locus listed in the figure title (e.g., B alleles found with A*01:01 in (a)). In each case, a single allele pair in the upper right quadrant (A*01:01 ~ B*08:01 in (a)) showing high positive LD and frequency along with the linear pattern for the negative LD values is indicative of selection. This linear pattern is not expected if selection is not acting, in which case a random scatter of values is typical. Adapted with permission from Williams, F., Meenagh, A., Single, R., *et al.*, 2004. High resolution HLA-DRB1 identification of a Caucasian population. Human Immunology 65, 66–77.

the frequency of the unshared allele. This is illustrated in Figure 1 for HLA data, adapted from Williams *et al.* (2004), for HLA class I data in a Caucasian population.

Three-locus systems impose additional constraints on the range of possible pairwise LD values. In the simplest case of three bi-allelic loci (*A*, *B*, and *C*) there are eight haplotypes which can be completely specified by seven parameters: three allele frequencies p_{A_1}, p_{B_1}, and p_{C_1} (with $p_{X_2} = 1 - p_{X_1}$), three pairwise LD parameters denoted D_{AB}, D_{AC}, and D_{BC} (with $D_{XY} = D_{X_1Y_1} = -D_{X_1Y_2} = -D_{X_2Y_1} = D_{X_2Y_2}$) and one three-locus LD parameter denoted D_{ABC} (with $D_{ABC} = D_{A_1B_1C_1} = -D_{A_1B_1C_2} = -D_{A_1B_2C_1} = D_{A_2B_1C_1} = -D_{A_2B_1C_1} = D_{A_2B_1C_2} = D_{A_2B_2C_1} = -D_{A_2B_2C_2}$). The general formulation (Geiringer, 1944; Bennett, 1954; Feldman *et al.*, 1974) for three-locus haplotypes is:

$$f_{ijk} = f(A_iB_jC_k) = p_{A_i}p_{B_j}p_{C_k} + p_{A_i}D_{B_jC_k} + p_{B_j}D_{A_iC_k} + p_{C_k}D_{A_iB_j} + D_{A_iB_jC_k}$$

The CDV method has been used to detect selection events in the HLA region (Robinson *et al.*, 1991b; Grote *et al.*, 1998) by examining the pattern of pairwise LD values imposed by a three-locus system (D'') compared to those in the respective two-locus system (D'). The difference between the two measures, $\Delta = |D'' - D'|$, has a distribution which can be indicative of selection (e.g., if one of the three Δ values is positive and the other two are zero or negative – see Robinson *et al.*, 1991a; Grote *et al.*, 1998 for complete details). The DPA and CDV methods do not capture all signals of selection, but often show agreement in these conditional analyses.

Lophotrochozoa, Diversification of

KM Halanych, Auburn University, Auburn, AL, USA

Introduction

Lophotrochozoa is a monophyletic group of animals that includes annelids, molluscs, bryozoans, brachiopods, platyhelminthes, and other animals that descended from the common ancestor of these organisms. Lophotrochozoa is one of the three major clades that comprise bilateral animals, or Bilateria. Another superphylum Ecdysozoa, comprising nematodes, arthropods, and their relatives and which are defined by molting, are the sister taxon to Lophotrochozoa. The third major bilateral group is Deuterostomia, which includes hemichordates, echinoderms, and chordates (vertebrate organisms belong to this group). Of the three major bilaterian groups, Lophotrochozoa possesses the greatest morphological disparity as judged by the greatest diversity of distinct body plans.

The lophotrochozoan hypothesis was first posited based on 18S nuclear ribosomal subunit gene DNA data by Halanych *et al.* (1995). Prior to the 18S results, lophophorate phyla, that is brachiopods, phoronids, and bryozoans (**Figure 1**) were generally considered to be more closely allied to deuterostome animals than annelids (**Figure 2**) and molluscs (**Figure 3**). The lophophorate taxa are characterized by the presence of a ciliated tentacular apparatus that surrounds the mouth but not the anus and is invaded by mesoderm. Ribosomal gene data showed that these three taxa were actually nested well with protostome taxa challenging concepts about evolutionary importance and conserved nature of developmental processes such as spiral cleavage, coelom formation, and blastopore fate. The name 'Lophotrochozoa' was chosen to refer to the fact that taxa with a lophophorate feeding structure were allied to those with a trochophore larva (a larva most typically characterized by annelids and molluscs that possess specific sets of ciliated feeding bands).

In 1997, Ecdysozoan paper was published by Aguinaldo *et al.* which established that nematodes, arthropods, and their allies formed a clade, but it also affirmed support for the Lophotrochozoa hypothesis (Aguinaldo *et al.*, 1997). This paper was also based on 18S ribosomal gene data. Importantly, Aguinaldo and colleagues placed platyhelminth flatworms within Lophotrochozoa and put forth an expanded definition of the group. In the 1990s, molecular phylogenetics was still a relatively new field and these results met considerable skepticism. In particular, the Articulata concept, which posited that segmented annelids and arthropods are closely related, was firmly entrenched as a popular hypothesis prior to the molecular revolution. Although several papers also using 18S ribosomal data consistently supported the lophotrochozoan and ecdysozoan hypotheses over others, skepticism persisted until de Rosa and colleagues showed that the Hox genes, transcription factors used in early development, supported placement of brachiopods within protostome animals (de Rosa *et al.*, 1999). Within the Hox complex there are ortholog groups (e.g., Post 1, Post 2) that show fidelity to either Lophotrochozoa, Ecdysozoa, or Deuterostomia. Shortly thereafter, topologies based on other sources of molecular data (e.g., 28S nuclear ribosomal gene, myosin II heavy chain – Mallatt and Winchell, 2002; Ruiz-Trillo *et al.*, 2002, respectively) also confirmed the 'New Animal Phylogeny' (Halanych, 2004). As this consensus was emerging, multigene studies based on expressed sequence tag (EST) data were becoming feasible. Some of the early genome scale studies (e.g., Philippe *et al.*, 2005; Dunn *et al.*, 2008) confirmed that the existence and membership of these three animal super groups: Deuterostomia, Ecdysozoa, and Lophotrochozoa.

Unlike ecdysozoans, where the shared derived trait of molting has been hypothesized to define the group, there is not a single well-defined feature that can be used to circumscribe lophotrochozoans. Given that organisms were placed in separate phyla due to the lack of similarities, this lack of a common character is indicative of the great diversity of animal forms. The clade Lophotrochozoa has incorrectly been equated to 'Spiralia' (e.g., Giribet, 2008). The term 'Spiralia' is problematic, due to its long and variable use, the fact that numerous lophotrochozoan taxa do not have spiral cleavage, and that early development is more variable than traditionally realized.

Members and Relationships

Lophotrochozoa is perhaps the least understood 'superphylum' in terms of evolutionary relationships within the group. As such our understanding of the group has been changing and will continue to do so as more data is brought to bear on issues of memberships and evolutionary relationships. Here, a general consensus at the time of writing this article is presented, and **Figure 4** serves as a guide to our current understanding of lophotrochozoan evolution. Lophotrochozoa includes two major groups of phyla, Trochozoa and Platyzoa. The names and even monophyly of these groups varies among different studies. Trochozoa includes molluscs, annelids, and nemerteans (aka ribbon worms). Additionally, brachiopods and phoronids, which are sister taxa, are also clearly associated with these taxa, but were not typically considered trochozoans. Exact relationships among these groups are less certain. Dunn *et al.* (2008) placed annelids sister to a brachiopod, phonorid, nemertean clade with molluscs just outside this group. Hejnol *et al.* (2009) recovered molluscs as sister to a brachiopod and nemertean clade with annelids sister to these taxa. Kocot *et al.* (2011) on the other hand found annelids and molluscs to form a clade with brachiopods as the sister taxon and nemerteans outside of this group. Thus, relationships of the Trochozoa group are, at present, still unclear. Sipunculids (peanut worms), echiurid (tongue worms), and myzostomids (parasites of echinoderms) have been shown to be within the annelid radiation (Struck *et al.*, 2007; Weigert *et al.*, 2014) and thus are not considered individually here.

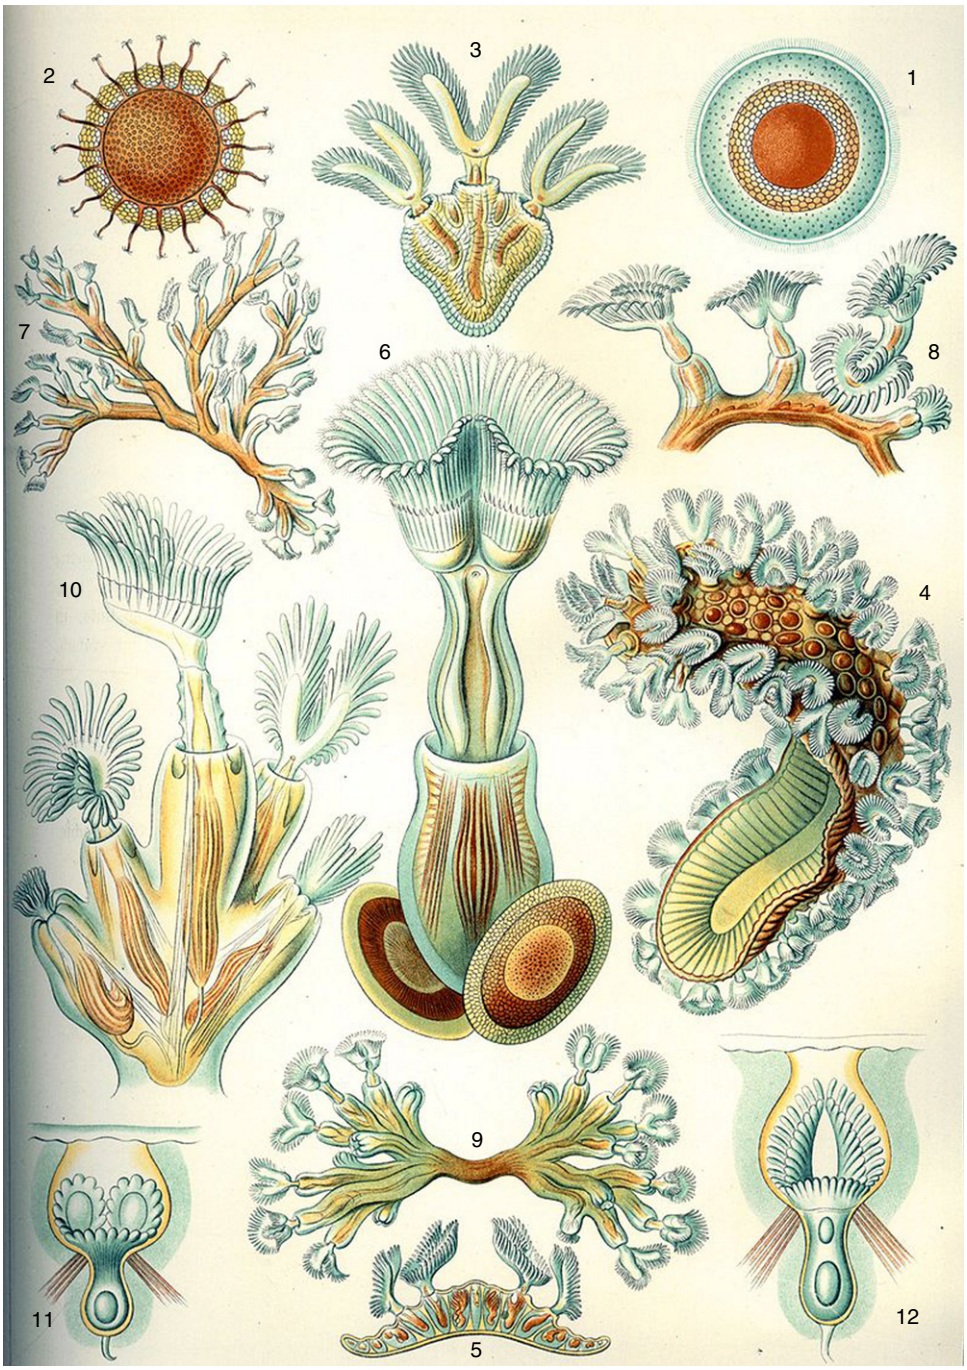

Figure 1 Haeckel's plate for Bryozoans, also known as moss animals. Reproduced from Haeckel, E., Bibliographisches Institut Leipzig, 1904. Kunstformen Der Natur. Leipzig und Wien: Verlag des bibliographischen Instituts. Available at:https://en.wikipedia.org/wiki/Bryozoa#/media/File:Haeckel_Bryozoa.jpg (accessed 21.12.15).

Both reviews and primary data papers (Halanych, 2004; Giribet, 2008; Hejnol *et al.*, 2009; Kocot *et al.*, 2010) report a Platyzoan clade that consists of at least Platyhelminthes (exclusive of Acoelomorpha), Gastrotricha, Gnathostomulida, Micrognathozoa, and Syndermata (which includes Rotifera and Acanthocephala). However recent phylogenomic work (e.g., Struck *et al.*, 2014) argues that Platyzoa is not a monophyletic group and that a platyhelminth plus gastrotrich clade is more closely related to trochozoans than syndermatans. Unfortunately, this region of the animal tree is not well understood for several reasons: (1) many platyzoans have reduced morphology and modified lifecycles due to a parasitic or meiofaunal lifestyle, (2) taxa in this region of the tree have been poorly sampled for molecular work, and (3) many taxa have elevated rates of nucleotide substitution relative to other metazoans. In particular, the issue of elevated substitution

rates can lead to artifacts in phylogeny reconstruction (e.g., long-branch attraction) that can be very hard to correct.

Other taxa that are clearly within Lophotrochozoa are bryozoans, entoprocts (or kamptozoans), and cycliophorans. There is considerable evidence that cycliophoran (symbionts that live on lobsters lips) are closely allied if not within entoprocts (Hejnol *et al.*, 2009; Kocot *et al.*, 2011; Struck *et al.*, 2014). However, this group and bryozoans are typically very unstable in phylogenetic analyses. Their exact position varies within the topology based on taxon and gene sampling and the choice of phylogenetic reconstruction method. For example, some analyses place bryozoans next to platyzoans

Figure 2 Annelids are segmented representatives of lophotrochozoans that include this earthworm, *Eisenia fetida*. https://en.wikipedia.org/wiki/Eisenia_(annelid)#/media/File:Redwiggler1.jpg

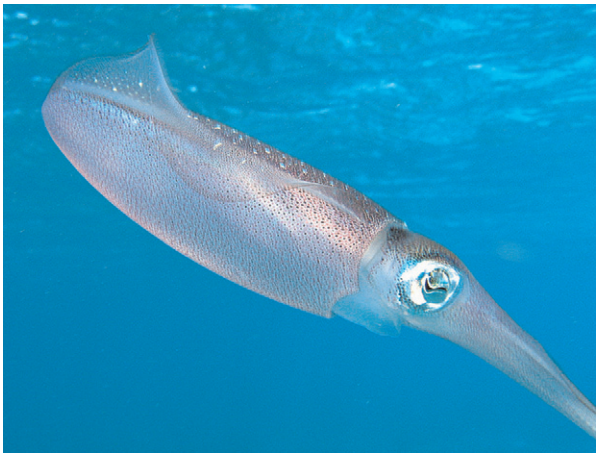

Figure 3 Molluscs, including this squid, have a long fossil history dating back to the Cambrian. https://en.wikipedia.org/wiki/Lophotrochozoa#/media/File:Caribbean_reef_squid.jpg

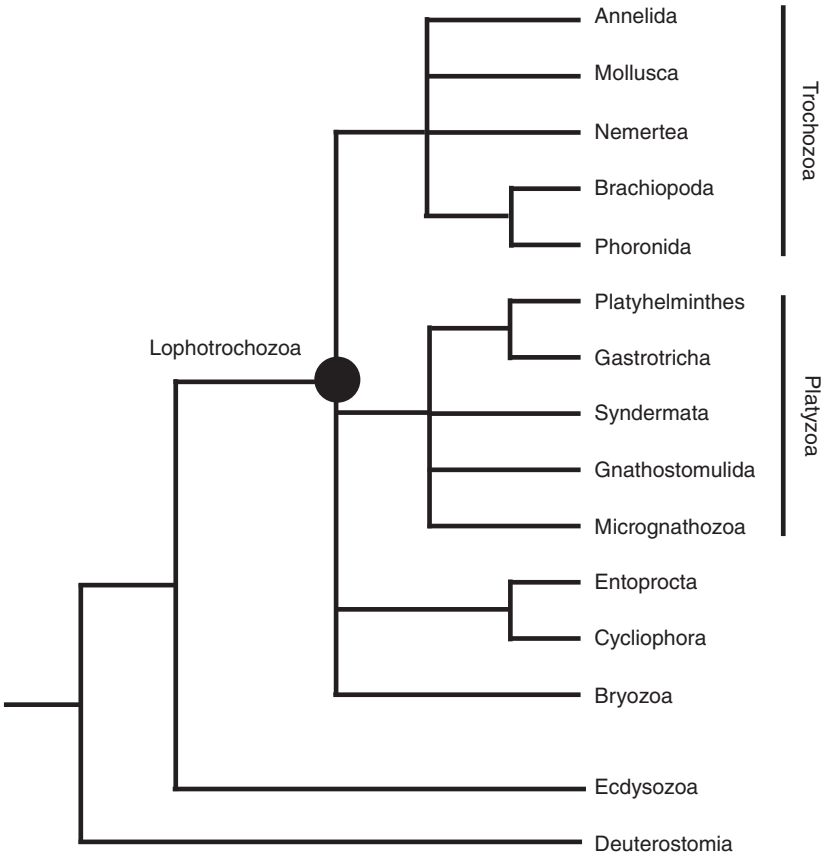

Figure 4 Summary of the present understanding of Lophotrochozoan relationships. Some regions of the tree are shown as unresolved as placement of some groups is currently under debate.

whereas other studies place them next to trochozoans. At present, the position of these taxa in the tree is not certain.

Origins

All three major bilaterian clades arose prior to the Cambrian period, which marks the beginning of the Paleozoic Era at 542 million years ago. Fossils from this period show a marked increase in the number of multicellular organisms. Moreover, the Cambrian explosion near the middle of the period is renowned for the diversity and complexity of animal fossils with many phyla and taxa belonging to modern-day crown groups. Organisms that belong to molluscs, brachiopods, and annelids are reported from the Cambrian implying the origin of the group is older. Although lophotrochozoan clearly existed before the Cambrian, whether Ediacaran fossils can be assigned to extant lophotrochozoan groups is less certain. For example, much debate has surrounded *Kimberella*, a sluglike form first found in the Edicara Hills of Australia that has been debated to be mollusc. Similarly, *Wiwaxia* is concerned within the lophotrochozan radiation but placement in a crown group has been debated.

PD Polly, Indiana University, Bloomington, IN, USA

Glossary

Adaptive peak A mathematical model for evolution toward an adaptive optimum symbolized by a hill peak, the top of which represents the point of maximum fitness.

Brownian motion A pattern of evolution in which a trait changes randomly from one generation to the next, thus serving as a null hypothesis for the outcomes expected from random evolutionary processes. Brownian motion produces evolutionary outcomes that have similar statistical properties as diffusion processes in physics and chemistry.

Drift Random evolutionary change with a Brownian motion pattern. Neutral drift occurs because of chance sampling in the survival of an offspring generation, with a rate that is determined by the reproductive population size. Selective drift occurs by natural selection in which the direction and magnitude of selection change randomly over time.

Evolutionary trajectory The evolutionary path of a quantitative trait through a morphospace.

Macroevolution Evolution over longtime scales. It can refer to the long-term history of a population lineage through time (anagenesis), to divergence between populations after reproductive isolation, or to processes other than the microevolutionary processes associated with drift, selection, and reproductive isolation.

Morphospace A mathematical space, usually multidimensional, with axes that represent the range of possible values of phenotypic traits. One of the simplest morphospaces is a bivariate plot of simple measurements such as the length and width of a structure. Morphospaces are frequently used to show the relative similarity of individual organisms, populations, or species.

Neo-Lamarckian A school of evolutionary thought that was dominant in the late nineteenth and early twentieth centuries that placed importance on the now-discarded theory of inheritance of acquired characters. Neo-Lamarckism was abandoned in light of discoveries about Mendelian inheritance and the development of population genetic theory leading to the Modern Evolutionary Synthesis.

Ornstein–Uhlenbeck process A process that produces a pattern of evolution in which the phenotypes evolve around an optimum and are constrained from diverging too far from it. Evolution on an adaptive peak is an example of an Ornstein–Uhlenbeck process.

Orthogenetic An evolutionary process, now largely disproven, in which the phenotype evolves in a continuous direction because of factors internal to the organism, eventually driving the species to extinction as the phenotype becomes less and less fit. Orthogenesis arose from early twentieth century discoveries about genetic inheritance, especially homeotic mutations, and largely replaced Neo-Lamarckism until orthogenesis itself was replaced by the Modern Synthesis evolutionary theory in which selection and drift act on mutations within a population structure.

Parsimony An algorithm for reconstructing phylogenies from discrete (noncontinuous) characters in which the number of character changes is minimized.

Phylogeography Phylogenetic divergence among geographically separated populations that occurs within species and between closely related species.

Saltationist An evolutionary process in which phenotypic changes occur in large bursts without continuous intermediates between ancestor and descendant. Like orthogenesis, saltationism arose from twentieth century work on homeotic mutations and was replaced by Modern Synthesis population-based theory.

UPGMA An early algorithm for constructing trees from continuous phenotypic traits, now superseded by Neighbor-joining and maximum-likelihood algorithms.

Introduction

Whether quantitative genetic processes can explain macro-evolutionary processes has been an important question in evolutionary biology since paleontologist George G. Simpson applied the concept of an adaptive landscape to explain the origin of grazing horses by natural selection and environment-driven changes in fitness (Simpson, 1944). While Simpson did not literally apply quantitative genetic models to his fossil data, he did adopt quantitative genetic concepts like adaptive peaks

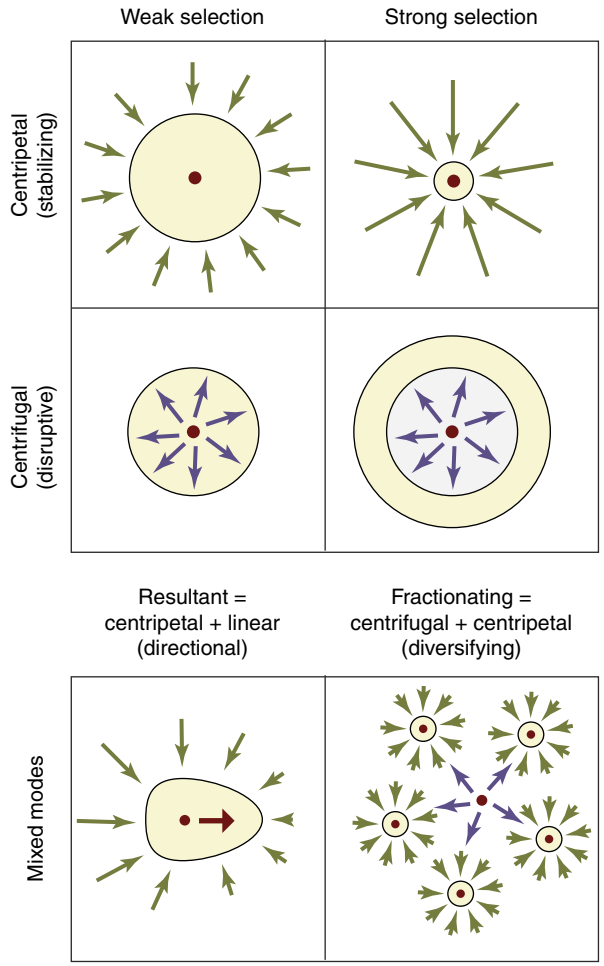

Figure 1 Modes of selection used by Simpson (1944) to explain macroevolutionary patterns, with today's equivalent terms. The top four examples result in no net change in the group (red dot shows the group mode), but affect the pattern of within-group variation (cream colored area). Centripetal selection, which is the same as stabilizing selection, pushes variation toward the mode; centrifugal selection, which is the same as disruptive selection, pushes variation away from the mode equally in all directions. Simpson envisioned many combinations of selective patterns, two of which are shown in the bottom panels. Centrifugal selection that is unequal results in directional change in the group mode. A combination of centrifugal selection on individual groups but centripetal selection between groups, perhaps as a result of intergroup competition, results in fractionating selection (diversifying selection in current terminology).

from Sewall Wright's work on mutation, allele frequencies, selection, and population divergence (Wright, 1932). Simpson argued that the long-term evolution documented by the fossil record – macroevolution, including not only the origin and evolution of species, but also their phylogenetic and phenotypic diversification – could be explained by the same microevolutionary population processes that are studied by quantitative geneticists (Figure 1). Simpson's goal was to demonstrate that the varied rates of evolution in phenotypic traits measured from sequences of fossils could be explained by varied regimes of natural selection. His integration of genetics, paleontology, and macroevolution made him one of the architects of the Modern Synthesis theory of evolution, which in the 1930s and 1940s replaced the orthogenetic, saltationist, and neo-Lamarckian theories that were current at the beginning of the twentieth century (Bowler, 1992).

Controversies

The Modern Synthesis view that macroevolution is the result of population-level microevolutionary processes quickly dominated the field but not without controversy. Simply put, the Synthesis view is that evolution is a population-level process, that phenotypic variation in populations arises from mutation and recombination, that population means change from one generation to the next by natural selection that differentially preserves those phenotypes that increase individual fitness or by the chance sampling process of drift. Coupled with factors that isolate one population from another, these processes are arguably sufficient to account for macroevolutionary patterns observed at a geological time scale such as the origin and diversification of major clades, changes in taxonomic diversity through time, or phenotypic changes within a long-lived species through time.

Challenges to this Synthesis view have come primarily from scientists who have argued that additional, non-population processes are required to explain some macroevolutionary patterns. Examples that are relevant to this discussion are punctuated equilibrium, the hypothesis that most species do not change much during their history except for rapid bursts of change at speciation (Eldredge and Gould, 1972); developmental constraints, the hypothesis that processes of organismal development channel and constraint variation and thus strongly influence macroevolutionary outcomes (Alberch, 1982); neutral evolution, the hypothesis that most evolutionary change occurs by random fixation of mutations or variants rather than by selection based on improved fitness (Kimura, 1983); and species or clade selection, the hypothesis that selective processes not only at the level of individual fitness but also on emergent traits of species and clades (Jablonski, 2008). Scientific debate about the impact of these three processes on macroevolution has encouraged the development of fully quantitative models for phenotypic evolution and their application to comparative and paleontological data to test whether quantitative genetic patterns observed at the population level are commensurate with long-term macroevolutionary patterns observed in comparative phylogenetic and paleontological data.

Nonmetric Traits

Early applications of quantitative genetics to macroevolution fell into two categories: nonmetric trait analysis, which was modeled on the analysis of allele frequencies, and continuous trait analysis, the theory for which was slower to develop. Nonmetric trait analysis focused on the frequencies of minor variations of the phenotype, such as numbers of foramina (small openings in bones for vessels and nerves), numbers of cusps on teeth, numbers of bristles on fruit flies, and numbers of spots on moth wings. The frequencies of

these traits, which were either known or assumed to be heritable, were compared within and between populations and species to determine the amount of divergence and whether drift alone, including founder effects, could explain the divergence or whether selection needed to be invoked. The nonmetric trait approach was grounded in the early genetic work of Sewell Wright (e.g., Wright, 1934) and extensively elaborated by Ford (1945), whose seminal evolutionary work on industrial melanism in moths used it; Berry (1978), who used it to study founder effect, selection, and phylogeography in mainland and island populations; and Sjøvold (1977), who enlarged the statistical toolkit for analyzing nonmetric trait divergence at macroevolutionary scales. Theory and process of the evolution nonmetric phenotypic traits were developed at length in the book *Phenetics* by Yablokov (1986), a student of the prominent geneticist Timofeev-Ressovsky. Despite the potential of nonmetric traits for studying the relationship of quantitative genetic processes and macroevolution, this approach has received little attention since the 1980s.

Continuous Quantitative Phenotypic Traits

Selection Regimes and Rates of Evolution

While nonmetric traits were important in early research on evolution of the phenotype, most studies of genetic processes and macroevolution have been based on quantitative traits. Advances in multivariate morphometrics and phylogenetic theory of quantitative traits have allowed complex new questions to be asked, as described in more detail below. Simpson's early work, and those who followed his lead, involved relatively simple phenotypes, usually sizes of teeth and bones that could be measured in both living and fossil animals, and focused on questions that could be answered by comparing rates of evolution, direction of selection, or intensity of selection.

Simpson, Haldane, and Kurten made early contributions to our understanding of how selection changes as environments change by measuring rates of evolution in living taxa from different environmental regimes and measuring sequences of fossils through major environmental transitions (Simpson, 1944; Haldane, 1949; Kurtén, 1959). Simpson (1944) classified evolutionary rates into three classes based on the distribution of their magnitudes within a taxonomic group or clade: horotelic distributions are the norm, with many bursts of rapid evolution interspersed with lower rates; bradytelic distributions are characterized by slow rates with most near zero, arising in situations where evolution is constrained by stabilizing selection, diminished genetic variation, or other factors; tachytelic distributions are unusually rapid and include exceptionally fast bursts of 'quantum evolution' as lineages cross from one adaptive zone to another. Simpson explained all three of these modes of evolution – stabilizing, random, and directional modes of selection are their parallels – in terms of population genetic processes, especially variation in the environmental and evolutionary context controlling the intensity of selection (**Figure 1**). Wright's (1932) shifting balance explanation for how a species could shift from one adaptive peak to another was an important model for Simpson's explanation for the origin of higher taxa, or adaptive radiations, by colonization of new adaptive zones, an idea that has been tested by comparing rates of evolution (Kurtén, 1959), comparing modes of selection in a quantitative phylogenetic framework (Schluter, 2000), and by measuring phylogenetic evolution of multivariate phenotypic traits in morphospaces (Polly, 2008a). The study of rates of evolution was formally placed in a quantitative genetic framework by Gingerich, who proposed that rates be measured in units of haldanes, which is the average change in standard deviations per generation, that they be scaled to take into account the probability of evolutionary reversals that occur over longtime periods, and that measurements of macroevolutionary divergence be scaled in a comparable way (Gingerich, 1993, 2001). This work made it possible to convert phenotypic rates of evolution measured over thousands or millions of generations to quantitative genetic parameters such as heritability and selection intensity. Selection has also been measured directly from sequences of well preserved fossils from which demographic age structures and, hence, individual survivorship can be estimated (Van Valen, 1965; Bell, 1988).

Adaptive Peaks

Although the adaptive landscape was used as a metaphor for the processes governing variation in rates of phenotypic evolution and the origin of taxa, it was not placed in a fully quantitative framework until Lande's work in the late 1970s. Lande presented equations that describe the intensity and direction of selection on the population mean of a quantitative phenotypic trait at any point on an adaptive peak (**Figure 2**), derived estimates of the

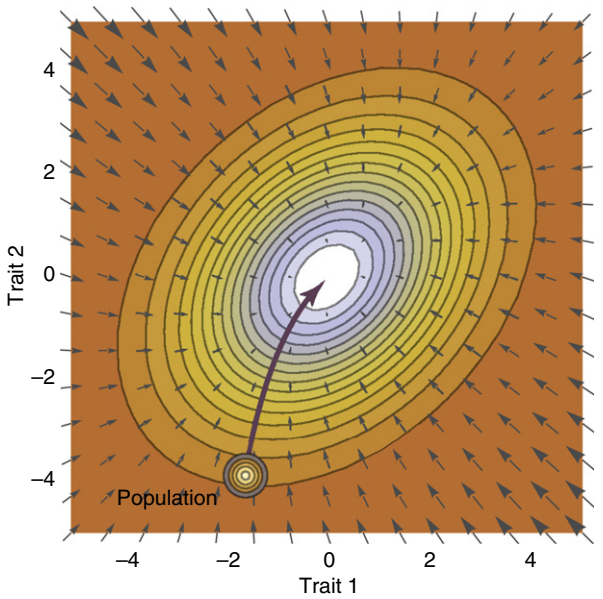

Figure 2 Graphic depiction of evolution on an adaptive peak. Joint fitness of two phenotypic traits defines the contoured peak (lighter colors indicate higher fitness). Selection vectors (small arrows) show the direction and intensity of selection at different points on the peak. A population is shown as a smaller set of contours that show the mean and variance of phenotype. Over time, selection will push the population in a predictable path up the peak (heavy arrow).

rate and direction of evolutionary response to that selection, and described the trade-offs between drift and selection on the evolution of the phenotype (Lande, 1976). Lande's equations were based firmly in population quantitative genetic principles of population variance, heritability, fitness, and multilocus genetic underpinnings of phenotypic traits. One of the goals of the quantitative framework was to determine whether challenges to the Modern Synthesis, especially the hypotheses that most evolution was neutral or random, that developmental and other constraints channel the direction of long-term evolution, and that most phenotypic change occurs at speciation, were consistent with quantitative genetic principles (Charlesworth *et al.*, 1982), so it was elaborated to include adaptive peak shifts as model for long-term changes in the environmental context that defines fitness (Lande, 1986) and for correlated phenotypic traits (Lande and Arnold, 1983). Lande's own conclusions were that drift, selection, and a phenotypic version of Wright's shifting balance theory were adequate to explain, perhaps even to predict, patterns of punctuated equilibrium and that developmental and other constraints on evolution were consistent with quantitative genetic models for multivariate phenotypic traits (Lande, 1985, 1986). Importantly, expansions of Lande's model now form the basis for most of the quantitative analysis of phenotypic evolution (Arnold *et al.*, 2001; Gingerich, 2009; Hansen, 2013; Doebli, 2013; Bell, 2013).

Phylogenetic Comparative Methods

In parallel to adaptive peak models, methods for analyzing traits in a phylogenetic context were also developed. Felsenstein (1973) proposed a maximum-likelihood algorithm for reconstructing phylogeny from continuous phenotypic traits when they have evolved by a Brownian motion process such as drift or randomly changing selection. Unlike previously existing morphometric tree-building algorithms such as the unweighted pair-group averaging (UPGMA) method, or then-emerging discrete-trait algorithms such as parsimony, Felsenstein's method was explicitly grounded in probabilistic evolutionary quantitative genetic theory and balanced the probability of character reversals with character change using the statistical properties of Brownian motion. In the simplest situations, the phenotypic divergence between taxa evolving by Brownian motion is a function of their rate of evolution and shared phylogenetic history. A single phenotypic trait evolving in an ancestor-descendant lineage by Brownian motion will have a possible distribution of descendant phenotypes whose mean is equal to the ancestor's phenotype and whose variance is equal to the squared rate of change per generation times the number of generations elapsed (Felsenstein, 1988). Because the statistics of Brownian motion are nondirectional, the same distribution describes the range of possible ancestor phenotypes given an observed descendant phenotype. The likelihood of phenotypes of the ancestor of two observed descendants is described by the joint probabilities of the descendants. By taking into account the ancestral likelihood distributions of many taxa, the overall likelihoods of competing phylogenetic hypotheses can be estimated and the most likely one identified. Using the same logic, the likelihood that traits evolved by Brownian motion can be evaluated if the phylogenetic tree is already known, their rate of evolution can be estimated, the likely ancestral phenotypes can be estimated, and the covariances that arise from shared common ancestry can be removed in order to study non-phylogenetic factors that cause trait covariance, such as genetic correlations or developmental constraints (Felsenstein, 1988; Harvey and Pagel, 1991). Furthermore, the statistical framework can be parameterized so that non-Brownian motion modes of evolution can also be evaluated (Martins and Hansen, 1997; O'Meara *et al.*, 2006; Revell and Collar, 2009; Hunt and Rabosky, 2014). These other modes include Ornstein–Uhlenbeck processes that arise from centrifugal (stabilizing) selection associated with an adaptive landscape with a broad peak, and diversifying (directional) selection. Collectively, these tools for analyzing phenotypic traits among taxa whose phylogeny is known are called phylogenetic comparative methods.

Hypothesis Testing

Because they are underpinned by a common quantitative genetic framework, the tools derived from Lande's quantitative theory for the evolution of phylogenetic traits and Felsenstein's phylogenetic methods can be combined to test quantitative genetic hypotheses about macroevolution, or to generate hypotheses about population-level genetic processes from comparative phenotypic data. Population-level parameters such as phenotypic variance, heritability, population size, and selection intensity can be extrapolated over hundreds, thousands, or millions of generations using any one of the several existing models of evolutionary pattern (Brownian motion, stasis or stabilizing selection, directional or diversifying selection, shifting adaptive peak, etc.) and the resulting predictions can be compared to data collected from species with comparable phylogenetic divergence times. The expected rate of phylogenetic divergence in the phenotype will be a function of population-level phenotypic variance, population size, and heritability (Lande, 1976). If these parameters are known for all the species being compared, then the average selection intensity and the long-term pattern of selection can be inferred. Conversely, the population parameters can be inferred if the long-term patterns are known from paleontological or phylogenetic data and tested at the population level.

An example of macroevolutionary hypothesis testing based on quantitative genetic predictions is Gingerich's (2001) study rates of evolution in lineages of fossil species tracked through millions of years. He found that average per-generation selection intensity was about 0.2 phenotypic standard deviations per generation, similar to the rapid rates of change measured in lab selection experiments for large and small body size. Interestingly, long-term diversification (maximum range of phenotypes in a clade) was less than expected if evolution continued directionally at this rate over millions of generations, suggesting that, while evolution is not constrained over short timescales, there are large-scale constraints on phenotypic disparity, a finding that has been replicated in other macroevolutionary studies covering many taxonomic groups at a several phylogenetic timescales (e.g., Hunt, 2007; Evans *et al.*, 2012).

Units of Analysis

An important requirement for comparing data drawn from different evolutionary scales is that the units of analysis must be comparable (Gingerich, 2001; Houle *et al.*, 2011). Evolutionary divergence times, for example, can be measured in units of millions of years (meganna), in molecular sequence differences, or in phenotypic character counts, but the time scale of the evolutionary process is the generation. Similarly, phenotypes can be measured in millimeters, kilograms, or Procrustes units, but it is the amount of change proportional to the genetic and phenotypic variance that is relevant to processes such as selection and drift. In order to compare population-level and macroevolutionary processes, the units of analysis must be standardized across the scales on which data are observed. Rates of phenotypic evolution are most easily compared across scales when they are measured as standard deviations per generation, a unit known as the 'haldane' (Gingerich, 1993), which is the same unit as quantitative genetic parameters such as selection intensity.

An example of how scaling matters is determining whether an observed Brownian motion pattern of species divergence arises from neutral genetic drift or selective drift. Neutral genetic drift is a process due to chance sampling from parent to offspring generation and is dependent on population size. Divergence between species due to drift is therefore a function of the average population size over time, the number of generations since common ancestry, and the genetic variance in the trait and will have a Brownian motion pattern (Lande, 1976). Selective drift is a process in which a trait is evolving by directional natural selection, but the direction and magnitude of selection are changed randomly over time (Kimura, 1954). Polly (2004) used this scaling relationship to show that divergence in tooth morphology in a species flock of shrews whose last common ancestor lived about 40 million years ago had diverged randomly (Brownian motion) but at a rate much faster than expected from neutral genetic drift, even if heritability in tooth structure was exceptionally high and population sizes were consistently small. Only selection could explain the observed divergences, yet there was no evidence that selection followed a consistent, directional trend, despite the clear functional role that teeth have.

Morphometrics and Multivariate Phenotypes

This comparative framework for hypothesis testing is especially powerful when it can be applied to complex traits that are commonly preserved in the fossil record. Quantitative genetic studies have traditionally focused on traits that are easy to measure in lab or field settings, especially univariate traits such as body size, color, bristle number, and fecundity, but these traits are rarely preserved in fossils or in the museum research collections that are used for large-scale comparative phenotypic studies. Instead, complex structures such as teeth, bones, shells, and leaves are commonly studied in macroevolution, even though we know comparatively little about their developmental and genetic underpinnings. Developments in geometric morphometrics now allow extraordinarily complicated structures to be measured efficiently, allowing multivariate structures such as these to be studied quantitatively in large numbers (Bookstein, 1991; Dryden and Mardia, 1998). Studies of the genetics, development, geography, phylogeny, and phenomics of complex traits have abounded in the last decade and the opportunity for studying phenotypic evolution across these scales has never been greater.

Complex traits present new challenges, both in terms of analytical methods and evolutionary theory. Morphometric analysis of the shapes of two-dimensional structures, even extraordinarily complex ones, has become trivially easy, merely requiring a source of digital photos and software for capturing Cartesian coordinates that represent the structure of interest (Bookstein, 1991). The mathematical dimensionality of the resulting morphometric traits is often very large, but nevertheless easily tractable in mathematical terms. The analysis of three-dimensional shape, which includes most real biological structures, is far more challenging. Capturing three-dimensional data requires specialized equipment such as CT-scanning or laser scanning, and the methods available for representing the full three-dimensional structure of a trait as Cartesian coordinates, whose orientation on the object must be homologous, are difficult to apply to varied structures and fraught with concerns about biological homology, algorithmic optimization, and unintentional weighting of one part of a structure over another (Gunz *et al.*, 2005; Polly, 2008a; Shen *et al.*, 2009).

The high dimensionality of morphometric traits itself is an issue, because the number of mathematical variables represented by the landmark coordinates used to represent the structure may be much greater than the trait's biological dimensionality. Three-dimensional morphometric representations of mammal teeth, for example, can easily have several hundred mathematical dimensions, each of which can be thought of as a potentially independent sub-trait, but quantitative trait locus (QTL) analysis and molecular developmental studies suggest that a much smaller number of genes may be involved in variation in tooth phenotypes (Workman *et al.*, 2002; Harjunmaa *et al.*, 2014). Because rates of evolution, standard deviation units, trait covariances, and other fundamental parameters are themselves dimensional, a new consensus about the concept of trait dimensionality is urgently needed. Multivariate traits might be thought of as coherent individual phenotypes with no sub-traits (Adams, 2014), they might be thought of in terms of the number of different genes underpinning them (Workman *et al.*, 2002), they might be thought of in terms of the number of developmental factors that control them (Salazar-Ciudad and Jernvall, 2010), or they might be thought of in terms of their number of functional units (Stinchcombe *et al.*, 2012).

An important challenge for quantitative phenotypic evolution is the study of evolutionary novelties – the gain and loss of limbs and digits, the multiplication of body segments, and the origin of eyes. The origin of novel structures is one of the most interesting aspects of macroevolution, and a better understanding of which is the primary goal of evolutionary developmental biology (Raff, 1996). However, the origin of new structures is almost impossible to quantify in morphometrics because each homologous point on the structure must be present in all structures in the analysis. Some morphometric approaches, such as outlines and surfaces, are 'homology free' in that they can accommodate the gain and loss of features on

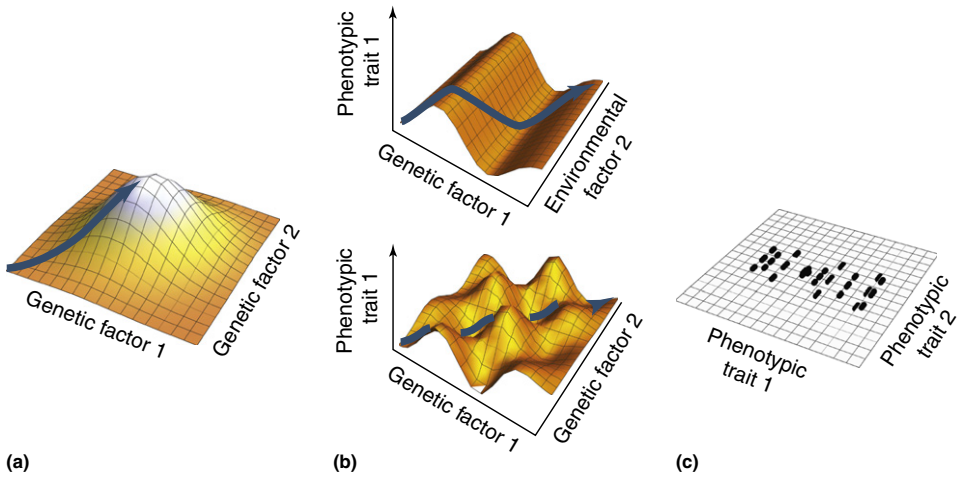

Figure 3 Diagram showing how genotype–phenotype maps might be combined with geometric morphometrics to model evolutionary trajectories in which developmental interactions result in discontinuous phenotypic change. (a) Continuous, linear evolution toward an adaptive peak in genetic space. (b) Two genotype–phenotype maps that describe the relationship of phenotypic traits to genetic and environmental factors. The same evolutionary trajectory is shown crossing both surfaces. (c) The genotype–phenotype maps result in a nonlinear, discontinuous distribution of phenotypes in the morphospace shown in this panel. This figure is based on ideas presented in Polly, 2008b.

a larger homologous structure, but even these cannot be used to represent an evolutionary transformation such as the evolution of limbs (Polly, 2008b). The most promising approach for studying evolution that involves the origin and loss of traits is the nonmetric approach described above, but no new developments have been made in this area.

An even more important challenge is that the evolutionary transformations that are reconstructed as shortest paths through a multivariate mathematical morphospace may not be the shortest biological paths from one phenotype to another (Polly, 2008b). The quantitative genetic and morphometric frameworks that were introduced above are based on trajectories through mathematical spaces, but as evolutionary distances increase to the macroevolutionary scale, the correspondence between mathematical and biological transformations becomes less certain. Dynamic relationships between tissues and gene signaling during development are known to produce nonlinear transformation in phenotypes that jump across gaps in morphometric spaces (Salazar-Ciudad and Jernvall, 2010). Thus, a continuous linear change in the level of expression of a developmental signaling gene may result in a discontinuous jump in the phenotype, one that may involve the origin of novel features. This phenomenon has important implications for quantitative theory for phenotypic evolution and is the object of ongoing study (Wolf *et al.*, 2001; Hansen, 2008; Rice, 2008). Morphometric algorithms may require elaboration to provide a nonlinear mapping between developmental genetic spaces and morphospaces (**Figure 3**).

Conclusion

The challenges raised about the ability of the Modern Synthesis to reconcile microevolutionary processes with macroevolutionary patterns have as yet only been partially answered, in large part for want of data and analytical methods. The rapid advances in both now offer opportunities for comprehensively addressing these questions. For instance, the preponderance of data suggest that phenotypic evolution is usually more rapid than expected by truly neutral processes like drift over short timescales, but over broad timescales there appear to be constraints operating that prevent lineages from becoming as disparate as they might, given their per-generation rates of evolution (Gingerich, 2001; Hunt, 2007; Evans *et al.*, 2012). However, despite the huge variety of data that underpins that observation, most of the traits that have been analyzed are essentially proxies for body size. Body size has fairly obvious constraints imposed on the small end by the requirements of cellular function and on the large end by the force of gravity (McNeill Alexander, 1998). Data for other kinds of traits are incomplete, but those that are available suggest that the pattern is different.

Rates of evolution in complex traits, such as the form of teeth and bones, for example, is still usually faster than expected from drift and long-term divergence often appears to be constrained; however, the constraints appear to change to allow lineages to move in new directions that their ancestors and relatives could not. The lifting of constraints is associated with large, seemingly correlated changes in form and function. For example, ankle structure in mammalian carnivores has evolved for about 50 million years constrained to a relatively small area of morphospace within which lineages have evolved and revolved similar structures; only the pinniped lineage (seals and sea lions) have broken out of those constraints, and out of the terrestrial locomotor system of their relatives (Polly, 2008a), consistent with Simpson's concept of adaptive zones (Simpson, 1944; **Figure 4**). The evolutionary dynamics of developmental systems appear to generate similar patterns in which phenotypes evolve within constrained areas of morphospace then jump to new areas at points where the system passes a threshold (Salazar-Ciudad and Jernvall, 2010). Added to the complexity of these processes is the complexity of selection surfaces and adaptive landscapes for

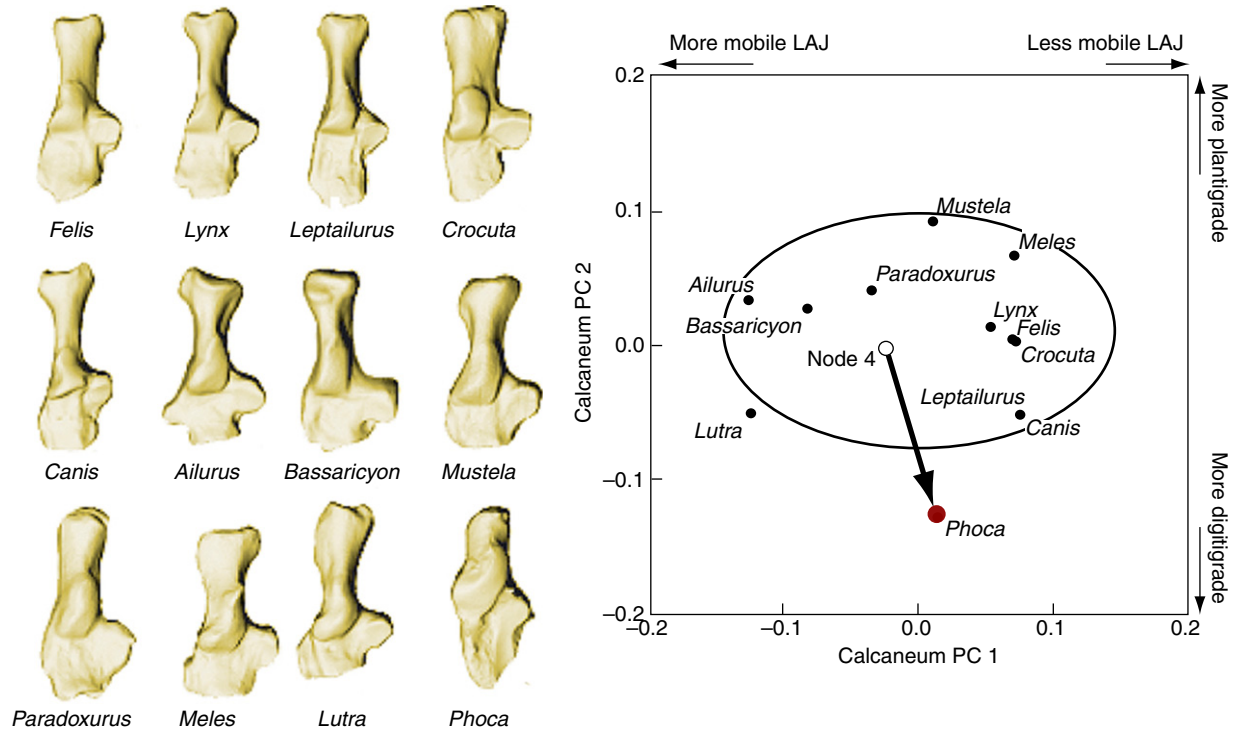

Figure 4 Complex patterns of evolution in multivariate phenotypes illustrated with the evolution of the ankle in mammalian carnivores. The calcaneum, the main supporting bone in the mammalian hind foot, of 12 taxa are shown at left, including cats (*Felis*), dogs (*Canis*), otters (*Lutra*), weasels (*Mustela*), and seals (*Phoca*). The morphospace at the right shows the distribution of their shape. Most of these species have evolved in a limited area of the morphospace defined by the functional constraints of supporting their weight and moving in their terrestrial environment (ellipse). The dark arrow shows an evolutionary trajectory estimated with maximum-likelihood for the seal lineage from its last common ancestor with terrestrial carnivores (Node 4). The rate of evolution of ankle structure in the seal lineage is similar to the rates in terrestrial species, but the seal's ankle is able to become more different by passing out of the constraints of terrestrial locomotion. This figure is based on research presented in Polly (2008a).

highly multivariate traits, which may have 'holes' that cannot be crossed, isometric lines of equal fitness in which phenotypes can wander randomly, and complex peaks and valleys that defy the simple metaphor of a landscape (Gavrilets, 1999). Some processes, such as species selection, are only starting to be formulated in a quantitative framework that will allow their effects to be compared in the same equations. Notably, Simpson (2011) has used a modified version of Price's (1972) evolutionary equation to partition phenotypic change in clades into change arising from evolution within lineages and change that arises from turnover in traits due to differential survival of lineages.

Opportunities exist not only for empirical research on how evolution works, but on methodological developments to deal with the evolution of complex traits. In addition to the morphometric challenges raised above, new ways of conceiving evolutionary modes are needed for multivariate traits. For univariate traits, the only alternatives to Brownian motion are directional evolution and stasis. Multivariate traits evolving on multivariate selection surfaces behave in ways that hardly fit the latter definitions. The models used to estimate evolutionary modes are therefore difficult to apply to multivariate evolution in a meaningful way, even though considerable progress has been made to develop multivariate equations (Arnold *et al.*, 2001; Gavrilets, 1999). Furthermore, most of the quantitative apparatus that is available for estimating rates and modes of phenotypic evolution are algorithms that find a single optimal parameter. The complex patterns and processes of multivariate evolution require methods that allow the relative support for competing hypotheses to be compared, ones that use a maximum-likelihood or Bayesian statistical framework. Some such methods are already available (Schluter *et al.*, 1997; O'Meara *et al.*, 2006; Goldberg and Igić, 2008; Slater *et al.*, 2012), but more are needed, as are development of new models for the evolution of nonmetric traits and, ideally, synthesis with continuous multivariate traits.

Mammalian Diversification

E Eizirik, Faculdade de Biociências, PUCRS, Porto Alegre, Brazil

Introduction

The spectacular morphological and ecological diversity of present-day mammals has long fascinated both scientists and the general public. Such diversity is even greater, and more fascinating, when extinct mammalian lineages are also considered. Living and extinct mammals include many small, generalist species along with lineages that have adapted to a variety of specialized life histories, including large-bodied terrestrial herbivores, aquatic and terrestrial predators, fossorial (i.e., underground-adapted) species, ant-eating specialists, as well as tree-dwelling, gliding, and even flying forms. Many of the specialized forms evolved multiple times in different mammalian lineages, providing some of the most remarkable and best-documented examples of evolutionary convergence across all animals.

Mammalian diversification has been an ongoing process for the last 200 million years, but some periods during this time have been particularly relevant. Many different mammalian lineages have arisen and subsequently diversified, while others seem to have maintained a much lower diversity for a long time. Even lineages that diversified substantially in some cases have gone extinct, being replaced by other diversifying lineages. There is therefore a very rich history of mammalian adaptive radiations, which have been extensively analyzed on the basis of their fossil record, as well as with the use of molecular approaches. This article presents an overview of the present understanding of mammalian diversification, attempting to summarize the main results from many recent studies. There will be a brief treatment of the early phases of mammalian diversification, pointing to relevant primary sources, and then a more extended description of the diversification of living (extant) mammalian groups. The final section addresses the evolution of morpho–ecological diversity in mammals, including some discussion on the occurrence of convergent morphological features in different lineages. The goals of the article are to provide a concise summary of the main conclusions emerging from recent studies in this field, and to point the reader to examples in the primary literature (as well as recent reviews) that provide more detailed information on particular topics.

Early Phases of Mammalian Diversification

Mammals arose in the Upper Triassic period (Mesozoic Era), *ca.* 220 million years ago (MYA), as a subgroup of the synapsid amniotes. A common perception in the earlier literature is that Mesozoic mammals were all very small and not particularly diverse, and that their burst of diversification occurred when dinosaurs went extinct at the end of the Cretaceous period (a time known as the Cretaceous–Paleogene (KPg) boundary), *ca.* 66 MYA. This view has been shown to be inaccurate by many recent studies. There is now abundant evidence that Mesozoic mammals were quite diverse, including small, tree-dwelling insectivores and rodent-like forms, along with burrowing and swimming forms, and even medium-sized predators (e.g., Hu *et al.*, 2005; Luo, 2007; Bi *et al.*, 2014; Close *et al.*, 2015). There were clearly many different lineages, occupying a variety of habitats throughout the planet. Although most of them remained quite small (around the size of a shrew or a rat), it is now known that some of them could achieve a much larger size, including a >4 kg carnivorous form that was even found to have preyed on small dinosaurs (Hu *et al.*, 2005). It is therefore correct to say that mammals already comprised a successful and quite diverse radiation of terrestrial vertebrates during the Jurassic and Cretaceous periods in the Mesozoic, when they coexisted with dinosaurs in many different ecological settings. At the same time, it is still accurate to say that their morphological disparity (implying ecological diversity) was still modest compared to the levels that would eventually be achieved in the Cenozoic, and that we still see today. For example, there were no flying mammals, nor highly specialized marine forms such as cetaceans or sirenians. Moreover, the vast majority of known Mesozoic mammals were indeed quite small, with the largest known forms estimated to have attained a mass of $\sim$14 kg. In contrast, many mammalian lineages that are known from the Cenozoic fossil record and from present-day faunas achieved much larger body sizes, surpassing 100 kg or even weighing several tons (e.g., the largest mammal, the blue whale, can weigh up to $\sim$130 t). The history of mammalian diversification thus includes both a turnover of many distinct phylogenetic lineages that often replaced each other over the last $\sim$200 million years, and a trend for increase in body size and morphological disparity that mostly occurred in the Cenozoic.

Origin and Diversification of Living Mammals

From the early phases of mammalian diversification in the Mesozoic, three main lineages have survived up to the present (**Figure 1**): Monotremata (the egg-laying platypus and echidnas), Marsupialia (marsupials such as kangaroos and opossums), and Placentalia (placental mammals). Recent molecular studies (e.g., Meredith *et al.*, 2011; Dos Reis *et al.*, 2012) have strongly supported the conclusion that Monotremata represents the earliest divergence of the three groups, having split from the other two clades *ca.* 180–220 MYA. Marsupialia (representing the broader clade Metatheria) and Placentalia (representing the broader clade Eutheria) are sister-groups, having diverged from each other *ca.* 170–190 MYA. The monophyletic group encompassing Eutheria and Metatheria is known as Theria. Fossil evidence demonstrates that each of the three extant lineages underwent considerable diversification during the Jurassic and the Cretaceous periods (see **Figure 1**), when they also coexisted with additional mammalian groups that did not leave any living

 doi:10.1016/B978-0-12-800049-6.00283-3

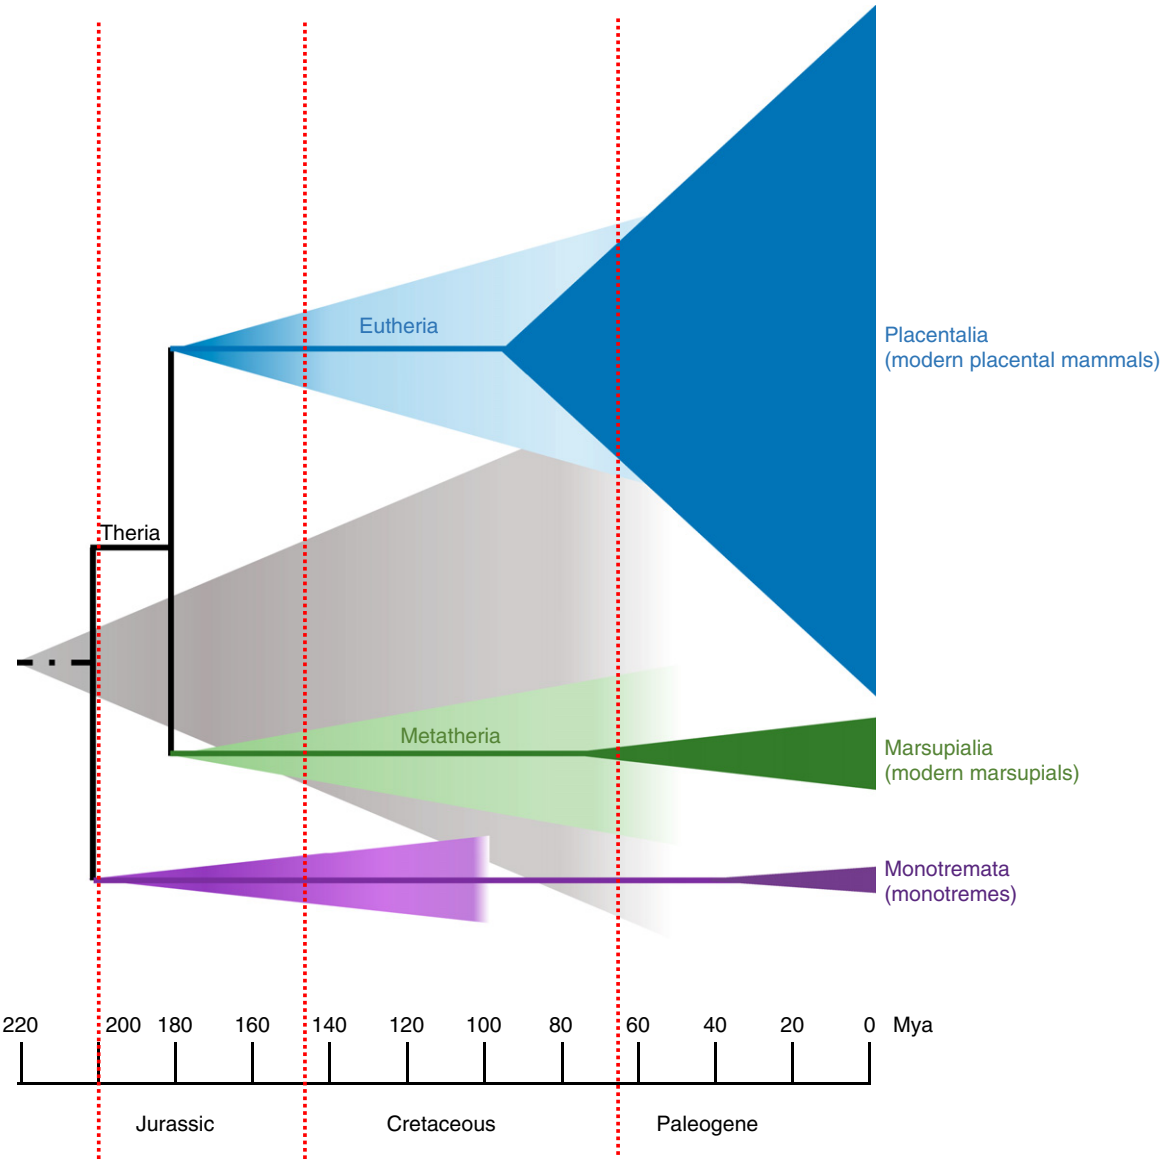

Figure 1 Schematic representation of the diversification of mammals. The timing of divergence (in million years ago (Mya)) among the three extant mammalian lineages (Placentalia, Marsupialia, Monotremata) is based on the mean between the values reported in two recent and comprehensive molecular analyses (Meredith *et al.*, 2011; Dos Reis *et al.*, 2012). The chronological range of stem taxa in each group is drawn from Luo (2007) and Bi *et al.* (2014). Within each of the three main lineages, the more recent triangle (shown in stronger color) represents the timing and intensity of diversification of the crown group (i.e., the most recent common ancestor of all living species and all the descendants from this ancestor). Also within each lineage, the older triangle (depicted in lighter color) represents the diversification of stem groups (i.e., having diverged prior to the origin of the crown group). The light gray triangle represents the diversification of mammalian stem groups that are not contained in any of the three extant lineages.

representative. Much of this early diversity encompasses what is known as 'stem taxa' within each of the three lineages, i.e., species that are less closely related to the living forms than the latter are to each other. The crown-group within each lineage (defined by the common ancestor of all presently living species and all its descendants) arose later, *ca.* 90–100 MYA in the case of Placentalia, 65–87 MYA in the case of Marsupialia, and only *ca.* 40 MYA in the case of Monotremata (Meredith *et al.*, 2011; Dos Reis *et al.*, 2012; Mitchell *et al.*, 2014).

Each of the three main lineages has achieved a different level of present day diversity. Extant monotremes comprise only two families and five species (MacDonald, 2001), and their known fossil record does not indicate that the crown-group has exhibited high levels of diversity in the past (Springer and Krajewski, 2009). Marsupials display a different pattern, with considerable present-day diversity (>300 species belonging to seven orders) and morphological disparity, including hopping, climbing, gliding, burrowing, predatory, and semiaquatic forms. Extinct marsupial lineages further extend this diversity, with various large forms that even included lion-like and saber-toothed predators (Savage and Long, 1983). Marsupial diversification mostly took place in the southern

continents, especially South America and Australasia. The most ancient among the extant lineages are all South American, and they are paraphyletic with respect to the Australasian radiation (Meredith *et al.*, 2011; Mitchell *et al.*, 2014). This phylogenetic pattern has been robustly supported, and implies a biogeographic reconstruction that postulates an origin of crown marsupials in South America, followed by colonization of Antarctica and Australia while these landmasses were still connected in the Late Cretaceous. The early divergences in South America have been dated at 69–87 MYA, while the diversification of the Australasian lineages was rapid, and clustered around the KPg boundary, 60–67 MYA (Springer *et al.*, 2009; Mitchell *et al.*, 2014). Such a pattern is suggestive of a rapid radiation following the colonization of new landmasses, but may also have been influenced by new ecological opportunities that arose in the aftermath of the KPg mass extinction.

The third main group of living mammals, the placentals, is the most speciose, comprising 19 orders, >100 families, and >5000 species (MacDonald, 2001; Wilson and Reeder, 2005). They have undergone a remarkable diversification since their origin in the Mesozoic (see **Figure 1**), giving rise to fantastically disparate forms that include whales, bats, tigers, moles, humans, anteaters, and elephants. How did they diversify? When did they diversify? And where did it happen? These questions have attracted the attention of numerous scientists, and the attempts to address them using a variety of approaches have led to some of the liveliest debates in evolutionary biology in the second half of the twentieth century. A key discussion revolved around the required resolution of the phylogenetic relationships among living groups of placental mammals, without which it would not be possible to test alternative hypotheses regarding the timing and biogeography of their diversification, as well as the sequence of morpho–ecological changes that accompanied the divergence of evolutionary lineages. Due to the rapid radiation of different placental lineages, as well as the major (often extreme) morphological specializations of extant groups, piecing together their relationships and reconstructing their history using traditional approaches (e.g., comparisons of their bones and teeth) proved to be remarkably challenging (e.g., Eisenberg, 1981; Novacek, 1992; Murphy and Eizirik, 2009). Different studies yielded different phylogenies, leading to conflicting hypotheses regarding the history of placental mammal diversification. Many controversies persisted up to the end of the twentieth century, including highly publicized conflicts between phylogenetic reconstructions derived from early molecular data sets and groups retrieved with morphological characters (e.g., D'Erchia *et al.*, 1996). As larger molecular data sets began to be assembled, improved resolution could be obtained for various sections of the mammalian tree, in some cases revealing phylogenetic groups that had not been anticipated based on morphology (e.g., Springer *et al.*, 1997; Stanhope *et al.*, 1998).

Diversification of Placental Mammals

In the early 2000s, analyses based on large molecular data sets finally allowed the resolution of most relationships among placental mammal orders (Eizirik *et al.*, 2001; Madsen *et al.*, 2001; Murphy *et al.*, 2001a,b). These studies corroborated some classical groups strongly supported by morphology (e.g., Glires, comprising Rodentia and Lagomorpha), as well as others revealed by previous molecular studies (e.g., Afrotheria). Many subsequent studies consolidated the resolution of the placental mammal tree, and progressively refined the estimation of divergence dates among its contained lineages (e.g., Springer *et al.*, 2003; Murphy and Eizirik, 2009). The following description of the timing and biogeography of placental mammal diversification is based on a compilation of sources that used large molecular data sets to directly estimate phylogenetic relationships and divergence times among extant lineages, and especially on two recent articles that included extensive sampling of taxa and genomic regions (Meredith *et al.*, 2011; Dos Reis *et al.*, 2012).

Extant lineages of placental mammals began to diversify in the late Cretaceous, 90–100 MYA (**Figure 2**). There are three well-supported lineages that emerged at this time: Afrotheria, Xenarthra, and Boreoeutheria (which in turn comprises two large and well-supported sub-lineages: Laurasiatheria and Euarchontoglires). The identification of these major groups and the timing of their divergence supported the view that early placental mammal diversification was strongly influenced by biogeographic processes, likely related to the breakup of supercontinents in the late Cretaceous (Eizirik *et al.*, 2001, Madsen *et al.*, 2001; Murphy *et al.*, 2001a,b). The geographic ranges of living and fossil representatives of these clades suggest that Afrotheria originated in Africa, Xenarthra in South America, and Boreoeutheria in the northern continents (Eurasia or North America). The timing of their divergence coincides with the period of final separation between South America and Africa (both formerly part of the supercontinent of Gondwana), and also with the likely intermittent connection between South and North America via the proto-Antilles corridor (Murphy *et al.*, 2001b).

The exact sequence of biogeographic events leading to the separation of these groups depends on the resolution of the phylogenetic root of living placental lineages (i.e., the relationships among Afrotheria, Xenarthra, and Boreoeutheria). Unfortunately, this has proven remarkably difficult to resolve. All three possible resolutions (Afrotheria diverging first, Xenarthra diverging first, or a sister-group relationship between these two groups) have been retrieved by various molecular studies, and in general, the alternative topologies could not be significantly rejected. An early view of placental evolution suggested that Xenarthra was the most ancient extant group, with the remaining lineages comprising a clade called Epitheria (McKenna and Bell, 1997). This topology is not retrieved very frequently as the best solution, but remains a viable alternative. Several studies have retrieved a sister-group relationship between Xenarthra and Boreoeutheria (e.g., Murphy *et al.*, 2001a), forming a clade named Notolegia (Springer *et al.*, 2007) or Exafroplacentalia (Waddell *et al.*, 2001). This resolution, with Afrotheria as the most divergent clade, suggests that the breakup between South America and Africa, *ca.* 100 MYA, would have caused the initial split in crown placental mammals. Afrotherian progenitors would have remained in Africa, while those of all other living placentals would be in South America, whence they would have colonized the northern continents via the proto-Antilles

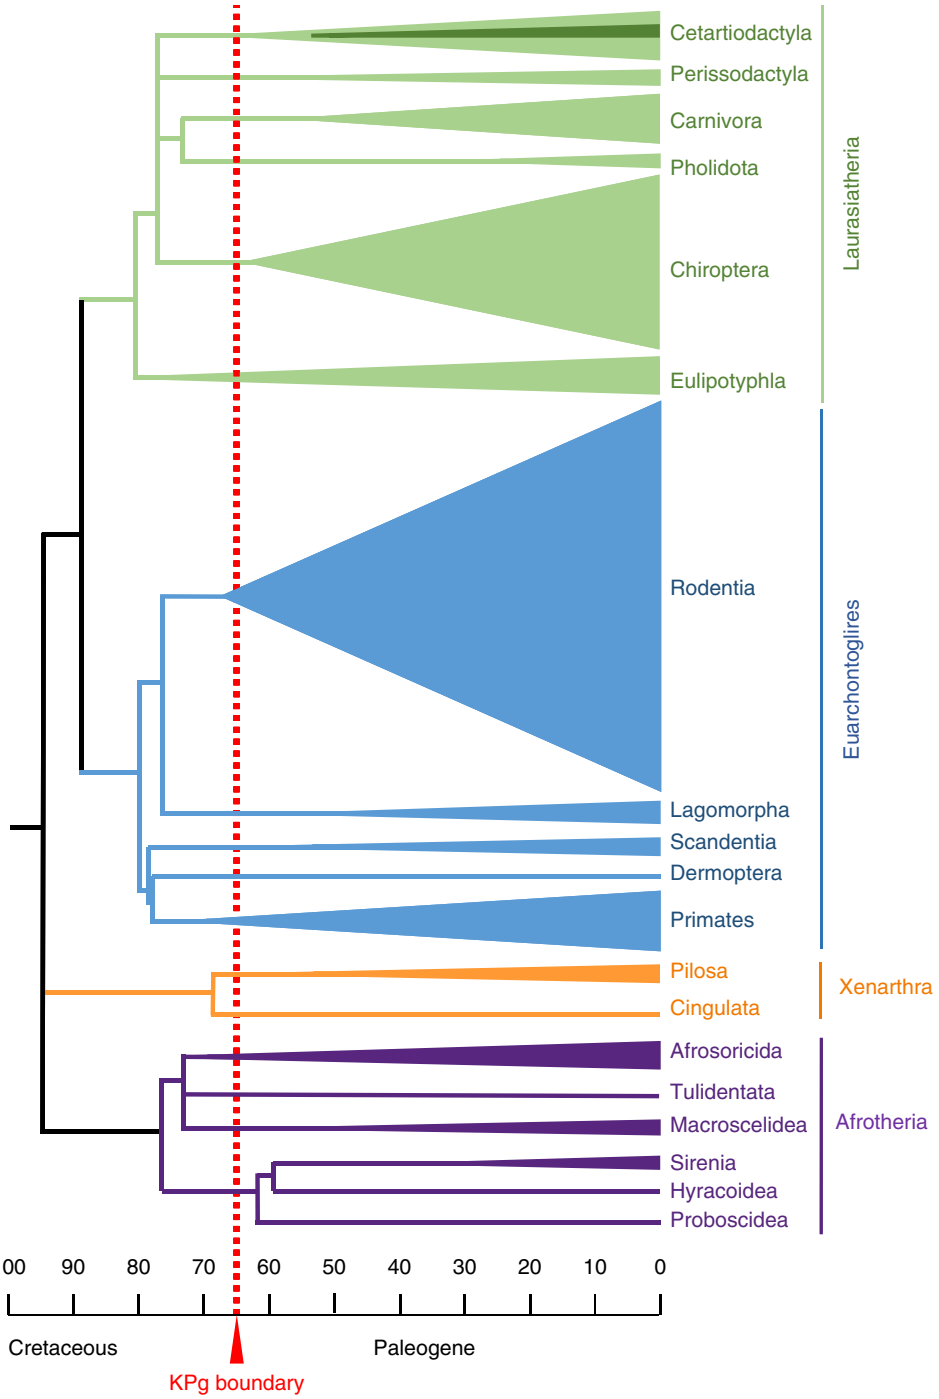

Figure 2 Schematic representation of the diversification of placental mammals. The relationships among extant placental orders are based on the tree reported by Meredith *et al.* (2011). The current diversity of each order is represented (approximately) by the width of its respective line or triangle. The timing of divergence among orders, as well as the timing of diversification within each order, is based on the node ages reported by Meredith *et al.* (2011) and Dos Reis *et al.* (2012). For nodes in which both of these studies reported dates, the average between their two values is depicted here. Each of the four main lineages of placental mammals (Laurasiatheria, Euarchontoglires, Xenarthra, and Afrotheria) is shown in a different color. Within the order Cetartiodactyla, the nested line in darker green represents Cetacea (whales, dolphins, and kin), indicating its origin and diversification from within the order that contains even-toed ungulates (cows, deer, hippos, camels, and kin).

corridor to North America and further to Eurasia (Murphy *et al.*, 2001b, Springer *et al.*, 2007). An alternative, non-exclusive scenario is that Notolegia was more widespread in Gondwana, and at least some of its members were present in India before it was separated and drifted northward; when India collided with Asia *ca.* 55–65 MYA, these lineages would then have colonized the northern continents *via* Eurasia (see Murphy *et al.*, 2001b – online supplemental item 15). The

third possible scenario has been retrieved most often in recent studies (e.g., Meredith *et al.*, 2011), and supports a sister-group relationship between Afrotheria and Xenarthra (which jointly form a clade known as Atlantogenata). Under this phylogenetic reconstruction, the initial split in Placentalia is between southern and northern groups, with the final breakup between South America and Africa likely underlying the separation between the two southern lineages. Given these intriguing biogeographic implications, the effort to resolve the position of the placental mammal root will likely remain a topic of active research in the coming years.

Morpho–Ecological Diversification and Convergent Evolution

A key aspect in the evolutionary analysis of mammalian diversification is to understand the history of the remarkable morpho–ecological adaptations that are a hallmark of many extant lineages. Once the main sections of the phylogeny of living mammals were resolved, new insights could be gleaned onto this topic. There were clearly periods of rapid phylogenetic diversification in the history of both placentals and marsupials (Meredith *et al.*, 2011; Mitchell *et al.*, 2014). In the case of crown placentals, recent analyses indicate that the main bursts of diversification occurred prior to the KPg boundary, and may have been associated with continental breakup but also to novel ecological opportunities associated with the Cretaceous Terrestrial Revolution (Meredith *et al.*, 2011). The main lineages of placental mammals were already established prior to the KPg boundary, and each of them underwent a rapid diversification *ca.* 80 MYA. An assessment of morphological diversity (both extant and fossil) within these lineages indicates that each of them likely still comprised primitive forms (i.e., small and insectivorous) at the time of this diversification (Eizirik *et al.*, 2001), and subsequently underwent a separate adaptive radiation giving rise to specialized forms (Madsen *et al.*, 2001). The timing of this morpho–ecological diversification (i.e., originating elephants and manatees in Afrotheria, or bats, whales, and moles in Laurasiatheria, etc.) is difficult to assess based on molecular data alone, but fossil evidence strongly suggests that it postdates the KPg boundary. It therefore remains a viable hypothesis to postulate that larger, specialized forms of modern mammals arose after the KPg mass extinction, driven by rapid adaptation to novel ecological opportunities that emerged after the extinction of nonavian dinosaurs. However, such processes would have occurred within lineages that were themselves a product of previous diversification processes.

It has been known for a long time that convergent evolution could be observed between lineages belonging to different mammalian groups. This was especially the case when one compared marsupial and placental morpho–ecological 'equivalents,' such as mole-like forms or gliding forms. These comparisons can also include monotremes, as in the case of forms specialized on feeding on social insects: echidnas clearly show morphological convergence with respect to placental and marsupial lineages that eat ants or termites. In addition to these classic cases, the resolution of the placental mammal phylogeny in the last 15 years has revealed many other remarkable case of morpho–ecological convergence (Madsen *et al.*, 2001; Springer *et al.*, 2004). For example, specialized fossorial (mole-like) and marine forms evolved independently in Afrotheria and Laurasiatheria. Specialized ant-eating forms evolved independently in Xenarthra, Afrotheria, and Laurasiatheria, and display remarkable convergence in their morphology (e.g., comparing South American anteaters, Old World pangolins, and African aardwarks). Such cases of extreme adaptations to very diverse life histories, repeated in separate lineages in the context of rapid radiations, contribute to fostering continuous fascination for mammals as a highly attractive subject to in-depth evolutionary analyses.

Mammals Everywhere

BD Patterson, Integrative Research Center, Field Museum of Natural History, Chicago, IL, USA

Introduction

Mammals represent the smallest class of terrestrial vertebrates, comprising approximately 6000 known species. Despite their modest number, mammals are found on all continents, in all oceans, and in all biomes. They range from the abyssal depths to the tops of mountains, living in water, underground, on the surface, in trees, and some can even fly (Macdonald, 2009). Few in number, mammals exert far-reaching effects on the ecosystems in which they live and may serve as landscape architects (Wright *et al.*, 2002; Sukumar, 2003) or regulate trophic cascades (Estes *et al.*, 1998; Terborgh, 1988).

Hallmarks

The earliest mammals relied on hearing and smell to guide their largely nocturnal activities (Ji *et al.*, 2009), leading to the prominence of these sensory modalities in most modern mammals. Uniquely, mammals possess three middle-ear ossicles, which transmit sound waves striking the eardrum to the inner ear (**Figure 1**). Olfactory receptors located in the nasal cavities are well developed in most mammals (Buck, 2004) and are used in a variety of contexts: to find food, detect predators, and, in concert with a host of glandular secretions that are variously produced and expressed, in intraspecific communication and reproduction (Eisenberg and Kleiman, 1972; Doty, 1986). Vision is also well developed in some groups of mammals, especially among diurnal species and in Primates, the group that includes humans.

Hair, another mammalian hallmark, provides insulation, camouflage, a means of communication, and is a sensitive mediator of touch, particularly through sensory vibrissae on the face and extremities (Noback, 1951). All mammals nourish their young via mammary glands (Oftedal, 2002), which give the group its name. One lineage (monotremes) lays and incubates eggs while another (marsupials) gives birth to early-term embryos that complete their development attached to a teat. A specialized complex of fetal and maternal tissues – the placenta – nourishes embryos in the uterus (Wildman *et al.*, 2006). In different groups, this organ involves various degrees of intimacy between fetal and maternal bloodstreams.

Unlike most other vertebrates, mammalian teeth are structurally and functionally diversified (**Figure 2**): from front-to-back, nipping incisors, stabbing and tearing canines, and grinding and shearing premolars and molars (Stock *et al.*, 1997). This variety of functions has permitted mammals to efficiently utilize a wide range of diets. Mastication was particularly important in the exploitation of plants as food by homeotherms, because it quickly exposed ingested cellulose to

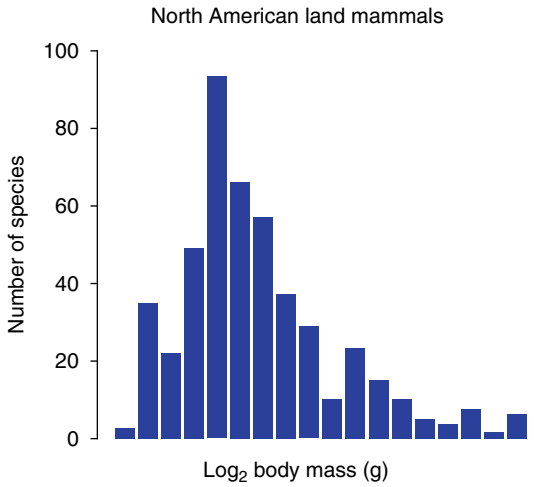

Figure 3 A frequency distribution of body sizes for North American land mammals (465 species). As is the case globally, most mammal species weigh between 50–100 g. The North American fauna shown here encompasses species ranging from 3 g to 393 kg in size (Public domain).

microbial action in the gut (Ley *et al.*, 2008). The gastrointestinal tract of plant-feeding mammals is also compartmentalized to aid cellulose digestion by microorganisms. Ruminants, sloths, kangaroos, and colobus monkeys use foregut fermentation in a compartmentalized stomach, whereas possums, elephants, horses, and many rodents rely on hindgut fermentation (Feldhamer *et al.*, 2007). Smaller species (e.g., rabbits, pikas, and rodents) with shorter digestive tracts and gut passage times often rely on coprophagy (ingestion of select fecal pellets) to extract more nutrients from their diet (Hirakawa, 2001).

Body size

Body size is correlated with so many features of organisms – from their metabolic rate and generation time to space use and diet – that body size has been called the single most fundamental organismal trait (Lomolino *et al.*, 2010). Mammals range over eight orders of magnitude in body size, from the 2 g pygmy shrew to the 180–200 t blue whale (Smith and Lyons, 2011). In this respect, they exceed all other animal groups. Even insects, which outnumber all others combined, only range over three orders of magnitude (Chown and Gaston, 2010).

Surely, this amazing variation in body size both underlies the ecological diversity of mammals and has helped give rise to it (**Figure 3**). It helps mammals exploit a range of ecological opportunities that are beyond the reach of less variable organisms. For example, elephants can detect infrasound waves as low as 10 Hz, whereas some insectivorous bats echolocate at over 200 kHz. Mammal diets are highly varied and include virtually all items eaten by other tetrapod groups and some that only mammals can exploit. The smallest mammals tend to exploit energy-rich resource patches needed to maintain their exorbitant metabolic rates, whereas larger mammals are more wide-ranging, have slower metabolisms and longer gut retention times, and can exploit lower-quality foods (McNab 2007; Brown and Maurer, 1989). Mammals seem to have an optimal body mass of about 1 kg, which may explain the 'Island Rule' in which small mammals evolve to become larger and larger ones are dwarfed (Damuth, 1993; Brown *et al.*, 1993). Nevertheless, various lineages of Cenozoic mammals, especially larger ones, show evidence of progressive increases in body size consistent with Cope's Rule (Alroy, 1998).

Mammals vary geographically in ways that help them exploit different habitats and ultimately foster their diversification. Some of the most conspicuous 'ecogeographic rules' – general patterns of geographic variation in response to ecology – are embodied by mammals, although their interpretations are often complex (Lomolino *et al.*, 2010). Bergmann's Rule posits that races of warm-blooded animals from colder climates tend to be larger than those from warmer regions (Mayr, 1956; Meiri and Dayan, 2003), because the volume of thermogenic tissue increases as the cube of body size, whereas heat loss scales with surface area (square of size). The wide-ranging puma illustrates this pattern, with smaller tropical forms flanked by large subspecies in both the Northern Rockies and the Southern Andes (Gay and Best, 1996). Allen's Rule was coined to describe the progressive shortening of appendages (both limbs and extremities) in progressively colder climates. It has been used to explain the faces and ears of North American foxes and hares (but not rabbits; Stevenson, 1986) and even humans (Hurd and Van Anders, 2007). Gloger's Rule, hypothesizing that animals from humid environments

are darker than their relatives from drier ones, also seems applicable to mammals (Kamilar and Bradley, 2011). These rules may even be used to forecast animal responses to global warming (Millien *et al.*, 2006).

Socially, mammals range from solitary and promiscuous to eusocial forms. Groupings offer different mammals protection from abiotic factors or from predators, help them find and harvest food, and even rear young via cooperative breeding (Silk, 2007). Although many species are solitary and even territorial except during the breeding species, others form intra-group alliances and coalitions. Kin and group selection are implicated in the more dramatic examples of mammalian sociality (Clutton-Brock, 2002). Maternity colonies of the Mexican free-tailed bat may number as many as 20 million individuals (McCracken, 1986).

Life Modes

The locomotory diversity of mammals is exceptional in itself and has also served to foster their diverse trophic, physiological, ecological, and social adaptations. Surface dwelling and quadrupedal, plantigrade (flat-footed) locomotion is primitive for synapsids (Luo *et al.*, 2011), but mammals quickly adopted various other forms (Ji *et al.*, 2006; Luo and Wible, 2005). Their innovations involved pronounced modifications of the limbs, transforming a largely common *bauplan* into radically different products, such as wings, paws, hoofs, and flippers (Cooper and Tabin, 2009). Most mammals are terrestrial and either walk or run. Functionally, locomotion by quadrupeds must provide propulsion, maneuverability, endurance, and support and stability while the feet make intermittent contact with the substrate (Hildebrand, 1985). Different gaits are used to move at progressively faster speeds: walking, pacing, trotting, and finally galloping and bounding, in which all four feet may become airborne. Mechanical constraints on the ribcage and diaphragm link breathing frequency to the different footfalls in these gaits, strictly coupling respiration and locomotion to maintain aerobic capacity (Bramble and Carrier, 1983; Bramble and Jenkins, 1993).

Most ungulates, some carnivores, and even some rodents have become truly cursorial, in which limb movements are restricted to a single plane, parallel to the body. Cursorial mammals have elongated limbs, often with bone reductions and fusions in the lower leg so that only the tips of the digits (in the Equidae, a single digit) contacts the ground (**Figure 4**). A proximal shift of appendicular musculature reduces weight and increases running speed (Hildebrand and Goslow, 2001). Fast, efficient movements give them large home ranges and the ability to pursue prey or escape predators. Ricocheting is a specialized form of locomotion typically employed by smaller, open-country species in which the hind limbs provide propulsion and the forelimbs are shorter and used in feeding and slower, more precise maneuvers (**Figure 5**). Lengthening of one or more hind limb segments provides mechanical advantage, and long, elastic tendons that transcend the knee and ankle store energy from one jump that can be used in the next one (Berman, 1985).

Relatively modest transformations carried mammals from substrates into the tree tops, which are home to many marsupial groups, tree sloths and anteaters, some pangolins, most primates, tree shrews, and many groups of carnivores and rodents. Typically, recurved claws or grasping hands and feet provide secure purchase far aboveground (**Figure 6**). Prehensile tails have evolved independently in both American and Australian marsupials, anteaters, pangolins, platyrrhine monkeys, porcupines, and binturongs. Arboreal mammals typically possess forward-directed eyes for good depth perception and many can rotating their ankles for secure descents. Most scramble over branches, but some (sifakas and tarsiers) are powerful leapers. Lesser apes and some ateline monkeys can travel rapidly by brachiation, or arm swinging, while other arboreal mammals relying on suspension (sloths) are notoriously slow. Various arboreal groups, including some marsupials, squirrels and anomalurid rodents, and colugos, have developed extensive patagial membranes for gliding between trees.

Many terrestrial groups have also undertaken evolutionary transitions to subterranean habits, often adopting similar convergent adaptations. Diggers typically have cylindrical

Figure 6 A sifaka (*Propithecus verreauxi*), in the family Indriidae (Primates), showing the prehensile hands and feet possessed by many arboreal mammals. In addition, sifakas have long legs and a tail for leaping between trees and across the ground. Photographed by B.D. Patterson in the Berenty Reserve, Madagascar (© 2005).

bodies and short limbs so as to fit compactly within their burrows, and tolerance for the hypoxia and hypercapnia that often develop there (Begall *et al.*, 2007). Loose skin helps them to turn within a confined space. Many burrow dwellers move backwards nearly as adeptly as they do forwards, aided by stiff hairs on the hind feet and tail that may help move dirt and transmit information through touch. In lineages long committed to underground life, such as golden moles (Chrysochloridae) and African mole-rats (Bathyergidae), the eyes become nonfunctional and the ear pinnae are lost or reduced in size. Excavations may be accomplished with either the pectoral girdle or with the teeth, and the soil is moved with either fore or hind limbs. Forms that use the teeth for digging (e.g., pocket gophers and mole-rats) have well-haired lip folds behind the incisors that prevent dirt from entering the oral cavity (Diaz *et al.*, 2000).

The bats are one of three vertebrate groups to evolve powered flight (Kunz and Fenton, 2003). Their wings consist of elongated arm, hand, and finger bones that support elastic skin membranes extending between them and the body, and variably to the legs and tail (**Figure 7**). Relative to birds, most bats fly slowly but are highly maneuverable, and most bat families are insectivorous and feed while flying. Bats emit high-frequency sound pulses through the mouth and/or nose to locate prey items, often via an ornate nose leaf to focus sound. Different wavelengths are sensitive to objects of different sizes, so that by exploiting different band-widths, species effectively partition their insect resources. Even the earliest known bats could both fly and echolocate, making it controversial to gauge which innovation came first (Gunnell and Simmons, 2012). Only 2 of 18 families of bats (New and Old World fruit bats) exploit plant resources, but each has explosively radiated to harvest pollen, nectar, and fruit, becoming vital partners in the life histories of many tropical plants (Lobova *et al.*, 2009).

Many groups of mammals swim and/or dive (Berta *et al.*, 2005). The buoyancy of water releases mammals from gravitational constraints, but poses challenges involving thermoregulation, locomotion, respiration, and pressure, especially for deep-diving species. The high thermal conductivity of water means most aquatic and marine mammals are larger than land-living relatives and smaller species are restricted to freshwater, near-shore or tropical waters (Williams *et al.*, 1998). Marine species commonly supplement the favorable surface-to-volume relationship of large body size with layers of insulating blubber and counter-current heat exchangers in their extremities. The body is typically streamlined (**Figure 8**) and propulsion may be from the forelimbs (platypus, some fissipeds), hind limbs (water opossum, other fissipeds and rodents), or modifications

Figure 7 Straw-colored bats (*Eidolon helvum*), family Pteropodidae (Chiroptera), taking flight from a tree roost. Flight offers rapid, efficient and long-distance movements that underlie both the explosive diversification of bats and the migratory habits of this species. Photographed by B.D. Patterson in Mbale, Kenya (© 2012).

Figure 8 Afro-Australian fur seals (*Arctocephalus pusillus*), family Otariidae (Carnivora), resting on a beach. Although recently derived from terrestrial carnivores, eared seals exhibit the fusiform bodies and flattened flippers of most marine mammals, as well as minute ears. The powerful pectoral fins are used by members of this family for propulsion. Photographed by B.D. Patterson in Walvis Bay, Namibia (© 2005).

of the tail (some rodents, manatees, and cetaceans). In different groups, each of these extremities may be involved in steering. Breathing is accomplished through dorsally positioned nostrils. Diving species are able to remain submerged for extended periods, up to 2 h in sperm whales, by virtue of efficient extraction of oxygen, elevated number of erythrocytes, and much higher concentrations of myoglobin in the tissues; because their lungs collapse completely during deep dives, they can avoid decompression sickness.

The Age of Mammals

The Cenozoic Era, extending from the Mesozoic to the present, is commonly called 'The Age of Mammals' because of the explosive radiations of mammals during this period. Recently, in recognition of the massive and irreversible changes wrought by an ever-expanding human population, many have suggested that we have entered a new era, the Anthropocene (Steffen *et al.*, 2011). Human activities threaten many mammal groups, both directly through habitat loss, fragmentation, and direct persecution for many terrestrial mammals, or pollution and accidental mortality, especially among marine mammals (Schipper *et al.*, 2008). It is a testament to the adaptability of mammals that a host of species (Brush-tailed possums, European rats and house mice, gray squirrels, house cats, rabbits, mink – all considered invasive or pest species) have been successful in exploiting this ever-changing landscape, often despite efforts by humans to control them.

Mammals, Origin of

FA Perini, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Introduction

Mammals are not the most speciose group of living vertebrates. Actually, far from it; among tetrapods alone, mammals are one of the groups with less living species, with approximately 5500 species (Wilson and Reeder, 2005), about 25% of all diversity of tetrapods, well behind Lissamphibians (~6600 spp), Lepidosaurians (~9000 spp), and Archosaurians (including birds and crocodilians; ~10 000 spp.) (Pough *et al.*, 2012). However, mammals are certainly the most disparate group of vertebrates, with a wide range of different kinds of adaptations including, but not restricted to, fossoriality, powered flight, and aquatic adaptations. They vary widely in shape and size, and the largest animal to ever exist is a mammal – the blue whale (*Balaenoptera musculus*). Mammals are also very conspicuous elements in many modern ecosystems and have a huge impact in shaping ecological landscapes; most large modern animals are mammals. We ourselves are mammals, so understanding mammalian evolution is also to understand a little about our own history.

Mammalian Characteristics

Independent of size and shape, all mammals share a unique set of characteristics both from soft tissue and the skeleton. Mammals' hearts have a single aortic arc, the right one, and enucleated red blood cells (**Figure 1**). Mammals usually have a very glandular skin, with different kinds of glands as sweat and sebaceous glands, which exercise many different functions as lubrication of the fur and thermoregulation (through evaporation of sweat, for example). However, the most characteristic and unique of the skin glands of mammals are the mammary glands, which give the group its name. Mammary glands are a very important aspect of mammalian life history, and allow mammals to provide nutrients and feed their young independently of the availability of food in the environment (Oftedal, 2002). All mammals suckle their young, and consequently all mammals show some degree of parental care (**Figure 2**).

Most mammals are viviparous, giving birth to live young, although there are exceptions. Monotremes, a group of mammals that is today restricted to Australia and New Guinea and

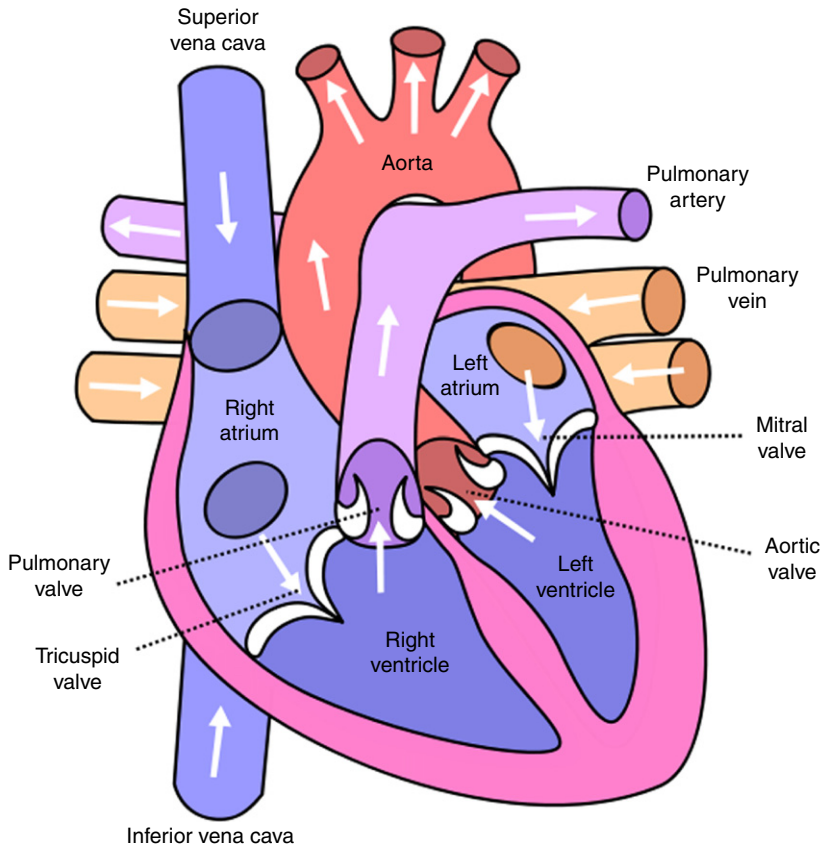

Figure 1 A diagram showing the mammalian heart. Creative Commons (https://commons.wikimedia.org/wiki/File:Diagram_of_the_human_heart_(cropped).svg).

 doi:10.1016/B978-0-12-800049-6.00282-1

include platypuses and echidnas, are the only modern mammals that lay eggs. Oviparity is a primitive condition for mammals, and probably was present in the non-mammalian ancestors of the group (Hopson, 1973). The remaining groups of mammals, the marsupials and placentals, share the derived condition of viviparity, despite the differences in reproductive mode that we find today between them. Endothermy is also frequently associated to mammals, although it is not an exclusive characteristic of them, having evolved independently in birds (Pough *et al.*, 2012). However, it is very likely that the evolution of endothermy may have had a big role in shaping the evolution of many of the other mammalian characteristics (McNab, 1978; Kemp, 2006). For example, the evolution of fur is probably related to the evolution of endothermy. Fur exert numerous functions, as defense (think about quills of porcupines or scales of pangolins), orientation (vibirissae), camouflage, and communication, but its primary function is thermal insulation, i.e., to avoid loss of body heat to the environment (Ji *et al.*, 2006).

Figure 2 All mammalians suckle their young. Here is a photograph of a sculpture illustrating the Rome's foundation myth in which a she-wolf suckles the founders of Rome. Creative Commons (https://commons.wikimedia.org/wiki/File:La_Louve_(349313603).jpg).

Mammals are also heterodont, which means that they have highly differentiated teeth, the incisors, canines, premolars, and molars. These differentiated teeth exert different functions during apprehension and mastication of the food, and contribute to better efficiency in processing and assimilation of the nutrients. Mammals have especially complex molars that have a wide contact surface between upper and lowers molars called the occlusal surface, which enhance the efficiency of mastication (Hillson, 2005). Living mammals, in almost all their totality, have tribosphenic molars, a kind of molar that primitively has three main cusps. Most of the varied and different dental morphologies that we see in today's mammals are modified from primitive tribosphenic molars (Kielan-Jaworowska *et al.*, 2004; Luo, 2007).

Mammals also have a bony secondary palate, a structure that isolate respiratory and swallowing functions, and allow feeding and breathing at the same time, which was probably crucial in the evolution of breastfeeding (Pough *et al.*, 2012). Breathing in mammals is also enhanced by the presence of a muscular diaphragm, a muscle that helps in the contraction and expansion of the thoracic cage (Vaughan *et al.*, 2013). The presence of the diaphragm is reflected on the skeleton: mammals usually have reduction of the neck and lumbar ribs, keeping only the ribs on the thoracic cage, creating a clear division between thoracic and lumbar portions of the vertebral column. This division corresponds approximately to the localization of the diaphragm (**Figure 3**).

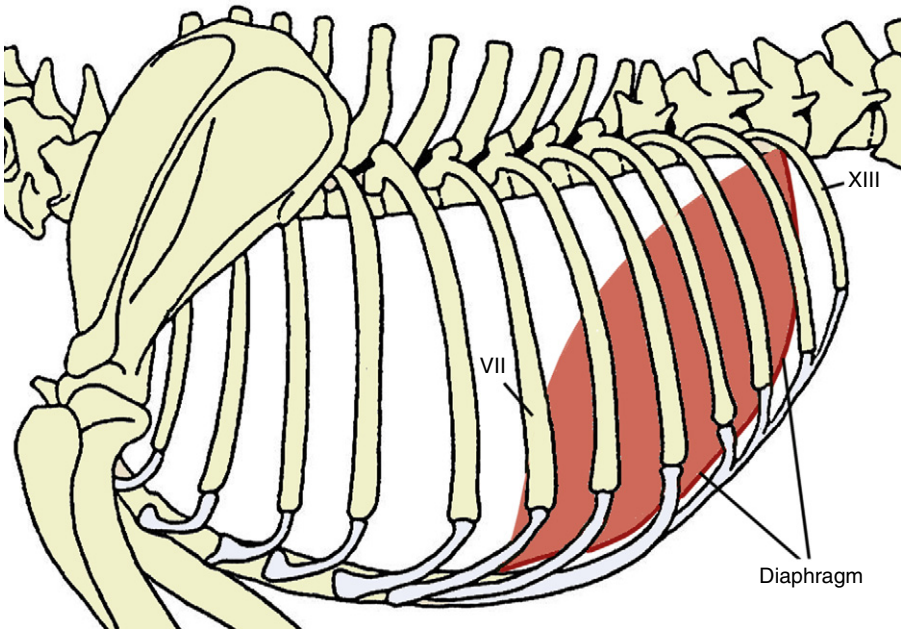

Figure 3 Illustration showing the diaphragm in the thorax of a dog. Creative Commons (https://commons.wikimedia.org/wiki/File:Thorax-withdiaphragm-dog.png).

However, the defining characters of mammals are the structures associated with the ear, jaw, and the temporomandibular articulation of the skull (Kermack and Kermack, 1984; Rowe, 1988). Mammals are the only vertebrates to have the middle ear composed by three ossicles: the incus, malleus, and stapes. Mammals also have the mandible formed by a single bone, the dentary, while all other vertebrates have the mandible composed by many different bones having, besides the dentary, many post-dentary bones. The dentary of mammals also participate in the articulation of the mandible with the squamosal bone of the skull. In most other vertebrates, this connection is formed by different bones, the articular in the mandible and the quadrate in the skull (Kemp, 2005).

To understand how those unique mammalian characteristics evolved, we have to understand the evolutionary processes by which the different lineages of Synapsida went through in the last 300 Ma.

Early Evolution of Synapsids

Mammals are the only living survivors of an ancient lineage of amniotes, the Synapsida. Mammals themselves are known from the Triassic, at approximately 205 Ma, but the first synapsids date from the Carboniferous, more than 320 Ma (Reisz, 1972). Synapsida are one of the oldest known groups of Amniota. They can be readily distinguished from other amniotes by the presence of a single temporal opening on the temporal region of the skull. Today, most amniotes are part of Diapsida, who share two temporal openings on the skull, and the mammals are the only surviving group of synapsids, not sharing a close relationship with any of the other living amniotes (Cracraft and Donoghue, 2004). Mammals are the last in a series of successive radiations of synapsids throughout the end of the Paleozoic and the beginning of the Mesozoic. Extinct species of non-mammalian synapsids are frequently known collectively as 'mammal-like reptiles'. The name, however, is misleading, since these organisms are neither reptiles nor mammals. 'Mammal-like reptiles' is not a natural group, since it excludes the whole of the mammalian radiation. Thus, it is a paraphyletic group in relationship to mammals. Reptiles themselves are paraphyletic, for they exclude both birds and mammals. To be considered a natural group, it must include all descendents from a common ancestor, that is, it should be a monophyletic group.

Synapsids were the first lineage of amniotes to radiate extensively in terrestrial ecosystems, and during the Permian and the first half of the Triassic, non-mammalian synapsids were the predominant group of large vertebrates (Kemp, 2005). The more primitive synapsids and the first group to irradiate are the 'reptile-looking' 'pelycosaurs' (**Figures 4–7**). They are also a paraphyletic group, that is, they are constituted of a sequence of successive radiations before the radiation of the more recent synapsids and do not form a natural group. They were the predominant group of terrestrial vertebrates during the lower Permian (300–250 Ma) (Kemp, 1982).

'Pelycosaurs' had a generalized body plan, with sprawling stance and heavy tails. In these aspects, pelycosaurs recall what most people would identify as a 'reptile' (**Figures 4–7**). Most early Permian ecosystems were dominated by pelycosaurs, which included very small and insectivore species as well as large animals, some attaining 3 m or more in length, and including both herbivore and carnivore species (Kemp, 1982). Herbivores typically had small skulls, large barrel-shaped bodies, and spatulated teeth, adapted to acquire and process vegetable matter (Sues and Reisz, 1998). Carnivores, on the

Figure 6 A skeleton of *Ophiacodon mirus*, a pelycosaur, at the Field Museum of Natural History in Chicago (https://commons.wikimedia.org/wiki/File:Ophiacodon_mirus_fm.jpg).

other hand, usually had big heads with dagger-like teeth to subjugate and dismember prey. Widely known species as *Dimetrodon* are frequently associated to dinosaurs, but they are actually pelycosaurs (from the family Sphenacodontidae), being more closely related to mammals than to dinosaurs (Angielczyk, 2009). Different species of pelycosaurs, including the carnivorous *Dimetrodon* and the herbivorous *Edaphosaurus*, evolved independently extremely elongated neural spines of the vertebrae (Romer and Price, 1940; **Figures 4** and **5**). These spines probably were covered in living tissue in life, forming a kind of 'sail'. It is thought that these 'sails' may have functioned during thermoregulation – they were restricted to large species, and were probably rich in blood vessels. When the animal would want to warm themselves, they would turn the 'sail' perpendicularly to the sun. Since the sail has a low surface–volume ratio, it allowed the animal to warm faster than other species (Kemp, 1982). Likewise, cooling was also enhanced by the presence of the 'sail.' If confirmed its role in thermoregulation, it is interesting to observe the evolution of early mechanisms of controlling the temperature in the lineage of synapsids.

Despite their generalized appearance, some pelycosaurs already showed the early stages of a series of characteristics that we will find in more advanced condition in later synapsids and mammals (Kemp, 1982; Kermack and Kermack, 1984). Those characteristics were especially developed in derived families as the Sphenacodontidae. Some of these derived pelycosaurs had a beginning of dental differentiation, with some carnivore species displaying clearly elongated caniniform teeth, and showing some differentiation between

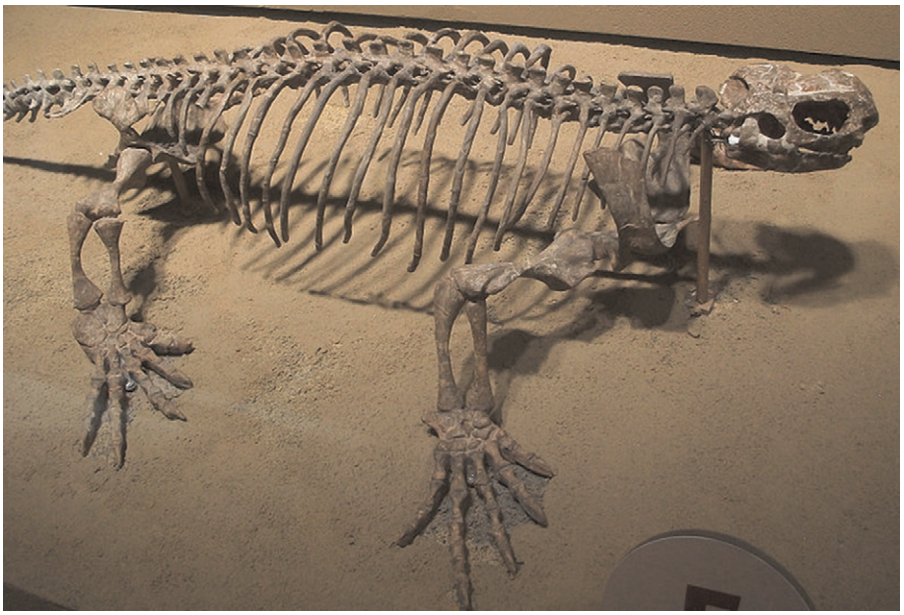

Figure 7 A skeleton of *Casea broilii*, a pelycosaur, at the Field Museum of Natural History in Chicago (https://commons.wikimedia.org/wiki/File:Casea_broilii.jpg).

pre-caniniform teeth (incisiviforms) and post-caniniform teeth. They had a typical primitive synapsid skull, but derived groups showed expansion of the dentary on the mandible at expense of post-dentary bones and an archeated palate, which may presage the development of a secondary bony palate (Kemp, 2005).

The next radiation of synapsids is the group known as Therapsida. Therapsids mostly replaced pelycosaurs from the middle until the end of the Permian as the dominant group of terrestrial vertebrates. As pelycosaurs, therapsids are a paraphyletic group, unless you include mammals in it (Kemp, 2005). There are many groups of non-mammalian therapsids that show characteristics progressively more mammalian. Non-mammalian therapsids irradiated throughout most of the upper Permian and lower Triassic, and extinguished around the upper Jurassic, but by then their diversity was much diminished.

Even some of the more primitive therapsids already show some characteristics that evoke the condition we see in mammals. Many of those characteristics are possibly associated with higher metabolic rates and higher levels of activity when compared to pelycosaurs (Hopson, 2012). There's a tendency for the enlargement of the primitive temporal fenestra of the synapsids, associated with the expansion of the masticatory musculature (Kemp, 2005). There is also further differentiation between the different kinds of dentition, with clearly defined caniniforms, incisiforms, and anterior and posterior post-caniniform teeth (Kermack and Kermack, 1984). The coanae (internal apertures of the respiratory tract) are connected to the external nares by a sulcus on the palate, and the dentary are much larger than in pelycosaurs, further usurping the function of the post-dentary bones. These characteristics are not restricted to the skull, and the post-cranial skeleton shows a simplified pelvic girdle with a more forwarding pointing ilium and less sprawling limbs, which suggests a semi-erect position, at least in the more derived therapsids (Rubidge and Sidor, 2001).

Therapsids are known from the upper Permian ($\sim$260 Ma) and irradiated extensively throughout the Upper Permian, effectively replacing the pelycosaurs in most of the niches available to large terrestrial vertebrates, evolving large specialized herbivores as the Dinocephalia, and large carnivores as the Gorgonopsida (Kemp, 2005), but also small insectivores and the first arboreal synapsids known (Fröbisch and Reisz, 2009; **Figures 8–12**). Some of the groups of therapsids were highly successful in terms of diversity and sheer numbers of individuals.

The dicynodonts, one of the longest living groups of Synapsida, spanned from the upper Permian, survived the great extinction at the end of this period and flourished in the Triassic, and perhaps, but controversially, extending into the Early Cretaceous (Thulborn and Turner, 2003), which, if confirmed encompass an astonishing long period of time. Dicynodonts included mostly herbivore forms, from small and fossorial to very large and semi-aquatic. They were one of the most widespread and diverse large herbivores from the Upper Permian and the Lower Triassic (Kemp, 1982). Dicynodonts had reduced dentition and the anterior part of the jaw was covered with a horny beak like those of turtles (Cluver and King, 1983; Kammerer and Angielczyk, 2009), being somehow different from the idea we have of a vertebrate from the lineage of mammals. The therapsids also included a wide range of carnivore forms, and during the Upper Permian most of the larger carnivores belonged to this group (Kemp, 2005).

Despite its diversity, by the end of the Permian most of the lineages of therapsids went extinct, associated with a mass extinction that occurred during this period. The extinction of the end of the Permian was actually the largest extinction known in the history of the Earth, when about 84% of

Figure 8 A skeleton of *Biarmosuchus tener*, a biarmosuchian therapsid at the Dinosaurium exhibition, in Prague (https://commons.wikimedia.org/wiki/File:Dinosaurium,_Biarmosuchus_tener_1.jpg).

Figure 9 A fossil skeleton of *Inostrancevia alexandri*, a gorgonopsid therapsid (https://commons.wikimedia.org/wiki/File:Inostrancevia_alexandri.JPG).

the genera and 90% of the species then known went extinct (Benton, 2005). The causes of this extinction are still debatable, including extraterrestrial impacts, climate change, increased volcanic activity, etc. Beyond the Permian/Triassic frontier, we have practically only two groups of surviving synapsids: the already mentioned Dicynodonts and another group, the Cynodonts (Smith and Ward, 2001), from which probably emerged the ancestor of modern day mammals.

The first record of cynodonts date from the Upper Permian, and they are one of the few groups of synapsids to survive the extinction at the end of the Permian, radiating extensively during the Lower Triassic (Kemp, 2005). Most of cynodonts were small vertebrates, mainly carnivores or insectivores, with a strong tendency for miniaturization in the lineage, especially in the Upper Triassic. Although in the beginning of the Triassic some cynodonts, like *Cynognathus* (with a snout-vent length of about 1 m), were relatively large, by the end of the Triassic no cynodont was larger than 200 mm (Ruta *et al.*, 2013; **Figures 13–15**). They were the most mammal-like of the non-mammalian therapsids, with high degree of dental differentiation, with post-caniniform teeth frequently multicuspidated and showing dental occlusion, development of a maxillary fossae on the dentary for the insertion of masticatory muscles, enlargement of the infraorbital foramen (Hopson and Kitching, 2001), which may indicate the presence of vibrissae, and evidence of the presence of turbinal bones (Hillenius, 1994). The

dentary was also very large, and a tall coronoid process has evolved, while most post-dentary bones were small and relatively unimportant (Kemp, 2005).

Evolution of Mammalian Characteristics

Since we are close to the origin of mammals, it may be useful to review the evolutionary tendencies that we observe along the lineage of synapsida leading to mammals. Synapsids were one of the earliest lineages of amniotes to diverge, and they remained as one of the most significative components of terrestrial faunas until they were mainly displaced by Diapsid reptiles by the end of the Triassic. Groups of Synapsida tend to show characteristics progressively more mammalian during the course of its evolution, and they are possibly associated to metabolic changes associated to endothermy and a better processing of the food (Sidor and Hopson, 1998). The exact time of evolution of endothermy and which groups of synapsids had any level of control of its temperature are still controversial. Cynodonts, in special, show so many mammalian characteristics that it seems pretty likely that they already were endothermic. Pelycosaurs, on the other hand, almost certainly were ectothermic, with a metabolism similar to modern lizards and crocodiles (Kemp, 2006). However, many of the characters that would strongly imply endothermic metabolism (as the presence of fur) only under exceptional circumstances fossilize (Ji *et al.*, 2006), so we usually have to extrapolate from the indirect evidence of the skeleton.

Among the synapsids there is a tendency for the enlargement of the temporal fenestra originally present in the ancestor of synapsids. This enlargement is associated to the increase of the cranial capacity, the enlargement of the brain, and mainly, with the development of the masticatory musculature. The enlargement of the temporal fenestrae is accompanied by the outward projection of the inferior bar

of the fenestra, which in mammals forms the zygomatic arch (Kemp, 2009). Pelycosaurs didn't have a secondary palate, but some advanced forms did have the palate slightly archeated.

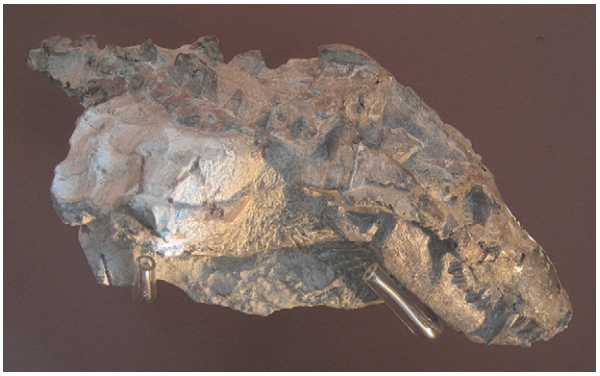

Figure 15 A skull of *Thrinaxodon liorhinus*, a cynodont therapsid at Cosmocaixa, Barcelona (https://commons.wikimedia.org/wiki/File:Thrinaxodon_liorhinus.jpg).

Some advanced non-cynodont therapsids had an incomplete secondary palate, i.e., the palate curved inwards almost closing in itself, and in life they probably were completely closed by soft tissue. Most cynodonts already had evolved a complete secondary palate (Angielczyk, 2009).

The postcranial skeleton also went through drastic changes during the evolution of synapsids. There's a tendency to the progressive positioning of the limbs under the body, in contrast with the primitive amniote condition, where the limbs were positioned perpendicularly in relation to the central axis of the body, resulting in a sprawling stance. The changes in the positioning of the limbs are also reflected in the limb musculature insertions, and consequently, in the structure of pelvic and scapular girdles (Kemp, 1982). Mammals have a reduced pubis when compared with its pelycosaurs precursors, and the ileum projects forward, reflecting the restructuring of the locomotor muscles (Jenkins and Parrington, 1976). There is also a tendency for the reduction of the scapular elements, like the interclavicule and choracoid bones, that are absent in most mammals, but present in non-mammalian synapsids (Jenkins

and Parrington, 1976; Ji *et al.*, 1999). The phalanges of mammals are also shortened when compared specially with pelycosaurs, as a consequence of the limbs being positioned under the body and shift in gait. In non-mammalian amniotes, the astragalus is positioned laterally to the calcaneous, while in mammals, the position of the astragalus is changed, being positioned over the calcaneus, restricting lateral movements, but emphasizing parasagittal movements (Ji *et al.*, 1999). Some primitive mammals (like monotremes) have the astragalus only partially superimposed over the calcaneus. Finally, there is the formation of a projection of the calcaneum for the insertion of the lower limb musculature (Kemp, 2005).

However, the most important changes are related to the evolution of the middle ear and the temporomandibular articulation. The dentition of the synapsid becomes more and more complex, starting from a homodont condition, where all the teeth share the same basic morphology and evolve toward dentary differentiation and dentary occlusion (Kermack and Kermack, 1984). The dentary expands progressively, taking the functions of the post-dentary bones, until those are greatly reduced. In most of the amniotes, the temporomandibular articulation is formed by the articular bone in the mandible and the quadrate bone in the skull. In mammals, the articulation is formed by the squamosal and the dentary. As the dentary expands, the articular and quadrate gradually loses the function of articulating the mandible with the skull. As those bones lose function, they are co-opted to the middle ear, and give origin to the ossicles of the ear of mammals. The articular then is homologous to the maleus and the quadrate is homologous to the incus. The other bone of the middle ear of mammals is the stapes, that is homologous to the single bone of non-mammalian amniotes, the columela. The angular bone of the mandible of non-mammalian synapsids is homologous to the ectotympanic bone, a ring-shaped bone which supports the tympanic membrane (Luo, 2011).

Some derived cynodonts and basal mammals had a double (mixed) articulation, where both the dentary and the articular participated in the articulation with the squamosal and quadrate, so these bones are not yet incorporated in the middle ear (Kermack and Kermack, 1984; Crompton, 1970). Interestingly, during the embryonic development, some mammals initiate the development with the middle ear ossicle and the ectotympanic connected to the mandible in the corresponding position of the post-dentary bones of synapsids, and only later in the development they migrate to the middle ear (Rowe, 1996).

Mammalian Evolution

By the end of the Triassic and the beginning of the Jurassic, non-mammalian therapsids were virtually extinct, and most of the niches for large terrestrial vertebrates were occupied by Diapsids, mainly dinosaurs. The only group of synapsids to flourish in this period was the mammals. The oldest mammals were from the Upper Triassic ($\sim$200 Ma) (Kielan-Jaworowska *et al.*, 2004). There is some debate if these early representatives of the group should be really called Mammalia. Some authors prefer to restrict the name to modern species and their fossil relatives, and those early mammals would be part of the more inclusive group Mammaliformes (Rowe, 1988). However, since they show the fundamental characteristics of mammals, as the articulation of the dentary with the squamosal, and probably were fully mammalian in their biology, we should use Mammalia in this more inclusive meaning, and consider those early representatives as mammals.

The earliest mammals like *Morganucodon* and *Megazoostrodon* show a continuation of the trend we observe in the cynodonts and were very small animals, with less than 100 g, and were probably nocturnal insectivores (Kermack and Kermack, 1984; Kielan-Jaworowska *et al.*, 2004). From these early forms, mammals irradiated extensively during the Mesozoic. The Mesozoic correspond to two-thirds of the history of mammals (Kielan-Jaworowska *et al.*, 2004). For a long time, Mesozoic mammals were thought to be relatively little diverse, being predominantly little scurrying insectivores. However, in the last decade, new discoveries showed a greater diversity of adaptive types among Mesozoic mammals than previously suspected, including species adapted for swimming, digging, and gliding (Luo, 2007). Despite this variety, the Mesozoic radiation of mammals was still greatly limited when compared to more modern groups, lacking the ecological equivalents of whales, bats, and antelopes.

The diversification of Mesozoic mammals occurred through successive radiations (Luo, 2007). The first one occurred in the Jurassic and Lower Cretaceous, involving mainly archaic groups that, in their majority, did not leave living descendents. The second radiation occurred mainly in the Middle and Upper Cretaceous and involved more derived forms, including the ancestors of today marsupials and placentals. The oldest metatherian (*Sinodelphys*) is from the Lower Cretaceous ($\sim$125 Ma) (Luo *et al.*, 2003) and the oldest eutherian (*Juramaia*) is from the Upper Jurassic ($\sim$160 Ma) (Luo *et al.*, 2011). Both are from China, and show that the divergence between those two groups occurred at least at the end of the Jurassic.

By the end of the Cretaceous there was a new mass extinction that, while less devastating than the extinction of the end of the Permian, extinguished most of the non-avian dinosaurs and many of the archaic groups of mammals. However, the ancestors of living placentals and marsupiais survived and thrived, irradiating extensively during the Cenozoic. As in the case of the extinction of the end of the Permian, the causes of the end of the Cretaceous extinction are still debatable, although there is some agreement that a large asteroid hit the Earth around this time (Schulte *et al.*, 2010). During the beginning of the Cenozoic, in the period known as Paleogene, the climate was hot and forests similar to today's tropical forests spanned to above the Arctic Circle (Blois and Hadly, 2009). During this time, many archaic groups of mammals evolved, as well as the first representatives of modern orders of mammals. Many unique types of mammals were known then, and the fauna would look unfamiliar to modern eyes. From the Oligocene onwards, the planet temperature started falling, leading to the formation of polar caps and restricting tropical-type forests to the equatorial regions. Consequently, there was an increase in the aridity of the planet and large plains covered in grasses started to spread. Many of the archaic groups of mammals became extinct during this time, opening avenues for new fauna to flourish with a more modern aspect (Rose, 2006).

Mate Choice and Sexually Selected Traits

S Dhole and MR Servedio, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Glossary

Genetic correlation or linkage disequilibrium A statistical association between alleles at two or more loci, where specific alleles at each locus are found together in a genome more often than expected by random assortment.

Indirect selection Selection that acts at a locus as a result of its genetic correlation with another locus that is the primary target of selection. During sexual selection, this often arises when a preference or choosiness allele spreads because it is in linkage disequilibrium with alleles that are favored by natural or sexual selection.

Marginal cost of display The cost of producing a unit level of display. This may also be thought of as the inverse of the efficiency of producing a mating display. For example, in the epistatic indicator mechanism, low quality males pay a higher cost for making a given amount (size/intensity) of a display compared to the cost paid by high quality males for producing the same display, thus resulting in higher marginal costs for low quality males.

Mate choice In the most general sense, a process that results in nonrandom mating, in which one sex, usually the female, determines her mate. Two components of mate choice are 'preference,' which determines the identity of the male trait toward which matings are biased, and 'choosiness,' which determines the strength of the bias. These two components may or may not be governed by the same genetic loci.

Mating system A description of the relative variation in mating success of males and females in a population or species. This can also include a description of whether individuals change mates over their lifetime.

Monogamy A mating system in which males and females form pair bonds. In genetic monogamy mating only occurs within the pair and both sexes hence have equal mating success (if there is social but not genetic monogamy, extra-pair copulations may take place, and mating success between the sexes may differ; there may also be serial monogamy if pairings change across breeding seasons).

Polygyny A mating system where females have low variation in the number of mates, but males exhibit a large amount of variation in their mating success. Usually, but not always, associated with low promiscuity in females and high promiscuity in males.

Speciation The process by which one species splits into two species via the cessation of gene flow between them.

Introduction

Elaborate male mating displays are common in a wide variety of taxa (Andersson, 1994). Courtship dances, powerful or complex song, pheromones, and showy visual features, ranging from ornate plumage in birds to colorful dewlaps in lizards, are just a few examples of traits that seem unnecessary for survival, but have another important function (Figure 1). Specifically, these traits can give males an advantage through the process of sexual selection if they increase male mating success. This benefit can arise if the trait improves success in male–male contests or if females prefer larger or more elaborate display traits in their mates. An important question in evolutionary biology is to understand the evolution of such male traits and female mate choice favoring them.

Although female mating displays do occur in some systems, males are generally the showier sex (but see Section 'Display traits in females'). In a polygynous mating system, the most common mating system in nature, there is little variation in female mating success, but males can vary widely in the number of mates that they acquire. In such cases, females have the opportunity to choose mates from the more numerous courting males. Male display traits can often form the basis for this mate choice. The fact that these traits can increase mating success is necessary to explain their evolution; many displays generally reduce the viability of males that produce them, and thus their evolution cannot be explained by natural selection alone. Given heritable variation, the evolution of male mating displays is then fairly straight-forward to understand; the advantage of gaining more mates simply needs to be large enough to compensate for the viability costs of producing the display. Why females evolve to favor certain male traits is often a more complex question.

Female Preferences for Male Traits

The intricacies of evolution through sexual selection due to mate choice largely focus on the selection that favors the evolution of preferences in females. Although the relative availability of males and females during polygyny gives females the opportunity for choice, it is likely that in most cases this choice is costly. For instance, searching for specific types of mates invariably involves spending energy and time. Females may also expose themselves to predation, or may not be able to start reproducing early. The maintenance of neural mechanisms to evaluate different aspects of a male display may also be costly. Given that mate choice may reduce female viability in these ways, some form of selection must overcome these costs for female mate choice to evolve.

Although often discussed as a single female characteristic, female mate choice can have two components that can potentially originate and evolve independently: (1) female mating preference, and (2) female choosiness (Jennions and

 doi:10.1016/B978-0-12-800049-6.00152-9

Figure 1 Types of male displays – (clockwise from top-left) a calling male Houston toad, a sharp-tailed grouse performing a courtship dance, a long-tailed widowbird with ornate, long tail feathers, a Honduran giant anole displaying brightly colored dewlap, and a male stalk-eyed fly with exaggerated eye-stalks (*Teleopsis dalmanni*).

Petrie, 1997). A mating preference describes the identity of the male trait that females prefer. For example, female mating preference could describe what sound frequency of a male call or what particular plumage color is preferred by females. Choosiness is the degree to which females express their preference. For example, all females may prefer the same type of call, but choosier females may sample a larger number of males or wait longer to find their ideal mate before mating. Thus, a preference is 'which' male trait is favored by females, while choosiness is 'how much' they favor it. The distinction between these components of female mate choice is important, because preference and choosiness may be controlled by different loci and face different costs. The cost of a mating preference may be restricted in some cases to the cost of maintaining neural mechanisms to evaluate different aspects of male displays (but see below). The cost of choosiness, on the other hand, would be influenced by factors such as availability of preferred mates or the cost of mate searching.

Certain properties of male traits may be important in determining the nature of selection that may act on female preferences. First, male traits may influence the cost of mate choice. Displays that are easier to evaluate may reduce the amount of time and energy that females have to spend on mate choice. The display traits themselves may also impose costs on females if aggressive displays reduce female viability or attract predators. Second, displays may influence the potential benefits that females gain through mate choice. By mating with attractive males, females, by default, are more likely to have more attractive sons, provided that male attractiveness is heritable. But females may also gain other benefits if male displays are correlated with the ability of a male to provide viability or fecundity advantages to females or their offspring.

These potential benefits and other explanations for the origin and elaboration of female mating preferences eluded Darwin when he first proposed the idea of sexual selection (Darwin, 1871), but have been the focus of extensive research on sexual selection in the past several decades. Below we first discuss how mating preferences may originate and then explore the factors that shape the elaboration of preexisting preferences (i.e., the evolution of preference for more extreme displays or the evolution of higher choosiness).

The Origin of Female Mating Preferences: Sensory Bias

In spite of the important role of mating preferences in the reproductive biology of a species, they may originate in contexts unrelated to mating. New mutations that produce mating preferences can, of course, spread in a population through the process of drift. More interestingly, selection on females in nonreproductive contexts can give rise to mating preferences. Evolution of the female neural system in response to the numerous sources of natural selection can result in females being more sensitive to certain external stimuli over others. For example, selection for more efficient foraging may make females more likely to notice colors that correspond to food. Even without this form of natural selection, the physical properties of the sensory system may result in sensitivity peaks for certain stimuli (e.g., the structure of the auditory system may cause higher sensitivity to a particular sound frequency). The evolution of the female sensory system in non-mating contexts can thus lead to sensory biases. Males that possess traits that match such sensory biases in females may be more easily noticed, potentially giving them a mating advantage. Evolution of male traits to exploit such preexisting sensory biases in females can result in these biases gaining the secondary 'function' of a mating preference. At this initial stage these preferences may not be very strong, but they can now be acted upon by sexual selection in addition to the natural selection that gave rise to them. Below we discuss how preexisting sensory biases may become exaggerated by sexual selection beyond their natural selection optimum.

Elaboration of Female Mating Preferences

A number of mechanisms have been proposed to explain how female mating preferences become more elaborate once variation in preferences and male traits is established. The different mechanisms discussed below are not mutually exclusive, and it is likely that multiple mechanisms shape the evolution of female mate choice even within a singe system. However, it is useful to consider these mechanisms separately for heuristic purposes.

Fisherian Process

Fisher (1930) was the first to provide a verbal explanation for the evolution of female mating preferences, which was later mathematically formalized by Lande (1981) and Kirkpatrick (1982). The Fisherian process (sometimes also called the Lande–Kirkpatrick model) is based on the fact that the mere existence of heritable variation in a female preference and male trait will inevitably build up a statistical correlation between them. Any selection, including both natural and sexual selection, acting on the male trait then results in indirect selection on the female preference. Because female preferences themselves place sexual selection on male traits, this results in a positive feedback loop. This may theoretically lead to a 'runaway' with both preference and trait becoming highly exaggerated. But even in the absence of a runaway, indirect selection on female preferences due to the Fisherian process is an inevitable component of all cases of sexual selection where heritable variation exists for a female preference and male trait. The Fisherian process (or Lande–Kirkpatrick model) has therefore been proposed as the null model for sexual selection through mate choice (Prum, 2010).

Direct Benefits of Mate Choice

In many cases, females may gain more than sperm from males; they may gain resources, territory, protection, or parental care, all of which can directly improve female viability or fecundity. If the amount of such 'direct benefits' provided by males is correlated with the size or quality of a display, females that preferentially mate with males with bigger or better displays would gain more direct benefits. When females can gain direct benefits from males, mating preferences may evolve due to the resulting direct selection even in the absence of heritable variation in male traits (e.g., when male displays and the benefits provided by males are completely determined by environmental factors). In such cases the Fisherian process would be absent. However, it is important to realize that as long as heritable variation exists in displays and preferences, female mating preferences would evolve due to both the direct benefits and the Fisherian process.

Good Genes

Females may gain benefits through mate choice even when males provide only sperm. If male display traits are correlated with any heritable component of viability, such as, for example, better resistance to parasites (Hamilton and Zuk, 1982) or higher survivability (Zahavi, 1975), females that preferentially mate with more ornamented males would sire offspring that are more likely to gain these genes for higher viability. Females can thus gain an indirect benefit of acquiring 'good genes' for their offspring through mate choice. The correlation between female preferences and alleles for higher viability that would result from this process can lead to the evolution of more exaggerated female preferences. The Fisherian process, which works through a correlation between female mating preferences and male display, still remains a part of the good genes process. The good genes benefit can thus only add to the Fisherian process.

For females to be able to gain indirect viability benefits through mate choice, it is necessary that male displays be phenotypically correlated with male genetic quality. That is, male displays must be honest indicators of male quality. Three mechanisms, which may work simultaneously in any given system, have been proposed to enforce honesty and cause the build-up of such a display–quality correlation (**Figure 2**). These mechanisms differ in how male genetic quality influences the production of the display.

Condition-Dependent Indicators

If high quality males are capable of producing a display that is larger or more elaborate than the displays that can be produced by low quality males, females may be able to use display size as an indicator of male genetic quality. The ability to produce a large display may be restricted to high quality males because they have more resources available to invest in costly display production. It may also arise due to physiological constraints that may enforce a dependency of display on male condition (e.g., the growth of horns in rhinoceros beetles, Emlen *et al.*, 2012). Because low quality males produce a smaller display, they pay a proportionally smaller cost; their mating benefit, however, is also lower because females do not prefer them (**Figure 2(a)**).

Revealing Indicators

It is possible that male genetic quality influences not the size of the male display, but the quality of the display that males are capable of maintaining. For example, male birds sensitive to feather mites may have their plumage deteriorate, while resistant males may be able to maintain a higher quality plumage. The displays thus produced would bear equal cost for all males, but would 'reveal' male genetic quality through the display quality. Revealing indicators thus differ from condition-dependent indicators only in that in this mechanism, low quality males pay the full cost of display production and yet do not get a proportional mating advantage (**Figure 2(b)**).

Pure Epistatic Indicators

The pure epistatic indicator mechanism can give rise to a phenotypic correlation between male display and male genetic quality because males of different quality pay different 'marginal costs' of display production. If low quality males bear a higher cost for producing displays compared to high quality males, males with elaborate displays are more likely to be the high quality males that were able to survive to the time of mating. Zahavi (1975) originally proposed this mechanism in the extreme form where low quality males simply do not survive when they produce a display. But a correlation between display and genetic quality may arise even with smaller differences in the viability costs of the display between males of different quality (**Figure 2(c)**).

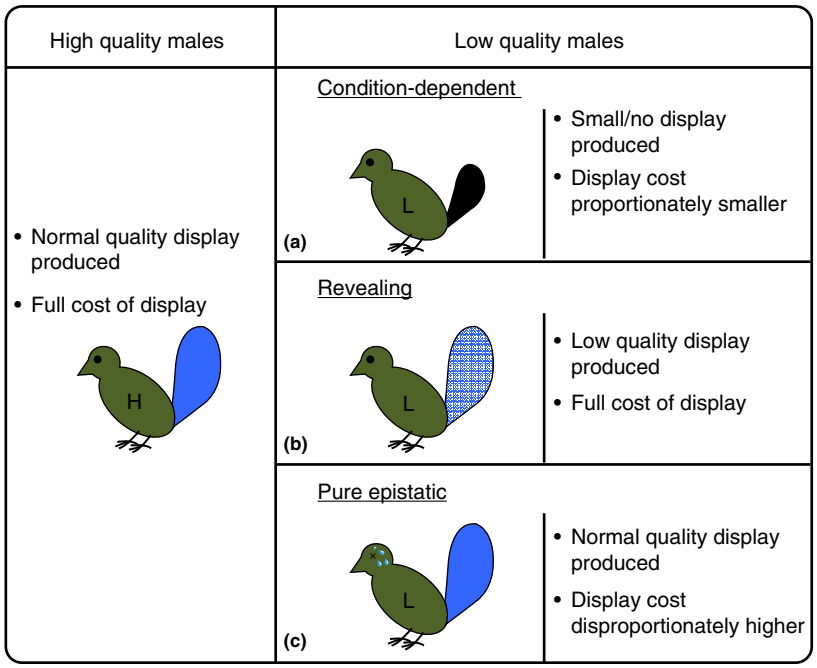

Figure 2 The three indicator mechanisms that can result in honest indication of male quality through a display differ in what gives rise to the correlation between male display and male quality – display size, quality, or cost. The left panel shows a high quality male that can produce a normal display. The three rows on the right show the three classic indicator mechanisms discussed in the text. High and low quality males are indicated by the letters 'H' and 'L' respectively.

The relative feasibility of these three good genes mechanisms and their relative importance in the evolution of female mate choice and male displays is highly debated. Part of the debate is focused around the theoretical feasibility of the different mechanism, with most mathematical models of these processes deeming pure epistatic indicators unlikely to evolve. Empirical evidence for good genes processes in general (i.e., a correlation between display and male quality) has been found in several systems (see Prokop *et al.*, 2012). Empirically distinguishing between the three specific good genes mechanisms above is, however, difficult. In particular, demonstrating that low quality males pay a 'disproportionately' higher cost for a display is especially challenging.

Heritability of Display Traits

The evolution of display traits, as of any phenotype, requires the trait to have a heritable basis. Yet there are many cases in which preferred trait phenotypes may be largely, or in some cases entirely, determined by the biotic or abiotic environment. Red plumage ornamentation, for example, can be affected by the availability of carotenoids in the diet. In this case, mating preferences that may exist for redder coloration could potentially have an evolutionary effect both on the ability of males to express red coloration given carotenoids in the diet, and on dietary preferences for foods with these carotenoids. Ultimately, however, phenotypic expression of the trait will still be highly dependent on dietary carotenoid availability.

Other traits that can influence mate choice, such as the song of oscine passerines, may be learned. Depending on the form of learning, these traits may still have a heritable component, even if this component is not genetic. Song learned from parents or siblings, for example, mimics genetically inherited phenotypic traits in that offspring phenotypes are correlated with those of their parents. Cultural evolution of such 'vertically transmitted' song traits is thus expected to proceed, in many cases, in a similar manner to that of genetic evolution of non-learned traits; in these two cases sexual selection may have very similar effects on phenotypic changes in traits over time. In other cases, birdsong or other culturally attractive behaviors may be learned from unrelated individuals in the population. Such traits have no heritable component, and so these traits are not necessarily expected to be similar between generations.

The Importance of Mating System

As discussed above, in a polygynous mating system, where the mating success of females is equal but that of males can differ, female preferences will impose sexual selection on male traits, leading to display trait evolution. Female mating preferences may not have the same effect, however, in other types of mating systems. In a mating system that is both socially and genetically monogamous, the mating success of both males and females should be equal. In other words, there would be no sexual selection on male (or female) traits, even if there were mating preferences. Preferences in this case would lead to genetic correlations between loci controlling the preferences and traits, but would not, by themselves, affect the frequencies of alleles at these loci. Mathematical models of monogamy show that additional effects, such as high fecundity of preferential matings or of preferred males, must be present in order

for showy male traits to evolve in such a system (O'Donald, 1980; Kirkpatrick *et al.*, 1990). Male traits can also evolve in some cases during monogamy, as during polygyny, if they are honest indicators of genetic quality (Andersson, 1986).

Display Traits in Females

The ability of ornamental traits to evolve in females, as in males, is highly dependent on the mating system. In sex-role reversed species (i.e., in a polyandrous mating system) such as the red-necked phalarope (Figure 3), there are fewer males available to mate than females at any one time, and females may have differential mating success. It is therefore expected that in such species, mate choice imposed by male preferences upon female traits may operate very similarly to mate choice imposed by female preferences upon male traits in a polygynous mating system. Female traits may then evolve by sexual selection in a manner very similar to that discussed for male traits above.

Mathematical models indicate that the situation is expected to be very different, however, if the mating system is changed. Female and male roles are expected to be indistinguishable during strict social and genetic monogamy; therefore, as discussed for male traits above, factors such as fecundity selection or condition dependence may have to be present to allow the evolution of showy female traits in monogamous systems. During strict polygyny, where all females have equal mating success, male mating preferences may be expressed as differential courtship by males toward ornamented versus unornamented females. Males that bias their courtship toward ornamented females would place themselves in a situation of many competitors vying for matings with these females, while males with no mating preference instead would often find themselves in a low competition situation, trying to mate with an unornamented female (see Figure 4). Because during polygyny both ornamented and unornamented females are expected to have equal mating success, males that prefer ornamented females would end up with lower mating success than would males that have no preference, due to the fact that the former males face higher mating competition (Servedio and Lande, 2006). The direct selection against male preferences resulting from these competitive effects would make it very difficult for male preferences for strictly ornamental female traits to evolve during polygyny. Furthermore, because females by definition have equal mating success under strict polygyny, male mating preferences during polygyny do not result in differential mating success of females; in other words, there is no sexual selection placed on female traits by male preferences during strict polygyny, so female traits will not evolve simply because of the presence of male preferences.

Despite these theoretical predictions, male preferences for female traits are sometimes found in polygynous mating systems (Amundsen, 2000; Bonduriansky, 2001). In such cases, however, these female traits are generally not strictly ornamental, but are instead direct indicators of high fecundity, such as large body size. In other cases, female traits may evolve due to pleiotropy between the expression of these traits in females and in males, where they are sexually selected.

Figure 3 Females (in the back) of the red-necked phalarope are more brightly colored than the males (in the front).

Trait Evolution during Speciation

Mating traits are thought to have great importance in the context of speciation. Mating preferences for traits that differ between conspecifics and heterospecifics can constitute a potent barrier to the exchange of genes between species. The traits that differentiate species are often very striking in their diversity among closely related taxa.

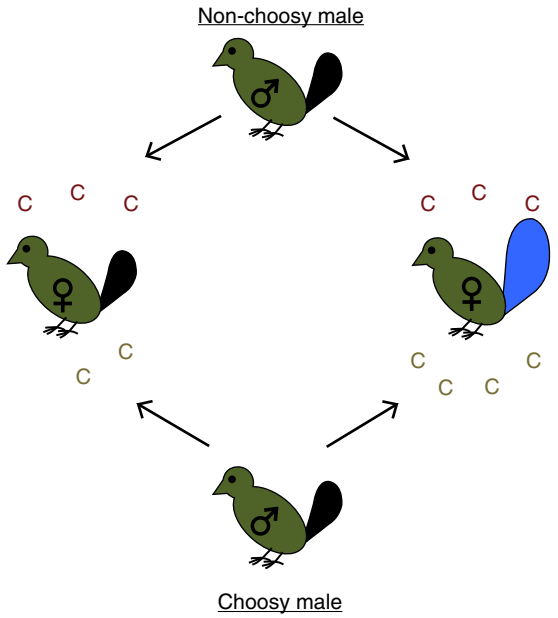

Figure 4 Imagine two males with equal amounts of resources available for courting females (total number of Cs). One male courts females randomly (non-choosy male; red Cs) and the other preferentially courts ornamented females (choosy male; green Cs). If mating success is proportional to the relative courtship effort perceived by a given female, choosy males would gain lower mating success than non-choosy males. In this figure, for instance, choosy males gain a small advantage with ornamented females (4 out of 7 Cs), but non-choosy males have a relatively higher advantage with unornamented females (3 out of 5 Cs).

Both mating preferences and traits are expected to respond, under certain cases, to evolutionary pressures resulting from the speciation process. This evolution is particularly easy to understand in the process of reinforcement, the evolution of characters involved in premating reproductive isolation to avoid hybridization (Dobzhansky, 1937). If partially differentiated species are still capable of successful hybridization, but hybrids have low fitness, this places selection on individuals in each species to mate with conspecifics, rather than heterospecifics. Individuals with mating preferences or traits that are more divergent from those in the other species will be less likely to hybridize, and thus have a selective advantage. This selection leads to the evolution of further differentiation between species in these mating characteristics. Ecologically divergent selection may also allow the evolutionary divergence of mating preferences and traits. Exploration of the evolution of mating preferences and traits during speciation is the subject of a rich literature consisting of both mathematical models and empirical work, but much more work remains to be done in this area before a synthetic consensus between these approaches is reached.

Glossary

Maternal effects Parental effects specifically caused by mothers.

Maternal effect coefficient The coefficient that gives the change in an offspring's trait value per unit change in a trait value of the mother, when this maternal trait has a maternal effect.

Parental effects Influences of maternal and/or paternal attributes on the offspring phenotype. The causality of the effects is not via direct genetic transmission of parental alleles.

Phenotypic plasticity The capacity of an organism to have different phenotypic trait values in response to environmental conditions.

Reaction norm A function describing how phenotypic trait values of a given genotype change across a range of values of an environmental variable.

Transgenerational plasticity The plastic change in the phenotype of an organism in response to an environment experienced by its parents and mediated by parental phenotypes.

Introduction

Mothers do not just provide genes to their offspring; they also often determine the phenotypes of eggs and newborn offspring and the environment in which they develop (Badyaev and Uller, 2009; Mousseau and Fox, 1998; Roach and Wulff, 1987; Uller, 2008; Wade, 1998; Wolf and Wade, 2009). Maternal effects are therefore defined as influences of maternal attributes on the offspring phenotype, where the causality of the effects is not via direct genetic transmission of maternal alleles but via maternal phenotypic traits and/or variable environmental properties that mothers experience (Mousseau and Fox, 1998; Wolf and Wade, 2009).

First identified by quantitative geneticists more than 60 years ago (Dickerson, 1947), maternal effects were first perceived to be environmentally determined sources of phenotypic variation that contaminated estimates of heritability (Falconer and Mackay, 1996; Wade, 1998). The substantial impact that maternal effects had on the artificial selection studies of animal breeders and the increasing realization that they might have a (indirect) genetic component, fueled the development of quantitative genetic models designed to understand, predict, and measure evolutionary dynamics when mothers, or more generally parents, directly affect the phenotypes of their offspring (Hadfield, 2012; McGlothlin *et al.*, 2009). We provide a brief overview of these models, focusing on the Kirkpatrick and Lande model (K–L) (Kirkpatrick and Lande, 1989) and its extensions as a framework for understanding how maternal effects can influence evolutionary dynamics. In retrospect, Kirkpatrick and Lande's (1989) paper had a pivotal role in summarizing previous modeling efforts and pointed out several consequences of maternal effects on changes in traits across generations. Empirical literature on the quantitative genetics of maternal effects has been reviewed extensively elsewhere (Cheverud, 1984; Kruuk *et al.*, 2008; Räsänen and Kruuk, 2007; Roach and Wulff, 1987; Shaw and Byers, 1998; Wilson and Reale, 2006). Therefore, we concentrate instead on studies that have expanded the quantitative genetic theory of maternal effects by incorporating coadaptation (Kölliker *et al.*, 2005; Wolf and Brodie III, 1998b) and within- and between-generation phenotypic plasticity (Ezard *et al.*, 2014; Hoyle and Ezard, 2012; Kuijper and Hoyle, 2015). We then discuss quantitative genetic theory in relation to nongenetic inheritance (NGI) (see Bonduriansky and Day, 2009; Danchin *et al.*, 2011; Day and Bonduriansky, 2011; Jablonka and Lamb, 2005 for reviews). We conclude by summarizing our understanding of the impact that maternal effects have on evolutionary dynamics and proposing directions for future research.

The Quantitative Genetics of Maternal Effects

Maternal effects are often conceptualized as the effects of 'maternal performance' (Cheverud and Moore, 1994; Wilham, 1972), a composite maternal character which is not directly observed. It summarizes all the effects that a mother has on an offspring trait and its variance and integrates effects of maternal phenotypic traits and maternal environments. Alternatively, if the maternal traits affecting offspring are known, then slopes of their effects on offspring can be estimated per trait separately (Hadfield, 2012; McGlothlin *et al.*, 2009). The maternal performance approach is useful and popular with plant and animal breeders (Falconer and Mackay, 1996; Lynch and Walsh, 1998; Walsh and Lynch, 2012) and empirical quantitative geneticists (McAdam *et al.*, 2014; Rossiter, 1996). The impact that maternal effects have on offspring trait variance can be calculated in an integrative manner by examining how much phenotypic variance is explained by maternal identity (Hadfield, 2012), if the experiment allows this variance component to be estimated separately. However, the approach tells us nothing about the cause of maternal effects (see Wolf and Wade, 2009) and can be inaccurate in predicting selection responses as discussed below. In contrast,

 doi:10.1016/B978-0-12-800049-6.00051-2

the trait-based approach (Kirkpatrick and Lande, 1989; McAdam *et al.*, 2014) assumes that maternal effects are mediated by specific causal maternal traits that can have different effect strengths. Causal effects of maternal environments are kept implicit or environmental properties are recast as 'traits.' Hadfield (2012) and McGlothlin and Galloway (2014) show how performance and trait-based approaches are related. They are comparable in some scenarios (McGlothlin *et al.*, 2009; McGlothlin and Galloway, 2014). McAdam *et al.* (2014) provide a detailed discussion of the pros and cons of using either approach as well as presenting a hybrid strategy where maternal performance and maternal trait regressions are jointly modeled. Here we focus on the trait-based approach.

Models with Fixed Maternal Effect Coefficients

The landmark model for trait-based maternal effects was introduced by Kirkpatrick and Lande (1989, 1992) and generalized previous efforts to model maternal effects (see Hadfield, 2012). It assumes that the phenotype of an individual is the sum of an additive genetic component, the maternal effect contribution, plus an environmental contribution. In this case the phenotypic trait value z_o of an offspring individual can be written as

$$z_o = a_o + mz'_m + e_o \quad [1]$$

where a_o is the additive genetic effect in the (offspring) individual, z'_m is the phenotype of the mother affecting the phenotype of her offspring, and e_o is the environmental component of phenotypic variation in the offspring. We use a prime here to stress that the trait of the mother which has an effect does not need to be equal to the trait considered in an offspring, for example, when gestation time influences offspring birth weight (Kirkpatrick and Lande, 1989). Subscripts 'o' and 'm' indicate on which individual a quantity can be measured. The maternal effect coefficient m is special in this respect as it translates a trait of the mother into a trait component of the offspring. Its magnitude expresses the strength of the maternal effect and the sign can be positive or negative, but its absolute value is taken to be smaller than one (Kirkpatrick and Lande, 1989). The maternal effect is the product mz'_m.

Equation [1] can be extended to account for an arbitrary number of traits (k) by expressing the equation using matrix notation:

$$\boldsymbol{z}_o = \boldsymbol{a}_o + \boldsymbol{M}\boldsymbol{z}_m + \boldsymbol{e}_o \quad [2]$$

where $\boldsymbol{z}_o$ and $\boldsymbol{z}_m$ are now vectors of length k containing all distinct phenotypic traits. Equation [1] can be rewritten in this manner as well, with $\boldsymbol{z}=(z,z')$ and $\boldsymbol{M} = \begin{pmatrix} 0 & 0 \\ 0 & m \end{pmatrix}$. Some traits are potentially only investigated in offspring, others with causal effects are either only observed in mothers or both in offspring and mothers. Each individual is assumed to have values for all k traits, even when the trait is not expressed. Thus subscripts 'o' and 'm' are indicators of the individual where a trait can be measured, or where it is a latent variable. The additive genetic values and environmental components of the traits in offspring are given by $\boldsymbol{a}_o$ and $\boldsymbol{e}_o$, respectively. The matrix $\boldsymbol{M}=[m_{ij}]$ $(i,j=1,\ldots,\ k)$ contains all maternal effect coefficients m_{ij}, each the effect of a unit change in a maternal trait (j) value on a trait (i) in the offspring trait vector. Coefficients m_{ij} will be zero if maternal trait j has no effect on offspring trait i. For the purpose of estimation and in most theoretical modeling, the contribution of the individual environmental effect $\boldsymbol{e}_o$ to each separate trait is assumed to be zero on average.

When we want to follow phenotypic trait values across generations, we need to make additional assumptions about the population dynamics. Generally, it is assumed that generations are discrete and nonoverlapping, that populations modeled are diploid sexual and that mating is random. A few commonly used scenarios to model selection on maternal effects are presented below. If we assume that the maternal and offspring traits are in fact the same phenotypic character (no prime required), then a trait decomposition such as eqn [1] gives the following for the average trait value of offspring in generation $t+1$, before selection

$$\bar{z}(t+1) = \bar{a}(t+1) + m\bar{z}^*(t) \quad [3]$$

with $\bar{z}^*(t)$ denoting the average trait value of mothers in generation t contributing to the next generation ('after selection', Hadfield, 2012). We can drop the 'o' and 'm' subscripts here as generations t and $t+1$ already differentiate between mothers and offspring. Kirkpatrick and Lande (1989) showed for this case that one can derive the change between generations t and $t+1$ in average trait value of individuals before selection as

$$\Delta\bar{z}(t) = C_{az}\beta(t) + m\Delta\bar{z}(t-1) + mP\Delta\beta(t-1) \quad [4]$$

with C_{az} being the covariance between additive genetic value 'a' and phenotype 'z' in the maternal generation t, P the phenotypic variance, $\beta(t)$ the selection gradient on trait z in the maternal generation t and $\Delta\beta(t-1)$ the difference between selection gradients in generations t (maternal) and $t-1$ (grandmaternal). C_{az} and P are assumed constant. The first term accounts for the phenotypic change caused by selection in generation t and mediated by the direct genetic transmission of the trait. Additionally, the change $\Delta\bar{z}(t)$ depends on two factors mediated by maternal effects: the average trait change between the previous generations and the difference between the selection gradients in the parental and grandparental generations. The last term vanishes when the selection gradient does not change between generations t and $t-1$. In comparison to the classical breeders equation, $\Delta\bar{z}(t) = C_{az}\beta(t)$ where C_{az} is equal to the additive genetic variance for z, the covariance C_{az} itself becomes different from the additive genetic variance when maternal effects are present (Kirkpatrick and Lande, 1989).

For the multi-trait case, the population mean values of the traits are similarly updated between generations using the rule

$$\Delta\bar{\boldsymbol{z}}(t) = \mathbf{C}_{az}(t) + \boldsymbol{M}\Delta\bar{\boldsymbol{z}}(t-1) + \boldsymbol{MP}\Delta\boldsymbol{\beta}(t-1) \quad [5]$$

where $\boldsymbol{C}_{az}$ and $\boldsymbol{P}$ are now covariance matrices and β is the selection gradient vector.

Insights from the K–L Model

The K–L model demonstrates that when maternal effects are present, selection pressures in the maternal and grandmaternal generations affect the trait changes between maternal and

offspring generations. This generates time lags in the response to selection. With several traits involved (eqn [5]), the evolution of traits under selection can depend on maternal effects of traits that are not under selection. Moreover, in the case where n traits are coupled by maternal effects, lagged responses can occur up to n generations after a single generation of selection (Kirkpatrick and Lande, 1989). If we decide to subsume all n traits causing the maternal effects in a single maternal performance trait, then this will introduce imprecisions in the predictions of lagged selection responses.

Understanding how the maternal effect coefficient alters the resemblance of parents and offspring is critical. If selection starts from a population at equilibrium, a positive coefficient (e.g., larger mothers produce larger offspring or smaller mothers produce smaller offspring) will speed up a response to selection, whereas a negative maternal effect coefficient (e.g., larger mothers produce smaller offspring or smaller mothers produce larger offspring) can slow down or even reverse a response to selection temporarily (Falconer and Mackay, 1996; Hoyle and Ezard, 2012; Kirkpatrick and Lande, 1989; Kuijper and Hoyle, 2015; Räsänen and Kruuk, 2007).

Moreover, 'evolutionary momentum' can be generated where trait means continue to change when the directional selection pressure is removed. This occurs at a constantly decreasing rate and requires that a trait involved in a maternal effect alters the same trait in offspring or that the effects lead back to the original character after several generations (Kirkpatrick and Lande, 1989). When the absence of genetic variation for any of the traits in $\boldsymbol{z}$ would cause $\boldsymbol{C}_{az}$ to become zero, traits can still change through maternal effects rather than additive genetic variation in the traits directly under selection, but the selection gradient needs to continually change or the response will gradually decay due to evolutionary momentum. This is fundamentally different from exclusively Mendelian inheritance where characters without genetic variation cannot respond to selection (Badyaev, 2005, 2008; Bonduriansky and Day, 2009; Jablonka and Lamb, 2005).

Trait Covariance and Coadaptation

The K–L model demonstrates that a trait can respond to selection via two pathways: via the transmission of alleles between mothers and offspring (additive genetic variance) or via the maternal trait effects. However, Kirkpatrick and Lande (1989) did not make any predictions regarding the joint distribution of genotypic values of maternal and offspring traits and assumed it to be fixed. Wolf and Brodie III (1998b) relaxed that assumption and found in a two-trait model with stabilizing selection on offspring phenotype alone, that the sign of the genetic correlation evolves to match the pattern of coadaptation favored by selection. Maternal and additive genetic effects evolve negative genetic correlations, which reduces the variance in average fitness. With directional selection and a particular model where the maternal effect coefficient is in fact the additive genetic value times a constant ($m = n\ a_o$), they found that the genetic correlation between maternal effect and additive genetic effect evolves to obtain the same sign as the directional selection gradient. Here, this pattern allows a faster selection response. Kölliker *et al.* (2005) considered how begging by offspring and provisioning by parents coevolve in a model with two traits having reciprocal maternal effects, finding that the sign of the genetic correlation between begging and provisioning depended on whether selection was primarily on the offspring or on the parental trait.

Empirical Validation

While it is clear that maternal effects are ubiquitous (Mousseau and Fox, 1998; Mousseau *et al.*, 2009) and may affect the evolutionary dynamics of traits (Falconer and Mackay, 1996; Hadfield, 2012; Hoyle and Ezard, 2012; Kirkpatrick and Lande, 1989), the impact that they actually have depends on the magnitude and sign of all the relevant model parameters. Räsänen and Kruuk (2007) reviewed the available data and found abundant evidence for maternal genetic effects in domestic and wild populations, suggesting that maternal effects cannot be left implicit as an environmental source of phenotypic variation. This is confirmed by studies such as Wolf and Cheverud (2012) that combined genotype information from parents and offspring with experimental cross-fostering in order to identify maternal effect quantitative trait loci. Räsänen and Kruuk (2007) also found evidence for positive and negative offspring–parent trait covariances and maternal effect coefficients but too few reliable estimates were available to draw conclusions about the conditions responsible for the magnitude and direction of specific parameters.

Evolving Maternal Effect Coefficients

Maternal effects have been seen as adaptations for a long time (Mousseau and Fox, 1998) and genetic variation for maternal effect coefficients has been demonstrated repeatedly (Hall and Ebert, 2012; Räsänen and Kruuk, 2007; Stjernman and Little, 2011; Wilson and Reale, 2006; Wilson *et al.*, 2005). But models have only recently begun to focus on how or why the strengths and directions of maternal effects evolve. We focus here on models that are closest to the K–L model of maternal effects and briefly convey their main general conclusions. Kuijper *et al.* (2014) and Kuijper and Hoyle (2015) investigated a single-trait model and a two-trait model. The general intuition from exploring a number of different stationary and cyclically varying selection regimes is that maternal effects evolve signs and magnitudes that make the best use of maternal phenotypes to predict and adjust offspring phenotypes to coming selective conditions when these are only partially predictable (**Figure 1**). In a scenario where the selection optimum shifts abruptly to a novel value, transient positive maternal effects evolve (**Figure 2**). Mothers that survive have phenotypes that are closer to the new optimum, but then also produce offspring that are closer, speeding up adaptation. In a constant selection regime, with selection favoring a fixed optimal trait combination, negative maternal effect coefficients evolve which minimize phenotypic variance (canalization) and therefore maximize mean population fitness. Kuijper *et al.*'s (2014) results indicate that intricate dynamic phenotypic effects can occur when each offspring trait is affected by more than one maternal trait. The maternal effect coefficients

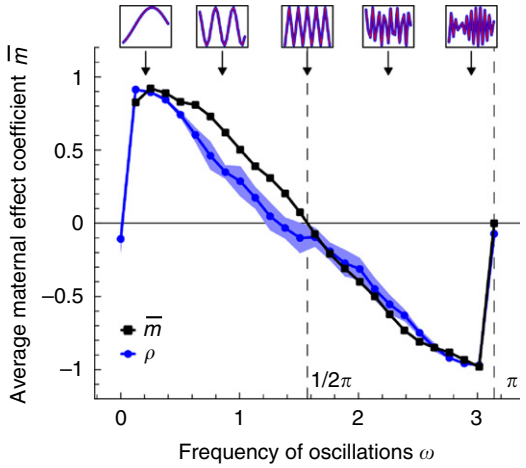

Figure 1 The evolution of maternal effect coefficients when the selection optimum for a trait shared by mothers and offspring cycles periodically. Parameter ω controls the frequency (speed) of oscillations. Each dot represents the average evolved maternal effect coefficient over 10 replicate simulations. The shaded areas indicate the corresponding standard deviations. Boxes above the graph show the cycles in the selective optimum over 20 generations. The black line gives the autocorrelation ρ of selective conditions between the parental and offspring generations. Note that the maternal effect coefficient evolves to match the autocorrelation between maternal and offspring selective environments. Adapted from Figure 2 of Kuijper, B., Johnstone, R.A., Townley, S., 2014. The evolution of multivariate maternal effects. PLoS Computational Biology 10(4), e1003550.

can then evolve in such a way that offspring phenotypes change periodically to track changes in environmental conditions over more than a single generation, for example, to make offspring phenotypes very different from those of their grandparents (Kuijper *et al.*, 2014).

Phenotypic Plasticity

In eqns [1] and [2] above, all responses to environmental variables other than maternal phenotypes are summarized by a single term e_o, which is on average zero by assumption. The dependence of offspring phenotype on specific environmental variables can be made explicit, similar to when we replace maternal performance by maternal trait effects. Consistent changes in phenotype when environmental variables are changed are called phenotypic plasticity. With plasticity, an offspring trait can be modeled as:

$$z_o = a_o + mz'_m + b\varepsilon_o + e_o \quad [6]$$

Compare eqn [6] with eqn [1]. It additionally includes a term $b\varepsilon_o$ which represents the effect of the value ε_o of an environmental variable on the phenotype. The strength of the effect is expressed by slope parameter b, which is often genetically variable. Maternal effects can be considered to be a kind of transgenerational plasticity (Agrawal, 2001; Mousseau and Fox, 1998) both by analogy, since the offspring phenotype depends explicitly on the maternal phenotype, which itself can be considered part of the offspring's environment (Badyaev and Uller, 2009; Day and Bonduriansky, 2011; Jablonka and Lamb, 2005; West-Eberhard, 2003), and also because the

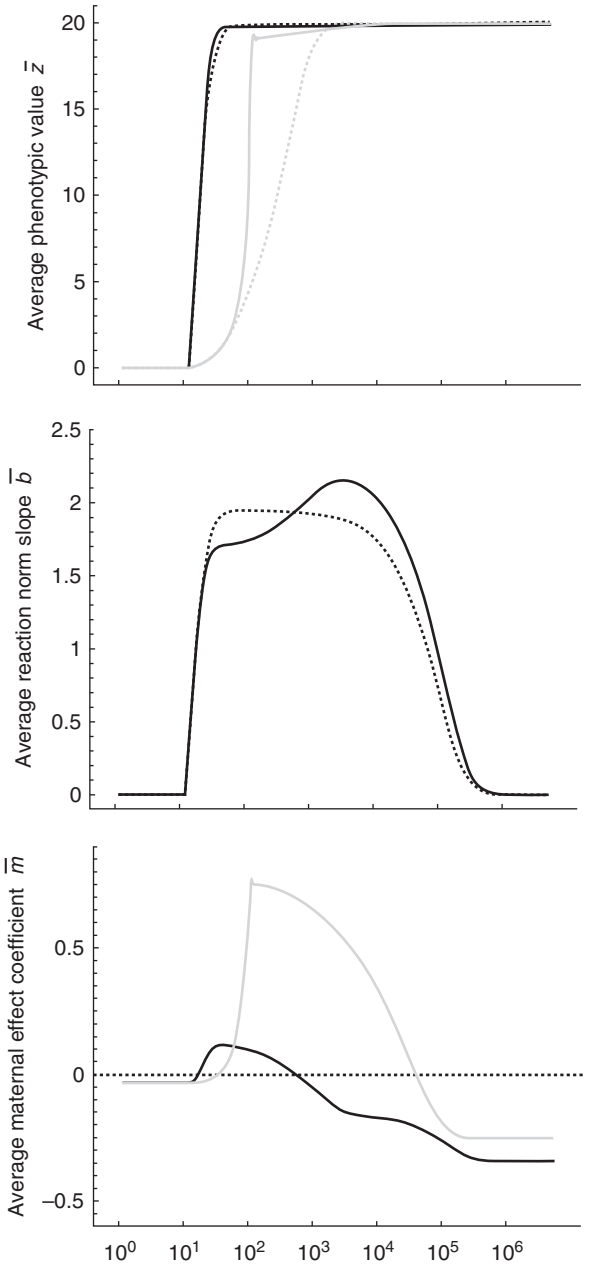

Figure 2 Adaptation to a sudden shift in the environment which occurs at generation $t=10$ and where the optimal phenotypic trait value shifts from 0 to 20. Populations differ in the presence/absence of plasticity or maternal effects, while the genotypic value a is always allowed to evolve. Solid black lines: within-generational plasticity and maternal effect coefficients are allowed to evolve. Solid gray line: only maternal effects evolve. Dashed black line: only plasticity evolves. Dashed gray line: neither maternal effects nor plasticity evolve. Top: Average phenotype per generation. Middle: Average reaction norm slope per generation. Bottom: Average maternal effect coefficient per generation. Adapted from Figure 2 of Kuijper, B., Hoyle, R.B., 2015. When to rely on maternal effects and when on phenotypic plasticity? Evolution 69, 950–968.

maternal phenotype can include a plastic response to the environment experienced by the mother, which thus indirectly affects the offspring. There are interesting parallels between

maternal effects and phenotypic plasticity, because the latter is also believed to use environmental variables to predict coming selective conditions. In that respect, the correlation between the state of the environment sensed and the properties of coming selection are important for plasticity evolution as well. Hoyle and Ezard (2012) and Ezard *et al.* (2014) explored effects of a fixed maternal effect coefficient in the presence of evolving plasticity. Kuijper and Hoyle (2015) allowed both to evolve simultaneously to study the interplay between additive genetic variance, within-generation plasticity (phenotypic plasticity) and between-generation plasticity (maternal effects) when adapting to constant, periodically cycling, or novel environments. In comparison to models with evolving maternal effects but without evolving plasticity, evolving phenotypic plasticity often removes the selective advantage of maternal effects and maternal effect coefficients evolve to smaller magnitudes (**Figure 2**). It often seems more advantageous for the offspring to observe the environment and adjust directly, instead of having to rely on maternal phenotypes. When the evolution of plasticity is constrained, either through costs or informational time-lags, larger maternal effects evolve (Kuijper and Hoyle, 2015). These predictions support the outcome of a recent meta-analysis that concluded that there is only weak support for adaptive transgenerational plasticity (Uller *et al.*, 2013).

Extensions

If we generalize the previous equations slightly to multivariate environments and phenotypes, we obtain

$$\boldsymbol{z}_{\mathrm{o}} = \boldsymbol{a}_{\mathrm{o}} + \boldsymbol{M}\boldsymbol{z}'_{\mathrm{m}} + \boldsymbol{B}\boldsymbol{\varepsilon}_{\mathrm{o}} + \boldsymbol{e}_{\mathrm{o}} \qquad [7]$$

where we allow matrices **M** and **B** to contain coefficients that can evolve, i.e., that are quantitative genetic traits themselves, and whose components and variability we can try to determine experimentally. Such studies of course involve more complex interactions between phenotypes and environments. If the maternal effect coefficient is an offspring trait itself, such as in models where these coefficients evolve (Kuijper and Hoyle, 2015), then it could also depend on environmental variables experienced by offspring. Maternal effect coefficients can be plastic in response to changes in the maternal environment (Marshall and Uller, 2007; Räsänen and Kruuk, 2007) and maternal state (Plaistow *et al.*, 2007, 2015) meaning that the maternal effect coefficient might itself be better modeled as a reaction norm rather than a fixed value. Empirical studies have also demonstrated that maternal effects are highly context-dependent influencing different traits in different offspring environments (Bernardo, 1996; Berven, 1990; Czesak and Fox, 2003; Gliwicz and Guisande, 1992; Lardies *et al.*, 2004; Parichy and Kaplan, 1992; Räsänen *et al.*, 2005), the fitness consequences of which probably depend on the coadaptation of mothers and offspring (Badyaev and Uller, 2009; Kölliker *et al.*, 2005; Wolf and Brodie III, 1998b) across these different environments.

Heritability Extended: Nongenetic Inheritance

Quantitative genetic models assume that genes are the sole basis of inheritance. However, there is an increasing realization that offspring inherit more than just DNA from their parents. NGI can be defined as any effect on offspring phenotype brought about by the transmission of factors other than DNA sequences from parents or more remote ancestors (Bonduriansky and Day, 2009; Danchin *et al.*, 2011; Day and Bonduriansky, 2011; Hallsson *et al.*, 2012). NGI mechanisms that operate alongside Mendelian-genetic inheritance are diverse and include transgenerational epigenetic inheritance and genomic imprinting, transmission of diverse cytoplasmic and somatic factors, nutrients, elements of the extra-organismal environment, and the transmission of behavioral variation through learning (Bonduriansky and Day, 2009). Some of these mechanisms are clearly covered already by current approaches to maternal effects, while others such as genomic imprinting are not seen to be maternal effects (Wolf and Wade, 2009). Day and Bonduriansky (2011) have worked out a unified approach to investigate NGI and selection across generations, which is in essence by separately following a genetic value and a nongenetic heritable value in individuals across generations and not just individual phenotypes or genetic values. Such an approach corresponds to our statement above that maternal effect coefficients or maternal effects can be seen as separate traits, which can be followed across generations explicitly and separately. The question then becomes: whose trait is it? As maternal effects can be instances of indirect genetic effects, where the environment is genetically variable (McAdam *et al.*, 2014; Wolf *et al.*, 1998a), the answer will be case-specific.

To conclude, we want to stress that maternal effects are often studied in behavioral ecology and elsewhere in biology using methods other than strict quantitative genetics. Intuition and predictions arising from these methods seem generally in line with what we have stated here (English *et al.*, 2015; Leimar and McNamara, 2015). The studies suggest further avenues to extend quantitative genetic modeling of maternal effects: for example, including maternal effects on offspring variance (Crean and Marshall, 2009) or taking more explicit account of developmental processes in the individual (Atchley *et al.*, 1994). There is a long history of developmental models of quantitative genetic variation (see references in Wolf *et al.*, 2001). These have in common that the progress of development is modeled by a chain of events where earlier traits and environmental inputs determine properties of later developmental processes and the subsequent development of new traits. Most traits that quantitative genetics focuses on are thus composite mosaics of earlier developmental traits (Wolf *et al.*, 2001) that may all be influenced by integrated genetic, nongenetic, and environmental cues. Such models that include maternal effects are required to better align current theoretical and empirical findings, to obtain a better understanding of how phenotypes integrate different sources of information and ultimately to understand how maternal effects influence the evolutionary trajectories of populations.

Mating and Parental Sex Roles, Diversity in

EJ Herridge and RL Murray, University of Stirling, Stirling, UK
DT Gwynne, University of Toronto at Mississauga, Mississauga, ON, Canada
LF Bussière, University of Stirling, Stirling, UK

Glossary

Anisogamy Unequal investment in gametes between the sexes.
Armaments Morphological characters used to gain an advantage over rivals in contests for access to mates.
Bateman gradient The slope of the regression of reproductive success on mate number for a given sex.
Direct benefits (material benefits) Processes that directly improve the fitness of an animal as a result of an additional mating event or a particular mate choice; direct benefits include nutritional resources provided by a mating partner, access to a territory or refuge, or parental care.
Indirect benefits (genetic benefits) Processes that improve the genetic quality of an animal's offspring (either their viability, attractiveness, or diversity) as a result of an additional mating event or a particular choice of mate.
Mate choice A preference for some phenotypic classes of mate over others.
Monogamy A mating system in which an individual mates with only one partner.
Ornament Morphological character used to attract the opposite sex during episodes of mate choice.
Operational sex ratio The ratio of sexually receptive males to females; usually expressed as a proportion (sexually receptive males/(sexually receptive males + sexually receptive females)).
Parental investment Investment in an offspring at a cost of investing in other components of parental fitness.
Parental care Parental investment that increases an offspring's chance of survival after fertilization.
Polyandry A mating system in which females mate with multiple partners.
Sex role reversal A controversial designation of deviation from the conventional sex roles (see Box 1).
Sex roles Aspects of mating receptivity, mate choice, and parental care that generally differ between males and females; typically masculine sex roles involve high levels of sexual receptivity and low levels of choice and care, while feminine sex roles are less receptive to mating, and have high levels of choice and care.
Social selection Differences in survival or reproductive success linked to variation in success in social competition for resources; sexual selection is a subset of social selection, in the form of social competition for mates.

Introduction

The sexes usually differ in morphology and behavior, but the degree of difference varies dramatically across species. Males typically compete for access to female mates, whereas females rarely compete for males. Instead, females tend to invest considerably more in offspring and choosing mates than males do. The sex difference in contest intensity over mates has selected for weapons and extravagant ornaments in males of many species, while females are rarely armed or adorned in this way. General differences in mating receptivity, mate choice, and parental care are collectively known as 'sex roles,' and species that deviate markedly from the general patterns (e.g., when females compete for mates, and males are choosy or provide care), are often described as 'sex role reversed' (a controversial designation; see Box 1).

Here, we focus primarily on animals with separate sexes (sexual selection theory has fascinating implications for hermaphroditic organisms, but these are beyond the scope of our article). We will explore the causes of sexual differences in both mating and parental behavior, and illustrate how some unusual systems deviate from conventional sex roles. We also highlight how many of these unusual systems provide strong tests of sexual selection theory, and suggest some directions for future work that may help clarify unresolved questions about the diversity of sex roles among animals.

Box 1 Sex Role Reversal

Ah-King and Ahnesjö (2013) critique the use of the term 'sex role reversal' in part because it reduces variation in behavior and morphology into two discrete categories, which obscures the tremendous variation in natural sex roles (including variation within species across different traits and ecological contexts – see section on Variation in Mating and Parental Roles). These problems have particular resonance for an evolutionary perspective that is motivated to explain diversity. The phrase is unlikely to disappear entirely, in part because its concise form is useful for instantly evoking in an audience something unconventional about a focal mating system. Nevertheless, we agree that it evokes different ideas in different audience members, and therefore endorse Ah-King and Ahnesjö's (2013) recommendation that authors should provide operational descriptions of the specific phenotypic features that are being referred to in any focal case.

What Causes Sexual Differences in Mating and Parental Roles?

There are behavioral and morphological traits that distinguish the sexes in many animal species. Typical sex differences are thought to have evolved because the sexes experience disparate

forms and intensities of selection. For most species this sex difference in selection is ultimately a consequence of unequal 'parental investment' in gametes ('anisogamy'); spermatozoa in males are small and relatively plentiful while eggs in females are large and relatively few (Bateman, 1948; Trivers, 1972; Williams, 1975). Females are typically constrained from producing more eggs because of the substantial cost of each of them, and this constraint has important consequences for sex differences in both mating and parental behavior.

Mating Roles

One consequence of greater female parental investment is that males can potentially produce many more offspring than females by parasitizing the substantial investment in gametes of many mates. A male's fitness is therefore often directly related to his ability to secure mates. By contrast, females sometimes gain little fitness by remating, especially if a male's only contribution during mating is sperm. The fact that males can gain much from remating, while females gain relatively little, means that selection for acquiring mates tends to be stronger on males. This contrast in how mating success covaries with fitness is central to sexual selection theory. The empirical measurement of the regression of fitness on mating success is known as the 'Bateman gradient,' acknowledging Angus Bateman's (1948) work on *Drosophila* that first highlighted the sex differences in relative fitness gains from mating (**Figure 1**).

Although males may gain more fitness by remating than females, the two sexes must on average mate equally frequently, because every mating requires an individual of each sex. Consequently, there are often many more sexually receptive males than females (if female fitness does not covary strongly with mating success, females should prefer to spend most of their time in activities other than mate seeking, such as foraging or caring for young). This resulting bias in the operational sex ratio (Emlen and Oring, 1977) often selects for investment in secondary sexual characters in males (Enders, 1993; Jirotkul, 1999) that help them to find, win, and guard mates from current rivals, and to displace ejaculates of previous rivals stored within females; such contests are responsible for the impressive array of male 'armaments,' fighting (Emlen, 2008) and, during copulation, penile traits that remove sperm (Simmons, 2001). When there is an excess in the number of sexually receptive males, females typically improve their reproductive success by carefully selecting from many willing potential partners ('mate choice') rather than by mating more frequently. The preferred mate can improve a female's fitness in several ways (Jennions and Petrie, 1997). The careful attention of choosy females in turn selects for the expression of numerous 'ornaments' that appeal to discriminating females (Houde, 2001).

Parental Roles

In addition to the general sex differences in mating roles described above, there are also typical parental roles involving the provision of post-zygotic care: in most animals the female invests more than the male in 'parental care.' The explanation rests in both the costs and benefits of deserting (i.e., failing to care for) the current brood (Trivers, 1972). The considerable investment required by females to produce ova prior to mating means that a female who abandons her current brood (e.g., to seek a better mate) may be unable to replace the brood using her metabolic reserves: she may be better off caring for the current brood (even if she cares alone, and even if the offspring are of below-average quality) than trying to start all over again with a new partner. In contrast, males can usually easily start over with another mate, because the cost of the initial contribution to mating is so much less, and therefore more easily reproduced from metabolic reserves.

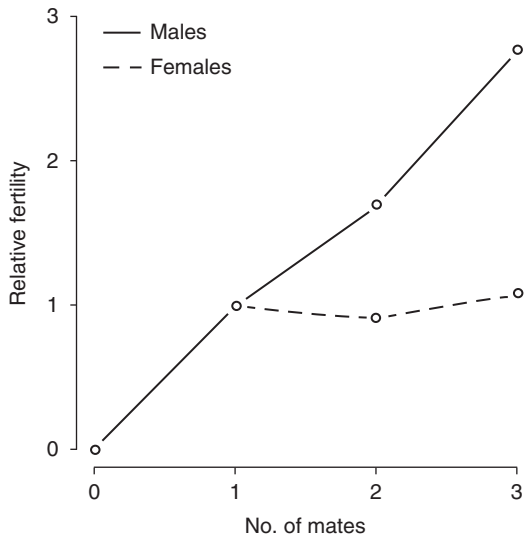

Figure 1 Bateman's (1948) *Drosophila* experiments first highlighted that the relationship between fitness (measured as 'relative fertility') and mating success differed between the sexes, with males gaining more fitness by remating than females. Here we reproduce his most famous figure of series 5 and 6 combined. Males are represented by a solid line, and females are represented by a dashed line. Adapted from Bateman, A.J., 1948. Intra-sexual selection in *Drosophila*. Heredity 2 (Pt.3) pp. 349–368, with permission from Macmillan Publishers Ltd.

Moreover, relative to females, males can usually gain substantially by deserting and acquiring further mates. First, males typically gain more by deserting due to an inherent risk of cuckoldry (where an individual provides care in another individual's offspring); male confidence of parentage is lower than that of females (especially in species with internal fertilization). With few exceptions, females have strong confidence that the offspring they invest in are their own. As the risk of cuckoldry increases, so should selection favoring male abandonment of offspring in favor of new mating opportunities, such as in the brood-rearing bluegill sunfish (*Lepomis macrochirus*) (Neff and Gross, 2001; but see Alonzo and Klug, 2012 for discussion). In addition, investing time and effort in male care comes at a cost to other opportunities to gain fitness, such as by pursuing further mates.

Variation in Mating and Parental Roles

There are many exceptions to the typical patterns of sex differences in behavior and morphology that we have described.

Box 2

When males limit the reproductive success of females, females can compete with each other for males. Gwynne and Simmons used an experimental approach to illustrate how environmental food availability altered the mating roles for *Kawanaphila nartee* bushcrickets (Gwynne and Simmons, 1990). Like many bushcrickets (Orthoptera: Tettigoniidae), *K. nartee* males provide nutritious spermatophylax gifts attached to their sperm packets (**Figure 2**). In *K. nartee*, these gifts comprise 10% of a male's weight and take 5 days to produce (Vahed, 2007). There is a reversal in the mating roles in nature when hungry females compete sexually for matings (male gifts). In experiments with *Kawanaphila* and other tettigoniid species, decreasing proteinaceous food causes a relative increase in male parental investment (gift nutrients in eggs increases), decreases the number of males able to mate (produce gifts) and (in field enclosures) causes a reversal in the mating roles by greatly increasing male choice and female–female competition for mates (Gwynne, 2001). Furthermore, there was even evidence of context-dependent sexual selection on female morphology: the heaviest females had a mating advantage in the control treatments but not food-supplemented treatments. Experimental role reversal also affects other aspects of life history apart from mating itself: as relative male parental investment increases, so does male immune activity, whereas sexually competing females have reduced immune function as paternal investment increases (Vincent and Gwynne, 2014).

Exceptional taxa showing unusual mating and/or parental roles provide fascinating examples of the diversity of natural systems. These exceptions have also provided strong tests of the putative causes of sexual differences highlighted above. Although most of the species mentioned below feature rather dramatic departures from the conventional sex roles described above, we note that sexual selection theory predicts (and empirical research supports) continuous variation in mating and parental behavior, with many taxa occupying the middle ground between the conventional stereotypes above and the departures listed below (Jones and Hunter, 1999; South and Arnqvist, 2008; South *et al.*, 2009).

Most studies of unusual sex roles have supported the links between relative investment by the sexes, the operational sex ratio, sexual selection, and sexual differences. In a few cases there is plasticity in mating roles that allow tests of factors controlling sexual differences (**Box 2**). For example, in certain environments males provide large material benefits to females in the form of nutritious 'nuptial gifts.' The cost of providing these material donations may constrain male ability to remate, while simultaneously increasing the value of remating for females. If male investment is sufficiently important to female fitness, females may be under so much selection to acquire male donations that the operational sex ratio becomes female-biased. Males in turn may then become more choosy than females about their mates (see **Box 2**). Unusual mating roles are not always directly driven by parental investment, however: in one exceptional case (in a butterfly) a female bias in mate availability is caused by extremely elevated male mortality (due to *Wolbachia* infection), which skews the sex ratio to such a degree that females form mating leks (Jiggins *et al.*, 2000).

Figure 2 *Kawanaphila nartee* bushcricket female eating a spermatophore gift. Photo by Darryl Gwynne.

Polyandrous Females

As we have seen, the relationship between mate number and fitness is usually strongest in males, whereas females often gain much less by remating (Bateman, 1948). The explanation for this sex difference lies both in the costs and the benefits of remating for females. Female mating costs include mate search and mate-assessment costs. Mating may also heighten the risk of predation (Arnqvist, 1989), or decrease lifespan, for example, due to injuries sustained during coupling (Crudgington and Siva-Jothy, 2000) or to damaging effects of seminal fluid (Chapman *et al.*, 1995). While males may also suffer costs such as mate searching, female costs appear to be generally greater. For example, females rarely transfer secretions to males that are costly to the partner's reproductive physiology (female Zeus bugs produce a glandular secretion thought to reduce costs of kleptoparasitism by males, but whether this secretion decreases or improves male fitness is unclear; see Arnqvist *et al.*, 2006).

Given these costs, what do females gain by remating? Most empirical studies point to 'direct benefits' of multiple mating, to replenish sperm supplies, acquire goods and services from males, or to avoid the costs of resisting harassment in male mating attempts. In contrast, there is substantially less evidence for 'indirect benefits,' including the acquisition of genetically superior or more compatible sperm, or more diverse offspring (Arnqvist and Nilsson, 2000; Slatyer *et al.*, 2012). The benefits of multiple mating for males always involve the direct benefits of fertilizing female ova. Consequently, even when sexually receptive females outnumber males, the covariance between male mating success and fitness will usually be positive. In such cases, male fitness may be constrained more by other aspects of their biology than by access to mates (e.g., if each mating requires substantial male investment).

Armed and Ornamented Females

When females are so eager to mate that they outnumber sexually receptive males, we expect females to compete sexually, but even in cases of unusual mating roles, females rarely use weaponry to compete or ornaments to attract mates. Examples of female armaments that function in mate competition are virtually unknown. One explanation is that the

cost of expressing weaponry includes structural and metabolic costs as well as the risk of injury during fights; any substantial investment in weaponry could therefore come at a direct cost to a female's own fecundity, and undermine the benefits of winning competition for mates (Berglund, 2013). In fact, in most examples, female armaments appear to have evolved in the context of direct competition with other females for resources rather than mates. Because female reproductive fitness is closely related to maximizing their own fecundity (even in systems in which females are relatively polyandrous), females are more likely than males to compete for resources that will benefit the development and production of their offspring (Clutton-Brock, 2007, 2009). The intensity of the reproductive competition between females, and the development of secondary sexual characters, is therefore closely associated with such resource acquisition. In acknowledging the importance of female competition for material resources essential to reproduction (including competition between potential reproductives (queens) in eusocial animals), some authors have advocated developing a broader perspective of 'social selection' (which emphasizes competition for all resources, not just mates, in social interactions) to facilitate comparisons of secondary sexual traits that arose in differing contexts (West-Eberhard, 1979, 2014; Tobias *et al.*, 2012; but see discussion by Shuker, 2010 and Clutton-Brock and Huchard, 2013).

Examples of female ornaments that function in attracting mates crop up in fishes, birds, and some insects (Tobias *et al.*, 2012). As with female weapons, investment in ornaments may come at a direct cost to a female's own fecundity, which may explain their rarity in spite of the fact that sexual selection on females is relatively common (Bonduriansky, 2001). Ornament evolution is also constrained because it is mediated by male preferences. Any potential trade-off between investment in ornaments and offspring is unlikely to be favored by choosy males, who would presumably prefer an unadorned but highly fecund mate (Fitzpatrick *et al.*, 1995). Furthermore, selection for mate attraction by females could be self-limiting in another respect: seductive females who attract more mates probably provide smaller paternity shares for focal males than relatively unpopular rivals that offer a lower risk or intensity of sperm competition (Wheeler *et al.*, 2012).

Choosy Males

Male choice is generally constrained by the opportunity cost of mate searching and assessment: if males can best gain fitness by acquiring additional mates instead of choosing among them, then choice seems unlikely to evolve. However, if sexually receptive females outnumber receptive males, female quality is variable (e.g., if many receptive females are not yet gravid) and males invest heavily in each mating, males tend to favor traits in females that directly increase their fertilization success (Bonduriansky, 2001). In taxa where female egg number varies substantially (e.g., invertebrates and fish), males generally prefer traits that signal high fecundity, such as large body size. For taxa where females have less variable fecundity (e.g., mammals and birds), males instead tend to focus on traits that signal reduced sperm competition, such as female mating status or age (Bonduriansky, 2001).

Caring Males

For male care to evolve, the benefit to the fitness of his offspring should be greater than the cost incurred by lost mating opportunities (Clutton-Brock, 1991). Relative parental investment is central to sexual selection theory because investment in offspring is both the ultimate cause of sex differences and one of its consequences (by shaping the respective care strategies for males and females). However, discerning cause and consequence can be difficult, as Trivers (1972) first noted (but see experiments in **Box 2**).

Although the circumstances described in the section on parental roles, above, suggest general sex differences in the likelihood of investing in care, male care is not uncommon. It may be that low certainty of paternity limits care, or alternatively care can enhance paternity (Kvarnemo, 2006). Whatever the cause of the association, high paternity confidence should usually be assured in species with male care (Smith, 1979; Møller and Birkhead, 1993). For example, in the water bug, *Abedus herberti*, males brood eggs that gravid females oviposit on their backs. Although females of this species can store sperm, males reduce the risk associated with uncertain paternity by copulating frequently with the female (approximately every second egg laid) during oviposition, which can last up to 2 days (Smith, 1979). A second factor selecting for male care is that care per se attracts additional mates as in certain fishes. Thus caring males can achieve higher mating success than non-caring males (Tallamy, 2000). This is more likely to enhance male than female fitness, because reproductive rate is less limited in males (Smiseth, 2014). In some systems, such female preferences lead to competition between females for males that can provide the best care (Petrie, 1983; Owens *et al.*, 1994).

Unresolved Questions about Sex Roles

The detailed causes of differences in sexual selection are not yet clear. The complex relationships between investment costs and mating opportunities make distinguishing between causes and effects difficult. Empirical tests (such as Gwynne and Simmons, 1990) have shown that varying parental investment can reverse mating roles. However, determining general drivers of patterns across diverse species is complicated (Borg *et al.*, 2002) because we still do not know the extent to which differences in parental care are a cause of the general sex role syndromes (the fact that males can avoid care may be what allows them to maximize fitness by mating repeatedly), or rather an ultimate consequence of differences in sexual selection (males may generally avoid care because they gain more by pursuing more mates than by improving the fitness of their existing offspring) (Kokko and Jennions, 2008). Similarly, there is ongoing controversy concerning whether the ratio of sexually receptive males and females determines sexual trait expression by controlling sexual selection intensity, or whether it emerges as a consequence of differences in sexual selection intensity (Kokko *et al.*, 2014).

These questions are compounded by ongoing debates about how to compare the conditions that affect mating and parental roles across sexes and species. For example,

Kokko *et al.* (2014) suggest that while operational sex ratios and Bateman gradients typically covary, they can provide different but complementary information on fitness benefits of investing in secondary sexual characters. For example, if obtaining new mates becomes more difficult for males, and fitness benefits of mate seeking decrease, there may be selection for paternal care, which affirms Trivers' (1972) insight that parental investment is both a cause and a consequence of differences in selection on the sexes. There have been similar debates about the best metrics for sexual selection intensity between the sexes and across species (measuring selection accurately is a prerequisite for explaining diversity in mating systems). Some authors contend that metrics based on variance in reproductive and mating success (such as the Bateman gradient and the opportunity for sexual selection) (Wade, 1979) are better predictors of sex differences in behavior and morphology across species than trait-specific measures of sexual selection (e.g., the covariance between reproductive success and body size) (Fritzsche and Arnqvist, 2013). One reason for using measures unrelated to phenotypic traits is that traits under strong directional selection can have depleted genetic variance (Prokuda and Roff, 2014), which can lead to lower trait-based estimates of sexual selection. Other authors have demonstrated that variance based measures are only good predictors of sexual selection intensity in very limited circumstances, such as when the potential for mate monopolization is high (Klug *et al.*, 2010; Jennions *et al.*, 2012).

Although what ultimately causes sexual differences, and how best to measure them, remains unresolved, there are some promising research directions involving species with unusual mating systems. We have already noted how such taxa have been instrumental in testing some of the key predictions of sexual selection theory, and they promise new insights thanks to some as yet understudied aspects of their biology. For example, one of the major ongoing questions in sexual selection concerns the relative importance of direct and indirect benefits in driving the evolution of mate choice. Species in which males provide substantial nutritional investment have already been deployed to study this problem (e.g., Fedorka and Mousseau, 2002; Iyengar and Eisner, 2004). Species with unusual sex roles may also shed light on general questions concerning life history, because the life history consequences of investing in costly weapons or ornaments are rather different for males than for females (Houslay and Bussière, 2012). Although the theoretical reasons for this rarity have been compellingly documented, there still remain some unexploited opportunities to test these arguments among taxa that possess impressive female armaments and ornaments. Rare examples of such work include that on female-specific armaments in *Onthophagus sagittarius* (**Figure 3**; Simmons and Emlen, 2008) and female-specific ornaments in *Rhamphomyia longicauda* (**Figure 4**; Funk and Tallamy, 2000). Such tests continue the tradition established by early work on species with unconventional mating systems of using exceptions to prove the rules.

Mating Systems, A Brief History of

H Klug, University of Tennessee at Chattanooga, Chattanooga, TN, USA

Glossary

Breeding system A description of mating and parental care behavior by males and females.

Mating success The number of social and/or genetic mates that an individual has during some specified period of time or its entire life.

Mating system The way that individuals are grouped in relation to mating and the way in which matings are achieved through time in a population.

Parental care Parental behavior that (1) occurs post-fertilization (or after the production of daughter cells if reproduction is asexual), (2) is directed at offspring, and (3) appears likely to increase offspring lifetime reproductive success.

Parental investment Any parental expenditure (time, energy, or other resources) that benefits the fitness of offspring but reduces the ability of a parent to invest in other components of fitness.

Reproductive success The number of viable and surviving offspring that an individual produces during some specified period of time or its entire life.

Sexual selection Covariation among a phenotypic trait and mating success.

Mating Dynamics Are Highly Diverse

Mating dynamics are highly variable and diverse. In many animals, such as the elephant seal (*Mirounga angustirostris* and *Mirounga leonina*), males compete intensely for access to female mates, and both sexes mate multiply (Hoelzel *et al.*, 1999). In other cases, such as the pipefish *Syngnathus typhle* females compete for access to males, males are choosy with respect to who they mate with, and males provide parental care to offspring (Berglund *et al.*, 1986). In some relatively rare cases, such as in the spotted sandpiper (*Actitis macularia*) females compete for and mate with multiple males, leaving each of those males to care for their offspring (Oring *et al.*, 1994).

Scientists who study mating systems are interested in explaining why such variation in mating dynamics exists. One thing that has become clear in recent decades is that mating dynamics, including mate competition and fertilization, are heavily influenced by sexual selection, parental investment, and ecological factors. The focus of mating system research tends to be twofold: First, researchers aim to categorize mating systems. Indeed, a great deal of work since the 1970s has focused on developing comprehensive qualitative and quantitative descriptors of mating systems, a challenging task given the huge variation in mating dynamics that exists in nature. Second, researchers aim to understand and explain variation in mating dynamics. For example, a large body of work has focused on understanding variation in the number of mates that each sex has in a given population or species, why sex-specific patterns of parental care vary across systems and how these patterns are linked to mating dynamics, and how resources required for mating can influence patterns of mating behavior.

Below, an overview of the history of mating system research is provided. The article begins with classic definitions and classification systems of mating systems. Then it describes the factors that have historically and/or are currently thought to have strong influences on mating systems. Finally, future directions in mating system research are briefly discussed.

History of a Name: Defining Mating Systems

The term mating system refers to the way that individuals are grouped in relation to mating and the way in which matings are achieved through time in a population (reviewed in Emlen and Oring, 1977; Davies, 1991; Shuster and Wade, 2003; Klug, 2011). Most simply, mating systems are classified by the number of mates that a given individual has during a specified period of time or throughout their entire lifetime (Emlen and Oring, 1977). For example, monogamy describes a mating system in which each individual has a single mate for some specified period of time (e.g., one or more breeding seasons) or their entire life; polygyny refers to the mating system in which females have a single mate during some specified period of time or their entire life and males mate with multiple females; polyandry describes a mating system in which males have a single mate during some specified period of time or their entire life and females mate with multiple males; and polygamy or multiple mating describes a system in which both sexes mate multiple times (reviewed in Emlen and Oring, 1977; **Table 1**). While these definitions of mating systems have been widely used, some researchers have argued that the way in which we categorize mating systems needs to be refined. For example, some authors have expanded simple mating system classifications to account for how individuals acquire mates (e.g., Emlen and Oring, 1977; Shuster and Wade, 2003), the pair bond duration between males and females (Davies, 1991; Shuster and Wade, 2003), details of parental care (e.g., Reynolds, 1996; Shuster and Wade, 2003), and other specific details of mating behavior, such as coercion (Shuster and Wade, 2003).

Shuster and Wade (2003), for instance, have suggested that variation in mating success is a key feature of mating systems and should therefore be accounted for in our categorization of mating systems. In addition to the classic mating systems of monogamy, polyandry, and polygyny described above, they provide a more detailed classification system for scenarios in

Table 1 A description of classic mating systems. Mating system categorizations have been expanded, and additional mating systems are described in the text

Mating system	*Description*
Monogamy	Both males and females have only one mate for their entire lifetime or some specified period of time
Polyandry	Females mate with multiple males and males have only a single mate over the course of their entire lifetime or some specified period of time
Polygyny	Males mate with multiple females and females have only a single mate over the course of their entire lifetime or some specified period of time
Polygamy or multiple mating	Both males and females mate with multiple opposite-sex individuals

which both sexes engage in multiple mating. According to their classification system, polygamy occurs when both sexes mate multiply and average male and female mating success is approximately equal, polygynandry occurs when both sexes mate multiply and there is greater variation in female mating success in comparison to male mating success, and polyandrogyny is characterized by both sexes mating multiply and greater variation in male mating success relative to that of female mating success (Shuster and Wade, 2003). Because there can be a large amount of variation in any mating system category, Shuster and Wade (2003) have also advocated quantitative measures of mating system that explicitly account for the variation in mating success in males and females (**Box 1**).

Reynolds (1996) additionally suggested that understanding parental care is key to understanding mating dynamics, and proposed the term 'breeding system' (rather than 'mating system') to more explicitly account for the role that care plays in mating dynamics. Reynolds (1996) defined breeding systems as a description of mating and parental care behavior by males and females, and argued that breeding system classifications should encompass the form and duration of parental care, the form and duration of pair bonds, the number of genetic and social mates that each sex has, forms of courtship and mate competition, details of resource that are required for mating, and the extent of mate choice, including sperm choice (Reynolds, 1996). Indeed, all of these factors can interact to influence mating dynamics, and there can be co-evolutionary feedback among sexual selection and parental care (discussed below and reviewed in Reynolds, 1996; Kokko and Jennions, 2008; Alonzo, 2010).

Developing a comprehensive system to categorize mating systems has been a key focus in mating system research. More broadly, though, mating system researchers are interested in understanding why there is so much diversity in the mating systems that exist in nature. Below, the factors that are thought to influence mating systems are discussed, and when applicable, an overview of how these factors have been incorporated into our classification of mating systems is provided.

Box 1 A quantitative descriptor of mating systems

Categorizing mating systems qualitatively (e.g., monogamy, polyandry, polygyny, polygamy) provides insight into the general mating dynamics that are occurring in a given population or species. However, qualitative descriptors of mating systems have been criticized as being too vague (e.g., Shuster and Wade, 2003). For example, when classifying a mating system, it is often unclear what time scale should be focused on, and empirically, there is frequently inconsistency in how mating systems are categorized. Additionally, with respect to mating systems in which one or both sex mates multiply, qualitative descriptors of mating systems provide little or no information about the extent of variation in mating success that each sex experiences.

Because of the limitations of qualitative mating system descriptors, Shuster and Wade (2003) have argued that quantitative descriptors of mating systems are needed. Specifically, they have suggested that measuring the variance in relative fitness (e.g., mating and/or reproductive success) for males and females will provide strong insight into the mating system that a population experiences. The opportunity for selection, (if reproductive success is the variable of interest), and the opportunity for sexual selection, I_s (if mating success is the variable of interest), are dimensionless measures of the variance in relative fitness for a given sex. Each measure (I and I_s) is calculated as the variance in mating or reproductive success divided by the mean mating or reproductive success squared (described in detail in Shuster and Wade, 2003). The opportunity for selection and the opportunity for sexual selection reflect the maximum possible selection that can be occurring during a particular episode or multiple episodes of selection. Importantly, however, these measures do not always correlate well with the actual strength of sexual selection (reviewed in Klug *et al.*, 2010), and should therefore not be used as a measure of the strength of sexual selection. Despite this limitation, I and I_s provide insight into the variation in mating dynamics that are occurring at a given point in time in a given population. Given that a major goal in mating system research is to categorize the mating dynamics in a given system, I and I_s can be useful for quantifying and understanding the variation in mating and reproductive success that occurs within and across different mating systems (Shuster and Wade, 2003). Once variation in mating and reproductive success is quantified using these measures, an obvious next step is to attempt to understand why such variation exists.

Mate Monopolization Matters

Emlen and Oring (1977) viewed mate monopolization as a defining and driving feature of mating systems and incorporated mate monopolization into their detailed classification system of mating systems. They argued that mating system will be affected by mate monopolization, and that mate monopolization will largely be determined by the spatial and temporal distribution of resources and mates that utilize those

resources. If, for example, females are the choosier sex and resources are evenly distributed in space, females who utilize those resources will be spread out over space, and, it potentially becomes more difficult for a single male to monopolize multiple females. Likewise, if females become sexually receptive in unison, it will be relatively difficult for a single male to monopolize multiple females (Emlen and Oring, 1977). In such cases, a polygynous mating system would be unlikely to occur. On the other hand, if resources, and hence females, are clumped in space and/or if females are sexually receptive at different points in time, then it becomes more likely that a single male can monopolize and defend multiple mates, and polygyny becomes more likely (Emlen and Oring, 1977).

Emlen and Oring (1977) expanded the classification of mating systems to account for the important role that resources can play in driving mating dynamics, and their classification system also accounts for the specific way in which mates are monopolized. For example, with respect to polygyny, Emlen and Oring (1977) identified three general scenarios: (1) resource defense polygyny, in which males indirectly control access to females by monopolizing resources; (2) female defense polygyny, in which males directly control access to multiple females; and (3) male dominance polygyny, in which males aggregate during the breeding season and females select mates from those aggregations. With respect to polyandry, they identified two general scenarios: (1) resource defense polyandry, in which females control access to males by monopolizing resources; and (2) female access polyandry, in which females limit and control access to mates.

In addition to expanding the way in which we classify mating systems, Emlen and Oring (1977) developed a conceptual framework to explain the way in which male and female mate availability, resources, and sexual selection interact to influence mating systems. In particular, they thought that the sex ratio of individuals currently prepared to mate would have strong effects on mating dynamics, and this topic is discussed in more detail in the following section.

The Link between Operational Sex Ratio, Sexual Selection, and Mating System

As mentioned above, Emlen and Oring (1977) suggested that there is a clear link between mate monopolization, resources, and mating systems. They argued that mate monopolization is likely influenced by the operational sex ratio, which is the ratio of males to females prepared to mate at a given time and in a given location (OSR; Emlen and Oring, 1977; Kvarnemo and Ahnesjö, 1996). In general, they predicted that a relatively small number of the mate-limited sex individuals will monopolize the more common sex when the OSR is biased (see also Klug *et al.*, 2010 for criticisms of this argument). Specifically, Emlen and Oring (1977) predicted that a male-biased OSR will lead to polygyny, and a female-biased OSR will lead to polyandry. Emlen and Oring (1977) additionally predicted that the strength of sexual selection on the mate-limited sex (males in most cases) will increase as the OSR becomes more biased and as mate monopolization increases (Emlen and Oring, 1977), because when mate monopolization is high, traits that allow a small number of individuals to monopolize mates will be strongly selected for. This view has recently been challenged (Shuster and Wade, 2003; Klug *et al.*, 2010; Jennions *et al.*, 2012), as there is no logical reason to assume a priori that mate monopolization, and hence the strength of sexual selection and polyandry or polygyny, will increase as the OSR becomes more biased toward one sex. Indeed, as OSR becomes more biased and there are more same-sex competitors, it is equally plausible that mate monopolization will become more difficult (e.g., due to interference among members of one sex) (**Figure 1**; Klug *et al.*, 2010).

Indeed, OSR is not a reliable predictor of mate monopolization, mating system, or sexual selection across many biologically-realistic scenarios (Shuster and Wade, 2003; Klug *et al.*, 2010; Jennions *et al.*, 2011). Mate monopolization, on the other hand, is a reliable predictor of the strength of sexual selection (**Figure 1**), and the strength of sexual selection will increase as mate monopolization increases if one or more phenotypic traits are under sexual selection (Emlen and Oring, 1977; Klug *et al.*, 2010). In addition to identifying the link between mate monopolization and sexual selection, Emlen and Oring (1977) recognized that mating behavior, parental care, and sexual selection are intimately linked and will have interactive effects on mating systems.

Parental Investment and Sexual Selection Shape Mating Systems

Emlen and Oring (1977) suggested that polygamy is more likely when one sex does not provide parental care and/or when parental care requirements are relatively minimal. They additionally suggested that monogamy is more likely to occur when the potential for monopolizing multiple mates is low and when fitness is maximized by providing care to current offspring (Emlen and Oring, 1977). These ideas have been expanded upon in recent years, and we now have a more complete understanding of the complex relationship between care, mate monopolization, sexual selection, and mating systems.

In many animals, one sex tends to be the choosier sex and the other sex is mate limited and engages in mate competition and/or attraction (Darwin, 1871; reviewed in Andersson, 1994). As mentioned in the previous section, the mate limited sex will experience relatively strong sexual selection if a small number of individuals possess traits that allow them to monopolize many opposite-sex mates (Emlen and Oring, 1977; reviewed recently in Klug *et al.*, 2010). Sexual selection can thus have strong influences on mating dynamics and the resulting mating system. For example, sexual selection can favor traits that increase mating success and mate monopolization, such as fighting ability, increased body size, traits that are preferred by the opposite sex, and traits that increase fertilization success (reviewed in Andersson, 1994). In general, males tend to be mate limited and experience greater sexual selection and females tend to be the choosier sex and experience relatively weaker sexual selection (reviewed in Clutton-Brock and Parker, 1992), although in some sex-role reversed systems, males are the choosier sex and females are mate limited.

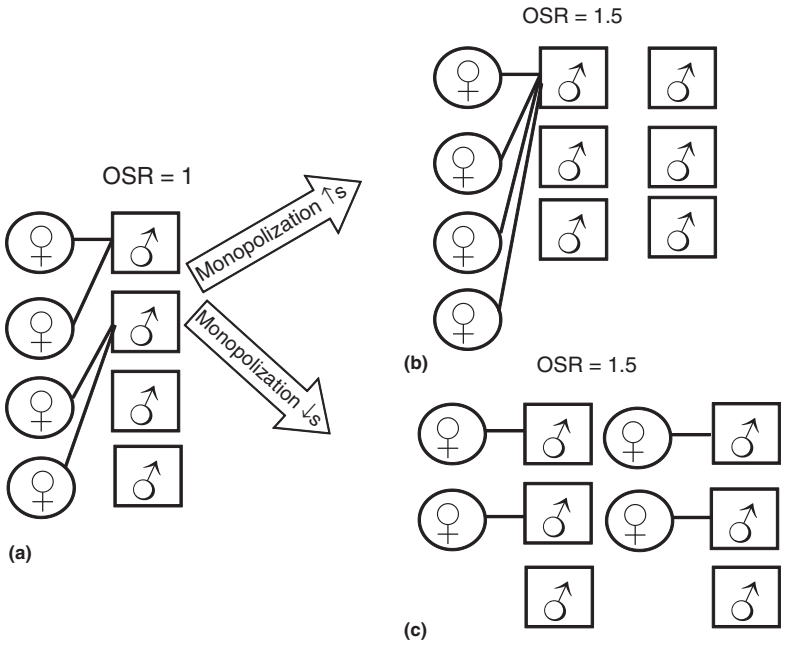

Figure 1 The complex relationship between operational sex ratio (OSR), mate monopolization, and sexual selection. Emlen and Oring (1977) suggested that mate monopolization will increase as the OSR becomes more biased toward one sex. Recent research has demonstrated that there is no a priori reason to assume that this will occur. For example, imagine an unbiased OSR in which there are four females and four males (a). In our scenario (a), if each of two males monopolizes two female mates, there will be a moderate degree of mate monopolization, and two males will remain unmated. If the operational sex ratio changes, it is possible that mate monopolization will also change. For example, if sex ratio becomes male-biased, such that we now have four females and six males ((b) and (c)), it is possible that a single male will now be able to monopolize all female mates, in which case mate monopolization would increase (b). Such a pattern would be consistent with the predictions of Emlen and Oring (1977). Alternatively, though, it is possible that the addition of two new males will make mate monopolization more difficult (e.g., if there is interference among males). In such a scenario, it is possible that mate monopolization will decrease as the OSR becomes more biased (c). Such a pattern is not predicted by classic theory (Emlen and Oring, 1977), but there is no reason to assume that either one of our scenarios ((a) → (b) or (a) → (c)) will be more likely. Mate monopolization is a key component of a mating system and affects sexual selection. If mate monopolization increases because one or a small number of males possess a trait that allows them to monopolize multiple mates, that trait will be favored by sexual selection. As the degree of mate monopolization increases, sexual selection on the trait that allows for monopolization will also increase. Thus, in our scenarios ((a), (b), and (c)), if mate monopolization occurs because of a trait, we would expect that trait to experience the greatest sexual selection in scenario (b). Modified from Klug, H., Heuschele, J., Jennions, M.D., Kokko, H., 2010. The mismeasurement of sexual selection. *Journal of Evolutionary Biology* 23, 447–462.

Historically, sex differences in parental investment have been used to explain why males tend to be mate limited and females choosy (Trivers, 1972). Trivers (1972) noted that females, by definition, produce larger gametes than males, and as a result have greater pre-mating parental investment than males. Trivers (1972) argued that females will be more likely to have greater post-mating parental investment than males because of their relatively high pre-mating parental investment. Additionally, because females produce larger gametes, males are expected to return to the mating pool faster than females after mating. As a result, the relatively high potential reproductive rate (PRR; Clutton-Brock and Parker, 1992) of males will create a male-biased OSR, and this in turn has been predicted to lead to greater sexual selection on male traits and a mating system in which some males monopolize and mate with multiple females (Clutton-Brock and Vincent, 1991; Clutton-Brock and Parker, 1992; reviewed in Kokko and Jennions, 2008). Both of these predictions – (1) that females will have greater post-mating investment because they have already invested more into gametes than males and (2) that a relatively large male PRR and male-biased OSR will lead to relatively strong sexual selection on males – have been questioned in recent years.

Dawkins and Carlisle (1976) noted that past investment should not necessarily affect future investment, and the prediction that females will have greater parental investment than males simply because they have already invested more in gametes than males commits the Concorde fallacy (Dawkins and Carlisle, 1976; Queller, 1997). While greater female investment in gametes can affect mate availability and the future reproductive opportunities that each sex experiences, we now know that past investment alone will not drive sex differences in future investment (reviewed in Kokko and Jennions, 2008). Males and females, however, do differ in many ways, and these differences can affect parental investment, sexual selection, and ultimately, mating system. For example, males and females might differ in (1) the costs and/or benefits associated with providing care and/or competing for mates, (2) the ability to provide parental care (e.g., one sex might be unable to provide essential forms of care), (3) certainty of parentage, (4) mate availability, and (5) the costs and/or benefits associated with mate preference (Queller, 1997; Houston and

McNamara, 2002; Kokko and Jennions, 2008; Alonzo, 2010; Klug *et al.*, 2012). Such differences can, in turn, affect mating system dynamics.

In particular, the costs and benefits associated with mate competition versus parental care can strongly influence sex roles and sexual selection (reviewed in Kokko and Jennions, 2008). When competing for mates is associated with higher mortality than providing parental care, the sex that provides less care and competes more for mates (i.e., the earlier deserting sex) will become relatively rare in the population because individuals of that sex will have greater mortality. Such a scenario is expected to favor earlier desertion by the sex that is relatively rare, and this, in turn, is predicted to lead to maternal care and greater male mate competition if females are initially selected to care or paternal care and greater female mate competition if males are initially more likely to care (Kokko and Jennions, 2008). In contrast, if providing parental care is more dangerous than competing for mates, individuals who provide less care and desert offspring earlier will experience reduced mortality, and the earlier deserting sex will become more common in the population. If the earlier deserting sex is more common, individuals of this sex will have difficulty finding mates, and this scenario will select for increased paternal investment by the deserting sex. In this case, selection would be expected to favor increased parental investment by both sexes (Kokko and Jennions, 2008). Additionally, if parental care itself is under sexual selection, such that the choosier sex prefers mates that provide parental care, the more competitive, mate-limited sex would be expected to also provide parental care in some cases (Alonzo, 2012). Indeed, the relationship between parental care, sexual selection, and mating dynamics can be complex.

Females Benefit from Multiple Mating and Paternity is often Uncertain

Two additional complexities of mating dynamics, and issues that have challenged the conventional resource-based and sexual-selection focused view of mating systems, is the fact that (1) females of many species choose to mate multiply even when a single male could fertilize all of their eggs and (2) that males often experience uncertain paternity (reviewed in Reynolds, 1996).

In a now classic study, Bateman (1948) examined the relationship between number of mates and the number of offspring produced in *Drosophila melanogaster*. While male reproductive success increased linearly with increasing mating success, female reproductive success increased only marginally (if at all) with increasing mating success after a single mating. If female reproductive success does not increase substantially with each additional mate, we would expect (1) sexual selection to act more strongly on males than females, and (2) females to avoid actively mating with multiple males if there are costs of additional matings. In contrast to this latter prediction, females of many species actively choose to mate with multiple males (reviewed in Reynolds, 1996; Birkhead *et al.*, 1997). A number of hypotheses have been proposed to explain why females mate multiply. In some cases, females might benefit from mating multiply because they gain indirect benefits (e.g., higher genetic quality in offspring), additional parental care from mates, and/or nutrients or other resources (reviewed in Birkhead *et al.*, 1997; Jennions and Petrie, 2000). Regardless of the specific benefit associated with female multiple mating, when females mate with multiple males during a given reproductive bout, their mates' expected certainty of paternity is expected to decrease. Paternity uncertainty is then expected to influence mating dynamics, parental investment, and sexual selection (Birkhead and Møller, 1998; recently reviewed in Alonzo, 2010).

Within a species, individual males are expected to reduce their parental care in response to decreased paternity if paternity is expected to be greater during future reproductive episodes (Houston *et al.*, 2005; Kokko and Jennions, 2008; Alonzo, 2010). Across species, a positive relationship is expected between paternity certainty and the level of paternal care provided (reviewed in Alonzo, 2010). Surprisingly, the support for these predictions is mixed. Within species, a recent review found that reduced paternity leads to decreased care in less than half of the studies considered (Alonzo, 2010). It is possible that paternity cues simply do not exist in some animals or that individual variation in male condition makes it difficult to detect a relationship between paternity and paternal care (Alonzo, 2010). In general, though, it is often unclear why paternity uncertainty does not appear to influence parental investment. Regardless, it is clear that more work is needed to fully understand how multiple mating and uncertain paternity affect mating systems and parental care.

Conclusions: Understanding Mating Systems Requires a Focus on Co-Evolutionary Dynamics

In the past 20 years, many researchers focused on mating system research have moved away from simplistic ecological classifications of mating systems and focused more explicitly on how sexual selection, ecology, and parental care interact to shape mating dynamics (e.g., Reynolds, 1996; Shuster and Wade, 2003; Kokko and Jennions, 2008; Alonzo, 2010). Nonetheless, we are still far from fully understanding mating dynamics. Indeed, post hoc explanations of mating behavior rather than well-supported a priori predictions are common (Alonzo, 2010). In the future, there are several avenues of research that are key to expanding our understanding of mating dynamics. First, recent theory has highlighted the important co-evolutionary feedback that can occur between parental investment, mate choice, mate competition, and fertilization (e.g., Kokko and Jennions, 2008; Alonzo, 2010). Additional theory is needed to more fully understand such links, and perhaps more importantly, experimental evolution and phylogenetic studies are essential to test predictions of this theory. Likewise, chance (Jennions *et al.*, 2012) and basic life-history differences between the sexes (Klug *et al.*, 2013) can have important roles in shaping mating dynamics, and both of these topics warrant further attention. Indeed, some studies have found large variation in mating success but no evidence of strong sexual selection (e.g., Westneat, 2006), and it is possible that random events have larger effects mating systems than is currently recognized. Finally, in the future, it will be key to give more focus on the genetic basis of mating and parental

behavior. Enhanced understanding of the mechanistic basis of mating behavior will allow us to develop a more complete conceptual framework of mating systems that links variation in genes with variation in populations and species.

Mating Systems in A Changing Environment

U Candolin, University of Helsinki, Helsinki, Finland
BBM Wong, Monash University, Melbourne, VIC, Australia

Glossary

Alternative reproductive behavior Discrete alternative behaviors involved in the pursuit of mating success.
Effective population size The number of individuals in a population that contribute offspring to the next generation.
Evolutionary trap Traits that have evolved under earlier environmental conditions that become maladaptive under changed environmental conditions. Includes ecological traps where animals make maladaptive habitat choices.
Mating system Describes the manner in which males and females associate during mating in an attempt to maximize their lifetime reproductive success. Animal mating systems are categorized according to the number of mates a given sex is able to monopolize (monogamy, polygamy, and promiscuity). Such categorizations can be based on social bonds (social mating system) or on genetic paternity and maternity of the resultant offspring (genetic mating system).
Operational sex ratio, OSR The average ratio of fertilizable females to sexually active males at any given time.
Potential reproductive rate, PRR The rate at which an individual is able to reproduce if it is not limited by the availability of mates.
Polygamy The situation that arises when members of one sex mate with multiple members of the opposite sex. Polygamy includes polygyny (when male mates with several females), polyandry (when female mates with several males), and polygynandry (when several males mate with several females).
Resource-based mating system Individuals of one sex (usually males) defend a resource that might sustain several members of the opposite sex (usually females).
Sexual conflict The conflict that arises when the reproductive interests of males and females are not aligned, resulting in sex-specific selection on traits.
Sexual selection Selection driven by competition among members of one sex (usually males) for access to the gametes of members of the opposite sex (usually females). Sexual selection can be divided into intrasexual selection, when members of the same sex compete among themselves for access to the opposite sex, and intersexual selection, when members of the same sex compete to be chosen by the opposite sex.

What Determines Mating Systems?

Animal mating systems are spectacularly diverse and exhibit considerable variation both within and between species. In some animals, males and females form lasting pair bonds and exhibit lifelong fidelity to a single mating partner. In others, sexual encounters may be little more than a fleeting tryst involving multiple mating partners or a chance encounter between the sperm and eggs of different individuals released into the surrounding environment. Ultimately, the mating strategy an animal adopts depends on the number of mates it can successfully monopolize as it attempts to maximize its reproductive success relative to others in the population. In this regard, competition among individuals for access to mates can often be taxing. A considerable investment of time and effort, for example, may be needed to successfully acquire and defend resources that are important in searching for, or attracting, mates or looking after offspring.

Not surprisingly, the costs and benefits of any mating strategy is expected to depend on a wide range of demographic and ecological factors, such as the density and distribution of the population, the abundance of resources, the potential reproductive rate of the sexes, the adult sex ratio, and the need for parental care (Emlen and Oring, 1977; Shuster and Wade, 2003; **Figures 1** and **2**). Moreover, the most 'profitable' mating system for one sex might be very different for the other (**Figure 3**).

Why are Mating Systems Sensitive to Environmental Change?

Ecological factors heavily influence animal mating systems. Such factors not only regulate the distribution and density of the population in space and time, but also determine the distribution and accessibility of resources that individuals require to monopolize mates and/or provide for offspring (Emlen and Oring, 1977; Clutton-Brock, 1989). In resource-based mating systems, a patchy distribution of vital resources, such as food, increases the potential for polygamy by allowing certain individuals of a given sex (usually males) to monopolize the resource and, with that, members of the opposite sex (**Figure 4**). In non-resource based mating systems, the distribution of the population itself is expected to be more critical. A spatially clumped distribution of mates (usually females) increases the potential for polygamy, while a temporally clumped distribution results in the opposite pattern.

Ecological factors also influence mating systems by affecting the efficacy of the communication system used to

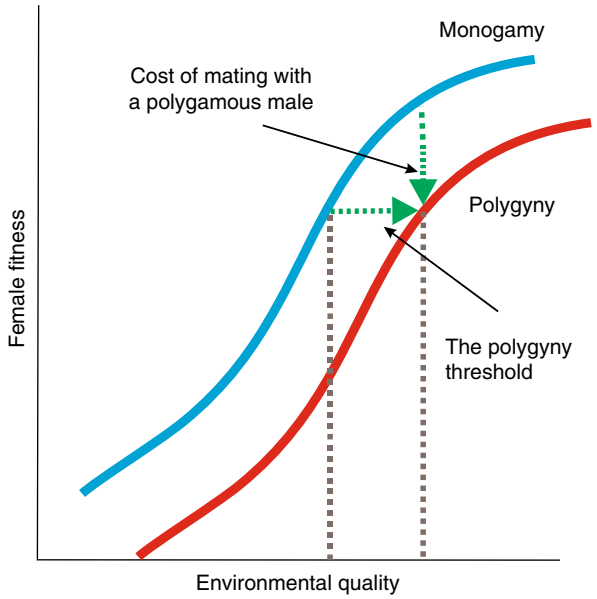

Figure 1 The benefit to a female of mating with a male that already has a mate depends on environmental quality, such as the availability of food that can be divided among the females. The switch-point when the benefit exceeds the cost is indicated by the polygyny threshold. As the environment improves, the net benefit of mating with a polygamous male increases and eventually becomes as high as mating with a monogamous male in the old environment. Reproduced from Orians, G.H., 1969. On evolution of mating systems in birds and mammals. American Naturalist 103, 589–603.

detect and select mates, the need for parental care and the potential reproductive rate of the sexes (Clutton-Brock, 1991).

How Does Environmental Change Influence Mating Systems?

Mating systems are susceptible to changes in the environment during acquisition and defense of resources, when searching for and attracting mates, during mate choice and sperm competition, and when providing for developing offspring (Figure 5). We discuss each of these in detail below.

Resource Acquisition and Defense

The ability of individuals to monopolize members of the opposite sex is sensitive to changes in the amount, quality, and distribution of critical resources needed to obtain and maintain mates (Clutton-Brock, 1989; Figure 4). Similarly, changes in the ability of individuals to defend resources can be altered by environmental change. Californian sea lions (*Zalophus californianus*), for example, defend territories close to the shore in an attempt to monopolize the females that preside within those territories. Higher temperatures, however, are forcing territorial holders to spend more of their time immersed in water, which reduces their ability to effectively guard the females against other males searching for mating opportunities (Bohorquez-Herrera *et al.*, 2014; Figure 6). As a consequence, such changes are likely to increase the incidence of extra-pair

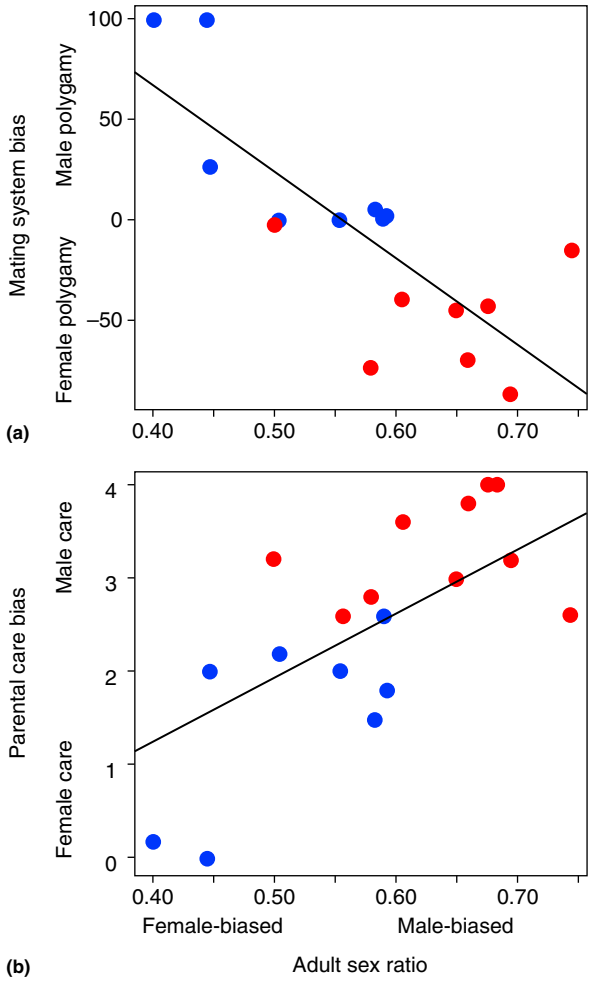

Figure 2 The mating system adopted depends on the adult sex ratio, as does biases between the sexes in parental care. (a) A more male-biased sex ratio lowers the probability that a male will be able to mate with several females, which increases the probability of female polygamy, while a female-biased sex ratio favors male polygamy. (b) A change in sex ratio also alters the sex-bias in parental care effort; when the sex ratio becomes more male-biased, and the potential for male polygamy decreases, males increase their parenting effort in relation to that of females. Blue and red dots are species with conventional and reversed sex roles, respectively. Reproduced from Liker, A., Freckleton, R.P., Szekely, T., 2013. The evolution of sex roles in birds is related to adult sex ratio. Nature Communications 4, 1587. doi: 10.1038/ncomms2600.

matings, reduce polygyny, and decrease the skew in mating success among male sea lions.

Mate Encounter Rate

Mate encounter rate depends not only on the distribution and density of individuals ready to mate, but also the probability that the sexes will be able to successfully encounter each other. Anthropogenic changes, in this regard, can affect encounter rates in a variety of ways. Habitat fragmentation can hinder dispersal (Banks *et al.*, 2007), global warming can alter hatchling sex ratios (Pen *et al.*, 2010), size-selective harvesting can reduce the abundance of the larger sex (Kendall and

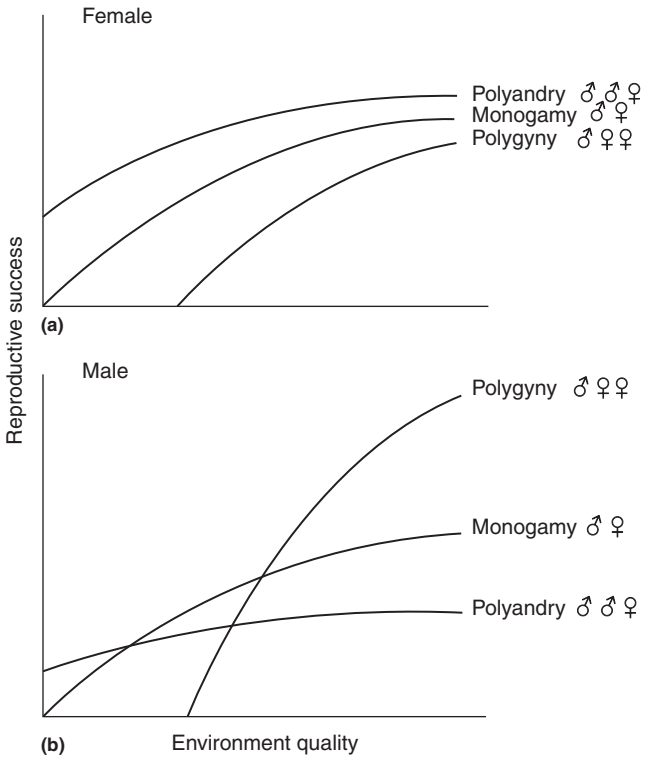

Figure 3 The mating system that is most 'profitable' in each environment varies between the sexes. Females always benefit from a polyandrous mating system, where several males provide for the female and the offspring, while males benefit from a polygynous mating system only in rich environments where enough resources are available to provide for several females and their offspring. This results in sexual conflict. Reproduced from Davies, N.B., 1991. Mating systems. In: Krebs, J.R., Davies, N.B. (Eds.), Behavioural Ecology: An Evolutionary Approach, third ed. Oxford: Blackwell Scientific Publications, pp. 263–294.

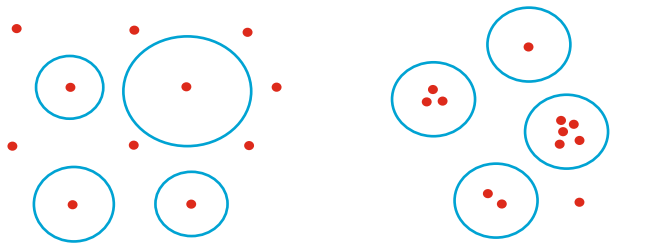

Figure 4 The distribution of resources, such as food or nest sites, determines the ability of individuals to monopolize resources and, hence, the potential for polygamy. The dots are resources and the circles are areas defended by individuals.

Quinn, 2013), and habitat changes can influence the use of signals important in mate detection. For instance, increased noise in urban areas is affecting the vocal signals of song birds (**Figure 7**) and frogs, while pollution of the aquatic environment is affecting the efficacy of chemical signals in fish (**Figure 8**; Fisher *et al.*, 2006; van der Sluijs *et al.*, 2011; Rosenthal and Stuart-Fox, 2012).

Mate Attraction and Mate Choice

Environmental conditions can profoundly affect mate competition and mate choice by altering the amount of effort the competing sex invests into conspicuous sexual displays, as well as the effort the more choosy sex invests in mate selection (Candolin and Wong, 2012). For instance, increased predation risk decreases the number of displays that guppies (*Poecilia reticulata*) perform to attract females, and instead increases the frequency of forced matings (**Figure 9**).

The possibility of making an informed choice about potential mates is hindered by environmental changes that hamper the production, transmission, and reception of signals used in mate choice (Rosenthal and Stuart-Fox, 2012). For instance, female threespine sticklebacks (*Gasterostues aculeatus*) have to spend more time evaluating males under eutrophied conditions where visibility is poor because of dense growth of

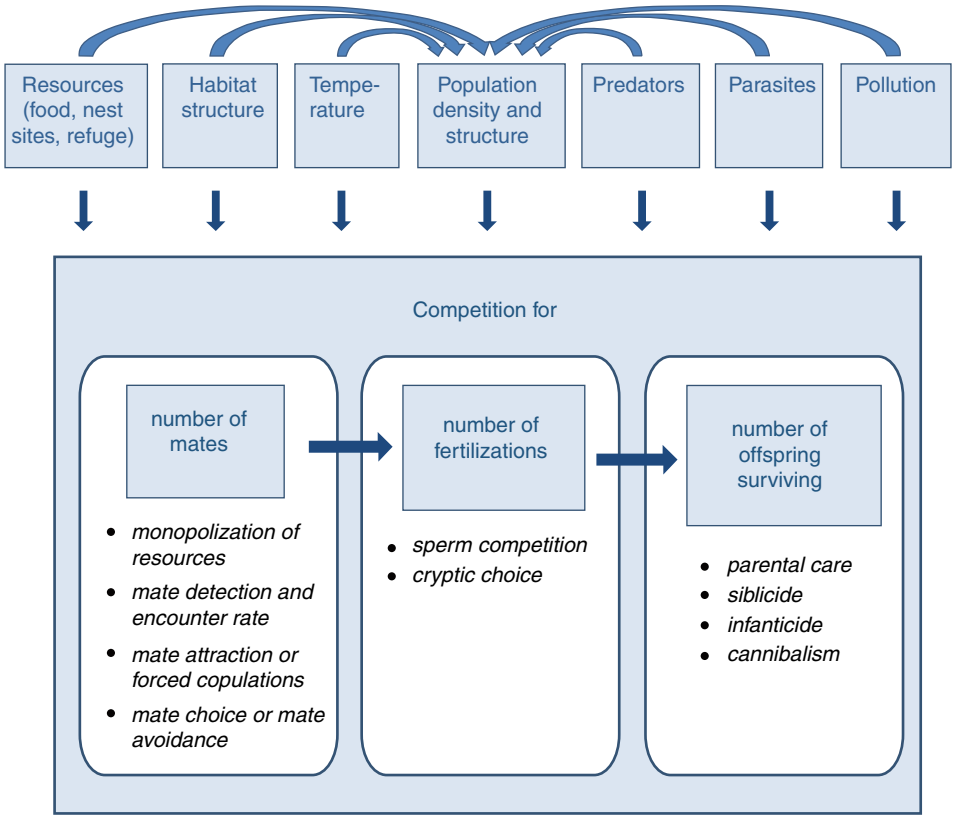

Figure 5 The reproductive success of an individual depends on the number of mates, the number of fertilized eggs the matings result in, and the survival of the ensuing offspring. Changes in the environment can influence any of these stages of reproduction, both directly and indirectly by influencing population demography.

Figure 6 The ability of sea lions to guard their females against intruding males searching for mating opportunities is hampered by the necessity to spend more time immersed in the water when temperature increases. Photo: Jimena Bohórquez- Herrera.

algae. This is true even though males attempt to compensate for the reduced visibility by increasing their courtship activity, a sexually selected trait (Figure 10).

If environmental changes alters the expression of heritable variation among individuals so that the difference in genetic makeup between individuals is altered, then this can

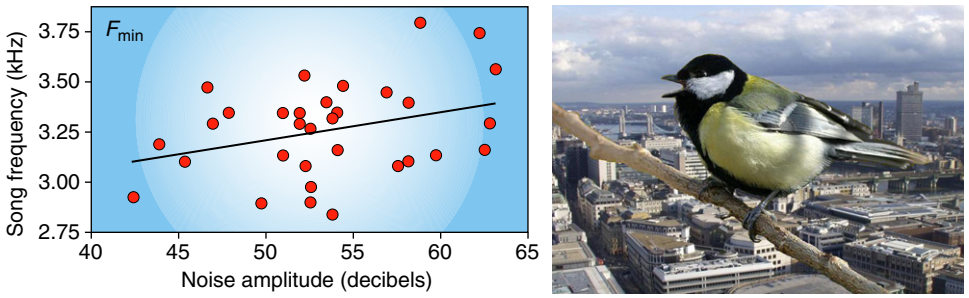

Figure 7 In urban areas where the background noise is louder (higher noise amplitude) great tits elevate the pitch of their songs (higher song frequency) to ensure that their calls can be heard despite the noise. Reproduced from Slabbekoorn, H., Peet, M., 2003. Ecology: Birds sing at a higher pitch in urban noise – Great tits hit the high notes to ensure that their mating calls are heard above the city's din. Nature 424, 267–267.

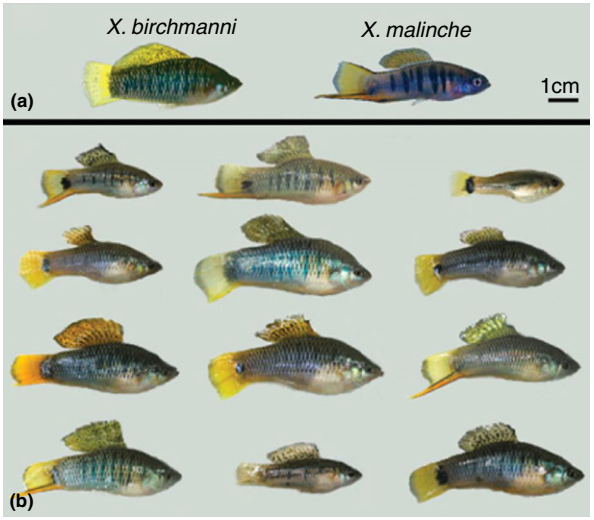

Figure 8 Pollution has been implicated in the disruption of chemical communication in two species of Mexican swordtail fish, leading to the formation of hybrids. (a) Males of the original parental species *Xiphophorus birchmanii* and *X. malinche* and (b) hybrid males (Fisher *et al.*, 2006).

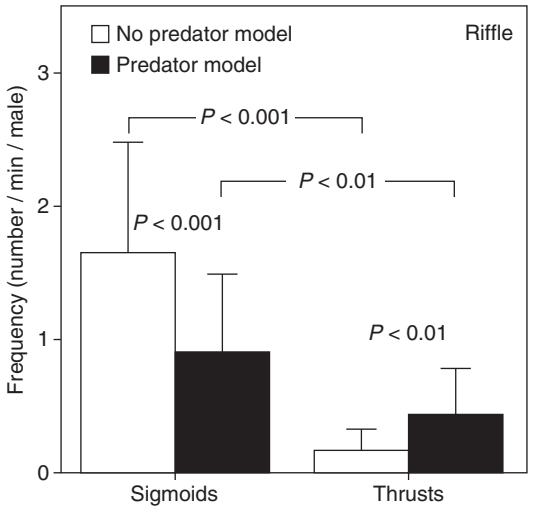

Figure 9 Male guppies reduce sigmoid courtship displays and increase the frequency of an alternative reproductive behavior, gonopodial thrusts, when predation risk increases. During sigmoid displays the male attracts females by arching his body into an S-shape. During gonopodial thrusting, males circumvent female mate preferences by approaching the female surreptitiously from behind and try to inseminate herusing his intromittant organ, the gonopodium. Data are mean + SD. Reproduced from Godin, J.G.J., 1995. Predation risk and alternative mating tactics in male Trinidadian guppies (Poecilia reticulata). Oecologia 103, 224–229.

affect mate choice for individuals that would confer 'good genes' to their offspring (Hoffmann and Merila, 1999).

Fertilization

The probability that mating results in fertilization can be altered by environmental changes that influence fertility, the intensity of sperm competition, and the possibility of adopting alternative reproductive tactics. For instance, environmental contamination by chemical pollutants known as endocrine disruptors can block or mimic the effect of hormones in exposed animals and result in modified reproductive anatomy and reduced fertility (Zala and Penn, 2004).

Some animals, despite being socially monogamous, engage in extra-pair matings, while others partake in 'sneak' fertilization attempts when others are mating. In those species, the benefit of adopting these alternative mating tactics can be altered by environmental change (Westneat and Sherman, 1997). For instance, as discussed above for guppies (**Figure 9**), an increase in the cost of ostentatious traits or behaviors required to attract members of the opposite sex can increase the prevalence of alternative mating tactics, such as forced copulations or sneak fertilizations, that do not rely on costly signals.

Parental Care and Offspring Survival

The amount of time and effort individuals devote to caring for offspring can potentially impinge on their ability to pursue additional mating opportunities (Gross, 2005). Hence, the decision to care for young will be affected by the demands of the current offspring, the willingness of the other parent to increase its investment into offspring care, and future reproductive opportunities. All of these components are sensitive to changes in the environment.

Future reproductive opportunities depend on mate encounter rate and attractiveness, and on the willingness of the

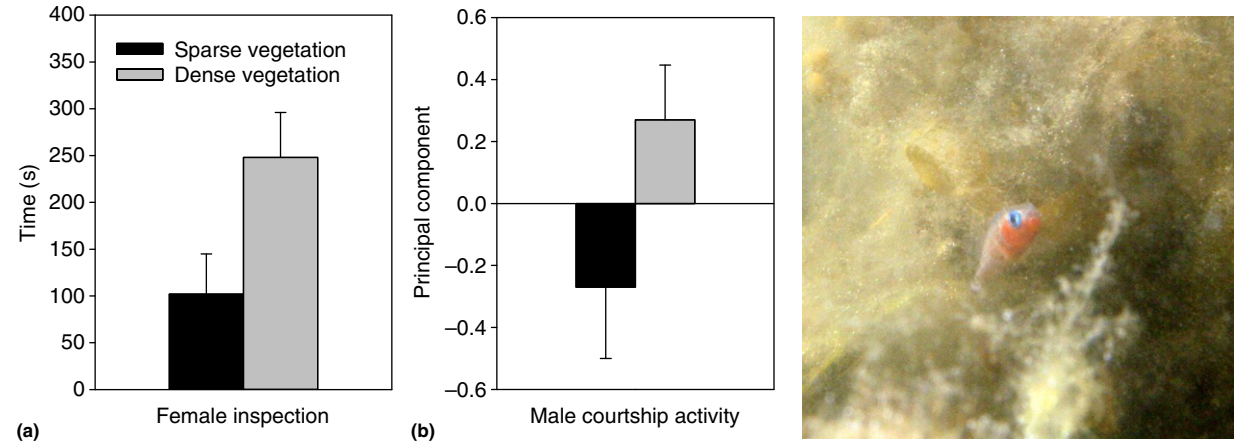

Figure 10 (a) When the density of filamentous algae increases because of human-induced eutrophication, female threespine sticklebacks have to spend more time evaluating males. (b) Males in turn increase their courtship activity, but still the females have a difficult time in making their choice. Data are means + SE. Photo: Jan Heuschele. Reproduced from Candolin, U., Salesto, T., Evers, M., 2007. Changed environmental conditions weaken sexual selection in sticklebacks. Journal of Evolutionary Biology 20, 233–239.

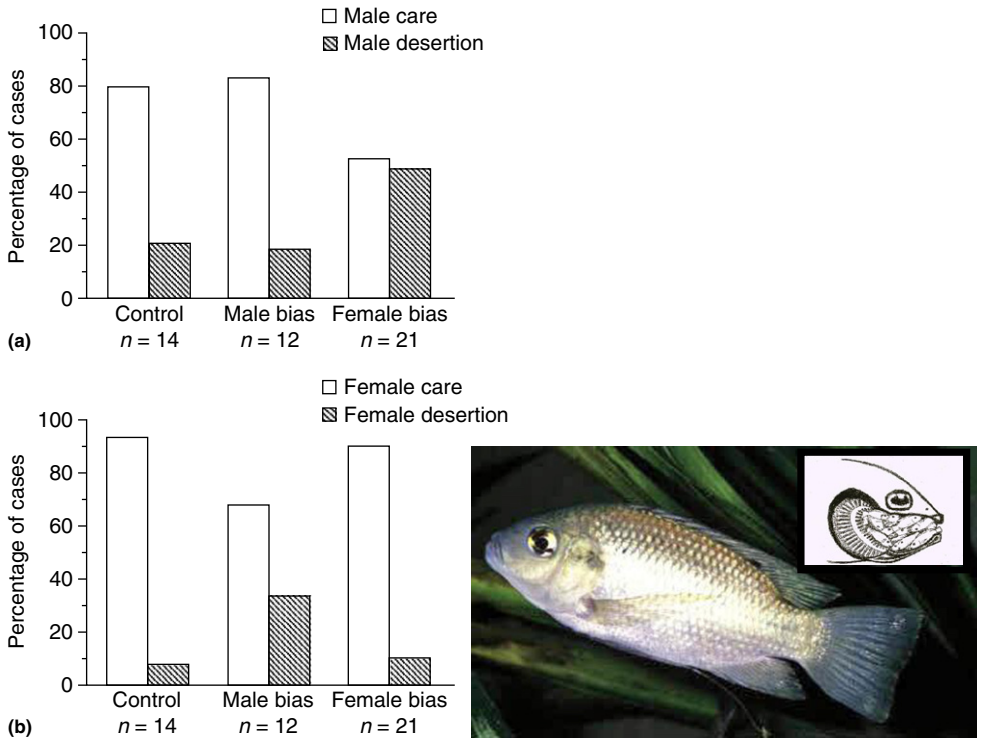

Figure 11 Investment of each sex into parental care depends on the sex ratio and future mating opportunities in the mouthbrooding Galilee St Peter's fish (*Sarotherodon galilaeus*). When the sex ratio is male-biased, females are more likely to desert their mate, and when it is females biased, males are more likely to desert. The control represents equal sex ratios. Photo: Sigal Balshine. Reproduced from Balshine-Earn, S., Earn, D.J.D., 1998. On the evolutionary pathway of parental care in mouth-brooding cichlid fish. Proceedings of the Royal Society B-Biological Sciences 265, 2217–2222.

other parent to increase its investment into parental care. For instance, changes in the operational sex ratio have a profound effect on parental investment in the Galilee St Peter's fish (Figure 11). Indeed, a switch to a male-biased sex ratio can even result in infanticide as has been reported in a group of primates known as langurs (*Presbytis* spp.), with males killing offspring sired by other males to bring females into sexual receptivity so that they, in turn, can reproduce with those females (Sterck, 1998).

Changes in population density and resource availability can also alter the ability of dominant group members to influence the breeding success of subordinates. For example, in the cooperatively breeding banded mongoose (*Mungos mungo*), older females are able to suppress the breeding of

younger females when resources are in short supply by evicting the females from the group (Nichols *et al.*, 2012). This, in turn, causes the expelled females to abort any pregnancies before returning to the group.

Consequences of Altered Mating System?

Mating systems determine the skew in mating success among individuals and, hence, the strength of sexual selection. If the mating system is adaptive, this skew ensures that individuals best adapted to local environmental conditions reproduce and pass on their genes to the following generation, which is important for ensuring a viable population. However, if changes to the mating system distort the correlation between mating success and individual quality, then population viability may be endangered. For instance, as we already have discussed, environmental changes that interfere with animal communication – and the efficacy of sexual signals – can prevent individuals from making adaptive mate choice decisions and result in the production of fewer offspring or those that are less well adapted to the environment.

In particular, environmental change can cause earlier evolved behaviors, signals, and mate preferences to become maladaptive, resulting in so called 'evolutionary traps' (Robertson *et al.*, 2013). An infamous example is seen in male jewel beetles (*Julodimorpha bakewelli*) from Western Australia, which have developed a sexual attraction to discarded beer bottles because the surface of the bottles resemble the look and texture of real females (Gwynne and Rentz, 1983; **Figure 12**). If individuals are not able to quickly adjust their traits and preferences to the altered conditions (or evolve traits that are better suited to the novel environmental conditions) then the reproductive output of the population may drastically decrease and undermine population persistence.

If, on the other hand, mating systems and sexual selection favor traits that increase individual fitness but are detrimental at the population level, then a relaxation of sexual selection could actually improve population viability. For example, male fruit flies (*Drosophila melanogaster*) in an attempt to increase their fertilization success, end up harming females during copulation by reducing their longevity and probability of mating with other males (Chapman *et al.*, 2003). This decreases the fecundity of the females and, hence, the reproductive output of the population. However, both male harm and the capacity for females to resist this harm depend very much on current environmental conditions and the conditions that they have evolved under (Arbuthnott *et al.*, 2014). Hence, a change in the environment because of anthropogenic disturbance that relaxes this sexually antagonistic selection could reduce female harm and, in so doing, have a positive effect on population growth.

Changes in mating system may also influence populations through effects on gene flow, inbreeding, hybridization, and effective population size. In particular, the loss of valuable genetic variation because of habitat fragmentation and inbreeding can reduce the population's capacity to adapt to environmental change (Frankham *et al.*, 2010). Hampered mate choice and altered signals in changing environments can, in turn, lead to the loss of biodiversity by breaking down reproductive barriers and resulting in hybridization between closely-related species. We already discussed the example of hybrids resulting from disruption of chemical communication in Mexican swordtail fish (**Figure 8**). Another example comes from Lake Victoria in eastern Africa where increased water turbidity, because of human-induced eutrophication, has

Figure 13 Variation in male nuptial coloration in *Pundamilia* cichlids from Lake Victoria, Africa. The top and bottom images are typical of the coloration of male *P. pundamilia* and *P. nyererei*, respectively. Turbid water hampers species recognition based on male coloration. In clear water, females mate with males of their own species based on differences in coloration. In turbid water, females are not able to distinguish between species based on coloration and hybrids are produced. Photo: Ole Seehausen.

hampered species recognition during mate choice and resulted in hybridizations among cichlid species (**Figure 13**).

Changes in mating systems – because of environmental change – can consequently alter the demography and genetic-make up of populations. This can have serious consequences for the viability and persistence of populations, and, ultimately, for the structure and function of ecosystems. It is therefore vitally important that we consider the consequences that human activities have for mating systems when evaluating the impact of humans on natural animal populations.

Mating Systems in Flowering Plants

SCH Barrett and D Crowson, University of Toronto, Toronto, ON, Canada

Glossary

Cosexual The most common sexual system in flowering plants, in which a population is comprised of a single sexual class of hermaphrodites (cosexes) and on average individuals reproduce equally through female and male function.

Dioecy A sexual system in which a population is composed of female and male plants usually differing in secondary sex characters. At equilibrium the sexual morphs are maintained at equal frequency because of negative frequency-dependent selection.

Gender strategies The femaleness and maleness of individuals as reflected in their relative contribution to fitness through maternal and paternal investment.

Gynodioecy and androdioecy Two contrasting polymorphic sexual systems; gynodioecious populations are composed of female and hermaphrodite individuals, a sexual system that is not uncommon; in contrast, androdioecious populations contain male and hermaphrodite individuals, a sexual system that is extremely rare.

Inbreeding depression The reduction in viability and/or fertility of inbred offspring compared to outcrossed offspring as a result of the expression of deleterious recessive alleles in homozygous genotypes. Inbreeding depression is a key factor in determining mating system evolution, can occur throughout the life cycle, and is usually expressed most strongly when inbreeding occurs in a predominantly outcrossing species.

Linked selection Changes in allele frequency due to linkage with positively or negatively selected alleles at other loci, resulting in the loss of genetic diversity across genomic regions.

Modes of self-pollination The different ways that self-pollination can occur in flowering plants; distinguished primarily by the timing of self-pollination, whether pollinators are involved or not, and whether self-pollination occurs within or between flowers on a plant.

Pollen discounting The reduction in outcrossed male siring success caused by self-pollination within and between flowers on a plant.

Pollination The transfer of pollen between the male reproductive organ (stamen) to the receptive area (stigma) of the female organ (pistil). Pollination is necessary for mating but may not result in successful fertilization owing to post-pollination mechanisms, such as self-incompatibility.

Reproductive assurance An increase in seed set caused by self-pollination when conditions for outcrossing are unfavorable as a result of the absence of pollinators or compatible mates; requires that plants are self-compatible and also have the facility for autonomous self-pollination.

Self-incompatibility The inability of a fertile hermaphrodite plant to set abundant seed following self-pollination; the primary mechanism preventing self-fertilization in plants, and the opposite condition to self-compatibility in which plants can self-fertilize.

Sex allocation The parental expenditure of resources to sexual activities, including the relative allocation to female (ovules and seed) and male (pollen) function and also to floral display.

Introduction

Flowering plants (angiosperms) exhibit exceptionally diverse mating systems as a result of several distinctive features of their biology. First, because of their sessile habit plants depend on external agents to transfer male gametes (pollen) between individuals. This reliance has led to the evolution of diverse floral adaptations associated with the three main vectors for pollen dispersal: animals, wind, and water (Harder and Johnston, 2009). Pollination is a key reproductive process as it affects mating opportunities and fitness by determining the quantity and quality of pollen dispersed between flowers. Second, most plants possess hermaphroditic flowers and are therefore susceptible to self-pollination, often at the expense of cross-pollination as a result of pollen discounting (Harder and Barrett, 1995). Diverse morphological and physiological mechanisms have evolved in angiosperms to limit the harmful effects of self-fertilization and promote effective pollen dispersal between flowers on different plants. Finally, the modularity of plants and production of multiple reproductive structures introduces considerable mating complexity as a result of the subdivision of parental reproductive effort. Sexual plasticity and opportunities for combining hermaphroditic and unisexual flowers in different structural and temporal combinations has given rise to diverse gender strategies (Lloyd, 1979). As a result, the distribution of gametes within and between plants in a population is far more complicated than in animals, and reproduction can be highly promiscuous with individuals mating with numerous related and unrelated partners during their lifetimes, as well as themselves.

The term mating system is often used in different ways by reproductive biologists, depending on the organismal group. Perhaps the broadest definition, used primarily by researchers working with organisms with separate sexes, is simply "who mates with whom and how often." Biologists working with hermaphroditic groups (such as plants, worms, snails, slugs, or corals) often use a more restricted definition that simply involves the average frequency of cross- and self-fertilization in a

population. This definition of maternal mating success largely ignores information on male reproductive function (paternity or male outcrossed siring success) but has nevertheless provided important insights on the ecology and evolution of populations. The use of genetic markers over the past few decades has enabled quantitative measurements of selfing rates (s), or its complement the outcrossing rate ($t = 1 - s$), for several hundred angiosperm species representing diverse families, pollination systems, and life histories (Barrett and Eckert, 1990). This body of data has been valuable for testing theoretical models and for gaining insights on the ecological and demographic factors influencing the evolution of mating patterns.

In this article, we begin by considering mating patterns in plant populations with hermaphroditic sex expression (cosexuality), a condition that predominates among angiosperm taxa and is the ancestral state for most plant lineages. We focus on the causes and consequences of evolutionary transitions from outcrossing to predominant selfing, as this is the most common mating system transition among angiosperm families and has attracted considerable attention since Charles Darwin's seminal work on the topic. We then look at plant species with unisexual flowers in which populations are composed of various combinations of female, male, and hermaphrodite individuals. We review models and empirical evidence concerning how these polymorphic sexual systems are thought to have evolved from hermaphroditism and pay particular attention to the evolution of separate sexes from combined sexes.

Evolution of Mating Systems

Among life-history traits, reproductive characters that influence mating are of profound adaptive significance because they govern the character of genetic transmission between generations, the fitness of offspring and the amounts and distribution of genetic diversity in populations. The diversification of many angiosperm families (e.g., the orchid and phlox families) has been attributed to adaptive radiation of pollination and mating systems, often accompanying changes in the ecology of populations. Reproductive versatility is therefore a hallmark of angiosperm evolution and this is manifested by considerable inter- and intra-specific variation in mating systems. This variation implies frequent evolutionary transitions between mating systems, which are usually associated with changes to floral characters, pollination systems, and sex allocation in concert with life-history evolution. Ecological factors play a key role in driving the evolution of reproductive traits and in the maintenance of different mating systems. For example, long-lived tree species of stable plant communities are usually predominantly outcrossing whereas weedy colonists that occupy ephemeral environments are more commonly highly selfing. A major challenge is to determine the specific environmental, demographic, and genetic factors promoting changes in mating system.

The evolution of predominant self-fertilization (autogamy) from outcrossing represents the most important reproductive transition in angiosperms (Stebbins, 1974). There is evidence from numerous herbaceous families (e.g., the mustard and tomato families: Brassicaceae and Solanaceae, respectively) of multiple independent origins of autogamy and these transitions are often associated with the evolutionary breakdown of self-incompatibility, the primary genetic mechanism preventing selfing in plant populations. Investigation of evolutionary transitions from outcrossing to selfing is an active area of research today using comparative, experimental and genomic approaches, and theoretical models (e.g., Lloyd, 1992) on the selective mechanisms governing this transition have been particularly influential in guiding empirical research.

Why has the evolution of selfing from outcrossing been the focus of sustained interest for over a century? First, multiple independent transitions to selfing provide valuable opportunities to study convergent evolution, particularly the genetic and developmental basis of floral traits (e.g., small flowers, reduced floral display, and pollen production) that constitute the selfing syndrome (Sicard and Lenhard, 2011; **Figure 1**). Second, because selfing enables single plants to found colonies following long-distance dispersal, the shift to selfing can have significant biogeographical consequences (**Figure 1**), for example, by facilitating island colonization or migration to range margins where plant density may be low, a phenomenon known as Baker's Law (Baker, 1955). Third, selfing leads to restricted gene flow and reproductive isolation from ancestral outcrossing populations, potentially influencing speciation and lineage diversification (Wright *et al.*, 2013). A persistent theme concerns the extent to which the evolution of selfing is an 'evolutionary dead end' as a result of the ephemerality of selfing lineages compared to those that are outcrossing (Igic and Busch, 2013). Finally, because predominant selfing reduces the effective rate of recombination and effective population size there has been much recent interest on the genomic consequences of transitions to selfing, and the demographic and genetic processes causing genome-wide reductions in diversity in populations (Wright *et al.*, 2008).

Diverse reproductive, demographic, and genetic factors influence mating system evolution in plants. Of particular importance is the relative fitness of progeny that results from cross- versus self-fertilization, a phenomenon known as inbreeding depression. Darwin (1876) conducted controlled pollination studies on 57 species from 30 families and, in virtually all cases, discovered that selfed offspring performed less well compared with outcrossed offspring. Darwin used this observation to explain the function of numerous floral adaptations in angiosperms; they were outcrossing mechanisms limiting the harmful effects of self-fertilization. Today, it is understood that inbreeding depression is near ubiquitous in outcrossing species and largely results from the expression of recessive deleterious alleles in genotypes made homozygous as a result of inbreeding (Charlesworth and Willis, 2009). Inbreeding depression features in most models of mating system evolution and its magnitude plays an important role in helping to explain the observed distribution of outcrossing rates in nature, although explaining the occurrence of a significant number of species with a mixture of outcrossing and selfing (mixed mating) has resulted in considerable debate (Goodwillie *et al.*, 2005). A current challenge is to determine ecologically relevant levels of inbreeding depression under

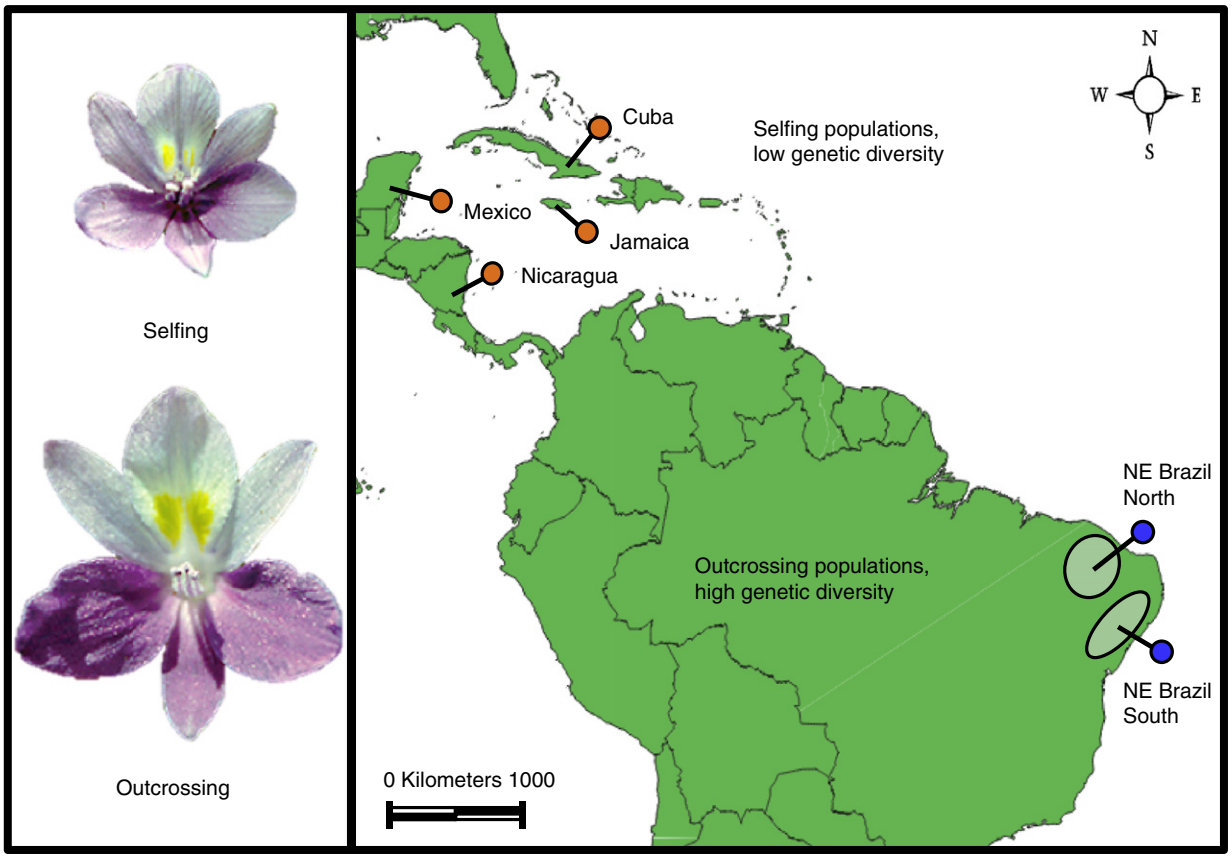

Figure 1 The phenotypic, biogeographical, and genetic consequences of evolutionary transitions from outcrossing to selfing, as exemplified by *Eichhornia paniculata* (Pontederiaceae). In this neotropical species, large-flowered outcrossing populations predominate in NE Brazil (bottom), and small-flowered selfing populations (top) have colonized the Caribbean and Central America. Outcrossing populations maintain high levels of diversity, whereas selfing populations are much less diverse. Further details are provided in Barrett *et al.* (2009).

field conditions as it is clear that comparisons conducted under glasshouse conditions significantly underestimate differences between selfed and outcrossed offspring (Dudash, 1990). Novel methods for estimating inbreeding depression in the field using genetic markers (Koelling *et al.*, 2012) may alleviate this problem, as should recent studies (e.g., Campbell *et al.*, 2013) on the extent to which biotic factors (pests and diseases) differentially influence the fitness of selfed and outcrossed offspring.

Inbreeding depression prevents the evolution of high selfing rates in most outcrossing populations. However, selfing evolves often and approximately 10–15% of flowering plants are predominant selfers, indicating that certain conditions can favor the selection of high selfing rates. The two most general mechanisms to explain the transition to selfing are: (1) The 'reproductive assurance hypothesis,' which traces back to Darwin and is the most frequently invoked explanation for why selfing often evolves under conditions of low density. It proposes that selfing is favored whenever pollen vectors and/or compatible mates are absent, limiting seed set by cross-pollination. (2) The 'automatic selection hypothesis,' which is based on R.A. Fisher's idea that a gene for selfing has a 3:2 transmission advantage when it arises in an outcrossing population. Determining the relative importance of these two hypotheses empirically is not straightforward, particularly if both processes operate during the transition to high selfing rates, as it requires determining the modes of self-fertilization in a population, and whether selection of genetic modifiers of the mating system occurs through pollen and/or seed (Busch and Delph, 2012). As yet, this has not been attempted in any species in which the transition to selfing has been investigated.

It has also been suggested that molecular data might be useful for distinguishing the two main hypotheses for the evolution of selfing. The demographic and genetic processes associated with reproductive assurance may result in a different genomic signature than those associated with automatic selection. This is based on the idea that when selfing evolves by reproductive assurance genetic bottlenecks causing the genome-wide loss of diversity should be common (Schoen *et al.*, 1996). However, recent work demonstrating that linked selection can also reduce genome-wide diversity rapidly following the transition to selfing casts doubt on whether it will be possible to use molecular data to distinguish the two main hypotheses for the evolution of selfing (Barrett *et al.*, 2014). It seems likely that reproductive assurance plays a more important role than automatic selection in initiating the transition to selfing; however, at present the case rests largely on correlative ecological evidence on the geographical distribution of selfing populations and their occurrence under conditions of low density. Experimental evidence on the

selective mechanisms driving the transition to selfing is generally lacking, despite a rich theoretical literature on the topic.

Sexual Systems and Gender Strategies

Most angiosperm species possess flowers with both male and female sexual organs and only ~10% have unisexual flowers (dicliny), with either female or male sex organs. There has been repeated evolution of dicliny across the angiosperm phylogeny, and variation in the temporal and spatial arrangement of unisexual flowers within and between individuals has given rise to the remarkable diversity of sexual systems found in flowering plants (Barrett, 2002). A population producing entirely unisexual flowers can be hermaphroditic if both male and female flowers are present on the same individuals (examples include maize and squash). This sexual system, termed monoecy (**Figure 2(a)**), prevents within-flower self-pollination and allows greater flexibility in the amount, location and timing of female and male investment in response to environmental cues during growth, or as a result of individual condition. Unisexual flowers can also be separated on different individuals, giving rise to male and female sexual morphs (dioecy; **Figures 2(b)** and **2(c)**); examples include kiwifruit and marijuana. However, in some species unisexuals are maintained in populations with hermaphrodite plants, resulting in gynodioecious (females and hermaphrodites; e.g., many members of the mint family, Lamiaceae) and androdioecious (males and hermaphrodites; e.g., annual mercury, *Mercurialis annua*) sexual systems. Finally, all three sex phenotypes can sometimes coexist within a population (subdioecy; e.g., broadleaf arrowhead, *Sagittaria latifolia*), although the extent to which this sexual system is stable over evolutionary time is unclear. Subdioecy is most often associated with evolutionary transitions from gynnodioecy to dioecy, as discussed further below (and see **Figure 3**).

From the perspective of mating patterns it is often more informative to consider the gender strategy of a population, an approach that involves a functional as opposed to morphological definition of plant sexual systems. The term gender strategy concerns the genetic contribution that each plant in a population makes to the next generation through maternal versus paternal expenditure and hence their 'femaleness' or 'maleness' (Lloyd, 1979). Although it is challenging to measure the true functional gender of individuals using genetic markers, many workers obtain a rough approximation of female and male mating success by describing the phenotypic gender of populations, which involves estimating allocation to alternate sex functions. Using this approach it is evident that all plant sexual systems can be divided into two fundamentally distinct strategies involving either gender monomorphism (**Figure 2(d)**) or gender dimorphism (**Figure 2(e)**).

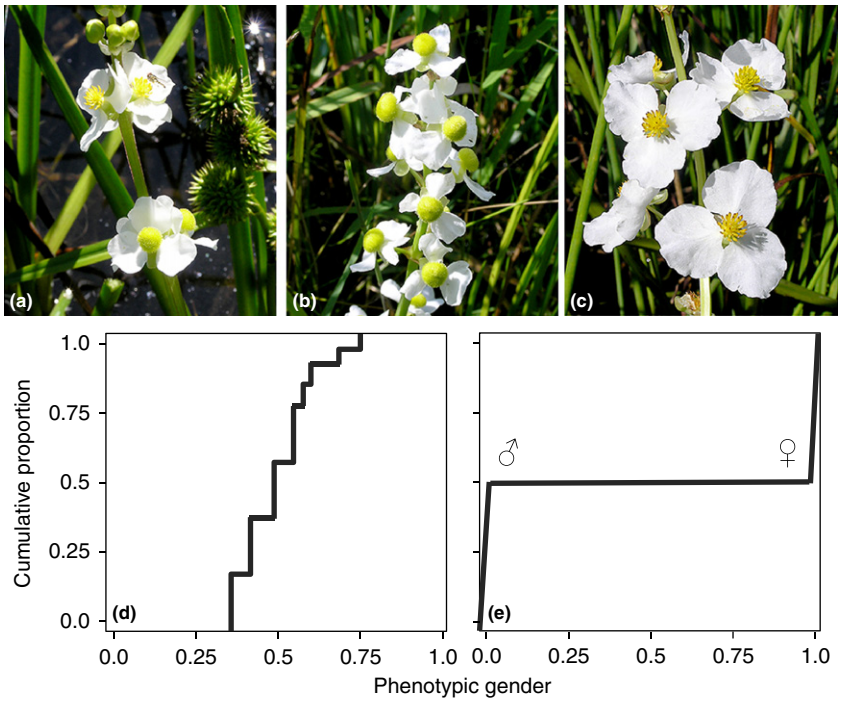

Figure 2 Intraspecific variation in sexual systems in a plant species: in *Sagittaria latifolia* (Alismatacae) three sexual phenotypes occur, with the majority of populations containing either hermaphroditic plants with separate female and male flowers (monoecy) as in (a), or unisexual plants (dioecy) that are either female (b) or male (c). (d) and (e) Illustrate phenotypic gender variation within and among populations of *S. latifolia*, based on allocation to female and male flowers. In (d) gender is monomorphic with continuous variation, whereas in (e) the distribution is dimorphic with approximately equal numbers of male and female plants. In some parts of the range populations with females, males and hermaphrodites also occur (subdioecy; Yakimowski and Barrett, 2014). See Lloyd (1979) for further details on the measurement of gender in plant populations and Sarkissian *et al.* (2001) for details of gender variation in *S. latifolia*.

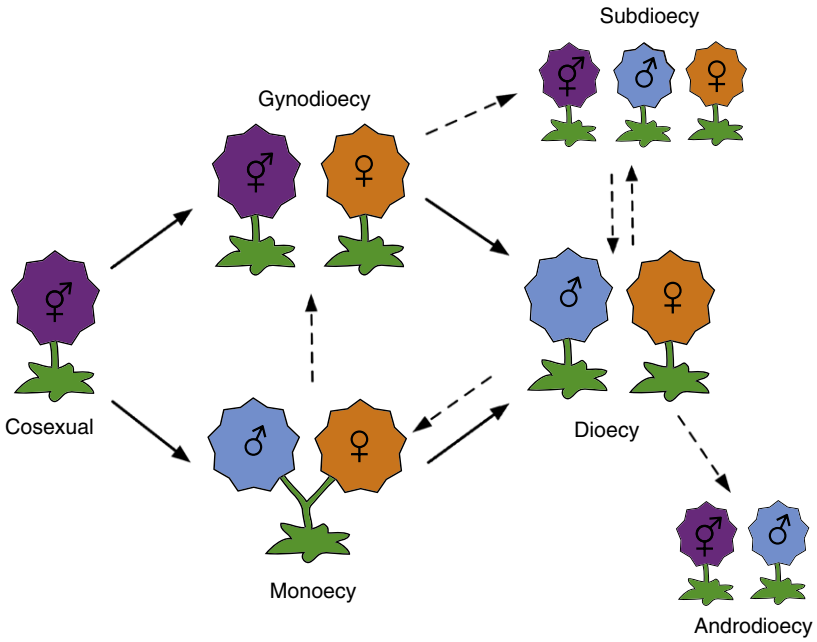

Figure 3 The primary evolutionary pathways by which polymorphic sexual systems originate from cosexuality in flowering plants. In the gynodioecy pathway (above), the first step is the invasion of females into hermaphrodite populations resulting in gynodioecy. This is followed by subsequent loss of female function in hermaphrodites giving males. This second step may often involve an intermediate stage in which hermaphrodites coexist with both females and males (subdioecy), although this condition can also arise from dioecy. The monoecy pathway (below) commences with increased specialization of female or male function by the origin of female and male flowers on hermaphroditic plants (monoecy). This is subsequently followed by gender specialization through gradual alteration in floral sex ratios and the evolution of unisexual plants (females and males). The monoecy pathway may occasionally involve an intermediate gynodioecious stage in which females invade monoecious populations, and occasional reversions from dioecy to monoecy are also known. Androdioecy is most commonly associated with the breakdown of dioecy, with females regaining male function and coexisting with males. For further details of the evolution of sexual system diversity see Barrett (2002).

In populations with gender monomorphism there is continuous (quantitative) variation in gender, with the average individual contributing genes equally through female and male function. All hermaphroditic plant species exhibit gender monomorphism. In contrast, in populations with gender dimorphism there is a bimodal distribution of gender, with a clear distinction between the gender of individuals belonging to different sexual morphs. Clearly, gender dimorphism occurs in dioecious populations, where male and female plants achieve all fitness through their particular gender and on average females and males contribute equally to the next generation, as every seed has both a mother and a father. However, gender dimorphism also occurs in gynodioecious and androdioecious populations, because the presence of unisexual individuals results in hermaphrodites contributing genes to the next generation mostly through the opposite gender to the particular unisexual morph in the population, rendering them functionally more male (gynodioecy) or female (androdioecy). Thinking about plant sexual systems in terms of gender strategies highlights the flexible and frequency-dependent nature of plant mating, with hermaphrodites acting 'more male' or 'more female' depending on the frequency of sexual phenotypes in the population, and this approach provides a functional framework for understanding the mating biology of plants.

The evolution of gender dimorphism from monomorphism requires the invasion of either males or females into a population of hermaphrodites, leading to androdioecy or gynodioecy, respectively. The frequency of these two dimorphic sexual systems is remarkably different among angiosperms families: gynodioecy occurs in ~7% of species and in many families, whereas only a handful of examples of true androdioecy are known. Furthermore, most cases of androdioecy involve a reversion from dioecy via the reacquisition of male function in females (**Figure 3**), rather than through male invasion of hermaphrodite populations, although this pathway does appear to occur rarely (Pannell, 2002).

Why then is gynodioecy much more common than androdioecy? This question can be addressed by considering the conditions that allow a unisexual individual to invade a hermaphrodite population, and how these conditions differ between the sexes. Intuitively, for a female or male individual to invade a population of hermaphrodites they must be at least twice as fit as hermaphrodites through female or male function, respectively (Lloyd, 1975). An important component in models for the evolution of gynodioecy is therefore the presence of inbreeding depression lowering the fitness of hermaphrodites. If hermaphrodites are self-compatible and through selfing suffer inbreeding depression this will lower the threshold over which a female can invade, because all offspring from females must necessarily be outcrossed and will therefore avoid inbreeding depression. However, in the case of androdioecy in a partially selfing population there will be

fewer ovules available for males to fertilize, which limits the potential siring success of invading males. Theoretical models indicate that with some degree of inbreeding depression females are not required to produce twice the number of ovules in order to invade a population of hermaphrodites, whereas males always have to produce at least twice the amount of pollen (Charlesworth and Charlesworth, 1978). Another constraint that reduces the frequency of male invasion relative to female invasion arises from the genetic mechanism causing the loss of male or female function. Cytoplasmic male sterility, where the sterility mutation occurs in either plastid or mitochondrial DNA as opposed to nuclear DNA, is a common phenomenon in plants, and is used in the production of hybrid seed in many crops. Unlike nuclear mutations, these mutations are inherited solely through the maternal line, making it unavailable as a mechanism of female sterility, as required for androdioecy. Furthermore, if male sterility is determined this way, only a slight advantage in female fertility is required for females to increase in frequency in the population (Lewis, 1941). Altogether, the conditions under which females can invade a hermaphrodite population are much less stringent than for males, explaining why gynodioecy is considerably more common than androdioecy in flowering plants.

Only ~6–7% of flowering plant species have separate sexes (Renner and Ricklefs, 1995). Despite being relatively uncommon, dioecy has a scattered distribution across the angiosperm phylogeny occurring in ~40% of all angiosperm families. This indicates that separate sexes have evolved independently many times from hermaphroditism, in concert with a suite of ecological and life history correlates (Vamosi *et al.*, 2003). The common occurrence of dioecy on the tips of phylogenetic trees and the apparent lower species richness of dioecious clades compared to their sister groups has led to the idea that dioecy, like predominant selfing, is an 'evolutionary dead end' either due to the high extinction rates or low speciation rates of dioecious clades (Heilbuth, 2000). However, this idea has recently been challenged based on comparative evidence that dioecious clades actually have a slightly higher net diversification rate than non-dioecious clades, and the phylogenetic distribution is instead a result of a combination of low transition rates to dioecy, as well as frequent losses (Käfer *et al.*, 2014).

The evolution of separate sexes requires two independent sterility mutations affecting female and male fertility, making it improbable that dioecy would arise directly from a hermaphrodite population without any intermediate stages. There has therefore been considerable interest focused on the evolutionary pathways that give rise to separate sexes, with the two most frequently invoked routes being the gynodioecy and monoecy pathways (**Figure 3**). In the gynodioecy pathway, females invade a hermaphroditic population leading to gynodioecy and subsequent selection on hermaphrodite sex allocation increases their 'maleness,' giving rise to an intermediate and often unstable stage of subdioecy and ultimately the evolution of dioecy (Spigler and Ashman, 2012), as has been shown in *Fragaria*, the strawberry genus (Liston *et al.*, 2014).

In contrast, the sequence of changes involved in the monoecy pathway is less well understood. It has often been suggested that disruptive selection on quantitative genetic variation in floral sex ratios within monoecious populations drives the evolution of different degrees of femaleness and maleness and ultimately results in completely separate-sexed plants (**Figure 3**). However, other evidence suggests that dioecy can sometimes evolve from monoecy via the gynodioecy pathway owing to large effect male sterility mutations and female invasion (e.g., broadleaf arrowhead, *Sagittaria latifolia*; Dorken and Barrett, 2004). Although the gynodioecy pathway has been well studied both theoretically and empirically, much less is known about the monoecy pathway, despite the strong correlation between dioecy and monoecy within clades, which has led to the suggestion that most transitions to dioecy follow this route (Renner and Ricklefs, 1995). However, there are two caveats that need to be considered in accepting this interpretation. First, in many clades the ancestral state is not clear and the polarity could therefore sometimes be reversed, with monoecy being derived from dioecy (e.g., in *Momordica*, the bitter gourd genus; Schaefer and Renner, 2010). Second, it is also possible that similar conditions promote the evolution of both monoecy and dioecy, resulting in a correlation independent of any particular transition sequence. What is clear is that more work is needed before a clear picture emerges of the evolution of dioecy via the monoecy pathway.

Glossary

π_N/π_S The ratio of non-synonymous to synonymous polymorphism rate. Similar to the K_a/K_s ratio, π_N/π_S captures the intensity and form of selection acting on protein sequences, but in polymorphism data and hence at a shorter time scale.

Androdioecy A breeding system characterized by the co-occurrence of hermaphroditic and male individuals in the same species.

Apomixis or asexuality or clonality Asexual species only reproduce via mitosis, daughters are genetically identical to mothers unless a mutation occurs. In apomixis a seed develops from an unfertilized ovule.

B chromosomes Supernumerary and facultative chromosomes that do not obey the ordinary Mendelian laws of inheritance.

Dioecy In dioecious species, sexes are separated, females produce only ovules and males produce only pollen.

Genetic drift The random sampling of genetic variants in a finite population that leads to the random loss of some variants.

Gonochorism Separated sexes in animals, individuals are either females (producing only ovules) or males (producing only sperm).

Gynodioecy A breeding system characterized by the co-occurrence of hermaphroditic and female individuals in the same species, often as the result of nucleo-cytoplasmic interactions.

Hermaphroditism In hermaphroditic species, individuals carry both male and female reproductive organs and produce both ovules and pollen grains.

Heterostyly In heterostylous species, obligate outcrossing is enforced by morphological differences in the length or shape of the pistil and stamen. Two or three flower morphs coexist in a species and each individual expresses only one morph for all its flowers. The pollen from a given morph cannot fertilize a flower of the same morph. Is opposed to homostyly.

K_a/K_s The ratio of non-synonymous to synonymous substitution rates. Because selection acts primarily on proteins and not DNA sequences, synonymous changes are often treated as selectively neutral. K_a/K_s ratio is a proxy of the intensity and form of selection acting on protein sequences (≈ 1 for neutral evolution, >1 for positive selection, and <1 for negative selection).

Linkage disequilibrium The non-random association of alleles along a portion of chromosome in a population or species.

Outcrossing Outcrossing species reproduce through the fusion of gametes from distinct individuals at each generation.

Recombination The process by which two DNA molecules exchange genetic information, resulting in the production of a new combination of alleles.

Selection The process by which genetic variants become more or less frequent in a population according to their effect on fitness. Positive selection favors the fixation of advantageous alleles. Purifying selection favors the elimination of deleterious alleles. Balancing selection maintains diversity at a locus.

Selection on codon usage In some species, natural selection may favor some synonymous codons over others for encoding an amino acid. The preferred codons confer greater efficacy and/or accuracy of translation. This may generate a biased use of synonymous codons (i.e., codon usage bias).

Self-incompatibility A genetic system that prevents self-fertilization in hermaphrodites through recognition and rejection of pollen expressing the same allelic specificity as that expressed in the pistils, is opposed to self-compatibility.

Selfing Selfing species are sexual and undergo meiosis, but (in the case of pure selfing) fertilization only occurs between gametes produced by the same hermaphroditic individual.

Sexuality Sexual species reproduce through the alternation of meiosis and syngamy (fusion of gametes). During meiosis, chromosomes recombine and then segregate in different gametes.

Synonymous It refers to a sequence modification that does not result in a change at the protein level, it is opposed to non-synonymous.

Introduction

Breeding systems exhibit the most extraordinary variety in plants, and particularly in angiosperms where most of our knowledge comes from (but see Bainard *et al.*, 2013). Animals are comparatively very uniform with gonochorism being the general rule ($\sim$95%). Plants can either reproduce sexually or asexually or combine both strategies (Neiman *et al.*, 2014). Sexually reproducing plants can either outcross, self-fertilize, or have mixed mating systems. A large diversity of mechanisms have evolved in plants that promote either outcrossing or selfing. As selfing is possible only in hermaphrodites, dioecy is an obvious way of avoiding it. Outcrossing is also obligatory for females in gynodioecious species and for males in androdioecious species. Other mechanisms prevent selfing from happening in hermaphroditic species, such as heterostyly in which individuals have different flower morphologies, or self-incompatibility in which self-pollen is rejected.

Table 1 Percentages of the breeding systems discussed in this article in angiosperms

Breeding system	*Percentage of angiosperms*
Dioecy	~6
Autogamy	~27
Apomixis	~0.2

Breeding systems are highly labile in plants and transitions from one to another are common. See **Table 1** for the percentages of the breeding systems discussed in this article in angiosperms (Hojsgaard *et al.*, 2014; Igic and Kohn, 2006; Renner and Ricklefs, 1995; Richards, 1997).

In this article, we will focus on the consequences of breeding systems on genome evolution in plants, including their effects on nucleotide diversity (both neutral and selective), genome base composition, genome structure, and genome size. We will focus on the nuclear genome.

Changes in Breeding Systems and Their Effects on Population Genetics Parameters

Effects on Heterozygosity Levels

When selfing evolves from outcrossing, homozygosity is almost complete after a few generations (F_{IS}, the inbreeding coefficient, is close to one). This reveals recessive mutations, whose effects were hidden in heterozygous outcrossers ($F_{IS} \sim 0$). In asexuals, due to clonal transmission of the genome, any new mutation appearing in a genotype endlessly remains at the heterozygous state, unless the exact same mutation occurs on the homologous chromosome (Meselson effect). Heterozygosity is thus high in asexuals ($F_{IS} \sim -1$) (Glémin and Galtier, 2012).

Effects on Effective Recombination

The efficacy of recombination depends on both crossing over and outcrossing rates (Glémin and Galtier, 2012). In asexuals, there are no crossovers so that the whole genome is non-recombining. In selfers, due to high homozygosity levels, homologous chromosomes are virtually identical inside an individual. Consequently, crossovers cannot break linkage between alleles in a selfing population and recombination is mostly inefficient (Glémin and Galtier, 2012; Nordborg, 2000).

Effects on Effective Population Size

With pure selfing, the effective population size, N_e, is decreased by half. Full homozygosity reduces the coalescent process to sampling diploid individuals (n) instead of sampling alleles ($2n$), since in selfers, two copies of the same allele are found in an individual. With partial selfing, $N_e = 2N/(1+F)$ with N the population size and F the expected equilibrium inbreeding coefficient (Nordborg and Donnelly, 1997; Pollak, 1987). N_e is also decreased by half in asexuals due to a similar process of genotype sampling during the coalescent process (Haag and Roze, 2007).

N_e is further reduced in selfers and asexuals due to inefficient or absent recombination, which results in selective interference among genetically linked loci (reviewed in Charlesworth, 2009; Gordo and Charlesworth, 2001). For instance, a strongly deleterious mutation will be removed by selection along with the mutations genetically linked to it, even if these are slightly advantageous ('ruby in the rubbish,' Charlesworth *et al.*, 1993; Peck, 1994). Similarly, mutations on a haplotype carrying a strongly advantageous mutation will reach fixation by genetic hitch-hiking, even though they are slightly deleterious (Maynard Smith and Haigh, 1974). These processes increase genetic drift and decrease genetic variation since more alleles are lost than would be without linkage, resulting in a reduced N_e. In small selfing and asexual populations, genomes without mutations cannot be regenerated by recombination of two genomes carrying different mutations and genomes tend to accumulate mutations until they are removed by selection, reducing N_e further (Muller's ratchet, Muller, 1964; Heller and Maynard Smith, 1978).

The ability of selfers to found new populations from a single seed (Baker 1955) combined with their reduced pollen migration (due to reduced allocation to male function) leads to small and isolated populations where drift is important and recurrent bottleneck events take place, which further reduces N_e (metapopulation dynamics, Ingvarsson, 2002; Pannell and Charlesworth, 2000).

In angiosperms, it has been suggested that dioecy is an evolutionary dead-end (Heilbuth, 2000). Dioecy may bring some handicaps. Only females produce seeds, which may cause less efficient dispersal of individuals and might lead to isolated populations with potentially reduced N_e (the seed-shadow handicap, Heilbuth *et al.*, 2001). Also, fertilization could be reduced: sexual selection drives male flowers to attract pollinators as much as possible, to the detriment of females if pollinators happen to be rare, which might decrease N_e further (Vamosi and Otto, 2002). This reduced N_e is expected to lead to the accumulation of more deleterious mutations in dioecious species compared to non-dioecious species, which could eventually cause their extinction. However, these theories were recently challenged by a study, which found higher (and not lower) diversification rates in dioecious versus non-dioecious clades (Käfer *et al.*, 2014).

Effects on the Efficacy of Selection

The outcome of natural selection depends on the product $N_e s$, where s is the selection coefficient that measures the fitness of a mutation (s is negative for deleterious mutations, positive for advantageous mutations, and equal to zero for neutral mutations) (Kimura, 1962). When N_e is reduced, mutations with low absolute values of s will behave almost neutrally. Weakly deleterious alleles may be fixed while weakly advantageous ones may be lost because of genetic drift overcoming selection. Because of reduced N_e, selfers, asexuals and perhaps dioecious species are expected to experience a reduced efficacy of selection assuming that many newly arisen mutations have low selection coefficients.

The next sections review the real data that tested these theoretical expectations (summarized in **Figure 1**).

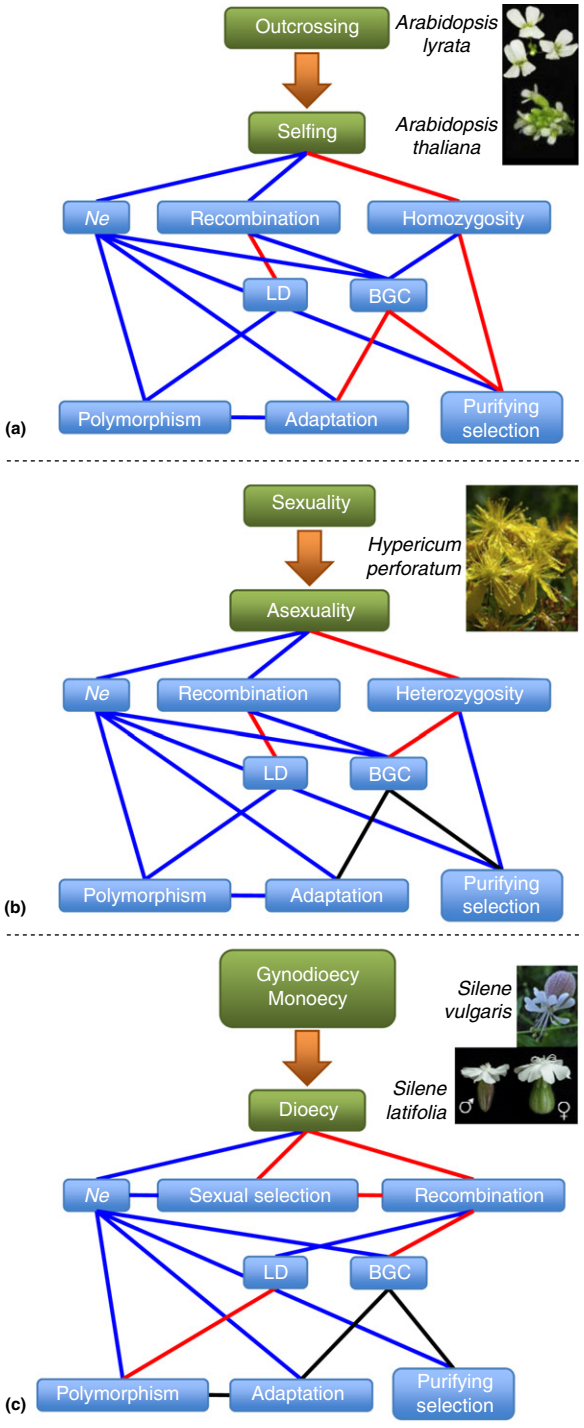

Figure 1 Summary of the theoretical expectations for the effects of three breeding systems on genome evolution in plants. Transitions to (a) selfing, (b) asexuality, and (c) dioecy. Blue lines indicate a negative effect, red lines a positive effect, and black lines an unclear effect. Examples of plant taxa with the studied transitions are shown. *Arabidopsis thaliana* flowers have been magnified three times compared to *Arabidopsis lyrata* ones. *Hypericum perforatum* includes both apomictic and sexual forms. BGC, biased gene conversion; LD, linkage disequilibrium; N_e, effective population size.

Breeding Systems and Within-Species Neutral Diversity

Neutral nucleotide diversity is directly linked to the effective population size ($\pi_s = 4N_e\mu$, where π_s is the population synonymous nucleotide diversity, assumed to reflect neutral diversity, and μ is the mutation rate per locus per generation) so that higher levels of within-population neutral diversity are expected in outcrossers compared to selfers and in sexuals compared to asexuals (reviewed in Charlesworth and Wright, 2001; Glémin and Galtier, 2012). No studies have compared dioecious and non-dioecious species diversity so far.

Selfing, Asexuality and Within-Species Neutral Diversity

Consistent with the theoretical expectations, selfing populations were found to be less diverse than closely related outcrossing populations and asexual species were found to have a lower diversity compared to their sexual counterparts (Table 2). Heterozygosity is, on the other hand, high in asexual individuals as discussed previously (Meselson effect). Selfing reduces within-population diversity while within-species diversity is not affected or is slightly increased because selfing increases population differentiation through reduced pollen gene flow (Charlesworth *et al.*, 1997). Extinction–recolonization dynamics, however, can reduce species-wide N_e in selfers with structured populations (Ingvarsson, 2002). The levels of neutral diversity in selfing and asexual species also depend on whether the change in breeding system has a single or multiple origin (Ness *et al.*, 2010) and whether partial sexuality is maintained in asexuals (Eckert and Barrett, 1993; Pappert *et al.*, 2000).

Self-Incompatibility and the S-Locus Neutral Diversity

In self-incompatible species, self-pollen is recognized and rejected by the pistil through protein interactions. The 'pollen' and 'pistil' genes are found in the tightly linked S-locus, which is under balancing selection: pollen carrying rare alleles are rejected at lower rates compared to pollen carrying common alleles, which prevents the loss of rare alleles through drift. The S-locus is indeed highly diverse (Castric and Vekemans, 2004).

Breeding Systems and the Global Efficacy of Natural Selection

When selection is reduced, species are expected to accumulate more deleterious mutations. Assuming that deleterious mutations are much more frequent than beneficial ones, both π_N/π_S and K_a/K_s should be higher in selfers compared to outcrossers, asexuals compared to sexuals, and perhaps in dioecious compared to hermaphroditic species. Codon usage bias (if under selection) should also be weaker (Marais *et al.*, 2004).

The Transition from Outcrossing to Selfing

Studies based on divergence (K_a/K_s) failed to detect reduced selection in selfers compared to outcrossers (Table 3). This could be due to the purging effect of homozygosity that

[a]Yes, if observation fits theoretical expectations (d*N*/d*S* significantly higher, π_N/π_S significantly higher, positive selection significantly weaker and codon usage significantly less optimized in selfing, asexual, or dioecious species); No, otherwise.
Source: Modified from Glémin, S., Muyle, A., 2014. Mating systems and selection efficacy: A test using chloroplastic sequence data in Angiosperms. Journal of Evolutionary Biology 27, 1386–1399. doi:10.1111/jeb.12356.

reveals recessive mutations in selfers and increases the efficacy of purifying selection (Glémin, 2007; Charlesworth, 1992). It has also been suggested that rare events of outcrossing in partially selfing plants could be enough to avoid the accumulation of deleterious mutations, and this could be promoted by the high recombination rates observed in selfers (Wright *et al.*, 2008). Moreover, selfing will increase K_a/K_s only if mutations have mild effects on fitness, which might not be the case: very little is known about the shape of the distribution of fitness effects of mutations (Glémin and Muyle, 2014). In agreement with this idea, selection on codon usage (involving small selective coefficients) is weaker in selfers than in outcrossers (Table 3).

Contrasting with results on K_a/K_s, most studies based on polymorphism (π_N/π_S) detected reduced selection in selfers: in *Arabidopsis*, *Capsella*, *Collinsia*, *Eichhornia* and in an angiosperm meta-analysis of about 30 species (Table 3). This suggests that selfing does result in selection being reduced but is probably of such recent origin that reduced selection can only be detected over short time scales (i.e., in polymorphism and not divergence data, Figure 2).

More efficient selection on recessive mutations in selfers than outcrossers could make positive selection and adaptation faster in selfers than in outcrossers (Glémin, 2007; Charlesworth, 1992). However, this is true for new beneficial mutations, and not for standing variation. When adaptation is underlain by standing variation, it is more efficient in outcrossers than in selfers (Glémin and Ronfort, 2013). In agreement with this idea, positive selection seems less efficient in selfers than in outcrossers (Table 3).

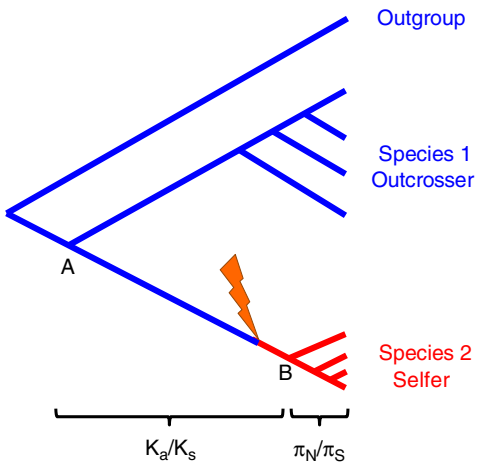

Figure 2 Timing of the transition from outcrossing to selfing and effects on divergence and polymorphism data. The transition is depicted by an orange lightning. If the transition is recent and a little older than the coalescent point of all mutations in the selfing population (node B), it will affect the polymorphism data (studied with π_N/π_S) strongly and the divergence data (studied with K_a/K_s) only weakly. This is because the divergence data will mainly reflect the evolution that took place from node A to B, whereas polymorphism will reflect the evolution that took place from node B to now. Adapted from Glémin, S., Marais, G., 2015. L'évolution du sexe: un carrefour pour la biologie évolutive. In: Thomas, F., Lefevre, T., Raymond, M. (Eds.), Biologie évolutive, Édition: Deuxième édition. Bruxelles: De Boeck Universite.

The Transition from Sexuality to Asexuality

Very few studies have so far compared sexual and asexual plant species (Table 3). Current data suggest adaptation is weak in asexuals. However, K_a/K_s analysis revealed no clear trend of reduced selection. No π_N/π_S analysis is available so that it is not possible to disentangle the possible effect of recent switches to asexuality from no accumulation of deleterious mutations.

The Transition from Hermaphroditism to Dioecy

The only study that tested the hypothesis of reduced selection in dioecious species using K_a/K_s is consistent with expectations when dioecy was several millions years old (Table 3). How the expectations are affected by the biology and ecology of the species remains to be explored: for example wind-pollinated dioecious species will not be affected by pollinator competition between sexes, and the reduction in N_e should not be as strong as in insect-pollinated species.

Breeding Systems and the Evolution of Genome Base Composition

Biased gene conversion (BGC) is a molecular process associated with recombination that drives genomic base composition toward a high GC content (Figure 3) (Lesecque *et al.*, 2013; Marais, 2003), which was shown to affect plant genomes (Glémin *et al.*, 2014; Serres-Giardi *et al.*, 2012; Muyle *et al.*, 2011). Because BGC will operate when recombination occurs in heterozygous loci, it will increase GC content in outcrossing and not in purely selfing species (Marais *et al.*, 2004). Because of the absence of recombination in asexuals, BGC should not affect GC content in these species. Also, as the effect of BGC is dependent on N_e (Lartillot, 2013), it should be reduced in selfers.

Observations fitted expectations for non-coding DNA (higher GC content in outcrossing Poaceae, Glémin *et al.*, 2006), unless a too small intron dataset was used (Brassicaceae, Qiu *et al.*, 2011). But studies using coding sequences gave conflicting results in Triticeae (Escobar *et al.*, 2010; Haudry *et al.*, 2008), or supported BGC but could not distinguish it from mutational biases in other groups (Hazzouri *et al.*, 2013; Wright *et al.*, 2007). More studies comparing selfing and outcrossing species are required, with appropriate methods that allow to distinguish BGC from mutational biases (equilibrium GC content, GC*, that a genome reaches if mutation and substitution rates remain constant, or derived allele frequency spectra) and large non-coding datasets in order to distinguish BGC from selection on codon usage. Similar studies also have to be carried out in asexual and sexual species.

Breeding Systems and the Evolution of Chromosomes and Genome Structure

Due to inefficient recombination, strong linkage disequilibrium is expected in selfers and was observed in the highly selfing *Arabidopsis thaliana* (Kim *et al.*, 2007; Nordborg *et al.*, 2005;

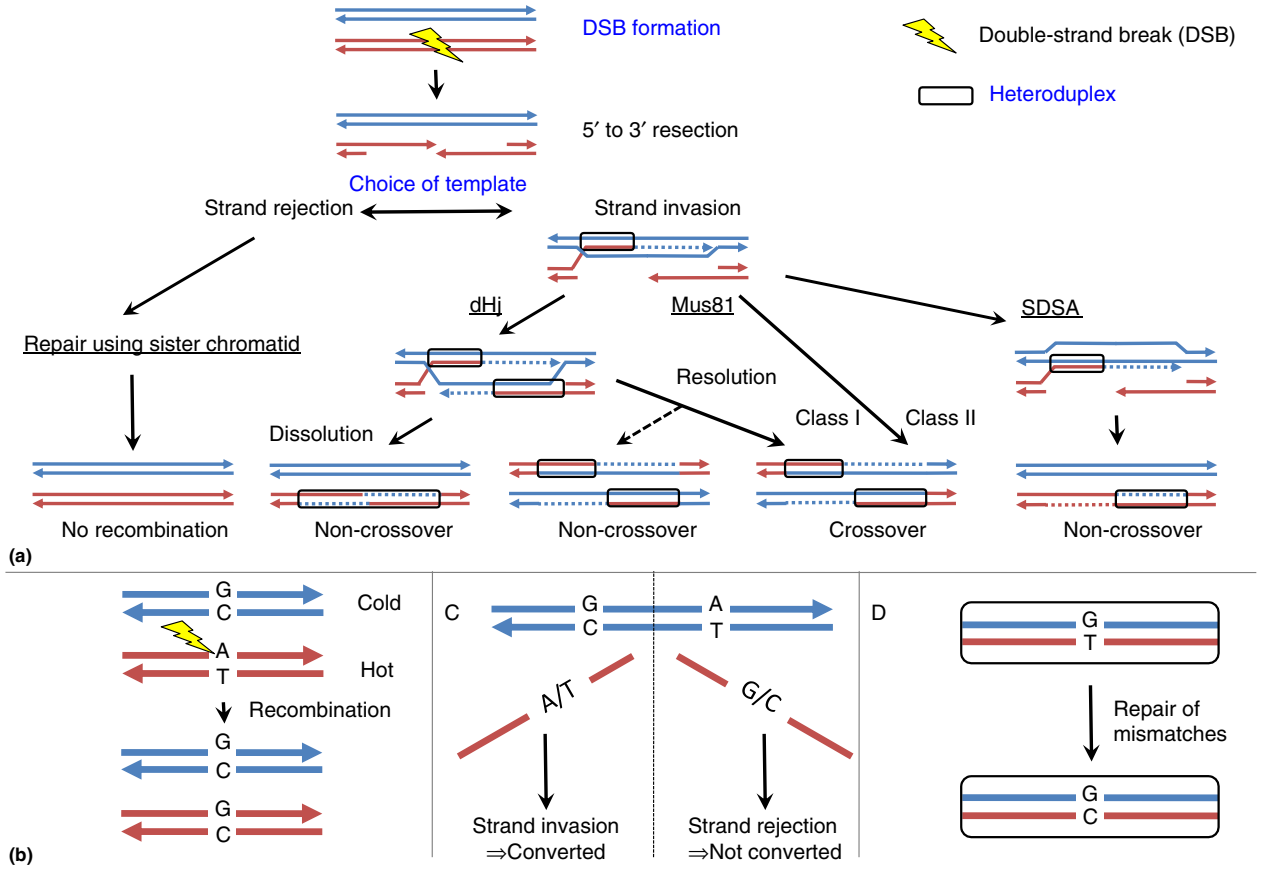

Figure 3 Possible mechanisms for the biased gene conversion (BGC). Different pathways for double-strand break (DSB) repair during meiotic recombination are shown in (a). Blue and red chromosomes indicate chromosomes from different parental origin. Recombination starts with the DSBs on one chromosome. Broken DNA is resected forming single-stranded DNA, which will be used to select a template for repairing the breaks. The mismatch repair (MMR) triggers the choice of template: if the degree of similarity between the single-stranded DNA and the potential template is sufficient, the template is invaded and a D-loop is formed. Otherwise, repair takes place by using the sister chromatin, no recombination happens. Recombination can take place by several pathways: the repair of the breaks by the MMR can lead to the formation of a double-Holliday junction (dHj) intermediate. Resolution of this intermediate may result in crossovers (COs) of class 1, i.e., showing CO interference (a mechanism by which 1 CO / arm / meiosis is ensured). Another pathway (Mus81) produces non-interfering COs. And the synthesis-dependent strand annealing (SDSA) pathway gives non-crosser (gene conversion) events only. Heteroduplexes (DNA with strands from different origins) can be found at various stages of the recombination pathway; they may include mismatches that are detected and repaired by different pathways (MMR and base-excision repair (BER)). BGC may result from different possible biases. (b) Initiation bias. If A/T alleles are recombinationally hotter than G/C alleles, G/C alleles will get copy-pasted onto the A/T alleles (recombination hot spots get converted by recombination cold spot, see the 'hot spot paradox,' Lesecque *et al.*, 2014), and this will increase GC content. (c) Choice of template bias. If the chance of the single-stranded DNA to invade the homologous chromosome is higher when it is GC-rich, this will also create BGC. (d) Repair bias. If repair of mismatches in heteroduplexes is biased in favor of G/C alleles, this may also generate BGC. A recent study in yeast suggests that BGC is found mostly associated with long gene conversion tracts and CO and may be due to MMR (Lesecque *et al.*, 2013). While evidence for BGC have been found in many organisms (Pessia *et al.*, 2012), in most cases the exact mechanism remains unknown and could be one of the three mechanisms outlined here. Adapted from Lesecque, Y., Mouchiroud, D., Duret, L., 2013. GC-biased gene conversion in yeast is specifically associated with crossovers: Molecular mechanisms and evolutionary significance. Molecular Biology and Evolution 30, 1409–1419. doi:10.1093/molbev/mst056.

Miyashita *et al.*, 1999; Wright *et al.*, 2008). Linkage disequilibrium decays with distance in *A. thaliana*, which fits with a transition to selfing >1 MY ago with some rare outcrossing events (Tang *et al.*, 2007). In the outcrossing *Collinsia linearis*, linkage disequilibrium decayed rapidly (over less than 1 kbp), whereas in the selfing *Collinsia rattanii* it could extend to several kbp (Hazzouri *et al.*, 2013).

Chromosomal rearrangements, when heterozygous, are deleterious as they cause chromosome disjunction and result in unbalanced gametes (Lande, 1985). However, selfing is associated with almost complete homozygosity and selection against chromosomal rearrangements will be weak. Fast karyotypic evolution is expected in selfers (Charlesworth, 1992). For example, *A. thaliana*'s karyotype includes 5 chromosome pairs and not 8, the standard karyotype in Brassicaceae (Hu *et al.*, 2011).

The mechanisms for sex determination is unknown in most of the ~15,000 dioecious species; sex chromosomes have been described in only 40 of them (Ming *et al.*, 2011). In male heterogametic systems males are XY and females XX, in female heterogametic systems females are ZW and males are ZZ, and in some species with a haplodiploid life cycle the

gametophytes have separated sexes and females are U and males are V (Bachtrog *et al.*, 2011). Y, W, U, and V chromosomes do not recombine which strongly impacts their molecular evolution. Self-incompatibility S-loci are also non-recombining and have similar properties (Castric and Vekemans, 2004).

Breeding Systems and the Evolution of Genome Size

Three major mechanisms influence genome size: ploidy levels, genomic parasite dynamics (transposable elements (TEs) and B chromosomes), and insertion/deletion events. We will review the effect of breeding systems on each mechanism impacting genome size and then consider the global effect of breeding systems on genome size.

Breeding Systems and Ploidy Levels

Virtually all apomictic plants are polyploid with some exceptions of recovered diploidy in apomictic hybrids (usually polyhaploid, see Asker and Jerling, 1992; Koltunow and Grossniklaus, 2003). This results in larger genomes in asexual compared to sexual plants as observed in *Hypericum* (Matzk *et al.*, 2003). Whether apomixis causes polyploidy, or whether polyploidy causes apomixis by disrupting developmental processes is, however, still unclear (Bhat *et al.*, 2005).

Gametophytic self-incompatibility systems can be directly broken down by polyploidy through the formation of diploid pollen grain (Robertson *et al.*, 2011). The inbreeding depression following self-incompatibility breakdown was proposed to trigger the evolution of dioecy in the Solanaceae family and 12 other genera (Miller, 2000). This proposed association was further tested in 22 genera (i.e., a small fraction of the dioecious genera) and hermaphroditism is indeed more common among diploid than polyploid species, whereas gender dimorphism (dioecy and gynodioecy) is more frequent among polyploid species (Ashman *et al.*, 2013). In most dioecious genera though, the transition to dioecy is probably not accompanied by polyploidization.

Liverworts are ancestrally dioecious and it has been suggested that polyploidy could happen more often in hermaphrodites. However, a test on 67 liverwort species, controlling for phylogenetic inertia, did not support this hypothesis (Bainard *et al.*, 2013).

Breeding Systems and Insertion/Deletion

A. thaliana has smaller introns than *Arabidopsis lyrata* because of different indel dynamics in both species (Wright *et al.*, 2002). A whole genome alignment of *A. thaliana* and *A. lyrata* showed that more than 50% of the *A. lyrata* genome is missing from the *A. thaliana* genome (Hu *et al.*, 2011), explaining the large difference in genome size between both species (*A. thaliana*: 125 Mb, *A. lyrata*: 207 Mb). Large deletions of TEs and intergenic regions, probably selected for, resulted in genome streamlining in *A. thaliana*.

Breeding Systems and TE Dynamics

TE amplification is predominantly deleterious when insertion occurs in or near functional regions or when functional regions are lost by ectopic recombination between TE copies (Charlesworth and Langley, 1989). The number of TEs in a population is determined by the balance between the capacity to invade the host genome through transposition and the efficiency of the host defense mechanisms against TEs. Old TEs end up being inactivated by the host defense mechanisms. A TE element will survive if it can jump from a host to another through horizontal gene transfer and contaminate new hosts, which do not have yet efficient defense mechanisms against that element (Schaack *et al.*, 2010).

In asexual species, TE do not have that chance and they will remain confined to a single host (Hickey, 1982). TE transposition is expected to decline on the long run (Bestor, 1999; Wright and Finnegan, 2001). However, reduced selection against TEs in asexuals might favor TE accumulation. The outcome of these two opposed effects is not easy to predict. It is not clear whether fewer or more TEs should be found in asexuals than in sexuals.

In *Hypericum*, the mean DNA content per chromosome for old asexual species is higher than that of closely related sexual species, suggesting an accumulation of TEs in asexuals (Matzk *et al.*, 2003). In a study comparing four pairs of closely related sexuals and asexuals for three TEs, no reduced selection against TEs was found in asexuals using K_a/K_s, suggesting their transposition capacity has not decreased. The recent origin of the asexuals could, however, explain the results, as shown by simulations (Docking *et al.*, 2006).

Similar expectations hold for selfing species: TE transposition should decline because of confinement to a lineage but this could be blurred by a globally reduced selection in selfers. But the dynamics of TEs in selfers are even more difficult to predict than in asexuals. Because of a high level of homozygosity, purifying selection is expected to purge more efficiently the deleterious recessive mutations from the population in selfers than in outcrossers. However, ectopic exchanges among TE copies will probably be rare in homozygotes (Montgomery *et al.*, 1991), and selection will not act against TEs this way in selfers. It is not clear which one of these many opposing effects should prevail (Charlesworth and Charlesworth, 1995; Wright and Schoen, 1999; Morgan, 2001; Boutin *et al.*, 2012).

Looking at some TE families have indeed returned contradictory results (Young *et al.*, 1994; Charlesworth and Charlesworth, 1995; Wright *et al.*, 2001; Lockton and Gaut, 2010; Tam *et al.*, 2007). However, more recently, a clearer view has started to emerge from whole genome comparisons between selfers and outcrossers. *A. thaliana* has less TEs than *A. lyrata* (24% and 30% of the genome respectively, Hu *et al.*, 2011). Interestingly, TEs are less frequent nearby genes in selfers than in outcrossers (Agren *et al.*, 2014; Slotte *et al.*, 2013). Also, deletions of TEs are selected for in *A. thaliana* (Hu *et al.*, 2011), clearly pointing to a more efficient selection against TEs in selfers than in outcrossers. In *A. thaliana*, most TEs are old, older than the *A. thaliana*–*A. lyrata* speciation. In *A. lyrata*, on the contrary, recent bursts of TEs have occurred (Hu *et al.*, 2011; Wright and Agren, 2011; Tsukahara *et al.*, 2012; de la Chaux *et al.*, 2012; Maumus and Quesneville, 2014). Similar

patterns were found in the selfers *Capsella rubella* and *Capsella orientalis* compared to the outcrosser *Capsella grandiflora* (Agren *et al.*, 2014; Slotte *et al.*, 2013). These observations suggest that reduced transposition and efficient selection against TE insertions are dominating TE dynamics in selfers.

Dioecy can be determined by sex chromosomes, which are known to accumulate TEs because of reduced selection triggered by the absence of recombination for the Y chromosome and a reduced N_e for the X chromosome. In papaya (trioecious), the male-specific and female-specific regions of the sex chromosomes have accumulated retrotransposons as predicted (Gschwend *et al.*, 2012; Wang *et al.*, 2012). In the dioecious plant *Silene latifolia*, the X and the Y chromosomes are much larger than other chromosomes, probably because of sex chromosome specific TE accumulation (Cegan *et al.*, 2012). Interestingly, *S. latifolia* has a much larger genome than *Silene vulgaris*, a non-dioecious close relative. However, whether dioecious species tend to accumulate TEs on the sex chromosomes only or on the whole genome as would predict the dead-end hypothesis is not clear.

Breeding Systems and B Chromosomes

B chromosomes are also considered parasitic DNA elements, which are mainly deleterious to their hosts. Their dynamics may be similar to TEs with outcrossing favoring their spread; they are therefore expected to be associated with outcrossing or to evolve into mutualists when associated with selfing (Burt and Trivers, 1998). A significant positive correlation was found between the presence of B chromosomes and outcrossing, when taking phylogenetic inertia into account (Burt and Trivers, 1998; Trivers *et al.*, 2004). However, B chromosomes do not seem to contribute significantly to the evolution of genome size (Trivers *et al.*, 2004).

Global Effect of Breeding Systems on Genome Size

An analysis of C-values of 14 pairs of closely related outcrossing and selfing species revealed that selfers tend to have smaller genome sizes than outcrossers, and this is not due to differences in ploidy levels (Wright *et al.*, 2008). A detailed analysis of genome size in the *Veronica* genus suggests that selfing, not annuality, is associated with genome size reduction after taking phylogenetic inertia into account (Albach and Greilhuber, 2004). The analysis of a dataset of 205 species showed a significant association between outcrossing and large genomes after taking phylogenetic inertia into account (Whitney *et al.*, 2010). However, these two studies used the phylogenic independent contrast method (Felsenstein, 1985) to correct for phylogenetic inertia. This simple approach (in which sister branches are compared along the tree and ancestral states of characters are inferred in internal nodes by averaging the values of the next lower nodes) has been criticized for the study of genome size as it neglects the possibility of parallel evolution (Lynch, 2011; Whitney *et al.*, 2011). The question of the global effect of selfing on genome size remains thus open. Studies on the effects of asexuality and dioecy on genome size are lacking.

Conclusion

Current data suggest that changes in breeding system can have a strong impact on genome evolution (**Table 4**). An important point is that the transitions to new breeding systems have to be recent for the data to fit with the theory. In the future, it will be important to date those transitions much more precisely than they are today (when such dating is available) to confirm this. Another important point is about the forces to explain the difference in genomic features between two species with different breeding systems. Breeding system is usually not the only difference, even among closely related species, demography for instance can be a confounding factor. This is a very difficult point; increasing the number of studied systems is probably the only way to address it. We are starting to be in this situation for the transition from outcrossing to selfing, which is the best studied. The transitions to asexuality and

dioecy have been less studied. Only a handful of studies are available on the effects of dioecy on genome evolution. However, dioecy is expected to drive substantial changes in evolutionary forces acting on genomes (**Figure 1(c)**). In particular, sexual selection should be much stronger than in non-dioecious species, probably driving the evolution of sex-biased expression for many genes in the genome. Future studies on dioecious species could provide data on sex-biased expression (for which we currently know very little in plants) and other aspects. It could help to understand why dioecy is surprisingly rare in angiosperms.

Mating Tactics and Mating Strategies

SH Alonzo, University of California, Santa Cruz, CA, USA

Glossary

Alternative mating tactics Discrete variation among individuals within a population in traits related to mating. These traits can be behavioral, physiological, and morphological.

Condition-dependent selection Selection that varies with individual condition such as age, size, energy reserves, or experience.

Genetic polymorphism Discrete genetic variation among individuals within a population.

Negative frequency-dependent selection Selection on a genotype or phenotype arising from a decrease in relative fitness as the frequency of that genotype or phenotype increases.

Phenotypic plasticity When the phenotype of an organism is not fixed but is instead plastic and depends on environmental conditions or individual circumstances.

Introduction

Evolution by natural selection tends to favor the genes or genotypes that allow some individuals to have more surviving offspring than others. One might, therefore, expect over evolutionary time that a single solution would arise to the problem of 'how best' to mate and reproduce in a given environment. What we actually observe is that many populations exhibit both continuous and discrete variation in reproductive behaviors and mating patterns (Oliveira *et al.*, 2008). Evolutionary biologists have puzzled for decades over how and why this variation is maintained (Austad, 1984; Dominey, 1984; Gross, 1984, 1996; Henson and Warner, 1997). A population is said to exhibit 'alternative mating tactics' (AMTs) or more generally 'alternative reproductive tactics' (ARTs) when there is discrete variation between individuals in how they mate or reproduce within the same population at one point in time. For example, some individuals might defend a reproductive territory to attract mates and rear young, while other reproductive individuals in the same population find mates without having a territory. Such alternative tactics can arise from a genetic polymorphism or because individuals respond plastically to an aspect of their environment or individual state. Traditionally (though not necessarily consistently), the term 'alternative tactics' has been used for alternative behaviors or phenotypes independent of their basis, while 'alternative strategies' is reserved for cases where the alternatives are known to be determined by a genetic polymorphism (Gross, 1984, 1996). This article focuses on AMTs, but it is worth noting that alternative tactics occur in many other aspects of an organism's phenotype.

What Form Do Alternative Mating Tactics Take in Nature?

In the bluegill sunfish (*Lepomis macrochirus*, a North American freshwater fish), three alternative male tactics coexist (Gross and Charnov, 1980; Gross, 1982). Some males build nests, attract females to these nests and take care of the developing eggs and young (called 'parental males'). Other smaller males called 'sneakers' do not build nests or care for young, but sneak in and release sperm when a parental male and female are spawning. Finally, 'female mimics' get close to another male's nest by looking and behaving like a female, but release sperm when a real female spawns in the parental male's nest. These three male types differ in their behavior, size, physiology, and morphology. And yet they are all one species. In meerkats (*Suricata suricatta*, African desert mammals from the mongoose family), individuals live in social groups with relatives and cooperate to defend and rear young (Clutton-Brock *et al.*, 2001; Russell *et al.*, 2007). Dominant males tend to sire young in their own social group, while subordinate males mainly sire young outside their social group, while helping to rear the young within their group instead of their own young (Young *et al.*, 2007). Subordinate and dominant male meerkats therefore exhibit AMTs with respect to their mating behavior and parental care. In the green-veined white butterfly (*Pieris napi*), females vary in their propensity to mate with one male (e.g., be monandrous) or multiple males (e.g., be polyandrous, Wedell *et al.*, 2002). The probability that a female will be monandrous or polyandrous depends not only on female genotype but also on the amount of energy and type of sperm they receive from their mate (Wedell, 2001, 2006; Wedell *et al.*, 2009). In goldeneye ducks (*Bucephala* sp.), and a variety of other water birds, some females build and lay eggs in their own nests, while others lay eggs in the nests of other females (a behavior called conspecific brood parasitism, Eadie and Fryxell, 1992; Eadie and Lyon, 1998; Lyon, 2008). Recent research on the common goldeneye duck (*Bucephala clangula*) suggests that females preferentially lay their eggs in the nests of related females and in nests more likely to be safe from predation (Poysa *et al.*, 2014). In guppies (*Poecilia reticulata*, a tropical freshwater fish), older females tend to choose mates independently while younger females often copy the mate choice of other females (Dugatkin and Godin, 1993). These examples illustrate that AMTs are found in both sexes, take a variety of forms, occur across taxa, affect patterns of mating, fertilization, and parental care,

and can involve discrete variation in behavior, physiology, and morphology.

Why Do Alternative Mating Tactics Interest Evolutionary Biologists?

First, the maintenance of genetic variation that underlies phenotypic variation is necessary for evolution by natural selection. Without such variation, evolution will not occur; understanding how and when variation is maintained remains an open question in evolutionary biology. Second, we learn more about how selection shapes reproductive behaviors and mating patterns by knowing how alternatives arise and affect individual fitness. For example, are some individuals territorial because they are larger and in better condition, while smaller or lower condition individuals cannot defend reproductive territories? Or, is there is a tradeoff between defending a territory and investing in some other aspect of reproduction, such as producing more gametes? Are these alternatives (e.g., being territorial with fewer gametes vs. not being territorial but making more gametes) two equally good solutions to the 'problem' of how best to reproduce? The answer to these questions informs our general understanding of selection on territorial behavior. Third, examining how the genome of a single species manages to generate strikingly different phenotypes helps us understand not only the mechanisms underlying the differences we see between species, but also what allows novel forms to arise over evolutionary time between species. Finally, in the case of alternative tactics arising from phenotypic plasticity, understanding more about how and why these alternatives exist can yield new insights into the evolution and expression of plasticity itself, a topic of general importance in biology. AMTs are therefore not only interesting in their own right, but also have the potential to yield insights into evolutionary innovations, the maintenance and production of diversity, and the mechanisms and evolutionary processes that allow and the limit the degree to which organisms respond plastically to their environment.

What Mechanisms Allow the Evolution of Alternative Mating Tactics?

As described above, AMTs can arise from a genetic polymorphism or phenotypic plasticity. While both can generate discrete AMTs, the evolutionary dynamics and predicted empirical patterns differ between these two mechanisms. This section reviews when and how these mechanisms are predicted to allow the persistence of AMTs and describes a few illustrative examples.

Discrete variation in mating patterns can exist if a genetic polymorphism (i.e., discrete genetic variation between individuals) affects which mating pattern an individual exhibits. For example, there could be a gene with two different alleles (or variants): one allele for being territorial and another for being non-territorial. Extensive theory has considered whether and when a genetic polymorphism of this kind will be maintained in a population at equilibrium (Rubenstein, 1980; Cooper and Kaplan, 1982; Maynard Smith, 1982; Gross, 1984; Shuster and Wade, 2003; Shuster, 2011). This theory predicts that the alternative tactics must have equal fitness on average for the genetic variation underlying the alternative tactics to persist. Otherwise, evolutionary theory predicts that one allele or genotype would become more common and eventually go to fixation in the population. How is a stable genetic polymorphism maintained? It is extremely unlikely that two alternatives would by chance have exactly equal fitness. Instead, negative frequency-dependent fitness is the most likely evolutionary explanation. Frequency-dependence arises when the fitness of a particular behavior or genotype is not fixed, but instead depends on the frequency of other behaviors or genotypes in the population. Negative frequency-dependence is when the relative fitness of an alternative decreases as it becomes more common (**Figure 1**). Consider the territorial/non-territorial example; it could be that when few individuals in the population are territorial that those individuals that defend a territory are able to attract more mates and raise more offspring because there is little competition for good territories. If everyone in the population is territorial, however, the cost of fighting for territories may be so high that non-territorial individuals attract more mates and have more surviving offspring. This is negative frequency-dependent fitness; the relative fitness of an alternative is higher when they are rare than when they are common (**Figure 1**). At equilibrium, however, the alternative tactics can coexist where they have equal fitness (i.e., where the two lines cross in **Figure 1**). Evidence for AMTs arising from a genetic polymorphism has been found in both sexes and in a variety of taxa from insects to birds (Neff and Svensson, 2013). While empirical examples certainly exist, it is still debated whether AMTs that arise from a

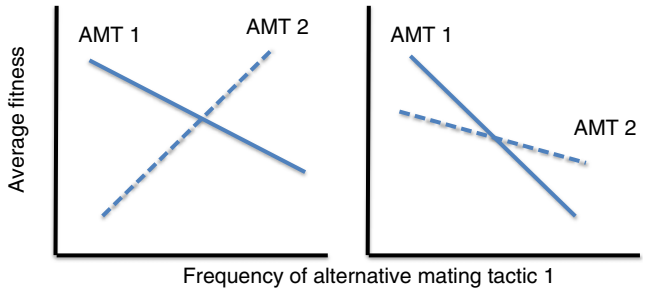

Figure 1 Negative frequency-dependent fitness: The fitness of each tactic declines with its frequency in the population. In both cases shown here, the two alternatives are predicted to occur on average at the frequency where the two fitness curves cross. Reproduced with permission from Henson, S.A., Warner, R.R., 1997. Male and female alternative reproductive behaviors in fishes: A new approach using intersexual dynamics. Annual Review of Ecology and Systematics 28, 571–592.

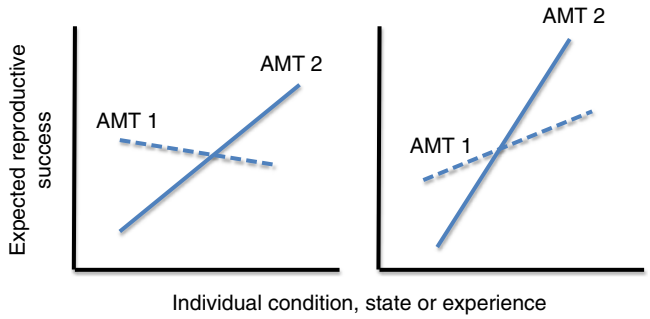

Figure 2 State-dependent fitness: The expected fitness of each tactics depends on individual condition or state (such as age, size, energy reserves, or experience). Individuals are predicted to adopt the tactics that leads to greater expected fitness for their state or condition. Reproduced with permission from Henson, S.A., Warner, R.R., 1997. Male and female alternative reproductive behaviors in fishes: A new approach using intersexual dynamics. Annual Review of Ecology and Systematics 28, 571–592.

genetic polymorphism are common in nature (Gross, 1996; Tomkins and Hazel, 2007; Oliveira *et al.*, 2008; Shuster, 2011; Neff and Svensson, 2013).

One fascinating and well-studied example of AMTs arising due to a genetic polymorphism is observed in the side-blotched lizard (*Uta stansburiana*). These lizards are found in western North America and reproduce in rocky grassland habitats (Sinervo and Lively, 1996). Males come in three discrete throat color morphs that differ not only in color but also in behavior and physiology (Sinervo and Lively, 1996; Calsbeek *et al.*, 2002). Orange males are more aggressive, defend large territories, and exhibit higher testosterone levels. Blue males defend smaller territories and are less aggressive while yellow males are non-territorial 'sneakers' (Calsbeek and Sinervo, 2002). The most likely explanation for their coexistence is negative frequency-dependent selection on a gene or gene region that codes for these differences (Sinervo and Lively, 1996; Svensson *et al.*, 2005; Bleay *et al.*, 2007). It is not only the males, however, that exhibit discrete variation in this species. Females exhibit two main throat color morphs (orange and yellow) that differ in their behavior as well as the size and number of eggs they produce (Svensson and Sinervo, 2000, 2004; Svensson *et al.*, 2001, 2002). These alternatives appear to be determined by the same gene region that affects male AMTs and selection on both male and female alternatives varies year to year. While the three male alternatives coexist in some populations, one or more AMTs have been lost in other populations (Corl *et al.*, 2010a,b).

In contrast to the relatively rare empirical evidence for AMTs arising from a genetic polymorphism, many examples exist where phenotypic plasticity appears to explain the existence of discrete ARTs within a population. One common pattern is that individuals adopt different reproductive behaviors depending on their age, condition, size, or social status (which can generally be called the individual's 'state'). For example, remember that male meerkats switch their mating and parental care behavior depending on whether they are currently subordinate or dominant in their social group (Clutton-Brock *et al.*, 2001; Russell *et al.*, 2007). And female guppies change from using mate choice copying when young to making independent mate choice decisions when older (Dugatkin and Godin, 1993). Why does this evolve? When the fitness of alternative tactics is differentially affected by the individual's state, the alternative that leads to greater reproductive success may change with individual state (**Figure 2**). If this kind of state-dependent fitness exists, it can select for phenotypic plasticity such that the alternative adopted by individuals depends on their state or experience (Gross, 1996; Alonzo and Warner, 2000c; Hazel *et al.*, 2004; Tomkins and Hazel, 2007). AMTs arising from phenotypic plasticity can take a variety of forms: individuals may switch frequently as their state changes (e.g., reversible alternatives), individuals may switch from one tactic to another over their lifetime as they grow or age (e.g., irreversible or sequential alternatives), and finally individuals may adopt only one alternative for life depending on their state at a key life history stage (e.g., fixed alternatives, Gross, 1984; Henson and Warner, 1997). These forms have the same underlying explanation but their expression and the mechanisms that control them will differ (Emlen, 2008).

In the ocellated wrasse (*Symphodus ocellatus*, a small fish found throughout the Mediterranean), three AMTs coexist: (1) Large colorful 'nesting' males build nests of algae, court females, care for eggs, and attempt to prevent mating by other males. (2) Smaller 'sneaker' males attempt to join a nesting male and female during mating, but do not court females or provide care. (3) 'Satellite' males court females, chase sneakers, and are tolerated by the nesting male, but sneak spawns at the nest and do not provide care. Females do not provide care and prefer to mate with nesting males (that provide care) but cannot avoid sneakers and satellites because fertilization is external (Alonzo *et al.*, 2000; Alonzo and Warner, 2000a,b; Alonzo, 2008). Sperm competition is intense and male types differ in the level of sperm competition they experience (sneakers the most, nesting males the least, Alonzo and Warner, 2000a). While males differ in many aspects of their behavior and physiology, we know that males can change between tactics over their lifetime. Male ARTs are determined by early differences in growth and fall along two life-history pathways (Alonzo *et al.*, 2000). Slow-growing males start reproducing as sneakers in their first year and then switch to being a satellite in their second and final year. Fast-growing males reproduce as a satellite male in their first year and switch to being a nesting male in their second and final year. While there is no evidence for a genetic polymorphism underlying these two life history pathways, it is possible that underlying

genetic variation interacts with environmental variation to generate differences in growth which then determine which of the two pathways males adopt.

Similar behavior differences exist in the Azorean Rock-pool blenny (*Parablennius parvicornis*) (Oliveira, 2001; Oliveira *et al.*, 2002; Ros *et al.*, 2006). When mating, males adopt either a nesting male, satellite or sneaker male phenotype. In this species, however, males seem to switch between AMTs over their lifetime as they become older and larger. In contrast, in many species of dung beetle (*Onthophagus* sp.) males develop either a horned (fighting) phenotype or a hornless phenotype during development (Emlen and Nijhout, 1999; Emlen, 2000, 2008; Moczek and Emlen, 2000). Although there is continuous variation in body condition during development, males with a body condition above a certain threshold develop horns with those below the threshold do not (Emlen, 1997, 2008) and the insect hormone 'juvenile hormone' seems to influence this developmental switchpoint (Nijhout and Emlen, 1998; Emlen and Nijhout, 2000). AMTs of this kind are a specific form of phenotypic plasticity, called threshold traits. There is an extensive general literature on phenotypic plasticity (extending well beyond discrete mating forms) and more specifically on the circumstances in which condition or state-dependent selection favors the kind of phenotypic plasticity that generates discrete alternative forms (Via and Lande, 1985; West-Eberhard, 1989; Scheiner, 1993; Via *et al.*, 1995; Sultan, 2000; Miner *et al.*, 2005; Ghalambor *et al.*, 2007; Roff, 2011). While this research does not necessarily focus on mating tactics, research on the evolution of phenotypic plasticity can help us understand the factors that lead to discrete alternative phenotypes in nature.

Some controversy exists regarding the best mathematical methods to use to model the evolution of phenotypic plasticity in the face of state or condition-dependent selection (Gross, 1996; Plaistow *et al.*, 2004, Tomkins and Hazel, 2007; Neff and Svensson, 2013, 2014; Buzatto *et al.*, 2014). Though the debate is methodological in focus, these differences have important implications for the kind of predictions one might test empirically (Tomkins and Hazel, 2007; Shuster, 2011). Debate also exists regarding whether plasticity or genetic polymorphisms are more likely to explain the many AMTs observed in nature (Shuster and Wade, 2003; Tomkins and Hazel, 2007; Shuster, 2011; Neff and Svensson, 2013, 2014; Buzatto *et al.*, 2014). In general, however, we know that alternatives arising from a genetic polymorphism should have equal fitness on average over time. In contrast, alternative tactics arising from phenotypic plasticity could but often will not have equal expected lifetime fitness. Given the challenges of tracking individuals over their lifetime let alone across generations in most organisms, unequivocal demonstration of either equal or unequal fitness of alternatives is most likely impossible. It is also worth noting that while we have discussed genetic polymorphisms and phenotype plasticity separately here, it is also possible that negative frequency dependent and condition-dependent selection operate in combination within single species. It is also known that phenotypic plasticity involves an underlying genetic component where the thresholds and developmental processes underlying plasticity respond to selection (Emlen, 2008) even when a genetic polymorphism does not underlie the alternatives. Therefore, AMTs, even when plastic, respond evolutionarily to selection on the underlying mechanisms that determine the degree of plasticity that exists and what form the AMTs take.

Conclusions and Future Directions

Clearly, controversy exists about some aspects of our understanding of AMTs. The existence of AMTs arising from both genetic polymorphisms and phenotypic plasticity, however, is undeniable. And these alternatives take a variety of fascinating forms in nature. We are only just beginning to understand how a single genome with either no or only small genetic differences can generate such diverse forms. While AMTs are just one specific example of how discrete variation in populations can be maintained, our understanding of them has implications for selection on mating behavior, the maintenance of diversity and the evolution and expression of novelty.

Extensive research, beyond the scope of this review, has also examined the neurological, hormonal, and physiological basis underlying AMTs. For a few species, we understand both the evolutionary processes and physiological or developmental mechanisms that generate discrete AMTs. For example, discrete throat color morphs in the size blotched lizard arise from a genetic polymorphism that initiates a cascade of hormonal, developmental, and immunological processes that shape their divergence in behavior and form. Few studies, however, integrate evolutionary and mechanistic perspectives simultaneously. Research that advances both evolutionary and mechanistic understanding of how AMTs arise within a single species has the potential to generate new insights that increase our understanding of the impressive variety of forms seen in nature as well as how novelty can arise from small change in the genome and the developmental and physiological systems it encodes. Finally, further knowledge of the evolution of the processes underlying alternative tactics will tell us what role these processes may play allowing and constraining organismal responses to a changing world.

Maximum Likelihood Phylogenetic Inference

A Dhar and VN Minin, University of Washington, Seattle, WA, USA

Glossary

Dynamic programming A general method for solving complex problems by breaking them down into a collection of simpler subproblems that are similar in structure to the original problem.

Hessian matrix A square matrix of second order partial derivatives of a real-valued function. It is often needed within numerical optimization techniques.

Hill climbing A generic optimization strategy that relies on local searches when trying to find the global maximum of a given function. Hill-climbing procedures incrementally modify variables in an optimization problem and check to see if the modified variables have achieved a higher function value (i.e., 'climbed the hill').

Law of total probability A probability formula that states how to calculate the probability of an event given a partition of the sample space.

Metric space A set of objects (i.e., real numbers, phylogenies, etc.) equipped with a distance between any two elements.

Reversible substitution model A Markov substitution model that, if started at the equilibrium distribution, can be run backwards in time, with the resulting backward Markov model following the same probability law as the original forward model.

Simulated annealing A probabilistic method for approximating the global maximum of a given function. It is a useful technique that avoids getting stuck in local maxima.

Stationary distribution A marginal probability distribution over the states of a substitution model that can be interpreted as a long-run steady-state distribution as evolution occurs over time.

Substitution model A model that specifies probabilities of state changes for DNA (or amino acid) sequence data along the branches of a given phylogeny.

Introduction

Maximum likelihood estimation is an extremely popular statistical inference framework that is used to estimate the parameters in a probabilistic data generating model. This conceptually simple method provides parameter estimates that have good statistical properties. Before delving into maximum likelihood techniques for phylogenetic tree reconstruction, we present a simple example of maximum likelihood estimation to illustrate how this procedure works.

Suppose we have a coin that has some unknown probability p of landing on heads. We are interested in estimating this unknown probability based on the outcomes of observed coin flips. For example, one could imagine flipping this coin independently 10 times, resulting in an observed sequence of *HTTHTHTHTT*, denoted by D. The maximum likelihood principle suggests that the best guess for p is obtained by choosing p so that the probability of observing the sequence *HTTHTHTHTT* is the highest. The probability of observing the sequence *HTTHTHTHTT* from this coin is:

$$L(p) = \Pr(D;p) = p(1-p)(1-p)p(1-p)p(1-p)$$

$$p(1-p)(1-p) = p^4(1-p)^6 \qquad [1]$$

We are able to take a product of p and $1-p$ terms because of the independence of the coin flips. Equation [1] is referred to as the likelihood given parameter p. Because we are picking the value of p that makes $L(p)$ the largest, this likelihood function is treated as a function of p, not as a function of the data D. From basic calculus, we know that finding the p that maximizes a differentiable function w.r.t. p is equivalent to solving the equation $L'(p)=0$, which is:

$$2(-1+p)^5p^3(-2+5p) = 0 \qquad [2]$$

This results in three roots $p=0$, 0.4, 1. A quick inspection of the likelihood function, depicted in Figure 1, evaluated at all three roots shows that $p=0.4$ is the maximum likelihood estimate of p. This is an intuitive estimate because it is just the proportion of heads observed in the sequence *HTTHTHTHTT*. It turns out that this maximum likelihood estimator (MLE) of p tends to the true, unknown value of p as we observe more and more coin flips this is called consistency in statistics. Also, this estimator uses available data in the most optimal way, again as we observe more and more coin flips — this is called efficiency in statistics. Under fairly general and reasonable regularity conditions, consistency and efficiency hold for a large class of MLEs (van der Vaart, 1998). This easy-to-understand estimation principle along with the associated optimality properties for a wide class of likelihood models make maximum likelihood an attractive procedure for many parameter estimation problems, including the problem of estimating phylogenetic relationships from molecular sequence data.

Phylogenetic Likelihood

Likelihood Description

Throughout this presentation, we restrict our attention to DNA sequence data for simplicity (although the methods we describe are compatible with other discrete character datasets as

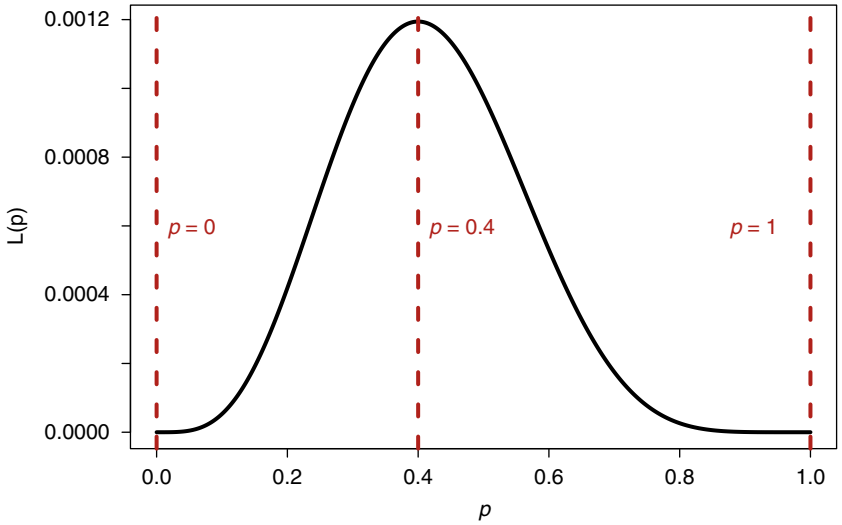

Figure 1 The likelihood of observing 4 heads in 10 coin tosses as a function of the unknown probability of heads p in a single toss. The likelihood function $p^4(1-p)^6$ is maximized at $p=0.4$, which corresponds to the observed proportion of heads. The red dashed lines represent critical points found by differentiating the likelihood function and setting it equal to 0.

well). Suppose we observe m aligned sequences of DNA (potentially corresponding to m distinct species), where each sequence has nucleotide observations recorded at n distinct sites. Gaps in the alignment are usually treated as missing data, but more accurate treatment of insertions and deletions is possible (Redelings and Suchard, 2005; Liu *et al.*, 2012). Just as we considered the likelihood of the observed coin flips as a function of the unknown parameter p, here we will examine the likelihood of the DNA sequence data as a function of the unknown tree topology and branch lengths. Given a tree topology with branch lengths, we can use a substitution model to calculate the probabilities of state changes along the branches of the tree; substitution models are described in great detail in the 'Models and Model Selection' article contained within this encyclopedia. Specifically if t denotes a branch length on a tree, substitution models allow us to calculate $p_{ij}(t)$, which denotes the probability of going from state i to state j on a branch of length t, where $i,j \in \{A,G,C,T\}$. Note that branch lengths are commonly measured in expected number of substitutions per site, not in clock time, because estimating substitution rates and branch lengths in units of clock time requires additional information about branching and/or sampling times in the phylogeny (Drummond *et al.*, 2006).

Two assumptions are made that are crucial to the rest of the analysis (Felsenstein, 2004):

1. Evolution at different sites (on a given tree) is independent.
2. Conditional on the internal node states, evolution proceeds independently on different branches of the phylogeny.

Let $L(\tau,\mathbf{t},\boldsymbol{\theta})$ be the likelihood corresponding to the $m \times n$ DNA sequence alignment matrix $\mathbf{y}$ for a given tree topology τ with branch length vector $\mathbf{t}$ and substitution model parameter vector $\boldsymbol{\theta}$. We can write the likelihood as:

$$L(\tau,\mathbf{t},\theta) = \Pr(\mathbf{y};\tau,\mathbf{t},\theta) = \prod_{i=1}^{n} P(y_i;\tau,\mathbf{t},\theta) = \prod_{i=1}^{n} L_i(\tau,\mathbf{t},\theta) \quad [3]$$

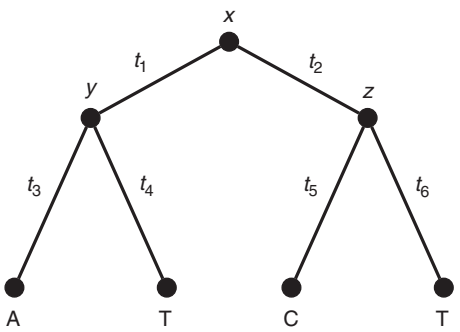

Figure 2 An example phylogenetic tree. Letters x,y,z represent the unobserved internal node states where x is associated with the root node, τ_{ex} specifies the tree topology, and $\mathbf{t}_{ex}=(t_1,t_2,\ldots,t_6)$ denotes the vector of branch lengths. Given the tree topology τ_{ex} and branch lengths $\mathbf{t}_{ex}$, we can calculate the likelihood of observing the nucleotide vector (A,T,C,T).

where γ_i is the $m \times 1$ vector of observed nucleotides at the i'th site and $L_i(\tau,\mathbf{t},\theta)$ is the site i likelihood. This factorization follows directly from the first independence assumption given above. Thus, we can find the likelihood of the whole sequence matrix by finding the likelihoods for each of the n sites. Suppose we observed the nucleotide vector (A,T,C,T) at a particular site (assuming there were only $m=4$ aligned sequences). We will use the example tree τ_{ex} given in Figure 2 to help illustrate how to calculate the likelihood at this site.

Using the tree τ_{ex}, we can deconstruct the likelihood of this nucleotide vector in the following manner:

$$\begin{aligned}\Pr(A,T,C,T;\tau_{ex},\mathbf{t}_{ex},\theta) &= \sum_x \sum_y \sum_z \Pr(A,T,C,T,x,y,z;\tau_{ex},\mathbf{t}_{ex},\theta) \\ &= \sum_x \sum_y \sum_z \pi_x p_{xy}(t_1) p_{xz}(t_2) p_{yA}(t_3) p_{yT}(t_4) p_{zC}(t_5) p_{zT}(t_6) \quad [4]\end{aligned}$$

where the summations are over the elements in $\{A,G,C,T\}$. We obtain eqn [4] by conditioning on the internal node states and

by invoking the assumption of independent evolution across branches. Note that, following common practice, we assumed that the initial distribution at the root of the phylogeny is $\boldsymbol{\pi} = (\pi_A, \pi_G, \pi_C, \pi_T)^T$, the stationary distribution of the substitution model (Page and Holmes, 2009). Looking at eqn [4], it is clear that we will need to take a sum over $4^3 = 64$ probabilities. For only $m = 4$ terminal nodes, this computation is reasonable; as m grows, the computation becomes problematic because the sum will involve 4^{m-1} terms over $m-1$ internal nodes. In the next section, we describe an algorithm that can efficiently calculate this site likelihood by eliminating redundant computations.

Likelihood Computation

First presented by Felsenstein (1973), the pruning algorithm is a standard technique used to efficiently compute phylogenetic likelihoods. This algorithm is a particular type of dynamic programming technique and takes advantage of the distributive law of algebra to achieve efficiency gains. For example, the expression $ab + ac + ad + ae$, where a, b, c, d, e are scalars, requires 7 computations (4 multiplications and 3 additions). By noting the scalar a appears in all 4 multiplications, we can use the distributive law to rewrite the above expression as $a(b + c + d + e)$, which requires 4 computations (3 additions and 1 multiplication). Thus by applying the distributive law to expressions that contain sums of product terms, like in eqn [4], we can reduce the number of computations required to evaluate them.

For the phylogenetic site likelihood given in eqn [4], we can utilize the distributive law by pushing the summations as far right as possible:

$$P(A,T,C,T|\tau_{ex},\mathbf{t}_{ex},\theta) = \sum_x \sum_y \sum_z \pi_x p_{xy}(t_1) p_{xz}(t_2) p_{yA}(t_3) p_{yT}(t_4) p_{zC}(t_5)$$

$$p_{zT}(t_6) = \sum_x \pi_x \left[\sum_y p_{xy}(t_1) p_{yA}(t_3) p_{yT}(t_4)\right]\left[\sum_z p_{xz}(t_2) p_{zC}(t_5) p_{zT}(t_6)\right] \quad [5]$$

This formulation suggests calculating $\sum_y p_{xy}(t_1) p_{yA}(t_3) p_{yT}(t_4)$ and $\sum_z p_{xz}(t_2) p_{zC}(t_5) p_{zT}(t_6)$ first, caching these intermediate results for all possible values x, and then computing the final sum over x. Note that we can visualize this procedure as traversing τ_{ex} bottom-up because the sums over y and z are evaluated before the sum over x. Instead of naively summing over $4^3 = 64$ terms, this reformulation requires a sum over $4 \times 3 = 12$ terms. For an arbitrary number of terminal nodes m, a similar reformulation will reduce the number of computations from being exponential in m to being linear in m.

The nested, bottom-up nature of the above computation leads naturally to a recursion for calculating site likelihoods. We define $L(k, i)$ to be the conditional likelihood of a subtree with root node k being in state i. Conceptually, it is the likelihood of the observed terminal nodes below node k, conditional on node k being in state i. For example, in τ_{ex}, $L(\gamma, i)$ represents the likelihood of observing (A, T) below node γ, conditional on node γ being in state i. For any internal node k (in state i) with children v,w and corresponding branch lengths t_v,t_w, Felsenstein (1973) defines the recursion to be:

$$L(k,i) = \left[\sum_{s_1 \in \{A,G,C,T\}} p_{is_1}(t_v) L(v,s_1)\right]\left[\sum_{s_2 \in \{A,G,C,T\}} p_{is_2}(t_w) L(w,s_2)\right] \quad [6]$$

for all states $i \in \{A,G,C,T\}$. This recursion uses the conditional likelihoods calculated for the children of node k to compute the conditional likelihoods for node k itself.

The derivation of the above recursion is based on the assumption of independent evolution across different lineages and the law of total probability. The former justifies decomposition of $L(k, i)$ into a product of the two terms, enclosed in square brackets, in eqn [6], where each term represents a conditional likelihood component from one of the two lineages below node k. The component from child v is computed by summing over all possible states ($s_1 \in \{A,G,C,T\}$) to which state i could have changed to and for each possible state computes the probability of changing to that state (i.e., $p_{is_1}(t_v)$) times the probability of everything that is observed below node v, given that node v's state is s_1. A similar reasoning can be used to describe the component corresponding the other child of k — node w.

To turn the recursion in eqn [6] into an algorithm, we need to initialize the recursion by defining the $L(k, i)$ values for all terminal nodes. For any given terminal node k, $L(k, i)$ is set to 1 when state i is the observed state and 0 otherwise. This initialization process can be adjusted to account for situations when data are either missing or partially observed at the terminal nodes (Felsenstein, 2004). Once all of the terminal node $L(k, i)$'s are initialized, we continue calculating conditional likelihoods for internal nodes up the tree, computing them only if the corresponding conditional likelihoods for their children have been computed. The procedure ends after calculating the conditional likelihoods at the root ($L(\text{root}, i)$, for all i); the resulting site likelihood is computed as $\sum_i \pi_i L(\text{root}, i)$, where $i \in \{A,G,C,T\}$.

Root Invariance and the Pulley Principle

Before discussing the specifics of maximum likelihood phylogeny estimation, it is essential to understand the types of phylogenetic trees that will be estimated. Even though it may seem like we are estimating rooted phylogenies, it turns out that under our assumption of substitution model reversibility and without further assumptions or external information maximum likelihood methods can only estimate unrooted trees. This result is a direct consequence of the Pulley Principle, first discussed by Felsenstein (1981). Under the assumptions of a reversible substitution model, unconstrained branch lengths, and a root nucleotide distribution at equilibrium, the Pulley Principle states that the root may be placed anywhere on the tree without affecting the likelihood. This implies that the root is unidentifiable using likelihood methods for phylogeny estimation because the likelihood is invariant to the placement of the root. In fact, we are not estimating a single rooted tree, but an equivalence class of rooted trees that corresponds to a unique unrooted tree (Felsenstein, 1981). In **Figure 3**, we present two rooted trees that lie in the same equivalence class; the unrooted tree that corresponds to this

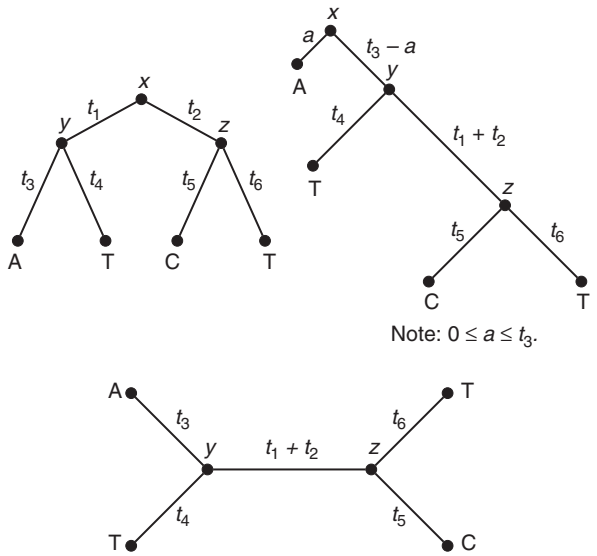

Figure 3 Three trees with equivalent likelihood values under the assumptions of the Pulley Principle. The Pulley Principle states that the root of a tree may be placed anywhere on the tree without affecting the likelihood value. The two rooted trees (top) are contained within a larger equivalence class of rooted trees that uniquely corresponds to the given unrooted tree (bottom).

equivalence class is shown below the two rooted trees. As we shift the root node associated with x, the tree topology and branch length parameters change, but the likelihood value remains the same.

Likelihood Maximization

Branch Length Optimization

Now that we have described how phylogenetic likelihoods can be computed, we will begin discussing how to maximize these functions with respect to the tree topology τ, branch lengths $\mathbf{t}$, and substitution model parameters $\boldsymbol{\theta}$. Phylogenetic maximum likelihood algorithms proceed by iterating between two major algorithmic steps: (1) for a given tree topology, find optimal branch lengths and substitution model parameters; (2) obtain a tree topology that maximizes the likelihood given branch lengths and substitution model parameters. We start with the continuous optimization problem.

The problem of optimizing the phylogenetic likelihood function, or equivalently the log-likelihood, over branch lengths and substitution model parameters falls into a class of nonlinear, non-convex optimization problems. This means that no existing optimization algorithm can guarantee to solve this problem. However, in practice, this problem can be solved by a myriad of hill-climbing optimization methods, including the Newton–Raphson method and the expectation–maximization (EM) algorithm. Although computational ingredients for the Newton–Raphson (Schadt *et al.*, 1998; Kenney and Gu, 2012) and the EM algorithm (Holmes and Rubin, 2002; Hobolth and Jensen, 2005) are available, often simpler methods are preferred. For example, many implementations of phylogenetic maximum likelihood estimation update branch lengths one at a time, rather than jointly (Guindon and Gascuel, 2003).

In addition to lack of optimization convergence guarantees, there is no theory that says that a phylogenetic likelihood will have a unique maximum, although multiple maxima are rarely seen in practice (Felsenstein, 2004). Steel (1994) provides an example that shows maximum likelihood branch lengths for a given tree are not necessarily unique. Chor *et al.* (2000) found sequence alignments that have multiple branch length optima on the same tree. In contrast, Rogers and Swofford (1999) performed numerous simulation studies and concludes that it's extremely unlikely that maximum likelihood estimation results in multiple local optima for a given phylogenetic tree. Given these intriguing results, it is not surprising that studying properties of the phylogenetic likelihood function remains an active research area.

Tree Topology Search

Because there exist finitely many tree topologies, we could, in principle, optimize branch lengths and substitution model parameters for every possible tree topology and choose the tree that had the highest likelihood value as the maximum likelihood tree. Unfortunately, the set of possible topologies is extremely large (Felsenstein, 1981) so naively searching over this tree space is computationally infeasible. Various heuristics are used to find the topology that has the highest likelihood. All of these methods use local modifications of the previously visited tree topologies to find a new tree with a higher likelihood. For example, early methods, such as the PHYLIP (Felsenstein, 1989) and PAUP* (Swofford, 2003) packages, traverse the tree topology space greedily by comparing the likelihood values between these modified trees and by choosing the topology that increases the likelihood the most; the procedure will end if there are not any trees that increase the likelihood. While this local tree search is faster than the exhaustive search over all possible trees, it is still inefficient because it has to optimize branch lengths and evaluate likelihoods for all of the rejected trees (Guindon and Gascuel, 2003).

Many other tree search heuristics have been introduced to improve upon the aforementioned hill-climbing methods. Salter and Pearl (2001) proposed a stochastic search algorithm that uses simulated annealing to move through tree space. This stochastic search was found to be faster and less likely to become trapped in local optima, when compared to PHYLIP and PAUP, for several simulated and real data examples. The improvement in speed is largely due to the fact that stochastic search algorithms gradually optimize branch lengths and other model parameters as the tree search goes on and avoid the full optimization steps used within hill-climbing methods for every candidate tree (Salter and Pearl, 2001). In addition, Guindon and Gascuel (2003) presented a simple hill-climbing algorithm that adjusts the tree topology and branch lengths simultaneously. By performing joint optimization, this procedure tends not to get stuck at local modes of the likelihood and produces extremely accurate estimates of the tree topology (Guindon and Gascuel, 2003). Although these optimization strategies work well in many practical situations, it is important to keep in mind that all local hill-climbing optimization

methods are prone to getting stuck in local maxima and may not return the true MLE phylogeny as a result.

Consistency of Maximum Likelihood Estimates

An important question of interest is whether the maximum likelihood phylogenetic estimation process is able to reconstruct the true phylogeny as we gather more and more data. More precisely, as we collect data at more and more sites for a fixed set of sequences, will the maximum likelihood phylogeny estimates tend to the true phylogenetic tree? As we briefly mentioned before, consistency holds for a wide class of MLEs under sufficiently broad regularity conditions (van der Vaart, 1998). Despite this, consistency for maximum likelihood phylogenies has been hard to establish due to the complex nature of the parameter space.

Felsenstein (1973) suggested that consistency could be proven for maximum likelihood phylogeny estimates by using a modified version of a general consistency proof found in Wald (1949), although the proof was never explicitly given. Chang (1996) presented one of the earliest proofs of consistency, but did not consider the branch length parameters in his setup. RoyChoudhury *et al.* (2015) provide a complete proof of consistency by verifying the Wald conditions in this setting; their proof is dependent on a previously constructed metric space for phylogenetic trees (Billera *et al.*, 2001). Thus, RoyChoudhury *et al.* (2015) show that consistency will hold for maximum likelihood phylogenies assuming the correct model of evolution is used. A discussion regarding phylogenetic MLE consistency under model misspecification can be found in Felsenstein (2004).

Bootstrap for Phylogenies

In the process of phylogenetic estimation, it is natural to desire an estimate of the uncertainty surrounding the reconstructed phylogeny. In this section, we explain how the nonparametric bootstrap, a general statistical technique for assessing sampling variability of an estimator (Efron, 1979), can be used to assign confidence to phylogenetic MLEs. Before getting into the details of the bootstrap procedure, it is instructive to imagine what would be a statistically ideal way to estimate phylogenetic uncertainty. Suppose we could repeatedly 'rerun' evolution along the same true phylogenetic history to obtain replicated molecular sequence alignments. Then, estimating phylogenies based on these alignments via maximum likelihood would tell us something about the sampling variability of our estimation procedure. For example, if the phylogenies obtained from the replicated reruns of evolution were nearly identical, we would conclude that our phylogenetic estimation procedure is very precise, enjoying low sampling variability. The idea behind the bootstrap is to get around rerunning evolution, which is clearly infeasible, by resampling the observed data.

Bootstrap Description

The bootstrap procedure starts by generating B replicate datasets. Each replicate dataset is obtained by sampling n alignment sites with replacement (i.e., sampling columns) from the observed alignment. Maximum likelihood estimation is then applied to each of these B bootstrapped sequence alignments, and uncertainty is assessed by summarizing the similarities between the bootstrapped phylogenies (Felsenstein, 1985). Figure 4 displays some bootstrap datasets drawn from an observed sequence alignment; note that each dataset consists of randomly sampled columns from this observed alignment. While bootstrap sampling is conceptually simple, summarizing bootstrapped trees is not an easy task so we devote the next subsection to this topic. For a more detailed account of bootstrap sampling, please see the other article contained within this encyclopedia.

Summarizing Bootstrapped Phylogenies

We are interested in understanding how to summarize the similarities among the B bootstrap trees because a high degree of similarity corresponds to a low degree of variability. For instance, if a particular tree split – a bipartition of the species set – appears in most of the bootstrap trees, then we will be more confident about that tree split being in the true phylogeny. One way to keep track of which tree splits appear most often in the bootstrap trees is to construct a majority-rule consensus tree – a tree that is constructed from tree splits that appear in a majority of the bootstrap trees. This is done by first enumerating all of the tree splits that occur on the bootstrap trees and then retaining only those splits that appear in more than 50% of the trees. We can then construct the consensus tree using this remaining collection of splits. In building the

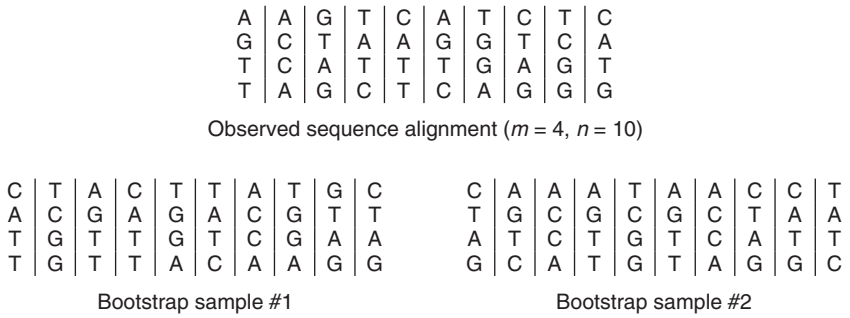

Figure 4 An example of bootstrap sampling for sequence alignment data. We obtain bootstrap datasets by randomly sampling $n=10$ sites (i.e., columns) with replacement from the observed sequence alignment (top). We provide two examples of possible bootstrap datasets (bottom).

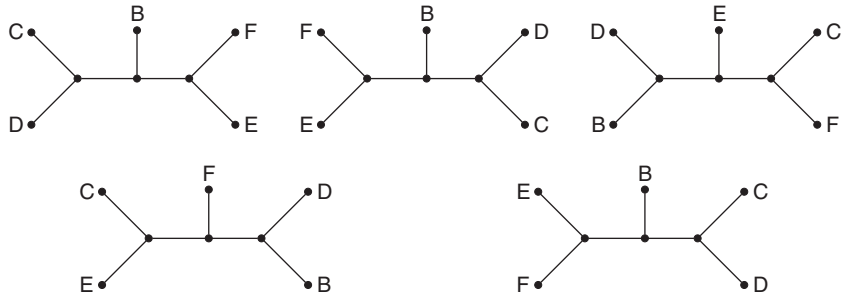
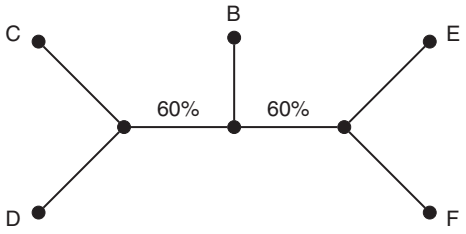


Tree collection

Tree splits	Counts
$\{C, D\}\|\{B, E, F\}$	3
$\{B, C, D\}\|\{E, F\}$	3
$\{B, D\}\|\{C, E, F\}$	2
$\{B, D, E\}\|\{C, F\}$	1
$\{C, E\}\|\{B, D, F\}$	1

Number of appearances of each tree split



Majority-rule consensus tree

Figure 5 Consensus tree example with five species $\{B,C,D,E,F\}$. At the top of the figure, we display a sample collection of trees from which we'll build a consensus tree. A table enumerating all possible tree splits from this collection and their respective counts is given in the middle of the figure. At the bottom of the figure, we display the only consensus tree that can be constructed from the majority tree splits, which are $\{C,D\}|\{B,E,F\}$ and $\{B,C,D\}|\{E,F\}$. Note that we label each tree split with the corresponding percentage of the tree collection it appears in.

consensus tree, the procedure always avoids putting two splits that might conflict on the same tree because there will always be at least one bootstrap tree where the two splits coexist (Felsenstein, 1985). Thus, it is guaranteed that a consensus tree can be built from these tree splits. Once the tree is constructed, it is common to label each split with the percentage of bootstrap trees it appears in. This helps us understand which parts of the consensus tree we should have strong or weak confidence in. Figure 5 illustrates how this tree building process works by constructing a majority-rule consensus tree for a simple collection of trees. For a more comprehensive treatment of consensus trees, please see the other article contained within this encyclopedia.

Maximum Likelihood and More Complex Models of Evolution

So far, we have limited our discussion of phylogenetic maximum likelihood estimation to the very basic models of molecular evolution. However, assuming more complex models does not significantly change the maximum likelihood machinery. For example, it is widely recognized that when modeling evolution of molecular sequences it is important to account for a possibility of different substitution rates across sites (Yang, 1994). Therefore, most implementations of phylogenetic maximum likelihood estimation include models that deal with such rate heterogeneity. Model extensions that relax the assumption of site independence (Hobolth, 2008) and that impose constraints on substitution rates across branches of the phylogeny (Rambaut and Bromham, 1998) are also possible. Increasing model complexity may eventually lead to a situation where maximum likelihood estimation ceases to produce a unique solution, so studying identifiability of models becomes an important avenue of research (Rhodes and Sullivant, 2012).

Example: Primate Phylogeny Estimation

In this section, we present an example of maximum likelihood phylogeny estimation applied to an alignment of mitochondrial DNA sequences from seven different primate species: human, chimpanzee, bonobo, gorilla, Bornean orangutan, Sumatran orangutan, and gibbon (Yang *et al.*, 1998). The length of the alignment is 9993 sites. We are interested in understanding the ancestral relationships among these species. We use a general time-reversible substitution model, with a gamma distribution used to model rate variation across sites. After finding the maximum likelihood phylogeny estimate using the PhyML package (Guindon *et al.*, 2010), we perform

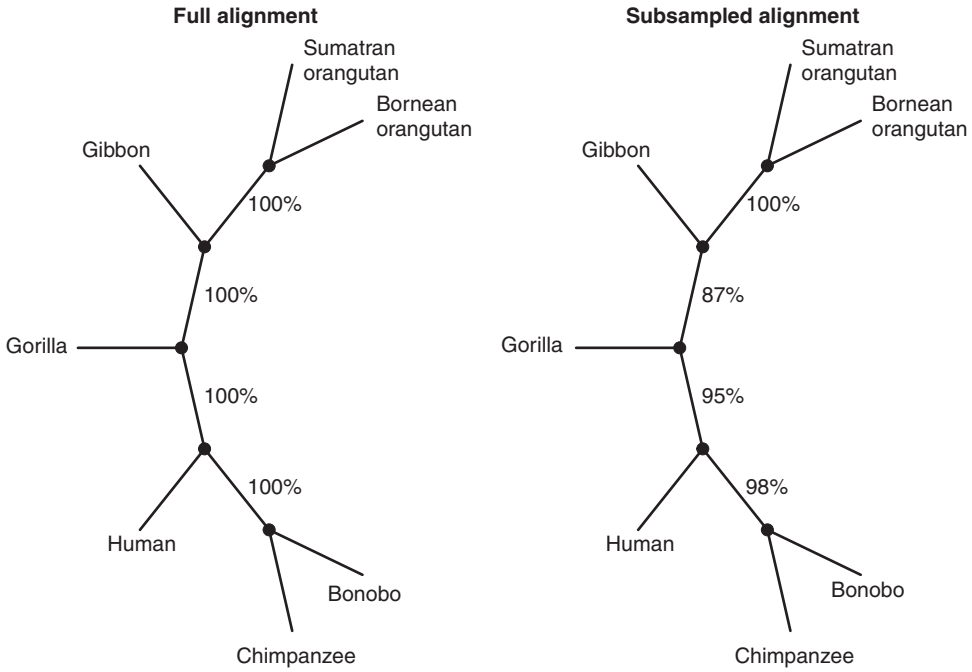


Figure 6 Maximum likelihood phylogenies with corresponding bootstrap percentages for the primate example using both the full sequence alignment and a randomly subsampled alignment containing 500 sites.

the bootstrap and obtain 1000 bootstrapped trees. We carry out this procedure on the full sequence alignment and on an alignment that we constructed by randomly subsampling 500 sites from the original alignment.

Figure 6 displays the maximum likelihood trees with corresponding labeled bootstrap percentages; note that the majority-rule consensus trees have been omitted from Figure 6 as they coincide with the maximum likelihood trees in this example. However, maximum likelihood trees and bootstrap consensus trees could be different, which usually happens when maximum likelihood phylogenetic inference is not very precise. In this example, maximum likelihood trees of both the full and subsampled alignment share the same topology and have similarly sized bootstrap percentages. However, notice that artificially reducing the size of the data yields more uncertainty reflected in lower bootstrap support of internal branches of the reconstructed phylogeny on the righthand side of Figure 6. Our analysis suggests an accepted relationship among the primates, with bonobos and chimpanzees being most closely related to humans (Mailund *et al.*, 2014).

EDITOR IN CHIEF

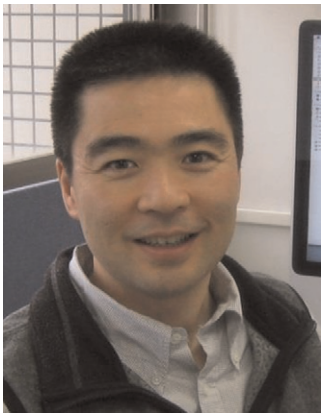
Richard M. Kliman, PhD, is Professor of Biological Sciences at Cedar Crest College in Allentown, Pennsylvania. He received his BA from Colby College in biology and music. His graduate work at Wesleyan University focused on quantitative genetics of circadian rhythms and photoperiodism in the Djungarian hamster, *Phodopus sungorus*. As a postdoctoral fellow at Rutgers University and Harvard University, he studied molecular evolution and population genetics. Prior to Cedar Crest College, he taught at Radford University in Virginia and Kean University in New Jersey. He has also served as a program director in the Division of Environmental Biology at the US National Science Foundation (NSF).

Kliman's research interests center on questions in molecular evolution, including the evolution of codon usage bias in a variety of organisms; speciation and natural history; and ecology and conservation. Much of this work has relied on population genetics/genomics and bioinformatics approaches. He has also collaborated with Cedar Crest colleague John Cigliano on an Earthwatch-supported "before-after-control-impact" study on the effects of a new marine reserve in Belize on queen conch populations. His research in evolutionary and ecological genetics has been supported by the US National Institutes of Health and by Conservation International.

Kliman has served on the editorial boards of *Genetica* and *The Journal of Molecular Evolution*. He has been deeply involved in evolution education, helping to coordinate "Undergraduate Diversity at SSE/SSB," an NSF-supported program to bring a diverse group of undergraduates to the annual Evolution research conference. He was a lead editor of population/quantitative genetics and evolutionary genetics for *Nature Education/Scitable* at its inception. He is a member of the Education and Outreach Committee of the Society for the Study of Evolution, and editor of the society's peer-reviewed educational resource, the *EvoEd Digital Library*.

SECTION EDITORS



Hiroshi Akashi is a Professor of Evolutionary Genetics at the National Institute of Genetics, Japan. He worked with Marty Kreitman for his PhD in Ecology & Evolutionary Biology from the University of Chicago (1996) and with John Gillespie as a postdoctoral fellow at UC Davis. He has been a faculty member at the University of Kansas (1998–2000), Penn State University (2000–2008), and NIG (2009–present). Akashi's research focuses on inferring causes of genome evolution, especially weak selection, from within and between species sequence variation. His studies of codon usage employed population genetic methods to detect natural selection acting at its limit of efficacy and identified a phenotypic basis of natural selection (translational accuracy) from sequence comparisons in *Drosophila*. Extensions of this work revealed constraints related to biosynthesis that act globally on compositional properties of microbial proteins. The interplay of weak evolutionary forces appears to shift frequently among closely-related species and current interests include tests of adaptive changes in protein/DNA composition.

Tim Coulson's primary interest is in creating better links between the fields of ecology and evolution. He does this by developing theory, parameterising models for field and laboratory systems, making predictions from these models, and, where possible, testing these predictions with experiments. He works on a range of systems, from bulb mites within the laboratory, to guppies living in streams in Trinidad, to wolves in Yellowstone. His motivation to do this comes from observations that ecological and evolutionary change can be observed occurring on similar time scales, yet ecological theory typically ignores evolutionary processes and vice versa.

Tim was awarded his PhD in plant ecology from Imperial College, London, in 1994. He moved on to research genotype-by-environment interactions as Natural Environment Research Council (NERC)-funded post-doc at the Institute of Zoology in London. He remained at the Institute on a fellowship where he developed models to investigate the economic and life history consequences of a range of population management strategies. In 2000 he moved to the University of Cambridge, where he briefly lecturered in the Zoology department. In 2004 he moved back to Imperial College London as a senior lecturer where he started developing models that allow the simultaneous investigation of the dynamics of life history, populations, and quantitative characters. In 2007 he became Professor of Population Biology at Imperial College London. He left Imperial in 2013 to take up his current position as Professor of Zoology at the University of Oxford. He is also a Professorial fellow of Jesus College, Oxford.

Andrew Forbes

Rosemary Gillespie is a Professor at the University of California, Berkeley, where she also holds the Schlinger Chair in Systematics. She is Past President of the *International Biogeography Society* and Trustee and Fellow of the *California Academy of Sciences*, and serves as Associate Editor for *Molecular Ecology*. Gillespie was born and educated in Scotland, receiving her BSc in Zoology from Edinburgh University in 1980. She came to the US to conduct graduate work on the behavioral ecology of spiders at the University of Tennessee. After her PhD she spent several months at the University of South in Tennessee, and then started work at the University of Hawaii in 1987, initially as a postdoc, and then in 1992 as Assistant Professor in Zoology and Researcher in the Hawaiian Evolutionary Biology Program. It was during her first year in Hawaii that she discovered an adaptive radiation of *Tetragnatha* spiders. She left Hawaii in 1999 to join the faculty at the University of California in Berkeley, where she continues her research focus on the islands of the Pacific, Hawaii in particular, using islands of known age and isolation to assess the combined temporal and spatial dimension of biogeography and determine patterns of diversification, adaptive radiation, and associated community assembly.

David Guttman received his PhD from Stony Brook University in 1994 working with Daniel Dykhuizen on questions related to the role and importance of recombination in structuring genetic diversity in bacterial populations. He followed this with a postdoc in molecular evolution with Brian and Deborah Charlesworth at the University of Chicago, and a second postdoc at the University of Chicago with Jean Greenberg to gain experience in the fields of molecular plant pathology and plant-microbe interactions. He started his faculty position at the University of Toronto in 2000, and is currently a Professor in the Department of Cell & Systems Biology (CSB). He is also the Associate Chair for Research in CSB, founder and Director of the University of Toronto Centre for the Analysis of Genome Evolution & Function, and Canada Research Chair in Comparative Genomics. He has served as the Chair of the American Society for Microbiology, Division R (Evolutionary and Genomic Microbiology), and was the *PLoS Pathogens* Section Editor for Bacterial Evolution & Genomics.

Dr. Guttman runs a highly diverse research program generally focused on bacterial evolutionary genomics, with three major foci: (1) the evolution of host specificity and virulence in plant pathogenic bacteria; (2) microbial comparative genomics; and (3) studies of the human and plant-associated microbiome. He is best known for elucidating and linking evolutionary and mechanistic processes that determine the course and fate of bacterial infections, and characterizing the impact of genetic variation on the balance between disease and immunity.

Norman A. Johnson, the section editor for Applied Evolution, is an evolutionary geneticist and author. He received his PhD from the University of Rochester in 1992 and did postdoctoral research at the University of Chicago. His research interests have generally focused on aspects of speciation, specifically those related to the genetics and evolution of hybrid incompatibility: sterility, inviability, or other reduction of fitness in hybrids between species. Dr. Johnson, an adjunct professor in the Biology Department at the University of Massachusetts at Amherst, has taught classes there, as well as at Hampshire College, the University of Texas at Arlington, and the University of Chicago.

Dr. Johnson also has a long-standing commitment toward improving the communication of science in general and evolutionary biology in particular to other scientists, educators, and the public at large. He is the author of *Darwinian Detectives: Revealing the Natural History of Genes and Genomes* (Oxford University Press: 2007), a book geared to general audiences that shows how biologists use DNA sequence data to make inferences about evolutionary processes. He also was the lead organizer for a working group on communicating human evolution at the National Evolutionary Synthesis Center (NESCent).

Laura Kubatko received a PhD in Biostatistics from The Ohio State University (OSU) in 1999. After seven years on the faculty at the University of New Mexico, she returned to OSU in the Fall of 2006, and is now Professor of Statistics and of Evolution, Ecology, and Organismal Biology at OSU. Laura served as an Associate Director of the Mathematical Biosciences Institute at OSU from 2013–2015. At OSU, she is a Faculty Affiliate of the Initiative in Population Research, and a Faculty Affiliate in Translational Data Analytics (TDA@OSU). She holds appointments as an Affiliate Faculty Member at the Battelle Center for Mathematical Medicine at Nationwide Children's Hospital in Columbus and as an Adjunct Research Scientist at Lovelace Respiratory Research Institute in Albuquerque, NM. Laura's research interests are in statistical genetics, with a focus on the development of statistical methods for inferring phylogenies from molecular data. Her recent work in this area concentrates on bridging the gap between traditional phylogenetic techniques and methodology used in population genetics analyses, primarily through the application of coalescent theory to species-level phylogenetic inference. She develops and distributes several software packages for phylogenetic inference, and has been an active member of the *Society of Systematic Biologists*. She has served as an Associate Editor for the journal *Systematic Biology* since 2007.

Amy Litt has been studying plant evolution and diversity since her PhD on floral structure and evolution in the neotropical plant family Vochysiaceae, known for its beautiful but unusual flowers many of which have only one petal and one stamen. While completing her PhD in plant systematics and morphology in the joint City University of New York/New York Botanical Garden Plant Sciences program under Scott Mori and Dennis Stevenson, she became interested in the molecular basis of plant diversity. She did her post-doc in the developmental genetics lab of Vivian Irish at Yale University on the evolution of a family of transcription factors involved in flower development, and she continues to study the functional evolution of this gene family currently. After one year on the faculty of University of Alabama, she moved back to The New York Botanical Garden as Director of Plant Genomics, where she developed her research program studying the evolution of plant form along two paths: studying evolutionary changes in genes to see how those changes affected flower and fruit form; and identifying the genes that underlie differences in form among closely related species. Dr. Litt also served as a program director in Plant, Fungal, and Microbial Development and Evolutionary Development at the National Science Foundation. She recently moved to the University of California at Riverside, where she continues to study the genetic basis of plant diversity.

Maria E. Orive is a professor of evolutionary genetics in the Department of Ecology and Evolutionary Biology at the University of Kansas. Her research in theoretical population genetics aims to develop mathematical models that provide a conceptual framework for exploring important questions in evolutionary biology and analytical tools for demographic and genetic data. Her work has considered levels of selection and mutation in organisms that reproduce both sexually and asexually, the relationship of population structure and life-history attributes to gene flow and genetic diversity, and models of within- and between-host pathogen and symbiont population dynamics. Orive received her BS from Stanford University and her PhD from the University of California at Berkeley. After spending two years as a postdoctoral researcher in genetics at the University of Georgia, she was an NSF-NATO Postdoctoral Fellow at the University of Edinburgh. Her research has been funded by multiple grants from NSF and NIH. In 2007–2008, she was the Carl and Lily Pforzheimer Foundation Fellow at the Radcliffe Institute for Advanced Study (Harvard University), and has served as the University Faculty Ombudsman for the University of Kansas since 2007.

Daniel Ortiz-Barrientos is an Associate Professor in evolutionary genetics in the School of Biological Sciences at The University of Queensland, Brisbane, Australia. During his scientific career he has investigated the ecological and genetic basis of speciation both in plants and animals. His current research program explores the early stages of speciation, the molecular basis of parallel speciation, and the interplay between recombination and natural selection during the origin of new species. His research funds come from The Australian Research Council. He is married to Antonia Posada, and is the father of three energetic and beautiful kids.

Claudia Russo was born in Leeds, England, but has lived in Rio de Janeiro, Brazil since she was two years old.

Claudia has an academic major in Ecology from Universidade Federal do Rio de Janeiro completed in 1989, and finished her Master's thesis in 1991 on population genetics of two actiniid species of sea anemones with different reproductive strategies, under the supervision of Associate Professor Antonio Mateo Sole-Cava. Her PhD dissertation was on the diversification of drosophilids and on the use of a known phylogenetic tree to estimate the reliability of tree building methods. The dissertation was completed in 1995 under the supervision of the Evan Pugh Professor Masatoshi Nei who recently received the prestigious Thomas Hunt Morgan Medal. Her graduate degrees were obtained as a student at the Genetics Program from the Universidade Federal do Rio de Janeiro and as a visiting scholar at the Pennsylvania State University (1992–1995).

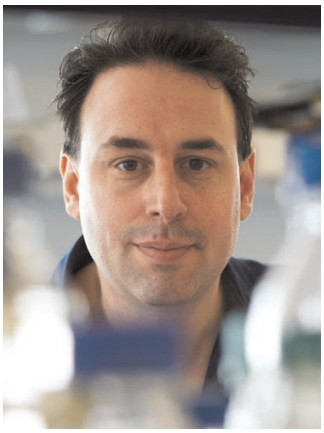
Claudia is currently the Head of the Genetics Department at the Federal University of Rio de Janeiro, having been a member since 1997. Claudia has supervised 13 Master's dissertations, eight PhD theses and seven post-docs, of which eight are now Assistant Professors at universities in Brazil and abroad. She has published 42 academic papers that have been cited over 1,200 times. Her *h-index* is 14. Since 2012, Claudia has been a member of the editorial board, and an associate editor of the *Molecular Biology and Evolution* journal. Since 2012 she has been a council member for the Pan American Association of Computational Interdisciplinary Sciences and since 2009 for the Brazilian Association for the Advancement of Science.

Claudia's general academic interests are on key aspects of animal phylogenetics, including their diversification patterns in time and space. She has worked with various metazoans groups but more prominently on marine sponges, sea anemones, arthropods, passerine birds, and mammals. Claudia has also published on the use of known phylogenetic trees to estimate the efficiency of phylogenetic methods in recovering and rooting those trees. More recently, she has developed some interesting *hands-on* educational tools for evolutionary biology practices in the classroom.

Karen E. Sears is an evolutionary developmental biologist whose primary research goal is to determine how developmental variation within a species produces congenital malformations in humans, and among species generates new evolutionary forms in mammals. Dr. Sears earned her PhD from the University of Chicago, did postdoctoral research at in the Howard Hughes Medical Institute (HHMI) lab of Dr. Lee Niswander, and joined the faculty of the University of Illinois at Urbana-Champaign. At Illinois she holds positions as an Associate Professor in the Department of Animal Biology, a Faculty Member in the Institute of Genomic Biology, and an Affiliate of the Program in Ecology, Evolution and Conservation Biology and the Department of Cell and Developmental Biology. She is also the President of the Pan American Society for Evolutionary Developmental Biology. She has authored or co-authored over 35 publications including first-authored publications in *Nature*, *Proceedings of the National Academy of Sciences*, and *Evolution*. She has served as a principal investigator on multiple, nationally-funded research projects, and presented invited seminars at more than 30 institutions and symposia. She is routinely ranked among the top 10% of Illinois professors for her teaching, and was a featured scientist in the PBS/HHMI documentary "*Your Inner Fish*."

Vassiliki "Betty" Smocovitis is Professor of the History of Science in the Department of Biology and in the Department of History at the University of Florida. Her areas of expertise include the history of evolutionary biology, genetics and systematics and the history of botany. She is best known for her contributions to understanding the historical event known as the "evolutionary synthesis" and in gaining greater understanding of the origins of the discipline of evolutionary biology. She has published extensively on both the intellectual and social aspects of the history of evolutionary biology including a history of the Society for the Study of Evolution, a history of the Darwin Centennial of 1959, and the integration of botany, genetics, and anthropology into the evolutionary synthesis. She was the contributor to the *Oxford Bibliographies* entry on Charles Darwin at over 25,000 words and the entry on the modern synthesis. She is the author of *Unifying Biology: The Evolutionary Synthesis and Evolutionary Biology* (Princeton: Princeton University Press, 1996).

Nina Wedell is a professor of evolutionary biology with research interests focused on the evolutionary ecology of sex. She has worked extensively on various aspects of sexual selection and sexual conflict, in particular on the role of selfish genetic elements in reproductive biology. Nina is the Academic lead for the Behaviour research group at the University of Exeter.



Jason Wolf is Professor of Evolutionary Genetics in the Department of Biology & Biochemistry and The Milner Centre for Evolution at the University of Bath. His research is unified with a special focus given to understanding the influence that frequently ignored or under-appreciated sources of genetic variation have on the genotype-phenotype relationship and how this, in turn, influences evolutionary processes. He integrates theoretical, computational and empirical quantitative and population genetic techniques to achieve this goal. He is particularly interested in understanding the evolutionary consequences of various types of interactions, including gene interactions (epistasis), parent-offspring interactions and social interactions. He received a PhD from the University of Kentucky, after which he was a postdoctoral researcher at Indiana University and a US National Science Foundation Postdoctoral Fellow at Washington University School of Medicine. Prior to moving to the University of Bath he held positions at the University of Tennessee and the University of Manchester. He won the Dobzhansky Prize from the Society for the Study of Evolution, a Young Investigator's Prize from the American Society of Naturalists and the Scientific Medal from the Zoological Society of London.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Alphabetical Contents List

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

All articles within the encyclopedia have an extensive list of cross-references which appear at the end of each article, for example:

Adaptive Mutation Controversy

> *See also*: Directional Selection and Adaptation. Microbial Experimental Evolution. Mutation, Population Genetic Models of. Natural Selection, Introduction to. Recombination in Bacterial Populations

3. Subject Classification List

A subject classification list has been developed by the editors to group articles under broad topics. This index is useful for making broad connections between articles and locating the relevant article for a topic that is covered in more than one article.

4. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

5. Contributors

A full list of contributors appears in the front mater of each volume.

PREFACE

The *Encyclopedia of Evolutionary Biology* was developed to provide an authoritative overview of the current state of evolutionary biology. It was an ambitious goal, especially given that the field did not pause for the two and a half years needed to complete the project. The encyclopedia's 15 section editors collaborated to ensure that content gaps were kept to a minimum, and their efforts show. When the project was completed, we had compiled 256 entries, covering a broad range of topics selected by the editors to ensure a comprehensive resource. It was a privilege to read every one of these entries, and I was truly humbled by the collective efforts of hundreds of authors to communicate the excitement and sophistication of a field of study that touches on every conceivable topic in biology today.

There are many ways to envision an encyclopedia of evolution, and we had to choose an approach that would lead to a cohesive resource. Readers will note that, in the more organismal-focused entries (edited by David Guttman, Amy Litt, and Claudia Russo), there is an emphasis on *diversification* of life. We did not set out to provide an overview of the diversity of life, as such a goal would be untenable; rather, we focused on the evolutionary processes and key events responsible for diversity. Numerous entries deal with speciation, life history evolution, evolutionary biogeography, and coevolution. These entries (edited by Daniel Ortiz-Barrientos, Tim Coulson, Rosemary Gillespie, and Andrew Forbes) bring to light how the evolution and diversification of life is intimately entwined with ecology. Of course, there is extensive coverage of population genetics, quantitative genetics, evolutionary developmental biology, the evolution of sex and mating systems, molecular/genome evolution, and phylogenetic analysis (edited by Maria Orive, Jason Wolf, Karen Sears, Nina Wedell, Hiroshi Akashi, and Laura Kubatko), all fundamental to our understanding of evolutionary processes. And as thematic bookends, several entries (edited by Betty Smocovitis and Norman Johnson) cover the history of evolutionary biology and applications of evolutionary biology.

Readers of the encyclopedia will find that entries are generally pitched at a somewhat advanced level, although with great effort by authors to make entries as accessible as possible to a broad audience. Encyclopedias, like living organisms, are compromises. If all entries could be readily understood in their entirety by first-year university students, this encyclopedia would be of limited value to experts. At the other extreme, if entries were extremely technical – and our authors were undoubtedly capable of producing such entries – the encyclopedia might be inaccessible to students. While there is, by necessity, variation among entries in this regard, we settled on a general target: the majority of an entry should be accessible to a motivated, advanced undergraduate. Readers are, of course, directed to additional resources, with authors providing bibliographies and lists of further reading.

As with any undertaking of this scale, there are many individuals who should be recognized for their roles in the development of this encyclopedia. Special thanks go to Norman Johnson for early discussions that helped us develop the general structure of the encyclopedia. The dedicated and distinguished team of section editors deserves the credit for drafting the table of contents, recruiting authors, and working extensively with authors to ensure the highest quality product. It should go without saying that the high quality of this encyclopedia ultimately reflects the efforts of the editors and authors. Finally, the project management and development teams at Academic Press were always ready to assist, and while it is not possible to name everyone who contributed to the effort, I am particularly indebted to Simon Holt, Will Bowden-Green, Paula Davies, and Justin Taylor.

Richard Kliman
Editor in Chief

FOREWORD

What is life, how did it originate, and what accounts for its great diversity? These are fundamental scientific questions that have and will always be the source of endless fascination and wonderment. Charles Darwin and Alfred Russel Wallace provided an answer to the latter question through the grand idea of evolution and the process of natural selection. Darwin also speculated on the where question of the origin of life by hypothesizing it originated long ago in a warm lagoon. Most importantly, however, Darwin shattered the notion that the natural world is static and replaced it with a biology that is dynamic and continually changing. Species are not fixed, typological entities. Rather, they are related by common descent in a great tree of life. Analogous to tracing one's ancestors back in time in a pedigree, one can climb down the tree along its branches and boughs that connect species in a hierarchy of phylogenic relationships until reaching the base of its trunk and the common ancestor of us all. One can also climb up the tree and quickly realize that evolution produces a seemingly endless array of new forms (and sometimes extinction). Thus, as the tree of life grows, populations are continuously evolving and diverging from one another, creating novel varieties and races (showing slight differences) that eventually evolve into new species (separated by distinct gaps). And natural selection – the differential survival of individuals in populations possessing heritable traits favorable for their survival and reproduction – is the primary materialistic process causing evolutionary change and the origin of new species.

The *Encyclopedia of Evolutionary Biology* chronicles our current state of understanding of the dynamics of evolution and its product, Darwin's great tree of life. A diversity of seminal topics are covered including overviews of the history of the field, the origin of life, the history of life (including the phylogentic methods used to reconstruct life's history), the myriad ways and means (including mechanisms other than natural selection) that evolution is affected, and the important roles that conflict versus cooperation, and mergers and acquisitions, occurring within across varying levels of biological organization, play in the narrative of life. In so doing, the *Encyclopedia* highlights the grandeur in Darwin's view of life. We are not separate, but rather a twig along a branch of life, a twig that has evolved the ability to comprehend the existence of and our connectedness to the tree, and climb around its branches to see what has been and think about what may come. It is a wonder of life that it can look at and understand the meaning of itself.

But Darwin's grand view has even larger ramifications, going beyond providing a materialist basis for organismal change and putting us in our place. The reality of evolution also answers the question of what life is. If pressed to define life, most of us would reply with a list of the things that living organisms do. For example, living organisms metabolize, grow, develop, move, behave, mutate (are variable), and reproduce with inheritance. One can investigate these different characteristics of life separately and discern the mechanistic basis for the different processes that constitute life – the "how" of life. And such studies represent the basis for many fields of the life sciences. However, these are only the components of life and, in isolation, produce a static view of the natural world. Rather, the seminal insight is that populations of living beings possessing these characteristics have the emergent property that they evolve. Darwin's "*On the Origin of Species*" therefore not only describes how populations evolve, and as a logical extension how new species form, but also conveys the essence of what life itself is – evolution. Thus, as Theodosius Dobzhansky famously stated "nothing makes sense except in the light of evolution." The Encyclopedia wonderfully brings this view of life to light, providing the reader with the breadth of knowledge and overview of the current state of the field of evolution needed to appreciate and participate in the next major ongoing synthesis in our understanding of life, the so-called "Omics Revolution."

The study of evolution is in an accelerated phase of discovery brought about by major technical advances in our ability to DNA sequence whole genomes (genomics), and to generate profiles of mRNA transcription (transcriptomics), protein levels and enzymatic activity (proteomics), and metabolic products (metabolomics) at varying stages in the life cycle and development of organisms. This "Omics Revolution" may not change foundational evolutionary principals, per se. Our understanding of evolution has been heightened by a series of such advances in the past, including the "Modern Synthesis" when Mendelian genetics was wedded to Darwinian thinking and the "Molecular Revolution" in which genetic technology increasingly allowed allele frequencies in natural populations to be analyzed. The Omics Revolution is an extension of these pervious advances, but one in which the workings of whole organismal systems and the composition of entire communities can be gleaned at once.

Perhaps, the most important discoveries in Omics will come from linking an understanding of the process occurring at the cellular and microevolutionary level with large scale patterns and trends at the macroevolutionary scale. Previously, processes occurring within and interactions occurring among cells could be studied in at least some detail. Omics is providing an opportunity to fully understand how all of these processes interact simultaneously to result in the development and functioning of integrated, multicellular systems of life. At the other end of the spectrum, fossils attest to the evolution of new life forms through time and the creation of great and observable morphological diversity. Genomic sequencing is providing a powerful means to help accurately place these fossils within the framework of a fully resolved molecular phylogenic tree to better understand the history of life, including major trends, themes, and variation in the tempo and mode of evolutionary change. But it is the middle of the micro and macro at the branching points in the tree of life that Omics may prove most insightful. Now it is possible to not only DNA sequence large numbers of individuals within populations, but to equate these genetic differences within and between populations to morphological, physiological, and behavioral phenotypes, and discern the developmental

and physiological mechanisms by which these genetic changes produce organismal variation, diversity, and reproductive isolation – the stuff of evolution and speciation itself. Thus, we will be able to not only understand the everyday processes responsible for how the tree of life grows, but be able to translate this into a mechanistic appreciation of how these processes result in new branches on the tree forming and others dying out, giving shape to the history of being on our planet.

The field of evolution is currently inundated with a mass of Omics data and the bottleneck is the development of bioinformatic analytical tools to edit, analyze, and interpret the results. However, it is clear that many new insights are on the horizon, and even if they do not affect the root principles of evolution, soon a deep connection of the how and why of life will emerge to help forge a truly integrative evolutionary biology: The *Encyclopedia of Evolutionary Biology* is an excellent guide to prepare readers to assimilate these new findings, keeping bioinformatics grounded in the bio and providing a valuable source for seeing the tree through the forest to understanding the grand synthesis of life that is flowering.

Metazoans, Origins of

M Klautau and CAM Russo, Universidade Federal do Rio de Janeiro, Instituto de Biologia, Rio de Janeiro, Brazil

Origin of Metazoans

Metazoans are also known as animals. These are heterotrophic organisms with a multicellular organization that develop via blastula. Their cells are eukaryotic and they lack chloroplasts or walls and are organized into tissues. All metazoans probably form a monophyletic group (**Figure 1**; e.g., Wainright *et al.*, 1993; Cavalier-Smith, 1996; Borchiellini *et al.*, 1998; Philippe, 2006, 2009, 2011) with a single hypothetical last common ancestor called the Urmetazoan. It has also been suggested that the Urmetazoan was a marine organism that first appeared around 600 million years ago (Mya) (Erwin *et al.*, 2011). Nevertheless, the shape and the origin of this ancient form are yet to be ascertained, and many different theories are still being debated. One aspect concerning the origin of the metazoans is not under heavy debate; the ancestor of all animals was a protozoan (King, 2004). But, what did the ancestor look like?

A Protozoan Ancestor

When the first animals arose from protozoan ancestors, this crucial evolutionary step was a result of genomic innovation, environmental forces, natural selection, and chance (Carroll, 2001; King, 2004). In order to become multicellular, protozoans had to develop integration systems. Such systems started with the formation of molecules involved in signal transduction, adhesion, and differentiation to facilitate the communication between the cells of a multicellular organism (King, 2004).

In this sense, the advent of multicellularity would permit cell specialization and the formation of tissues that would enable the organism to perform multiple and complex tasks (Maldonado, 2014). The easiest way to enlarge your body is to increase the number of cells, a single cell has a size limit beyond which the performance of its functions would be impaired. In this sense, even the first metazoans would have been more protected against predation favoring their survival.

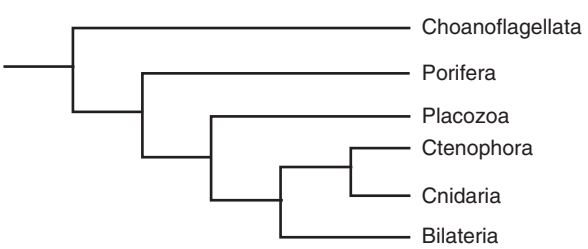

Figure 1 Tree of life showing the monophyletism of Metazoa.

The origin of the gene families involved in signaling and adhesion between cells is likely to have occurred in the first metazoans, but more recent molecular studies indicate that these gene families were already present in the protozoan ancestors. As molecular analyses strongly suggest that the choanoflagellates are the sister group of the Metazoa (Lang *et al.*, 2002; Ruiz-Trillo *et al.*, 2007, 2008; Shalchian-Tabrizi *et al.*, 2008), some of these studies also reveal the expression of genes involved in signaling in these protozoans. This finding indicates that these genes probably played a crucial role in the transition to multicellularity. But, in what context did the protozoan ancestors evolve to a multicellular life?

Another possibility is that the first metazoans appeared merging the life cycle of protozoan lineages, such as flagellates and ciliates. In this sense, flagellated and ciliated cells are not capable of division and motility at the same time. This condition might have favored mixed colonies alternating functions through the life cycle, such as the amoeboid for reproduction and the flagellated for dispersion. After some time, both cell types could have coexisted in the same colony that would be favored by natural selection and evolved to a metazoan life (Buss, 1983).

In light of this scenario, in which cell differentiation preceded the formation of colonies (Mikhailov *et al.*, 2009), the 'Synzoospore theory' (Zakhvatkin, 1949) was proposed. According to this theory, temporal cell differentiation would have preceded spatial cell differentiation in the origin of animals (Mikhailov *et al.*, 2009) and, hence, the metazoan ancestor would have been a protozoan with a complex life cycle. In time, the colony would have sedentary (or less mobile) cells capable of changing their phenotype from flagellated to amoeboid for example. The flagellated phenotype would remain attached to each other, forming the blastula (synzoospore), a primary flagellated larva (Mikhailov *et al.*, 2009; **Figure 2**). Even though it is a possible scenario, this is not the only theory for the origin of Metazoa and not even the most accepted. Traditionally, the most accepted theories are the Syncytial and the Colonial Theories.

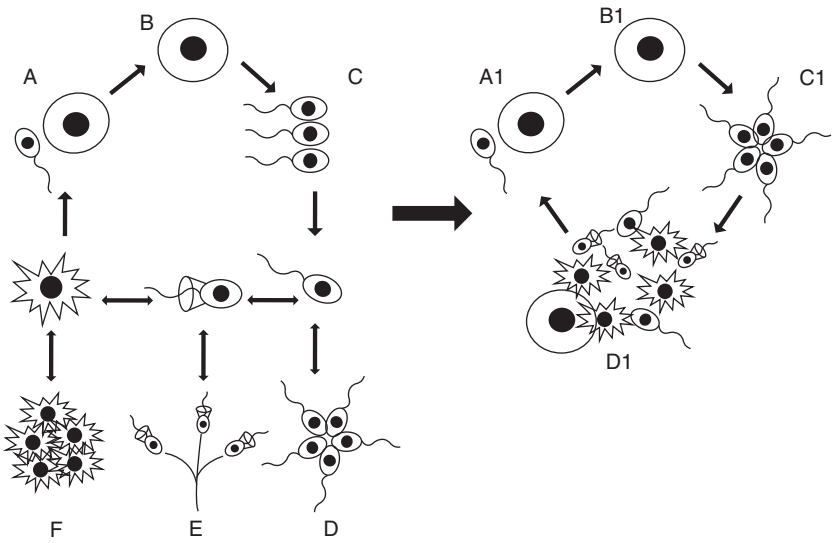

Figure 2 Synzoospore theory. A – gametes; B – zygote; C – non-feeding zoospores generated by palintomic cleavage of the zygote; D – free-living form of flagellates colony; E – sessile form of trophic flagelattes colony; F – reproductive form of amoeboid colony. A1 – gametes; B1 – zygote; C1 – synzoospore generated by palintomic cleavage of the zygote; D1 – sedentary colony with differentiated cells (trophic and reproductive cells). Redrawn from Mikhailov, K.V., Konstantinova, A.V., Nikitin, M.A., *et al.*, 2009. The origin of Metazoa: A transition from temporal to spatial cell differentiation. BioEssays 31, 758–768.

The second most accepted theory is the Syncytial Theory (Hadzi, 1953; Hanson, 1977), but it has met no strong support in current molecular analyses. The theory suggests that a multinucleate, bilaterally symmetrical, ciliate became benthic and went through cellularization, forming a cellular epithelium (**Figure 3**). This organism, that would be very similar to a flatworm (acoelomate triploblastic bilateria), would have been the ancestor of all metazoans. This would imply that simpler organisms such as sponges, ctenophores, and cnidarians would have derived from a more complex animal.

The Colonial Theory, originally proposed by Haeckel (1874), is the currently most accepted to explain the origin of metazoans. According to this theory, unicellular flagellates aggregated forming a spherical hollow colony of identical cells (the blastaea). In time, the colony went through an invagination event that produced a double layer of cells and, only then, cell differentiation started. The second stage was named gastraea by Haeckel (Mikhailov *et al.*, 2009; **Figure 4**).

Several modifications were proposed for this theory. For instance, the blastaea might have suffered ingression rather than invagination and might have been solid rather than hollow (Metchnikoff, 1883; **Figure 5**). On the other hand, Bütschli (1883) proposed the placula, a hypothetical animal that had two layers of cells and bilateral symmetry. The separation of these two layers had permitted the invagination of the ventral cells, forming the gastraea (**Figure 6**). This modification on Haeckel's original theory regarding the placula gained more strength when the *Trichoplax adhaerens* (Phylum Placozoa) was first discovered (**Figure 7**).

Metazoan tree of life. Although most researchers agree that sponges are the sister group of other animal lineages (Philippe *et al.*, 2009; Pick *et al.*, 2010; Worheide *et al.*, 2012), other authors suggest that Placozoa (Schierwater and DeSalle, 2007; Schierwater *et al.*, 2009) or Cnidaria and Ctenophora (Dunn *et al.*, 2008; Hejnol *et al.*, 2009) is the first branched off in the metazoan radiation.

The phylogenetic position of Ctenophora (**Figure 8**) as sister group of all Metazoa was originally proposed based on molecular analyses (Dunn *et al.*, 2008). This hypothesis was first received with caution as their taxon sampling was rather low (Pick *et al.*, 2010). Improving the taxon sampling, Pick *et al.* (2010) and, later, Philippe *et al.* (2011) found Porifera and not Ctenophora branching off first. Nevertheless, a very recent analysis indicated that this conclusion may be revised soon as other datasets indicate Ctenophora as the sister to the metazoans (see Halanych, 2015).

The hypothesis of Placozoa being the sister group of all the other Metazoa was proposed based on the morphological simplicity (i.e., the lowest number of cell types – 4–5 – lack of symmetry, organs, nerve or muscle cells, basal lamina, and extracellular matrix) of these organisms (Schierwater and DeSalle, 2007), and also by a combined molecular and morphological dataset (Schierwater *et al.*, 2009). Some criticism was made to this study, leading to a reanalysis of the same dataset a new topology was obtained with sponges branching off first (Philippe *et al.*, 2011; see also Miller and Ball, 2008; Srivastava *et al.*, 2008).

Therefore, although this discussion continues, sponges (**Figure 9**) are now considered by most researchers to be the

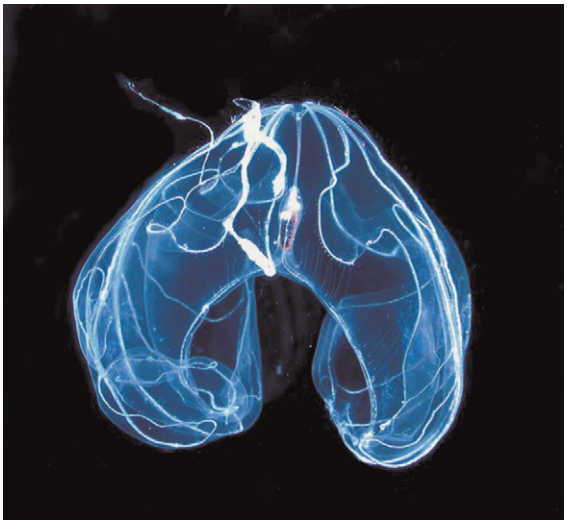

Figure 8 The Ctenophora *Bathocyroe fosteri* (http://en.wikipedia.org/wiki/File:Bathocyroe_fosteri.jpg).

oldest extant animals as most molecular analyses show Porifera as the sister group of all the other Metazoa (e.g., Philippe *et al.*, 2009; Pick *et al.*, 2010; Worheide *et al.*, 2012). Besides, they are morphologically simple and have a special cell type (the choanocyte) that is very similar to choanoflagellates. The hypothesis of choanoflagellate-like organisms being ancestors of the metazoans is related to the similarities between those protozoans and sponge choanocytes (King, 2004). Although the homology between sponge choanocytes and choanoflagellates has not yet been properly tested, DNA sequences do show that these lineages share several genes and that they are sister lineages (e.g., Wainright *et al.*, 1993; Cavalier-Smith, 1996; Philippe *et al.*, 2004). Moreover, if Ctenophora or Placozoa were the sister group of Metazoa,

Figure 9 Sponge (*Clathrina* sp.). Photo by A. Bispo.

these lineages and the ancestors of Cnidaria and Bilateria would have lost their choanocyte-like cells, which are not the most parsimonious scenario (Worheide *et al.*, 2012).

Origin of the Sponges

Sponges were most possibly originated from a benthic colony of choanoflagellate-like organisms that might have had cell types with distinct phases to feed (protochoanocytes) and to reproduce (protoarchaeocytes) (Valentine, 2004). However, to become a metazoan, sponges had to develop multicellular bodies with differentiated cell types and an extracellular matrix.

Cleavage was probably a vital step to a rapid development and to organize the differentiation and arrangement of cell lines (Valentine, 2004). Adding support to this early origin of eggs and cleaving embryos, fossils near 600 Mya have been found (Xiao and Knoll, 2000). Indeed, fossils that were originally identified as the protist group acanthomorphic (i.e., spinose) acritarchs were in fact hulls of diapause animal eggs (Yin *et al.*, 2004, 2007). This finding might suggest that sponges, and perhaps other animals, could have appeared before 580 Mya (before the Ediacaran fauna!) (Telford and Littlewood, 2009). Recently, a fossil sponge in a geological stratum of 600 Mya was reported (Yin *et al.*, 2015).

Although sponges are supposed to be morphologically simple, they have many features that are shared with metazoans. Apart from multicellularity, homebox genes, and task division, they exhibit collagen, septate junctions, integrins, fibronectins, and all apparatus to link the extracellular matrix to the cytoskeleton (Valentine, 2004). Sponges also developed cell specialization, although not rarely their cell differentiation is not final. The continuous totipotency/pluripotency of sponge cells provides these animals with a high level of plasticity that probably enabled them to survive along in the past 600 million years.

Sponges do not show nervous system or even organs. Basal lamina, a distinctive metazoan characteristic, is reported in a single out of the four extant Porifera classes. Currently, there are five recognized classes of sponges: Archaeocyatha, Calcarea, Demospongiae, Hexactinellida, and Homoscleromorpha. Archaeocyatha is a class of marine sponges with calcium

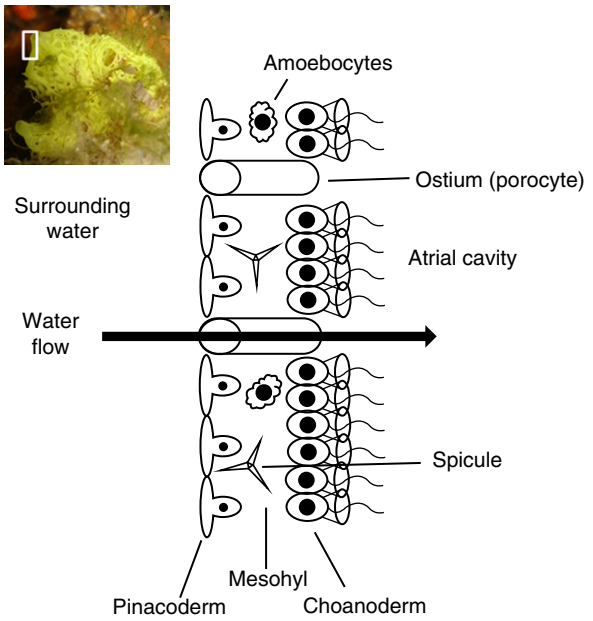

Figure 10 Schematic section of an asconoid sponge. Photo by E. Hajdu.

carbonate skeleton and that were reef builders in the Cambrian, when they became extinct. Calcarea is the only extant class that produce calcium carbonate spicules whereas the other three have silicium spicules. Demospongiae is the most speciose class, representing almost 85% of the phylum. These are the only sponges that have invaded freshwater and that developed carnivory. Hexactinellida are mainly deep-sea sponges and are the only ones that present syncytial tissues. Until recently, Homoscleromorpha was considered a subclass of Demospongiae, but it was recently elevated to a class status.

In order to grow in size, sponges developed a system of inhalant and exhalant canals and chambers with flagellate cells (choanocytes) (**Figure 10**) that continuously pump water through the body of the sponge. As the water goes through, the sponge is able to acquire oxygen and food (bacteria and macromolecules) and also to eliminate residues. These connected channels and chambers consist of the aquiferous system, the main synapomorphy of Porifera, but some carnivorous sponges lack this feature (Vacelet and Boury, 1995).

Sponges do not possess true symmetry, but they come in different forms such as spherical, cylindrical, radial, and even some present bilateral symmetry (i.e., hexactinellids) and they are morphologically very simple, as they do not have organs, or sensorial cells not even nervous system. As sponges lack nervous cells, all communication between cells is mediated possibly by chemical messengers. Additionally, sponge tissues are not considered to be true tissues, as most of the species do not have a basal lamina. The basal lamina is a membrane of proteins (laminins and collagens) working as a barrier to avoid that cells from one tissue infiltrates other tissues and, among sponges, it is encountered in Homoscleromorpha. As most sponges do not have this barrier, neither strong cell junctions to isolate their epithelia, their cells can move freely throughout the sponge body. Associated with cell totipotency, this feature makes sponges very plastic animals a key step that surely contributed for their adaptation and survival.

Although most sponges lack basal lamina, they share with other metazoans several characteristics, including multicellularity, type IV collagen, septate junctions, and work division among cells. If in one hand the monophyletic origin of Porifera has been already questioned (e.g., Lafay *et al.*, 1992; Borchiellini *et al.*, 2001; Sperling *et al.*, 2009), on the other hand studies with very large matrices of DNA sequences are showing that sponges are monophyletic (Philippe *et al.*, 2009, 2011; Pick *et al.*, 2010), but phylogenetic relationships among the classes are less clear. Many recent molecular studies have shown that Calcarea is more related to Homoscleromorpha and Demospongiae is closely related to Hexactinellida (Philippe *et al.*, 2009; Pick *et al.*, 2010), but more comprehensive studies are still required to settle this matter.

Glossary

Alleles Forms of a gene or the products of a gene carrying different mutations.

Allozyme Allozyme is an allele of an enzyme.

Chemostat It is a device to maintain a constant growth rate of bacteria at a rate between the maximum and very slow growth.

Electrophoretic alleles They refer to alleles that run at different rates in an electrical field. All electrophoretic alleles have mutations that change an amino acid, but not all mutations that change an amino acid are electrophoretic alleles.

Enzyme kinetics V_{max} and K_m are measures of an enzyme's activity. V_{max} is the maximal velocity of a reaction given excess substrate and K_m is the concentration of substrate given half the maximal rate of reaction.

Epistasis It describes the observation that the fitness of two mutations cannot be predicted by measuring the fitness of each mutation. Sign epistasis is when the fitness of the combined mutations is less than the fitness of either mutation alone.

Growth-limiting resource It is the resource that is in short supply such that it limits growth and the organisms compete for it.

Isogenic strains Strains that are identical genetically except at specified differences.

Mutation It is a change in the order of nucleotide bases along a strand of DNA.

Population A group of individuals of a species that live in close enough proximity that they interact.

Turbidostat It is a device that maintains the growth rate of a population of bacteria at its maximum rate by measuring the turbidity of the culture.

Introduction

Experimental Evolution

Experimental evolution is the use of the experimental method to study evolution. This simple definition hides considerable complexity and ambiguity. What are the minimal conditions to call something an experiment? What would be an ideal experiment? What do we want to know in evolution that can be tested experimentally? In this short essay, these questions will be answered so the reader can understand the strengths and limitations of experimental evolution. Also this essay will focus on microbial experimental evolution. For a discussion of the current state of experimental evolution generally, see 'Experimental Evolution: concepts, methods, applications of selection experiments' (Garland and Rose, 2010). They consider anything that is experimental and dealing with any question of evolution as experimental evolution. This paper narrows the definition of experimental evolution to exclude natural experiments, directed evolution, artificial selection and domestication from my definition of experimental evolution.

Natural selection as studied in experimental evolution is different from artificial selection. In artificial selection, the scientist selects the individuals who best exemplify the desired traits and breeds from those individuals. In experimental evolution, the scientist creates the environment where natural selection happens. However, the line between artificial selection and natural selection can be fuzzy when the investigator sets an environmental condition that is simply there to select a certain defined phenotype (e.g., selection for multicellularity, see below).

Experiments

An experiment is the controlled testing of a hypothesis, using an orderly and well-described procedure. An experiment should be done in such a way that any other scientist anywhere in the world can repeat the experiment and, by using the same logical analysis of the results, obtain the same conclusion. Usually experiments are designed to provide insight into cause and effect, but also can be used to describe an array of possible outcomes from an initial condition. When possible, experimenters try to design controls such that unknown or unexpected causes, such as the phases of the moon, the micro-contaminates of the water, etc., can be ruled out as a cause of the results. Repeatability is the hallmark of the experimental method.

Comparative Method

We can talk about natural experiments, meaning similar, independent and repeated outcomes that seem to have the same precursors. The controls are assumed to be the different outcomes that are assumed to have different precursors. For example, animals that swim through water, for example, fish, whales, penguins, etc., have similar shapes and different from the shapes of animals that swim through air, for example, bats, birds, and pterosaurs. However, this is not an example of the experimental method, but of the comparative method. The comparative method has been used with great success in evolutionary biology and should continue to be used regularly. The experimental method has been used very little in evolutionary biology. This is due to a number of reasons, some important and some trivial.

Experimental Method

The experimental method requires that the investigator create the conditions under which the experiment is carried out in such a way that the experiment can be repeated. This is usually done in a laboratory where conditions are not natural – constant temperature, regular light intensity, defined media without the mix of enzyme inhibitors, toxins, tannins, and other non-metabolizable compounds found in nature. Also, generally there are no predators or parasites in the laboratory along with the organisms studied. In such unnatural conditions, what can you learn about the evolution in the world out there? The traditional answer is: 'Not much.' In one respect this answer is correct but in another respect, incorrect. It is correct in that experimental evolution will tell us little about the evolution of a particular phenotype of a species in nature. But it is incorrect in that experimental evolution can be used to understand fundamental patterns in nature. Further, we will never really understand ecology and evolution without doing experiments.

It has been argued that experiments in physiology, biochemistry, and genetics can be carried out in the laboratory because the physiological, biochemical, or genetic system is not changed when pulled out of its natural environment. The DNA is the same whether it is in an organism in nature or in the laboratory. But, one cannot bring a piece of the environment into the laboratory and have it remain the same. The environment is too complex and too much of a network of cause and effect to do this. If you take a sample of a pond in a jar, the sample in that jar very quickly changes such that the dynamics in the jar become different than the dynamics in the lake. The conclusion is that the environment cannot be moved into the laboratory the way an organism can.

While true, this is an incorrect way to look at the problem. The environment in the laboratory does not need to be natural. When we measure the properties of enzymes, we measure the V_{max} and k_m in dilute salt solutions with excess substrate, an enzyme environment very different from its environment in a cell. The environment of an enzyme in a cell is almost a gel of other compounds, not a dilute salt solution, and contains little substrate, rather than an excess. But yet these parameters of V_{max} and k_m can predict the fitness ranking of allozymes in their natural environment of the cell (Dykhuizen and Dean, 1990). Thus, we believe that characterizing enzymes in dilute salt solutions with excess substrate gives us real information about enzyme function in its natural state. Likewise, we can study organisms in very unnatural conditions and learn about the process of evolution.

Controls in Short-Term Experiments

A second reason that experiments have been little used in evolutionary biology is that it is really easy to do dumb experiments. Let us pick some arbitrary environments and random genetic differences and study the differences in fitness. There will be results, but what do they mean? Very little! Instead, one has to start with a theory that can be experimentally tested: for example, different electrophoretic alleles of 6-phosphogluconate dehydrogenase (6PGD) from *E. coli* are selectively equivalent. Then the experiments have to be very carefully designed with all the proper controls. Controls! Controls! Do the proper controls so that the results can be correctly interpreted. As Michael Travisano (2010) has written:

> Unfortunately experimental evolution studies are prone to faulty analysis, largely because investigators assume they have greater control of the experimental conditions than they actually achieve. Responses to selection are determined by the actual selective conditions, not the selective conditions supposed by the experimenter. (p. 127)

The importance of controls, is illustrated by the experiment done to show that the electrophoretic variants of 6PGD are selectively neutral or nearly neutral (Dykhuizen and Hartl, 1980). First, strains have to be constructed such that different alleles are in isogenic backgrounds along with a wild-type allele and a mutation that renders 6PGD inactive (a null mutation). Then the environments are constructed. One environment is minimal media (media without any toxins, inhibitors etc.) with growth-limiting amounts of gluconate (the selective media). Another environment (the control environment) is minimal media with growth-limiting amounts of another sugar (in this case ribose + succinate to mimic the products of gluconate metabolism). It is assumed ribose and succinate can be metabolized without using the enzyme 6PGD. This assumption needs to be tested. The bacteria are not grown just in the media suspended in space, but the media has to be in something, a chemostat, a 96-well plate, an agar plate, etc. These containers create part of the environment in which the *E. coli* grows. In this case, the bacteria are grown in chemostats because, in the chemostat, the cells are always competing for the growth-limiting resource. This should promote and magnify any selective differences between isogenic strains that contain different alleles of 6PGD. With this experimental framework established, controls are done to show there is selection in the gluconate-limiting environment but none in the control environment. These are the system controls. When a wild-type strain is competed against a strain with null mutation, the selection in the selective medium will be maximal. This selection should be large, showing that 6PGD is an important enzyme in the metabolism of gluconate, but the selection need not be 100%. In the control media, the two strains should be selectively equivalent, since the control media has been designed such that 6PGD is not required for growth. If not, first remake the strains because, by chance, one might have picked up a mutation in the background during the strain construction. If the selective difference remains, pick a different control media, until one is found that the null and wild type are selectively equivalent. Now that the selective and control environments are determined, each different allele is competed against an isogenic standard strain in both control and selective media. In the control media, the strains should be selectively equivalent; otherwise there are background differences. These background effects will prevent assigning any fitness differences in the selective media to the allelic variant of 6pgd. Lastly, each allele is competed against the wild type in selective media to see if they are selectively equivalent or not. When this experiment was done on four different alleles, three were equivalent and one was selected against, with a limit of detectability of selection of 0.2%. The enzyme kinetics gave the

same result – the k_m of the allele selected against was significantly higher than the k_m of the other alleles. This allele was also the least frequent (0.011) in a sample of *E. coli* from nature (Dykhuizen and Hartl, 1980). Thus, we can conclude that most electophoretically distinguishable alleles are selectively equivalent, but that some are not. For a summary of the results of many different experiments using a number of different genes, and a discussion of the interpretation of these experiments, see Hartl and Dykhuizen (1985). This result was important in establishing the idea that many electrophoretic variants are selectively neutral, but some are nearly neutral, supporting the theories of Kimura and Ohta (see Kimura, 1983).

Long-Term Experimental Evolution

While the experiment described above had definite predictions with the required repetition and controls, there is another approach that is often used in experimental evolution. This approach starts with a number of identical populations in the same environment and follow the fitness trajectory. Richard Lenski and his collaborators have done the classic experiment of this type (Wiser *et al.*, 2013). They evolved 12 populations of *E. coli* for over 50 000 generations in glucose minimal media in flasks, diluting daily 1/100 into fresh media. The listing of the environmental conditions is important because we do not yet know the generality of the results for different conditions. This experiment has told us that identical cultures evolve generally the same, but with significant differences and that the rate of fitness increase slows over time.

The observed results of this experiment are about what was expected. The true value of this experiment is as a resource to test various hypotheses. Samples from this experiment were frozen over time giving a record of the evolution dynamics. Previous to the start of this long-term experiment, Lin Chao had shown that a mutator gene is selected in chemostats by raising the mutation rate of advantageous mutations. Then by hitchhiking, these mutators increase in frequency as the advantageous mutations are selected and increase in frequency. However, the mutator strain will decrease in frequency if the mutator strain is at such low numbers that it is unlikely that a single advantageous mutation will happen within it (Chao and Cox, 1983). What happens to new mutations that increase the mutation rate in these long-term experiments? Are they lost because they are so rare or do they get fixed in the population because of increased frequency of advantageous mutations? Using 10 000-generation strains, Sniegowski *et al.* (1997) showed that 3 of the 12 populations are fixed for mutators. By going back into the frozen cultures, the three mutators were fixed at about 3500, 8600, and 2500 generations. Another two cultures had picked up mutators by 40 000 generations at about 18 000 generations and at 26 500 generations (Kussell, 2013). As the fitness increase slows in these populations, the fixation of mutators also slows. This result shows that while mutations to strains with elevated mutation rates are common, most strains with mutators are lost because of rarity, but sometimes, by chance, they become common enough that the selection for higher mutation rates fix these mutator strains.

The short-term experiments described above that showed the selective equivalence of the 6GPD alleles and the density-dependent selection for the mutator gene are what have been described as bottom-up experiments while the long-term experiments are top-down. In the bottom-up experiments, various alleles are competed against each other to see which one is selected and by how much. Bottom-up experiments have the advantage that they can directly test hypotheses, but it is not clear that the alleles chosen would be selected if one ran a top-down, long-term experiment under the same conditions. The top-down experiments allow evolution of the whole system, but it is hard to test well-defined hypotheses. Dykhuizen and Dean (2010) describe a bottom-up analysis of the lactose system in *E. coli*, and Travisano (2010) discusses long-term experiments: the need for them and their successes and challenges.

Evolution

Microevolution

Experimental evolution has been most useful when studying the evolutionary change in populations, using either top-down (long-term) or bottom-up (short-term) experiments. Evolution can be studied either as a change in a trait (phenotypic change) or as a change in gene frequencies (genotypic change). I shall first discuss an example of experiments selecting for a trait change and then discuss the examples associated with gene frequency change.

Phenotype Change

When selecting for a novel trait in long-term experiments, the environment and experimental procedure have to be constructed in such a way that the trait should be selected. If a particular experiment is unsuccessful and the trait is not selected, the failure may be because the environment was wrong, the genetic potentiality was not there, or the experiment did not run long enough. It is very hard to run controls, so only successful experiments are usually reported. One of the successful experiments is the selection for multicellularity. Ratcliff *et al.* (2012) selected multicellular yeast colonies from unicellular yeast by selecting for cells that settled most quickly. These colonies evolved specified apoptosis such that colonies split more or less equally. Using *Chlamydomonas reinhardtii*, Ratcliff *et al.* (2013) repeated the experiment. Rather than getting many lineages that evolved multicellularity as with the yeast, only one out of twenty cultures evolved multicellularity. This single lineage had a complex life cycle, with single-cell dispersal when the environment was flush (right after transfer to fresh media) and then growth to large clusters at the end of the growth phase when the selection for rapid settling was applied. The complexity of the life cycle suggests that this life cycle had evolved in some distant ancestral species and then suppressed in *C. reinhardtii*, rather than have evolved during the experiment. If multicellularity had been strongly selected against in a recent ancestor of *C. reinhardtii*, a strong block on the development of multicellularity would have evolved and many genetic steps would be required to break the block.

The evolution of aerobic utilization of citrate in one of the Lenski long-term lines has been described as an example of the

evolution of novelty. However, the genetic analysis of this evolutionary dynamic shows that a number of genetic changes were required before this cit+ strain could dominate the culture (Blount *et al.*, 2012), suggesting that the ancestor had metabolized citrate aerobically, but this ability had been suppressed very effectively. Thus, one has to be careful not to think that the evolution of a new function as the evolution of novelty. It could be an example of reverse evolution!

Gene Frequency Change

Mutation, genetic drift, migration, and natural selection are the forces that change gene frequency. In microbial experimental evolution, population size is usually large enough that genetic drift is unimportant. However, in very small populations with a high mutation rate, detrimental mutations can become fixed, decreasing the fitness of the population. If this continues to happen, generation after generation, it is theoretically possible that multiple detrimental mutations are fixed until the population becomes unviable. This idea is called Muller's ratchet (Muller, 1964). When an RNA virus is passaged through a single plaque, the fitness decreases (Chao, 1990), showing that Muller's ratchet can effect populations. But as fitness decreases, compensatory mutations that increase fitness increase (Poon and Chao, 2005), reversing the effects of Muller's ratchet. Thus, it is extremely unlikely that Muller's ratchet will continue until the population becomes unviable.

Migration

Normally migration is called contamination in experimental evolution and is actively blocked through all the protocols of sterile technique. However, to study the evolutionary dynamics of metapopulations, migration should be included in the experimental protocol. It is required when extinction is likely within any single population. For example, a metapopulation was created by distributing the pathogen, phage T7, and the host, *E. coli*, across a number of wells in a 96-well plate (Kerr *et al.*, 2006). In some wells, both the phage and the host will be present. In these wells, the pathogen numbers will increase as the host becomes extinct. In some wells with only host, the host population will prosper. In wells with only pathogen, there will be no growth of the pathogen. Regularly, an inoculum from each well of the plate is diluted into a well in the same position of a fresh plate. If there is no migration, the phage will be diluted to extinction and only the wells with bacteria alone will have a continuous population. With migration, sometimes phage will be added to wells containing a thriving bacterial population, causing extinction of the bacteria, but an increase in the numbers of phage. Also, sometimes bacteria will be added to empty wells establishing new populations of the host. Depending on migration distance and rate, various stable arrays of populations can be established (Kerr *et al.*, 2006).

Mutation

Mutations continuously happen. They cannot be avoided, but fortunately happen at a low frequency. All the long-term experiments rely on advantageous mutations to evolve traits or increase fitness. The short-term experiments that measure fitness are limited to about 100 generations because of the accumulation of advantageous mutations rising to high frequency.

The properties of mutation accumulation are non-intuitive in large microbial populations. The numbers used in this calculation are from experiments using *E. coli* growing in chemostats. There are 3×10^9 bacteria per culture and the per nucleotide mutation rate for *E. coli* is about 10^{-10}. This means that about one-third of the nucleotides are mutated in at least one cell in the population every generation. Thus, in a few generations all single nucleotide mutational changes will be present in the population. There will also be insertion–deletion mutations happening at about the same rate. Even if advantageous mutations are rare, they will be present in the culture from the start of the experiment.

Evolutionary biologists have assumed that evolution is mutation limited. However, in microbial populations, advantageous mutations are common. This is a very different evolutionary model than one derived from animals and plants where population size is much smaller.

Natural Selection

The usual definition of natural selection is the differential survival and reproduction of different phenotypes, when at least some of the difference in phenotypes is generated by differences in genotype. This definition is incomplete because phenotypes are generated by genotypes in an environment (the epigenetic environment) and natural selection is generated by differences in phenotypes in an environment (the selective environment). As seen in **Figure 1**, the interaction of genetic variation, epigenetic environment, phenotypic variation, and the selective environment generate natural selection. These are the 'causes' of natural selection. The 'effects' of natural selection produce changes in allele frequencies giving rise to adaptive evolution. I think that the most important function of experimental evolution will be to figure out the causal rules or laws of natural selection. I have previously made the analogy of natural selection evolution with force in physics (Dykhuizen, 1995). Newton described the effects of force; the understanding of the causes of force were done over the next 300 years leading to an understanding of electromagnetism, thermodynamics, atomic energy, etc. This understanding has led to most of the practical applications from physics. Hopefully, the same can be done for natural selection as has been done for force.

The study of causes of natural selection will be an area of evolution where the experimental method is essential. An example of an experimental study of natural selection is discussed in the section above, 'Controls in Short-Term Experiments.'

The Environment

The environment for natural selection is not just out there in nature, but also in the laboratory. We are just beginning to realize that there are major differences between the commonly

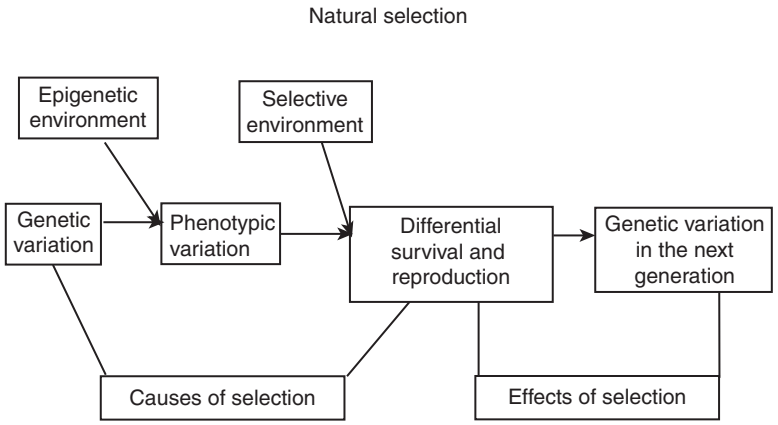

Figure 1 The current model of natural selection indicating the complexity of its causes and distinguishing the causes from the effects. Population genetics studies the effects of natural selection.

used environments in experimental evolution. The major environments are agar plates, tubes or flasks containing media, and chemostats. The agar plates can be a defined minimal media of salts and a sugar plus other defined nutrients, as an amino acid or vitamin or the agar plates can be a complex media made of yeast extract and tryptone or other semi-defined components. These different plates will undoubtedly give different epigenetic and selective environments. However, all plate environments have fixed neighbors. The interactions will primarily be with a few neighboring clones and this is very different than the selection in tubes or chemostats, which are well mixed. For example, a strain that produces an expensive-to-make toxin can invade a population of sensitive competitors on agar plates, but not in liquid, because the toxin concentration around a single colony on an agar plate will be high enough to kill the neighboring cells, but in liquid media the toxin will be diluted and not effective (Chao and Levin, 1981).

The tubes or flasks, and now 96-well plates, when used as growth chambers, can be shaken or not. If they are shaken, the environment will be homogeneous. If they are not shaken, the environment can be partitioned into different populations under different selective pressures (Rainy and Travisano, 1998). The media can be a simple defined media or a broth culture. While this has not been investigated, it is expected that the broth culture would provide many more niches, leading to more specialization and thus maintaining more genetic diversity. Normally, a simple defined media is used for experiments. The Lenski long-term lines (Wiser *et al.*, 2013) use a defined media, pH controlled by a phosphate buffer, with limited glucose (energy-carbon source). The cultures are diluted every day, meaning they go through a cycle of a lag after dilution, exponential growth until the glucose runs out, and then stationary phase until the next dilution. While most of the selection is to increase the maximal growth rate, some of the selection is to decrease the lag and some for the competition for limiting glucose as they go into stationary phase. Thus, the selection in this type of experiment does not have a single cause. One can isolate these components to select purely for maximal growth rate using the turbidostat or competitive ability using a chemostat.

A turbidostat is a continuous culture device that measures the turbidity in a culture by passing light through the culture and recording the turbidity. If the turbidity is too high, the dilution rate of the culture is increased, washing out cells faster than they can grow; if it is too low, the dilution rate is decreased, washing out cells slower than they can grow. In this way a turbidostat maintains a constant culture density while the cells are growing at their maximal rate in whatever environment used (media, temperature, etc.). Since the cells are growing at their maximal rate, any mutation that increases the maximal rate of growth would be selected. Even though in theory turbidostats sound like an ideal machines to carry out evolution experiments, trying to run one is hellish. Turbidostats are highly unstable because of the positive feedback in the selection for wall growth. You can go home in the evening thinking everything is OK and come back in the morning and the culture has been washed out because the growth on the wall has become thick enough to register as high turbidity, causing the pump to speed up in the futile effort to reduce the turbidity. A wall-less turbidostat or an Evolugator solves this problem (de Crécy *et al.*, 2007). They (de Crécy *et al.*, 2007) increased the maximal growth rate of a strain lacking elongation factor *P* threefold over 200 generations.

A chemostat is another continuous culture device where fresh media is added at a dilution rate less than would be required for the maximal growth rate and exhausted media and cells removed at the same rate. The dilution rate is set by the investigator, giving growth rates near the maximal rate to a rate just above stationary. For *E. coli*, which has a maximal growth rate in minimal media of about 1 h, chemostats are usually run at growth rates 2–6 h. One essential nutrient is added to the media at a concentration much lower than required, such that this nutrient is the nutrient first exhausted during growth. This is the limiting nutrient. If glucose is the limited nutrient, the chemostat is said to be 'glucose-limited.' The theory and use of chemostats in studying natural selection and adaptive evolution is given in Dykhuizen (1993). The selection in chemostats is for the efficient uptake and use of the limiting nutrient and for the deactivation of the global regulator for the transition into stationary phase (Gresham and Hong, 2015).

The environment can be made more complicated by using two limiting nutrients. These can be mixed or cycled. They can be substitutable or not. Sublethal concentrations of antibiotics could be added. All kinds of complicated environments could be used in experimental evolution. However, these environmental complications should be used only when the hypotheses to be tested require them. Complications for the sake of complication should not be done. But, still, environmental complications in experimental evolution will be needed to understand the complicated environment in nature.

Future of Experimental Evolution

Clearly, the major strength of experimental evolution is use of the experimental method. However, to utilize the experimental method at full strength, a complete array of controls is required. Even if a full array of controls are used, the conclusions could apply only to the particular organisms and environments used in the experiment. Is the strain used typical of the class of organisms considered (i.e., is strain K12 typical of *E. coli*? Or of bacteria? Or of life?) or is it some kind of outlier? Likewise, is the environment typical or not? Since organisms are a product of the historical process of evolution, there are no universal constants and the generality of any conclusion has to be determined by further experiments.

Experiments, where controls are not present, particularly long-term experiments, can be set up such that one can compare present results with past results. For example, if the experiment is to be run with succinate as the carbon source, a control with glucose should be run to check that all the other variables that might be different in this experiment from experiments run elsewhere by others with different strains of bacteria are not creating the difference between your experiments with succinate and the previous experiments with glucose. Only then can you say that succinate is a different resource than glucose. And only then will experimental evolution have a future.

The perceived greatest weakness of experimental evolution may be its greatest strength. The reason that it is so very hard to know how to argue that a constructed environment is meaningful is that the structure of the environment is very poorly understood. Our theory and, thus, our intuition may be wrong. For example, existing ecological theory says that two strains cannot coexist on two fluctuating resources, even when one is fitter on one resource and the other on the other, given that the selection is not frequency dependent. The strain with the highest average fitness over both environments will win. This is an example of the competitive exclusion principle and has many scientists wondering why there are so many coexisting species. As Yi and Dean (2013) have shown, using experimental evolution, the above theory is true only if the population growth is density independent, but if population growth has periods of density dependence, the two populations can coexist.

Experimental evolution gives us a way of seeing the environment as the organism sees the environment by following their evolution. Environments where the organisms select for different arrays of mutations are different. Environments that select for the same or very similar arrays of mutations are the same. The array of mutations selected in any one environment will tell us the changes in physiology arising in this environment.

At present, I do not see the limitations of experimental evolution. It will change ecology and evolution in the same way that applying the experimental method starting with Galileo changed physics.

Microbiome

R Knight, University of California San Diego, La Jolla, CA, USA

Glossary

Alpha diversity The diversity within a single biological specimen.
Amplicon A specific region of DNA amplified by the polymerase chain reaction (PCR).
Ancestral state reconstruction The process of inferring the ancestral states of extinct genomes or organisms using a phylogenetic tree.
Archaea The 'third domain' of life, lacking nuclei like the bacteria but more closely related to eukaryotes than to bacteria.
Bacteria A monophyletic group characterized by cells that lack nuclei, for example, *Escherichia coli*.
Beta diversity The dissimilarity in communities between a pair of samples, or the change in communities over a gradient.
C4 plants Plants such as corn and other grasses that assimilate carbon dioxide via a 4-carbon intermediate metabolite rather than a 3-carbon intermediate, as is more characteristic.
Chitinase An enzyme that digests chitin, a structural long-chain polymer found in insects and fungi.
Distance metric A method of measuring dissimilarity that meets several mathematical criteria (always nonnegative), distance from A to B same as B to A, and satisfying the 'triangle inequality' such that there can be no point C where the distance from A to B is longer than the distance from A to C to B.
Endemism Specificity to a particular environment.
Endosymbionts Microbes that live inside a host cell and contribute to their mutual benefit.
Eukaryotes A monophyletic group characterized by cells with nuclei, for example, human cells.
Foregut fermentation A physiological process where the front part of the gut is expanded to digest plants.
Hindgut fermentation A physiological process where the back part of the gut is expanded to digest plants.
Horizontal gene transfer The process by which genes can move from one strain to another (contrast with vertical transmission).
Microbiome The collection of genes within a microbiota.
Microbiota The collection of microbial cells that inhabit a specific organism, or a specific body site within that organism.
Myrmecophages Animals that eat ants and termites.
Shotgun metagenomics The practice of fragmenting all DNA in a biological specimen, sequencing it, and piecing it back together to draw conclusions about the organisms that live in the community.
UniFrac A method of measuring the distance between two communities in terms of the difference in coverage over a phylogenetic tree.
Vertical transmission Transmission of genetic material from parent to offspring.

Introduction

Host-associated microbial communities have received considerable attention recently, primarily because advances in DNA sequencing have made them far easier to access than was previously possible. Technically, the microbiota consist of all the microbes in a given body habitat; their genes comprise the microbiome. Because DNA sequences suitable for amplicon sequences are approximately 1 million times cheaper to acquire than they were 10–15 years ago, the capacity to ask evolutionary questions about microbiota and microbiomes has expanded considerably (Gonzalez and Knight, 2012). However, most taxa have still not been investigated systematically, and the process of studying coevolution of the whole microbiome with its host has only just begun. Although the 'microbiota' and 'microbiome' are often used to refer just to the bacterial members of a microbial community, which are easier to study due to the better state of the relevant reference databases and computational tools, and the distribution and evolution of marker genes, these terms should properly refer to all microbes, including archaea, microbial eukaryotes (including fungi), and, under some definitions, viruses.

How Do We Find Out About Microbiomes?

Three main strategies have been used to find out about host-associated microbes. The first strategy is to study individual microbial genomes. This has been especially effective in arthropod-associated microbial communities, as many arthropods have endosymbionts or intracellular pathogens such as *Wolbachia* (Werren *et al.*, 2008) or very simple gut microbial communities that can consist of as few as one species (Moran *et al.*, 2008), vertically transmitted. Building phylogenetic trees of host and microbial genomes (or marker genes taken from these genomes) can be illuminating for testing the degree of vertical transmission; the ability to sequence the complete microbial genome can then be useful for determining the ecological relationship between microbe and host, for example, the microbe may derive sugars and other nutrients from the host diet, and synthesize otherwise unattainable amino acids and enzyme cofactors (Moran *et al.*, 2008). The second strategy is to use a phylogenetic marker, such as the 16S rRNA (Pace, 1997), to obtain a readout of the microbial community in terms of which taxa are present. Because microbial communities are often very dissimilar from

 doi:10.1016/B978-0-12-800049-6.00190-6

one another, even the coarse-grained phylogenies obtainable using a small fragment of the 16S rRNA gene are often usable for this purpose, especially if the 16S rRNA fragment chosen is carefully considered (Liu *et al.*, 2007; Wang *et al.*, 2007; Soergel *et al.*, 2012). The third strategy is to perform shotgun metagenomics, in which all the DNA in a given sample is fragmented into small pieces and sequenced (Rondon *et al.*, 2000). The sequences so obtained can either be analyzed individually, by matching them to a reference database, or can be assembled into longer fragments. The advantage to shotgun metagenomics is that this technique can in principle recover the gene functions, and hence the repertoire of possible functionality, from a microbial community; this is especially important when key functional genes are horizontally transferred, or gained or lost, between closely related microbial strains. Although horizontal gene transfer can confuse the relationship between gene trees and species trees, in general horizontal gene transfers occur among arbitrary pairs of taxa and therefore do not obscure the overall phylogenetic signal. In other words, although genes are sometimes horizontally transferred (sometimes extensively: of the genes in the first three genomes of *Escherichia coli* to be sequenced, only 40% were in all three genomes (Welch *et al.*, 2002)), because the pattern is not consistent in terms of which genes or which taxa are transferred, overall phylogeny is a good guide to gene content (Konstantinidis and Tiedje, 2005). In fact, this property can be exploited to predict the metagenome from the taxon content, sometimes with high accuracy. The general strategy is to collect a list of genes in each known genome, use ancestral state reconstruction to predict what the genes would have been in unknown genomes, and then match the taxa detected in a sample (e.g., by 16S rRNA amplicon sequencing) back to these genomes. For well-characterized samples, such as those from the human gut microbiome where an intensive effort has taken place to obtain new reference strains, this technique can predict the metagenome with over 80% accuracy from far cheaper amplicon data (Langille *et al.*, 2013).

Several data analysis techniques have been especially effective in understanding complex microbial community data, and scale to the larger numbers of samples that it is possible to process today. Taxonomic inventories, essentially stacked bar charts or heat maps showing the relative abundance of each taxon (at some level, often phylum or genus level) provide a rapid way of comparing samples in terms of their overall composition (an equivalent technique for gene functions is also useful for shotgun metagenomic data). Alpha diversity measures, which essentially ask how many kinds of organisms (at some taxonomic level) are within a sample, sometimes taking the evenness of representation of the different taxa into account, are useful for getting a sense of whether samples differ in overall diversity. Beta diversity measures, which essentially ask how dissimilar the communities are in two different communities, are useful for getting a sense of which factors structure changes in microbial communities overall. UniFrac, a phylogenetic measure of beta diversity that takes evolutionary history into account in comparing two samples, has been especially effective in revealing biological patterns among communities (Lozupone and Knight, 2005), although many different beta diversity measures with varying strengths and weaknesses, and different theoretical motivations, are available (Kuczynski *et al.*, 2010).

What Differentiates Host-Associated Microbiomes from Environmental Samples?

Host-associated microbiomes, and especially the vertebrate gut, are very different from microbial communities in free-living environments such as water, soil, sediment, etc. In general communities in the vertebrate gut tend to consist primarily of microbes in the phyla Firmicutes and Bacteroidetes, with contributions from many other minor phyla including Proteobacteria, Verrucomicrobia, Fusobacteria, Actinobacteria, etc. In general, free-living microbial communities tend to have a much greater diversity at the phylum level but less at finer phylogenetic levels: this has been compared to a 'palm tree' structure for the vertebrate gut, versus an 'oak tree' structure for free-living environments (Dethlefsen *et al.*, 2007). Communities such as the skin and the mouth tend to bridge the gut to free-living environments, with sharing of Proteobacteria, Actinobacteria, and/or Spirochetes with free-living samples and Firmicutes and Bacteroidetes with the gut (Ley *et al.*, 2008). The level of microbial endemism is still a matter of controversy as it is still difficult and expensive to recover complete genomes from environmental samples, although this is rapidly improving with deeper shotgun metagenomic sequencing and improved algorithms to recover longer genomic fragments from environmental samples, including human samples (Sharon *et al.*, 2013). For example, the same strain of *E. coli* might be recovered from spinach, the human gut, and water; in contrast, even closely related species of insects may have distinct microbial inhabitants. Projects such as the Earth Microbiome Project (Gilbert *et al.*, 2010), by processing a large number of samples with common techniques, are seeking to address the issue of the general distribution of microbes across environmental samples. Interestingly, at the whole-community level, host-associated communities and especially the vertebrate gut are highly distinct from free-living communities.

What Factors Shape Microbiomes Across Different Animal Species?

Most metazoa are relatively poorly characterized in terms of their microbiota (exceptions include ants and termites, which have been studied extensively to study coevolution and for biofuels, respectively). However, some general principles are emerging. Microbes associated with invertebrates tend to resemble environmental samples, for example, microbes associated with the earthworm gut tend to resemble soils, and those associated with sponges and corals tend to resemble seawater, at least in terms of their overall composition (Ley *et al.*, 2008). Differences in the gut microbial communities in different mammalian species are dominated by diet; diet and lineage (which is often confounded with diet) have far stronger effects on the overall composition and structure of the gut microbiome than other factors such as geographical region, wild, or zoo specimen, etc. Interestingly, foregut and hindgut fermentation, each of which have independently evolved many times in different mammalian lineages as ancestrally carnivorous lineages switched to herbivory with the rise of the C4 grasslands about 20 million years ago, have

distinct and reproducible gut microbiota signatures. However, most microbes are unique to a given species, with relatively few taxa shared even among different members of the same species (Ley *et al.*, 2008). Intriguingly, this observation extends to skin microbes: even amphibians from the same pond pick up different, species-characteristic microbes from the same milieu, suggesting that host factors are critical for colonization (McKenzie *et al.*, 2012). One exception to the general pattern of diet effects is the bears, where differentiation from an ancestral omnivorous bear lineage into species that are strict folivores (pandas), strict carnivores (polar bears), and a range of diets in between still result in clustering by lineage rather than diet (Ley *et al.*, 2008). Current thinking in the field is that 5 million years may be insufficient time to differentiate the microbiota in the characteristic fashion seen on longer timescales, although detailed follow-ups in other taxa where lifestyle switches of this type appear are really required in order to answer this type of question regarding evolutionary timescale. Of note, however, humans eating diverse calorie-restricted diets tended to resemble the standard human microbiome rather than the microbomes of different nonhuman mammals. Interestingly, on the scale of different mammalian orders, there is a statistically significant but small influence of co-phylogeny on the overall microbial community (Ley *et al.*, 2008), but on smaller timescales, such as within the Great Apes, such co-phylogeny can be established (Ochman *et al.*, 2010; Moeller *et al.*, 2014), suggesting that co-phylogenetic signal may be lost as time passes. Moving from taxon inventories to gene inventories using shotgun metagenomics (Muegge *et al.*, 2011), we see a striking concordance between the taxonomic community structure and the collections of gene functions within each species, and a substantial core of metabolic functions shared among most microbiomes. However, in some cases, the directionality of key metabolic pathways (such as the connection between glutamine biosynthesis and the TCA cycle) run in opposite directions in carnivores and herbivores, underscoring the importance of checking the directionality as well as the abundance of genes in each key metabolic pathway. Interestingly, taxa with unusual diets, such as myrmecophages (ant- and termite-eaters), seem to converge in their gut microbial community metabolism, for example, by increasing the abundance of chitinases that can break down insect exoskeletons (Delsuc *et al.*, 2014). Confirming the general extent of convergent evolution in the microbiome during adaptation to different diets and lifestyles remains an exciting direction for investigation.

What Factors Shape the Microbiome Within a Species?

By far the best-studied microbiome is that of our own species, *Homo sapiens*, in part due to a $173-million investment by NIH in the Human Microbiome Project (Gevers *et al.*, 2012). The Human Microbiome Project primarily focused on characterization of a 250-member healthy cohort, sampled at up to 3 timepoints and at 18 locations on the body, using both 16S rRNA amplicon profiling (to reveal the members of the microbial communities at each site) and shotgun metagenomics (to identify gene functions) (Human Microbiome Project, 2012a, 2012b). Together with earlier efforts (Costello *et al.*, 2009; Grice *et al.*, 2009), this work provided the first overall picture of microbial distributions across the human body. One surprise was the high level of differentiation between human body sites, even compared to different free-living microbial communities. For example, even though they are topologically connected, the human mouth and gut share almost none of their microbes, and the differences in overall community structure between different human body sites are comparable to the differences between communities in different habitats, for example, soil and seawater (Ley *et al.*, 2008). A second surprise was the variation in microbial communities among different individuals. Remarkably, even within a body site, diversity between different subjects was very high: at the phylum level, some people had as much as 90% Bacteroidetes, whereas others had fewer than 10%, with many individual genera showing similarly broad ranges. Consequently, although human microbiomes resemble one another (for a given body site) more than they resemble the microbiomes of other species, they are still remarkably heterogeneous. In fact, even estimates of the 'core microbiome' typically suggest that the most dominant species in some humans are still as rare as 1 cell in 10 000 in others (Qin *et al.*, 2010). The relative importance of different sources of variation remain sources of considerable debate, as most attention has focused on proving that some factor is statistically significantly associated with differences in the microbiome, rather than using consistent methods to reveal the relative importance of different factors. Some of the variables that have been linked to the human gut microbiome with large effect sizes include age (especially the first three years of life, where the differences within the gut of a single individual over time are comparable to the differences among different species, or even different body sites) (Palmer *et al.*, 2007; Koenig *et al.*, 2011; Yatsunenko *et al.*, 2012), population (although typically location is confounded with many other factors, including diet and host genetics) (Yatsunenko *et al.*, 2012), use of antibiotics (Dethlefsen *et al.*, 2008; Ubeda *et al.*, 2010; Dethlefsen and Relman, 2011), and long-term diet (Ley *et al.*, 2006; Wu *et al.*, 2011). In humans, short-term diet typically has relatively little effect (Wu *et al.*, 2011), although extreme short-term diets such as all meat, eggs, and cheese can induce large shifts in just one day (David *et al.*, 2014). In contrast, in laboratory mice, many different manipulations can modify the microbiome drastically in a single day (Crawford *et al.*, 2009; Turnbaugh *et al.*, 2009). Similarly, in mice, many single-gene knockouts have been shown to have large effects on the microbiome, yet in humans genetic effects on the microbiome have been surprisingly elusive: only studies with hundreds of twin pairs and focusing on subsets of the microbiome have been able to find genetic effects (Goodrich *et al.*, 2014), whereas smaller studies have found no significant effect on the microbiome overall (Turnbaugh *et al.*, 2009) or only weak effects (Yatsunenko *et al.*, 2012). Interestingly, the strongest heritable effect in humans is in Christensenella, which causes increases in adiposity when experimentally transmitted to mice (Goodrich *et al.*, 2014). Relatively few studies have directly compared genetic and diet effects in mice, but the evidence to date suggests that host genetic effects on the microbiome are relatively small compared to dietary effects (Parks *et al.*, 2013). Understanding

these principles over evolutionary time is likely to be especially interesting, although preliminary indications from studies with wild species such as sticklebacks suggest that interactions such as diet × sex may be important for structuring the microbiome and its physiological correlates (Bolnick *et al.*, 2014).

Outlook for Evolutionary Biologists Interested in the Microbiome

The improved capacity for understanding the microbiome through better DNA sequencing methods and computational tools opens up many exciting possibilities for evolutionary biologists. The microbiomes associated with most body habitats in most taxa have not been characterized at all, and understanding the complex phylogenetic relationships of host and microbe holds considerable promise for understanding the microbiome, which can contain the majority of genes and the majority of cells in what we think of as a physiological organism. Understanding patterns of horizontal gene transfer, especially among microbial species exposed to a wide range of hosts and physiological environment, holds considerable theoretical importance for understanding its contribution to adaptation, as well as practical importance in the case of antibiotic resistance and the evolution of pathogenicity islands. Techniques such as genome-wide mutagenesis provide the capacity to understand which genes are critical for a given strain to establish in an ecological niche, including a complex ecosystem in which these genes must interact with genes housed in other microbes. Understanding how the microbiome ties into evolutionary ecology, from pathogen resistance to maintenance of sexually selected signals such as coat or feather condition to responses to stress, is very much an emerging direction. Modeling the dynamics of complex microbiomes, and extending models designed for a few species to hundreds or, thousands, remains both a practical and theoretical challenge, as does defining the repertoire of possible microbiome states and the trajectories that link them. Consequently, although our knowledge of microbiomes has expanded dramatically over the past decade, there is still much to discover.

Mitochondrial and Nuclear Genome Coevolution

A Blumberg, G Barshad, and D Mishmar, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Glossary

Co-regulation Correlation between the regulation of biological factors in either level of action, such as transcription, translation, or posttranscriptional/translational regulatory processes.

Cybrids These cytoplasmic hybrids (cybrids) are cultured cells, in which the original mitochondrial DNA was removed, and were re-populated using mitochondria (harboring their own mitochondrial DNA) from a different donor cell line. This can be performed when the donor and recipient cells belong to the same species, and to a certain degree between different species. Cybrid cells enable testing the functional effects of various mitochondrial genetic backgrounds in the same nuclear genetic background.

Dobzhansky–Muller model of speciation A hypothesis raised independently by two renowned geneticists, Theodosius Dobzhansky and Hermann Joseph Muller, during the first half of the twentieth century. This hypothesis suggests that interfering with interactions (genetic or physical) between two functionally important factors could create genetic incompatibilities, hybrid breakdown, and lead to speciation events.

Epistasis Genetic interactions between biological factors.

Haplogroup Group of phylogenetically related haplotypes.

Haplotype A combination of alleles from linked polymorphic sites (on the same chromosomal region).

Isoforms Proteins that share a function but are encoded by different genes (frequently ancient duplicates) and often differ in sequence.

Mitophagy The selective removal of mitochondria via a multi-component mechanism. This mechanism is thought to sense reduced mitochondrial membrane potential, remove dysfunctional mitochondria from the cellular mitochondrial network via mitochondrial fission, and in turn recycle their components.

mtDNA The mitochondrial genome.

Negative selection An evolutionary force acting to preserve the structure and function of biological factors (purifying selection).

Positive selection An evolutionary force acting to generate changes in the structure and function of biological factors as part of adaptive processes.

Introduction

The mitochondrion is the only organelle in animal cells with its own genome (the mtDNA) and is thought to have originated from an ancient alpha-proteobacterium (Lane and Martin, 2010; Gray, 2012). However, the mtDNA of higher eukaryotes harbors only a minority of the genes required for the operation of the mitochondria. As an example, the mtDNA in vertebrate animals has just 37 genes (see section Primer on Mitochondrial Genetics and Genomics), while the remaining genes required for mitochondrial function ($N \sim 1500$) are encoded by the nucleus. The latter are translated by the cytoplasmic ribosomes and, in turn, delivered into the mitochondrion via mitochondrial import machineries.

From where did these nuclear genes originate? One possibility is that during the course of evolution many nuclear genes acquired their mitochondrial functions subsequent to the origin of the mitochondrion. Indeed, many enzymes (such as uracil-DNA glycosylase, PEPCK, aconitase, and malate dehydrogenase) have cytosolic and mitochondrial isoforms (Ballard and Hanson, 1967; Domena and Mosbaugh, 1985; Yogev and Pines, 2011; Carrie and Small, 2013), or several variants resulting from alternative splicing (Kravchenko *et al.*, 2005; Kim and Gladyshev, 2006), suggesting ancient gene duplications and subsequent acquisition of a mitochondrial function. A non-mutually exclusive alternative is that genes with mitochondrial functions were once encoded by the genome of the mitochondrial bacterial predecessor, and were gradually transferred to the eukaryotic host nucleus during the course of evolution. The more than two billion years since the occurrence of the symbiotic event that gave rise to all Eukaryotes (Gray, 2012) is more than enough time for both processes to have occurred in tandem.

Two mitochondrial machineries are comprised of both mtDNA and nuclear DNA-encoded factors. These include the oxidative phosphorylation ATP production system (OXPHOS) and the mitochondrial-specific protein translational machinery (**Figure 1**). Additionally, both mtDNA replication and transcription of mtDNA-encoded genes are mediated by nuclear DNA-encoded proteins that bind mtDNA recognition sites (**Figure 2**; Bestwick and Shadel, 2013; She *et al.*, 2011). This bi-genomic cooperation introduces three problems: (1) whereas mtDNA-encoded factors are already within the mitochondria, nuclear DNA-encoded factors have to be imported into the organelle; (2) each cell has multiple individual mitochondria (~ 1000 per human somatic cell), each requiring the correct quantity of nuclear DNA-encoded factors; (3) in animals, the mtDNA evolves an order of magnitude faster than the nuclear genome. The solution to this third problem is mediated by natural selection: coevolution between factors encoded by the mtDNA and the nuclear DNA is necessary to preserve mitochondrial function. This process, and its consequences for cells, is the focus of this article.

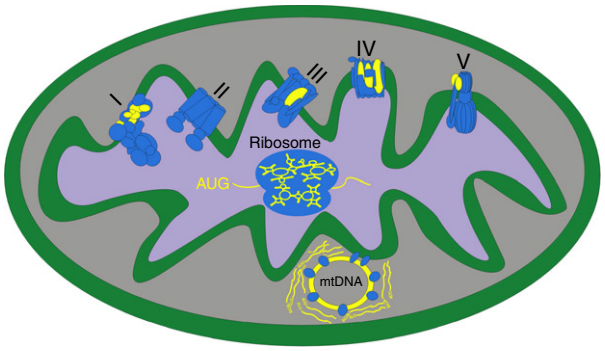

Figure 1 Bi-genomic systems within human mitochondria – an illustration of a single mitochondrion. Shown are the five oxidative phosphorylation complexes, the mitochondrial ribosome – representing the mitochondrial translation system and the mtDNA with its adjacent proteins and RNA products – representing the replication and transcription systems. Blue objects – nuclear DNA-encoded proteins that are imported into the mitochondria. Yellow objects – mitochondrial 'native' elements including the mtDNA, mitochondrial RNAs, and the mtDNA-encoded oxidative phosphorylation complexes' subunits I–V: OXPHOS protein complexes. The physical location of the mtDNA and 'cloud' of synthesized mRNA is based on our interpretation of recent high-resolution microscopic investigation of the mitochondrial nucleoid, i.e., the mtDNA-protein structure that undergoes replication and transcription (Brown *et al.*, 2011).

Primer on Mitochondrial Genetics and Genomics

The mitochondrion is the major source of cellular energy (Wallace, 2007). The vast majority of eukaryotic cells cannot survive without mitochondria and the mitochondrion cannot survive independently of its host cell. Most of the genes ($N \sim 1500$) required for the various activities of the mitochondria (such as apoptosis, nucleotide biosynthesis, fatty acids metabolism, the metabolism of iron and copper etc.) are encoded by the nuclear genome, whereas the mitochondrial energy producing system – oxidative phosphorylation (OXPHOS), and the mitochondrial translation machinery are encoded by both the nuclear and mitochondrial genomes (reviewed in Ryan and Hoogenraad, 2007). The small, circular mtDNA encodes for 37 genes in vertebrates (**Figure 2**): (1) 13 protein-coding genes, comprising members of four out of the five multi-subunit OXPHOS protein complexes. These include 7 protein subunits (ND1-6, ND4L) of NADH ubiquinone oxidoreductase (OXPHOS complex I), one subunit (cytochrome *b*) of cytochrome bc1 (OXPHOS complex III), three subunits (COI-III) of cytochrome *c* oxidase (OXPHOS complex IV) and two subunits (ATP6,8) of F1-F0 ATP synthase (OXPHOS complex V); (2) Two ribosomal RNA genes (*12SrRNA* and *16SrRNA*), which are components of the mitochondrial ribosome; and (3) 22 *tRNA* genes. These 37

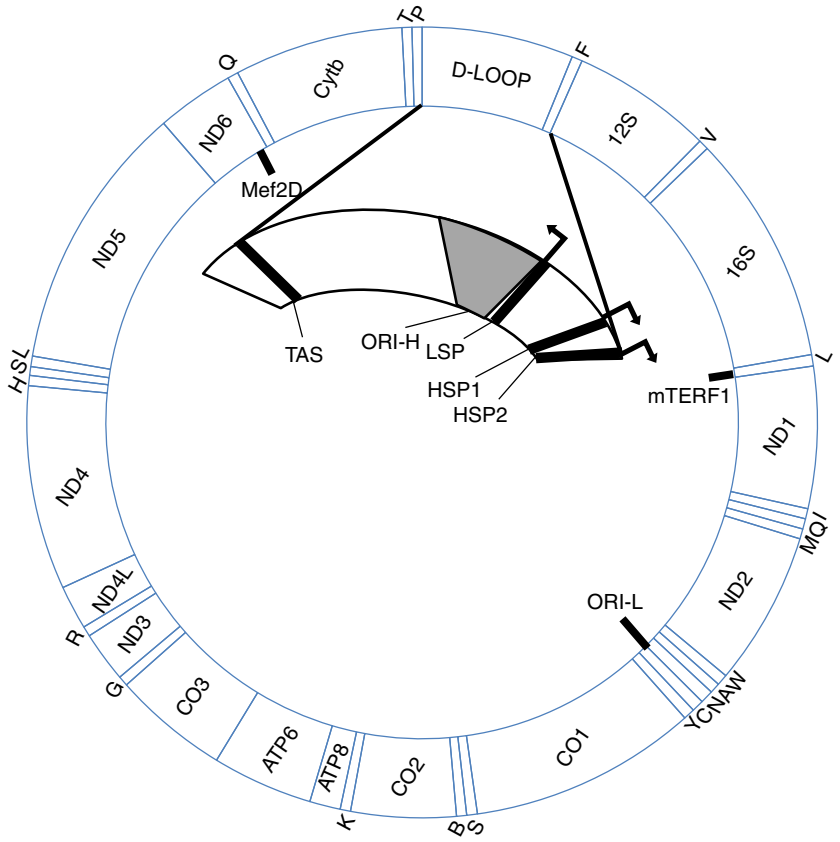

Figure 2 The human mitochondrial genome. Locations of all coding regions, transcription factors binding sites (such as MEF2D and MTERF1) and known regulatory elements are indicated. Letters on the outside of the circle refer to tRNA gene symbols. The D-loop and its known regulatory elements are expanded for clarity. LSP, light strand promoter; HSP1, heavy strand major promoter; HSP2, heavy strand minor promoter; ORI-H, heavy strand origin of replication; ORI-L, light strand origin of replication; TAS, replication termination associated sequence.

factors encompass more than 90% of the mitochondrial genome in vertebrates, although differences in gene order have been reported among species (Wallace, 2007). The remaining ~10% of the mtDNA comprises noncoding sequences harboring regulatory elements: (1) the D-Loop (~1000 base pairs in length), which includes the promoters for each of the two complementary DNA strands (e.g., the heavy and light mtDNA strands) as well as the origin of replication for the heavy strand (Ori-H), and (b) a shorter noncoding region (several tens of base pairs in length) encompassing the light strand origin of replication (Ori-L) – a stem and loop structure ~5000 base pairs apart from the D-loop. Although the heavy and light strand promoters (LSPs) are distinct entities in most vertebrates, the mitochondrial genomes of the African clawed frog (*Xenopus laevis*) and most fowl in super-order Galloanserae have a bidirectional promoter that governs the transcription of both the heavy and light strands. This alternative arrangement raises the attractive possibility that mutations in such sequences may affect transcription of both strands (L'Abbe *et al.*, 1991; Bogenhagen and Romanelli, 1988; Randi and Lucchini, 1998).

Mitochondrial–Nuclear DNA Mutation Rate Differences, Resultant Incompatibilities, and Coevolution

The mitochondrial and nuclear genomes of plants have similar mutation rates. In contrast, the calculated mutation rate of the mtDNA in animals in general, and in vertebrates in particular, is approximately an order of magnitude faster than that of the nuclear genome (Bar-Yaacov *et al.*, 2012b; Castellana *et al.*, 2011). This rate difference poses a particular problem for mitochondrial processes that require the interactions of factors, of which some are encoded by the mtDNA, and some by the nuclear genome. These include: protein–protein interactions within OXPHOS protein complexes I, III–V (but not within OXPHOS complex II which comprises only nuclear DNA encoded proteins), interactions between nuclear DNA-encoded proteins and mtDNA-encoded rRNA within the mitochondrial ribosome, and interactions between nuclear DNA-encoded transcription and replication factors and their mtDNA recognition sites. In order to cope with these rate differences, tight coevolution has occurred between interacting factors encoded by the two genomes (Gershoni *et al.*, 2010, 2014; Grossman *et al.*, 2004; Schmidt *et al.*, 2005; Yadava *et al.*, 2002; Rand *et al.*, 2004; Meiklejohn *et al.*, 2007; Rand, 2008). High-resolution 3D structures of OXPHOS complex IV have enabled investigation of coevolution between nuclear and mitochondrial DNA-encoded subunits (Schmidt *et al.*, 2001). Correlated mutations among mtDNA- and nuclear DNA-encoded factors allow for predictions about and experimental verification of protein–protein interactions within human OXPHOS complex I (Gershoni *et al.*, 2010, 2014; Mishmar *et al.*, 2006).

When coevolution is interrupted, mitochondrial dysfunction can occur (Gershoni *et al.*, 2014). This is the case for human cells in which the mitochondria were replaced either by chimpanzee or gorilla mitochondria (xenomitochondrial cybrid cells) (Barrientos *et al.*, 1998). These cybrids experienced a 40% reduction in the activity of OXPHOS complex I. Similar reduction in complex I activity was described in human children with inherited mutations in complex I subunits, which led to generalized hypotonia, developmental arrest, and death before their second year of life (Rubio-Gozalbo *et al.*, 2000). These findings suggest that functional incompatibilities between the mitochondrial and nuclear genomes of humans and our close phylogenetic relatives affect mitochondrial function in a manner analogous to known mitochondrial diseases. Likewise, reduced activity of OXPHOS complexes I and IV have been found in interspecific rodent cybrids (Dey *et al.*, 2000; Yamaoka *et al.*, 2000; McKenzie and Trounce, 2000). Moreover, backcross experiments have demonstrated that incompatibilities between the mitochondrial and nuclear genomes can affect mitochondrial function (Sackton *et al.*, 2003), sex-specific fitness in *Drosophila* flies (Rand *et al.*, 2001) and yeast (Lee *et al.*, 2008), and mortality rate in the parasitoid wasps *Nasonia girault*i and *Nasonia vitripennis* (Niehuis *et al.*, 2008; Ellison *et al.*, 2008).

Mitochondrial–nuclear coevolution can also impact interactions between populations of the same species. A series of inter-population breeding experiments in the copepod *Tigriopus californicus* revealed reduction in hybrid fitness and activity of OXPHOS complexes (mainly complex IV) (Burton *et al.*, 2006; Ellison and Burton, 2010). Similarly, reduced fitness in interpopulation breeding in *Drosophila* was attributed to mito–nuclear interactions (Dowling *et al.*, 2007; Rand *et al.*, 2001). A cybrid clone series carrying a single common human nuclear genetic background matched with a range of mtDNAs from diverse human or mouse lineages exhibited reductions in mitochondrial function (Kazuno *et al.*, 2006; Moreno-Loshuertos *et al.*, 2006; Kenney *et al.*, 2014) and variation in nuclear gene expression. This likely occurred via signals carried by small molecules from the mitochondria to the nucleus, termed retrograde signaling (Kenney *et al.*, 2014). Finally, mitochondrial–nuclear incompatibility may have played a role in the divergence of natural sparrow populations (Trier *et al.*, 2014) and possibly in other vertebrates (Bar-Yaacov *et al.*, 2012a). Such observations have led to the suggestion that mito–nuclear incompatibility could play a role in the generation of reproductive barriers, an essential step toward the emergence of new species (Gershoni *et al.*, 2009).

Coevolution and Physical Interaction

Interaction between factors is not unique to the mitochondria. Most biological activities require the interactions of several factors. Interacting residues within biological proteins are frequently conserved to retain physical contact and corresponding biological activity. However, it has been shown that in many cases interacting biological factors undergo correlated changes during the course of evolution (De Juan *et al.*, 2013). Such changes reflect adaptive processes which act to retain biological activities in response to changes in environmental conditions. In order to maintain critical biological functions and prevent incompatibilities, a mutation within a gene that codes for a particular protein can trigger selection for compensatory mutations either elsewhere in that same protein or in other physically or genetically interacting factors

(Pazos and Valencia, 2008). This phenomenon has been utilized to predict protein–protein interactions, in combination with parameters mainly derived from 3D structural information (Lewis *et al.*, 2010). Other modes of physical interactions between molecules, such as those between RNA and proteins in either the cytosolic or mitochondrial ribosomes, or between DNA binding sites and their associated transcription factors, frequently occur in biological systems, and are profoundly important in sustaining biological activities.

Indeed, co-adaptation occurs among physically interacting factors in the context of many biological functions. However, unlike most cellular activities which are coded by the nuclear genome, the relatively fast mutation rate of the mitochondrial genetic system requires especially tight coevolution among its interacting factors (Saccone *et al.*, 2006).

Mitochondrial–Nuclear Coevolution in the Mitochondrial Protein Translation System

The OXPHOS and the mitochondrial translation machinery are the only two mitochondrial complexes consisting of factors encoded both by the mitochondrial and the nuclear genomes. Similar to the OXPHOS system (which is discussed in section Primer on Mitochondrial Genetics and Genomics), mtDNA-encoded rRNAs and their interacting nuclear DNA-encoded ribosomal proteins (Desmond *et al.*, 2011; Smits *et al.*, 2007) have likely coevolved to maintain structure and function of the ribosome (Barreto and Burton, 2013). Additionally, it has been reported that the RNA component of the mitochondrial ribosome is reduced in size compared to its bacterial homologue, with a compensatory increase in protein content to maintain the 3D structure (Mears *et al.*, 2006; Greber *et al.*, 2014), further supporting mito–nuclear coevolution. Coevolution between the mtDNA-encoded rRNAs and their interacting proteins has yet to be studied, though it is known that the nuclear DNA-encoded mitochondrial ribosomal proteins evolve faster than cytosolic ribosomal proteins (Barreto and Burton, 2013).

In order to better investigate patterns of coevolution of interacting factors within the mitochondrial ribosome, high-resolution structural information is desirable. However, unlike the OXPHOS mammalian complexes for which high-resolution structural information is available (excluding complex I, and part of complex V) the structure of the mammalian mitochondrial ribosome was, until recently resolved only in relatively low resolution (Greber *et al.*, 2014; Kaushal *et al.*, 2014). Recent high resolution structures will enable elucidating the direct physical interactions between nuclear DNA-encoded proteins and the mtDNA-encoded rRNAs (Amunts *et al.*, 2015; Greber *et al.*, 2015). Additionally since the closest structural relative of the mitochondrial ribosome is the bacterial one, and since the ribosome structure is highly conserved from bacteria to human (Ben-Shem *et al.*, 2011), patterns of coevolution within the bacterial ribosome are likely to assist in understanding the nature of evolutionary dynamics and interactions within the mitochondrial ribosome. Indeed, patterns of correlated changes have been observed between the 23S rRNA (the orthologue of mtDNA-encoded 16S rRNA) and a directly interacting protein–alpha helix 3 of ribosomal protein L11 in bacteria (Guha Thakurta and Draper, 1999). Recent advances in identification of mitochondrial RNA-binding proteins may assist in isolating the binding proteins of mtDNA-encoded rRNAs and investigating their coevolution (Wolf and Mootha, 2014).

Another aspect of mito–nuclear RNA-protein coevolution is reflected in the need for compatibility between the mtDNA-encoded tRNA Tyr and the nuclear DNA-encoded tRNA Tyr-synthase to maintain normal development and mitochondrial function among *Drosophila* taxa (Hoekstra *et al.*, 2013; Meiklejohn *et al.*, 2013). As such, mito–nuclear coevolution is not restricted to protein–protein interactions.

Mitochondrial–Nuclear Coevolution of Regulatory Elements

The genome of the mitochondrial progenitor is believed to have harbored all the genes required for its activities, including all of the OXPHOS genes which are currently divided between the mitochondrial and nuclear genomes. Similar to its free living relatives, contemporary mtDNA genes are transcribed in a polycistronic manner, thus retaining their ancestral prokaryotic mode of regulation. Accordingly, it is reasonable to assume that the genome of the mitochondrial free-living bacterial ancestor harbored genes that were co-regulated and co-transcribed as a polycistornic RNA molecule. However, the genes currently encoding the protein subunits of the OXPHOS protein complexes are dispersed throughout the human genome and are mapped to different chromosomes; hence the problem of their co-regulation is a major issue as they have to collaborate within the multi-subunit protein complexes in many different tissues. Indeed, co-expression has been identified among genes that encode protein subunits that participate in the same OXPHOS complexes (Duborjal *et al.*, 2002; Garbian *et al.*, 2010; Van Waveren and Moraes, 2008). Accordingly, the expression pattern (mRNA) of genes belonging to the OXPHOS pathway was jointly altered in type 2 diabetes patients (Mootha *et al.*, 2003). Furthermore, changes in the expression pattern of nuclear DNA-encoded proteins have been described in cells originating from patients with mtDNA-encoded tRNA disease-causing mutations, suggesting signals delivered from the mitochondria to the nucleus and coordinated regulation (Rabilloud *et al.*, 2002; Chae *et al.*, 2013). These pieces of evidence point to the possible existence of a mechanism (or mechanisms) that govern co-regulation of mtDNA and nuclear DNA-encoded factors of the OXPHOS system.

If such mechanism indeed exists, there should be factors that are involved in the joint regulation of mitochondrial genes and nuclear genes. Indeed, some transcription factors, including NRF1, NRF2, PGC1a, and YY1, have been suggested as regulators of multiple proteins related to the OXPHOS system (Van Waveren and Moraes, 2008; Leigh-Brown *et al.*, 2010). NRF1 and NRF2 also regulate the transcription of factors that directly operate mtDNA transcription such as mitochondrial transcription factor A (TFAM) (Scarpulla, 2008). Furthermore, changes in the methylation status in promoters of nuclear DNA-encoded genes with mitochondrial function have been observed in a tissue-specific manner, suggesting differential regulation of

mitochondrial transcription across tissues (Takasugi *et al.*, 2010). Finally, other transcription factors, such as the thyroid hormone receptor, MEF2D, (**Figure 2**) and the glucocorticoid receptor, are known to regulate the transcription of nuclear genes but are also imported into the mitochondria, where they bind the mtDNA and regulate its transcription (Enriquez *et al.*, 1999; Leigh-Brown *et al.*, 2010; Psarra and Sekeris, 2011; She *et al.*, 2011; Szczepanek *et al.*, 2012). Similar to the components of mitochondrial transcription, some mtDNA replication components, such as hDNA2, APE1, Pif1, and DNA ligase III, co-localize and perform their functions both in the mitochondria and in the nucleus (Duxin *et al.*, 2009; Chattopadhyay *et al.*, 2006; Futami *et al.*, 2007; Lakshmipathy and Campbell, 1999). These findings indicate that nuclear and mtDNA transcription and replication could be co-regulated by a set of shared factors.

In addition to the mitochondrial localization of regulatory factors with known nuclear function, non-mitochondrial cellular localization has also been reported for some mitochondrial proteins (Yogev and Pines, 2011). Among these are the mtDNA transcription factor A (TFAM) (Pastukh *et al.*, 2007), and the mtDNA RNA Polymerase (POLRMT) (Kravchenko *et al.*, 2005), which are localized and involved in transcription both in the mitochondria and in the nucleus, although recent evidence question these interpretations (Kühl *et al.*, 2014). Hence, co-regulation of mtDNA and nuclear DNA-encoded proteins with mitochondrial activity is plausible (Bar-Yaacov *et al.*, 2012b).

The above findings raise the possibility of coevolution between factors that directly regulate mtDNA transcription and/or replication along with their binding sites in the mtDNA. This possibility is supported by the finding that human mitochondrial RNA polymerase, POLRMT, cannot bind and initiate transcription at the mouse light strand mtDNA promoter and vice versa (Gaspari *et al.*, 2004). Additionally, human mtDNA genetic variants can alter *in vitro* transcription and affect the binding capacity of TFAM (Suissa *et al.*, 2009). Certain genetic variants in TFAM have been associated with altered tendency to develop Parkinson's disease in Polish patients, in close correlation to the mtDNA genetic background haplogroup HV, suggesting that interfering with mitochondrial–nuclear interaction at the transcription level is involved in the etiology of the disease (Gaweda-Walerych *et al.*, 2010). Although such an association was discovered in the Polish population, no association was identified in the Spanish population (Alvarez *et al.*, 2008), thus implying the involvement of other factors that modulate the phenotypic effect of TFAM. Thorough investigation of the coevolution between nuclear DNA-encoded transcription factors and their mtDNA binding sites both within and between species should be performed in the near future. As selective constraints are different in noncoding versus gene-coding sequences one should take into account the rapid change rate of noncoding regulatory elements within the mtDNA (Montooth *et al.*, 2009). With this in mind, it is also plausible that there are regulatory elements that reside within the mtDNA-coding sequences, as was recently shown in the nuclear genome (Birnbaum *et al.*, 2012; Blumberg *et al.*, 2014). This suggests dual roles for such putative sites – they may code for genes but also promote binding of regulatory factors (Stergachis *et al.*, 2013). The discovery of such sites could pave the way toward new models of coevolution governed both by constraints acting on both gene sequences and transcription factor binding sites.

Heteroplasmy and Its Effect on Mitochondrial–Nuclear Coevolution

Unlike the nuclear genome, the mtDNA resides in multiple cellular copies that may differ in sequence, thus creating a mixed population of mtDNA molecules within a cell, termed heteroplasmy (Larsson, 2010). This phenomenon adds another dimension to mitochondrial–nuclear interactions: intracellular diversity within a single individual. Heteroplasmic mutations may be inherited as existing mtDNA diversity within the ovum, but may also appear *de novo* during the lifetime of the individual (Avital *et al.*, 2012). Pathogenic mtDNA mutations and deletions are thought to cause disease only when they constitute more than 80% (point mutations) or 60% (deletions) of the mtDNA population within the diseased tissues (Schapira, 2012; Zeviani and Di Donato, 2004). However, patterns of heteroplasmy in monozygotic twins demonstrate that even low-abundance heteroplasmic mutations are subjected to strong negative selection (Avital *et al.*, 2012). This suggests that even low-grade heteroplasmy can have functional implications and that a mechanism for the selective removal of dysfunctional mitochondria, such as mitophagy (Twig and Shirihai, 2011), can act at the subcellular level, maybe even on the activity of the single mitochondrion.

One could hypothesize that disease-causing heteroplasmic mutations affect mitochondrial–nuclear interactions, thus partially explaining the molecular basis underlying the phenotypic impact of these mutations (Carelli *et al.*, 2003). Support for this hypothesis comes from the fact that mtDNA pathological mutations have partial penetrance which is modulated by nuclear DNA modifiers (Hudson *et al.*, 2005; Shankar *et al.*, 2008; Luo *et al.*, 2013; Carelli *et al.*, 2003). Finally, it has been shown that while artificially creating a heteroplasmic cell with mixed mtDNA haplotypes, during cell divisions there has been a skew toward overrepresentation of the mtDNA molecules from the same strain of the nucleus (Lee *et al.*, 2008). All these pieces of evidence set the basis for the attractive possibility that mitochondrial–nuclear coevolution is subjected to strong selective constraints acting to protect mitochondrial–nuclear factor interactions from mutations at the population level, but even from heteroplasmic mutations.

Interference with Mitochondrial–Nuclear Interactions Cause Diseases

Since coevolution between interacting factors is important to maintain function, it is reasonable that interfering with such coevolution may have phenotypic consequences. This thought led two renowned geneticists, Theodosius Dobzhansky and Hermann Joseph Muller to independently suggest during the first half of the twentieth century that changes in one factor without compensatory response from its genetically interacting partner play an important step in the erection of reproductive barriers and, eventually, speciation events (Dobzhansky, 1936;

Muller, 1942; Gavrilets, 2003). Since interactions among mtDNA and nuclear DNA-encoded factors are important for cellular function and since some modes of co-regulation exist, at least at the transcriptional level (Leigh-Brown *et al.*, 2010), it is logical that disruption of the mito–nuclear association may cause diseases. Indeed, the penetrance of mtDNA mutations that cause Leber's hereditary optic neuropathy (LHON) was shown to be modulated by X-linked nuclear DNA encoded elements (Shankar *et al.*, 2008; Hudson *et al.*, 2005). Nuclear DNA-encoded modifiers of mtDNA mutations causing hearing loss were also suggested (Luo *et al.*, 2013; Johnson *et al.*, 2001; Guan, 2011; Kokotas *et al.*, 2011). A recent study in mitochondrial-nuclear exchange mice (which were generated by repeated backcross experiments) showed that mitochondrial–nuclear genetic interactions affect the tendency to develop nonalcoholic fatty liver disease (NAFLD) (Betancourt *et al.*, 2014). Work in conplastic strains of rats, i.e., strains with identical nuclear genomes but divergent mitochondrial genomes, which encode amino acid differences in OXPHOS proteins, exhibit differences in major metabolic risk factors for type 2 diabetes (Pravenec *et al.*, 2007). Accordingly, the association of a certain mtDNA genetic background (haplogroup J1) with a tendency to develop type 2 diabetes mellitus in Jews is modulated by nuclear DNA-encoded factors (Feder *et al.*, 2009; Gershoni *et al.*, 2014). Moreover, the susceptibility to develop type 2 diabetes mellitus in Indian patients depends on specific association of mtDNA and nuclear DNA common variants (Rai *et al.*, 2007). The disease-causing phenotype of a mutation in *NDUFA1*, a nuclear DNA-encoded subunit of OXPHOS complex I, is dependent on mtDNA-encoded factors (Potluri *et al.*, 2009). Disruption of mito–nuclear interaction due to disease-causing and evolutionary convergent mutations in mitochondrial tRNAs has also been reported (Kern and Kondrashov, 2004). Taken together, all these findings suggest that disruption of the connection between certain mtDNA-nuclear DNA-encoded factors can lead to diseases (De Magalhaes, 2005).

Model Systems: The Key Roles of Traditional and New Models in Evolutionary Developmental Biology

A Stollewerk, Queen Mary University of London, London, UK

Glossary

Convergence It is the evolutionary concept of the existence of similar structures or genes that have evolved independently as a result of adaptation to similar environments.

Fate map It is used to trace a particular cell or region from an early embryo into a differentiated body plan.

Homology It is the evolutionary concept of the existence of similar structures or genes due to shared ancestry.

***In situ* hybridization (ISH)** It is a technique for localizing specific nucleic acid targets (DNA or RNA) in prepared tissues, cells, or even whole organisms to obtain temporal and spatial information about gene expression and genetic loci.

Microarrays They are DNA chips consisting of a collection of microscopic DNA spots attached to a solid surface such as a glass slide. They are used for the comparative measurement of gene expression levels.

Ontogenesis It is the development of an organism including all stages from the time of fertilization of the egg to the mature, reproductive form.

RNA interference (RNAi) It is a naturally occurring mechanism in which RNA molecules inhibit gene expression via the RNAi pathway. Small interfering RNAs can be generated *in vitro* and are used in EvoDevo to reduce or inhibit the expression of specific genes to study their function.

RNAseq (RNA sequencing) RNA sequencing is a technique that uses next-generation sequencing to reveal the presence of transcripts and their quantity in a given tissue/organism at the time of collection.

Introduction

In order to understand the key roles of model systems in EvoDevo, it is important to first define the term model system (or organism which will be used interchangeably here). In developmental biology, a few species are recognized as model organisms, for example, the fruit fly *Drosophila melanogaster*, the worm *Caenorhabditis elegans*, the zebrafish *Danio rerio*, and the mouse *Mus musculus*. They fulfill several requirements that make them suitable for a wide range of developmental questions: (1) They have short generation times and can be cultured in the lab. (2) Embryos are easily accessible and can be manipulated for functional studies. (3) Mutant and transgenic lines are available and the genome is sequenced. (4) Substantial knowledge of the development of the organisms has been collated, including detailed subdivisions of the developmental processes and stages (staging system) and fate maps. (5) Databases are available as repositories of genetic, molecular, and expression data, including descriptions of mutant alleles and phenotypes, gene expression data (e.g., *in situ* hybridizations, RNAseq, microarrays), and anatomical data.

Species that have been developed into model systems over the past decades ('traditional' model organisms) have been – and still are – invaluable for deepening our knowledge of the molecular and morphological processes of development. However, studies in additional vertebrate and invertebrate species have made it clear that the regulation of developmental processes is substantially different not only in different clades of the same phylum but also within clades and even in species of the same order (Choe and Brown, 2007; Krol *et al.*, 2011). For example, variations have been detected in the insect orders Diptera (true flies) and Hymenoptera in the formation of the embryonic midline cells which play an important role in organizing the bilateral symmetry of the nervous system (Zinzen *et al.*, 2006). In the fruit fly *D. melanogaster*, a fixed number of eight midline precursor cells per segment generates individually identifiable neurons and glial cells (Bossing and Technau, 1994). While the midline precursors arise from the same tissue ('mesectoderm') in both species, three times as many precursors develop in the honeybee *Apis mellifera*. This is due to changes in the regulation of *single-minded*, a transcription factor which is involved in the formation of the midline precursors (Zinzen *et al.*, 2006). Although the molecular mechanisms of midline formation have not been resolved in basal representatives of the insect clade (e.g., grasshopper) (Jia and Siegler, 2002), it is clear that their origin must differ from dipteran and hymenopteran midline precursors due to the overall difference in body formation. This example shows that developmental processes are highly variable and findings within a single species – regardless of it being recognized as a model organism or not – cannot be generalized. It is therefore clear that a model organism's value depends on the question in focus. Since the concepts and questions addressed in developmental biology and evolutionary developmental biology (EvoDevo) are fundamentally different, the traditional developmental model organisms can only contribute a small part to the latter research field. However, as we shall see below, they were indispensible at the start of the molecular area of EvoDevo.

The Role of Traditional Model Organisms in Evolutionary Developmental Biology

EvoDevo combines evolution and development and compiles new concepts of how developmental processes link the

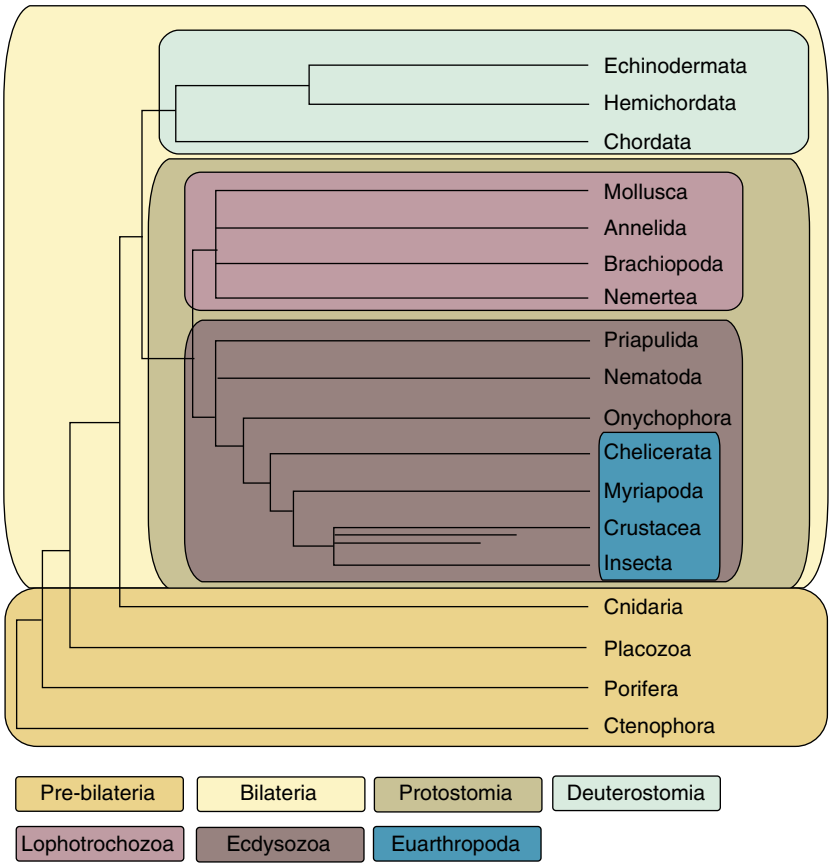

Figure 1 Phylogeny of the animal kingdom. The phylogeny shows the major subdivisions of the animal phyla and some selected taxa within each group. It is based on the Tree of Life web project (http://tolweb.org/tree/phylogeny.html) and references given in the main text. See also references in the main text for alternative scenarios.

genotype and the phenotype in the formation and evolution of traits and organisms (Moczek *et al.*, 2015). Over the past 150 years, the main approach of EvoDevo research was the comparative analysis of developmental processes in a phylogenetic context with the aim of understanding the morphological variations and the origin of structures. In the past decades this approach has been extended to the comparative analysis of developmental genes and their expression and function. Based on the knowledge of the genetic regulation of development in traditional model organisms, EvoDevo research identified homologous genes in a variety of different species across the animal kingdom. An important concept that emerged from these studies is that of the 'toolkit genes,' which means that developmental genes are used over and over again for various developmental processes across the animal kingdom (Shubin *et al.*, 2009). The Hox genes were one of the first toolkit genes that were discovered (Heffer and Pick, 2013). They confer segmental identity along the anterior–posterior (AP) body axis, among others, across the animal kingdom. For example, in vertebrates they determine the structural difference between the cervical, rib, lumbar, and sacral vertebrae and in the fruit fly *D. melanogaster* the identity of the various gnathal, thoracic, and abdominal segments (Horan *et al.*, 1994; Maeda and Karch, 2009). Most importantly, developmental genes are not only used in developmental processes that produce homologous structures but have also been redeployed for the generation of structures that evolved by convergence. For example, a specialized cell type, the neural progenitor cell, which can potentially generate all cells of the nervous system, has evolved by convergence in the invertebrate phylum Arthropoda and in the phylum Chordata, which contains the vertebrates. Yet, in both cases the Achaete-Scute bHLH transcription factors and the Notch signaling pathway regulate early steps of neural progenitor formation and differentiation (Ungerer *et al.*, 2012).

Traditional model organisms were not only used for cloning homologous genes in other species but also as a first reference point for comparing and understanding evolutionary changes in gene function. For example, insects belong to the euarthropods whose bodies are composed of segments (**Figure 1**). In the traditional model organism, *D. melanogaster*, all segments are generated at the same time in the embryo. A hierarchical gene cascade subdivides the embryo into smaller and smaller units (Nüsslein-Vollhard and Wieschaus, 1980). However, in most other euarthropods, the cellular material which is present at the start of the segmentation process only corresponds to the anterior part of the embryo; the remaining segments are generated one by one from a posterior growth zone. Despite this difference, the '*Drosophila*' segmentation genes are expressed in all analyzed euarthropods (Arthur and Chipman, 2005; Cerny *et al.*, 2008; Eriksson *et al.*, 2013). However, significant differences in the expression and function

have been reported, in particular for the so-called pair-rule genes, which are expressed in alternating segments in *D. melanogaster* but in every segment in many euarthropods or even in opposite register as *Tc-sloppy-paired* in the flour beetle *Tribolium castaneum* (Choe and Brown, 2007; Eriksson *et al.*, 2013; Schoppmeier and Damen, 2005).

Are traditional model organisms only useful for comparative purposes or can they be used directly for addressing EvoDevo questions? Several research groups have in fact shown that the traditional model organism *D. melanogaster* is useful for investigating host–microbe evolution (Richardson *et al.*, 2012; Teixeira *et al.*, 2008; Versace *et al.*, 2014). *Wolbachia* is a common bacterial endosymbiont of arthropods and transmitted to the offspring via the egg cytoplasm (Werren *et al.*, 2008). *Drosophila* benefits from *Wolbachia* by increased fecundity and antiviral protection, among others (e.g., Fry *et al.*, 2004; Hedges *et al.*, 2008; Olsen *et al.*, 2001; Teixeira *et al.*, 2008). Various *Wolbachia* strains originating from different climates and grouped into five clades are capable of infecting the flies at the same time (Richardson *et al.*, 2012). The naturally occurring diverse infection patterns are poorly understood, partially due to the complexity of influencing environmental factors. This problem can be approached by experimental evolution. *Drosophila* populations infected with several *Wolbachia* strains were exposed over many generations to single environmental cues in controlled laboratory conditions (Versace *et al.*, 2014). Schlötterer and co-authors found that after 15 generations in a cold environment, *Wolbachia* clades I to III were lost from the *Drosophila* populations, while clade VI was reduced in frequency; however, clade V showed an increase of about 50% (Versace *et al.*, 2014). This does not occur when the flies are exposed to a hot environment. The selective loss can be explained by the origin of the clades. Clades I to III originate from warm climates (the Afrotropics), while clades V and VI derive from colder Eurasian climates.

Evolutionary experiments using *Drosophila* populations have also improved our understanding of longstanding fundamental questions in EvoDevo. In the 1940s Waddington observed that ontogenesis results in the same phenotypic outcome over a wide range of internal and external variations suggesting that internal buffering mechanism canalize the developmental processes (Waddington, 1942). Waddington named this phenomenon 'canalization.' By exposing *Drosophila* to ether, he unveiled hidden ('cryptic') genetic variations resulting in dramatically different phenotypes such as flies with two pairs of wings instead of one (Waddington, 1956). After several generations the flies even showed the phenotypic variation without the environmental cue. The experiment shows that environmentally induced phenotypic variants can become genetically stabilized and thus demonstrates the influence of the environment on morphological evolution. What are the underlying mechanisms? Again the traditional model organism *Drosophila* has provided possible answers. The heat shock protein Hsp90, for example, masks genetic variations due to its role as a chaperone in correcting misfolding of proteins. In Hsp90 mutants phenotypic variations of nearly any adult structure are produced showing that genetic variations for multiple developmental pathways exist (Rutherford and Lindquist, 1998). Recent expression studies show the canalization effect on a genome-wide level (Chen *et al.*, 2015; Levine *et al.*, 2011). For example, the different alleles of two *D. melanogaster* strains show the same expression levels at moderate temperatures (18 °C) but significant differences appear when the flies are exposed to extreme temperatures indicating that extreme environmental changes unmask existing genetic variations ('decanalization') (Chen *et al.*, 2015).

To summarize, traditional model organisms have played a significant role in directing the research at the start of the molecular area of EvoDevo and continue making valuable contributions both as benchmark for comparative developmental studies and as independent EvoDevo model organisms.

The Role of New Model Organisms in Evolutionary Developmental Biology

In the previous section, I briefly addressed the question of how diverse molecular processes can lead to the same morphological outcome. On the other hand, the discovery of the toolkit genes raises the question of how conserved molecular pathways perform their role regardless of major differences in morphology. The integration of evolutionary changes into existing organ systems is another unsolved question in evolution. How are evolutionary changes in a certain organ system integrated with the remaining developmental processes to generate a functional phenotype? And how do novel traits evolve? These questions make it clear that an important criterion for choosing EvoDevo model organisms is their phylogenetic position. Thus, there are strong links between EvoDevo and taxonomy and adjustments in the phylogenetic positions can change our view of how and when characters have evolved.

For example, the question of when the nervous system has evolved requires the investigation of representatives of phyla across the animal kingdom. Comparative analysis of all major bilaterian groups, the deuterostomes and the protostomes which are divided into the supertaxa Ecdysozoa and Lophotrochozoa revealed that all bilaterians have nervous systems, while they are missing in some pre-bilaterian phyla (reviewed by Hartenstein and Stollewerk, 2015; **Figure 1**). Traditionally it was thought that the nervous system evolved once in pre-bilaterians. However, the two pre-bilaterian phyla with nervous systems, the cnidarians and ctenophores, might not be as closely related as was assumed. In a recent molecular phylogeny, the latter were placed close to the origin of the metazoan tree (Moroz *et al.*, 2014). In this scenario, two phyla without a nervous system branch off between ctenophores and cnidarians suggesting that the ctenophore nervous system has evolved independently (but see Ryan *et al.*, 2013; Marlow and Arendt, 2014 for discussion; **Figure 1**).

The presence of a nervous system can be determined by morphological analysis of adult specimen and by genome sequencing or transcriptome analysis to identify neural genes. However, different, more challenging strategies are required for addressing the question of how the various nervous systems have evolved because this requires ontogenetic and functional studies, among others. There is a huge variety in the structure and degree of centralization of bilaterian nervous systems (reviewed by Hartenstein and Stollewerk, 2015). Since

developmental processes ultimately determine the adult structure, a detailed knowledge of the development of the nervous system is required. If we want to analyze the evolution of the nervous system on a larger evolutionary scale, representatives of various phyla with diverse CNS structures have to be chosen such as euarthropods with tripartite brains and metameric ventral ganglia, vertebrates with complex brain centers and dorsal ganglia as well as animals with simple brain structures such as Platyhelminthes (flatworms) and prebilaterians like Hydra which show some degree of centralization (reviewed by Hartenstein and Stollewerk, 2015). In such large-scale studies, we can investigate how the different areas of the CNS are established. The Wnt/β-catenin pathway, for example, patterns the CNS along the AP axis in vertebrates and in planarians (flatworms) which belong to the lophotrochozoans (Niehrs, 2010). In contrast, in arthropods (Ecdysozoa) Wnt signaling regulates posterior elongation and segmentation (Janssen *et al.*, 2010). It is not required for overall AP patterning of the brain, rather it determines AP fate within neuromeres (Bhat *et al.*, 2000). Although many of the genes downstream of the primary patterning mechanisms are conserved across the animal kingdom, such as the Hox genes which subdivide the neurogenic region along the AP axis (e.g., Gummalla *et al.*, 2014; Nordstrom *et al.*, 2006), considerable differences in their function and requirement for the formation of specific parts of the CNS are observed even within the same phylum (e.g., Janssen *et al.*, 2014; Merrill *et al.*, 1989; Posnien and Bucher, 2010; Schaeper *et al.*, 2010). These evolutionary changes might explain evolutionary differences in the functional and morphological subdivisions of the bilaterian CNS.

On a cellular level, the identification of potentially homologous structures can be obscured by multiple evolutionary changes if they are compared over a large evolutionary distance. In order to understand, for example, the finer details of how specific neuronal lineages have changed during evolution to support the function of new or modified morphological structures and behaviors, the comparative analysis of closely related taxa is required. Arthropods are highly suitable for addressing this question because they comprise the largest animal phyla and show a great variety of shapes and behaviors. Again, the traditional model organism *D. melanogaster* is a good starting point since the neuronal lineages in the ventral nerve cord have been described in detail (e.g., Bossing *et al.*, 1996; Doe, 1992; Landgraf *et al.*, 1997; Schmid *et al.*, 1999). However, a comparison of neuronal lineages across all euarthropod phyla (insects, crustaceans, myriapods, chelicerates) is not possible because of the different modes of neurogenesis (**Figure 2(a)**). In chelicerates and myriapods groups of neuroectodermal cells differentiate directly into neurons and glia, while in insects and crustaceans neuroblasts divide asymmetrically to generate fixed neural lineages (Bate, 1976; Dove and Stollewerk, 2003; Eriksson and Stollewerk, 2010; Stollewerk *et al.*, 2001; Ungerer and Scholtz, 2008). The neural precursor groups and neuroblasts are arranged in similar patterns in rows and columns in the ventral nerve cord allowing for the comparison of areas of neurogenesis between euarthropod groups (**Figure 2(a)**). However, the evolutionary comparison of single neurons and precursors is hampered by the differences in their formation (Döffinger and Stollewerk, 2010). Within euarthropod groups, individual, potentially homologous neuronal lineages can be identified and studied as has been shown in insects. The arrangement of neuroblasts is highly conserved across insects and maps have been established for various species (references in Döffinger and Stollewerk, 2010). Recent comparative studies in *D. melanogaster* and *T. castaneum* revealed that the expression profile of presumably homologous neuroblasts varies considerably, which might explain evolutionary changes in the neural lineages (Biffar and Stollewerk, 2014, 2015; **Figure 2(b)**). Despite the molecular changes conserved pioneer neurons are produced which establish the axonal scaffold (Biffar and Stollewerk, 2015; **Figure 2(b)**). This suggests that internal buffering mechanisms exist ensuring that the early part of the neuronal lineages is stable over a wide range of molecular changes.

Ideally, one would like to study evolutionary questions such as those discussed above systematically, filling in the knowledge gaps and generating a complete set of comparative data that would allow for piecing together the evolutionary history of shapes and behaviors across the animal kingdom. This is complicated by the sophisticated techniques that are required, in particular when nontraditional model organisms are included in the study. Methods have to be developed for culturing the animals in the lab as well as collecting and manipulating the various ontogenetic stages. Furthermore, protocols have to be established for morphological, gene expression, and functional studies. In many cases animals in either crucial or uncertain phylogenetic positions have proved to be difficult to work with and functional techniques could not be established despite considerable efforts. For example, myriapods have a crucial position within euarthropods for understanding the evolution of neurogenesis in arthropods. They are a sister group of the pancrustaceans (insects and crustacean; also called Tetraconata), together forming the Mandibulata (but see also Boore *et al.*, 1995; Friedrich and Tautz, 1995; Kusche and Burmester, 2001; Mayer and Whitington, 2009). Myriapods could significantly improve our understanding of the evolution of neuroblasts in arthropods since they show unique mechanisms of neurogenesis that can be interpreted as intermediate between the neural precursor groups of chelicerates and the neuroblasts of pancrustaceans. However, it has neither been possible to culture myriapods in the lab nor to establish functional techniques to address the question of how asymmetric divisions of neural precursor cells have evolved.

Fortunately, however, the continuous progression of molecular techniques has made it possible to perform functional and expression studies in a wide range of nontraditional model organisms. It is outside the scope of this article to discuss the whole range of techniques but here main inventions that had a considerable impact on the EvoDevo field are briefly mentioned. Mutagenesis screens have been used successfully in traditional model organisms (e.g., *D. melanogaster* and the zebrafish *Danio rerio*) to analyze gene function; however, they require selective crosses and reproduction in the lab as well as short generation times – requirements that most nontraditional model organisms do not fulfill. The discovery that RNA interference is a widespread phenomenon and can be induced by injection/uptake of synthetic double-stranded RNA has made it possible to transiently disrupt the expression

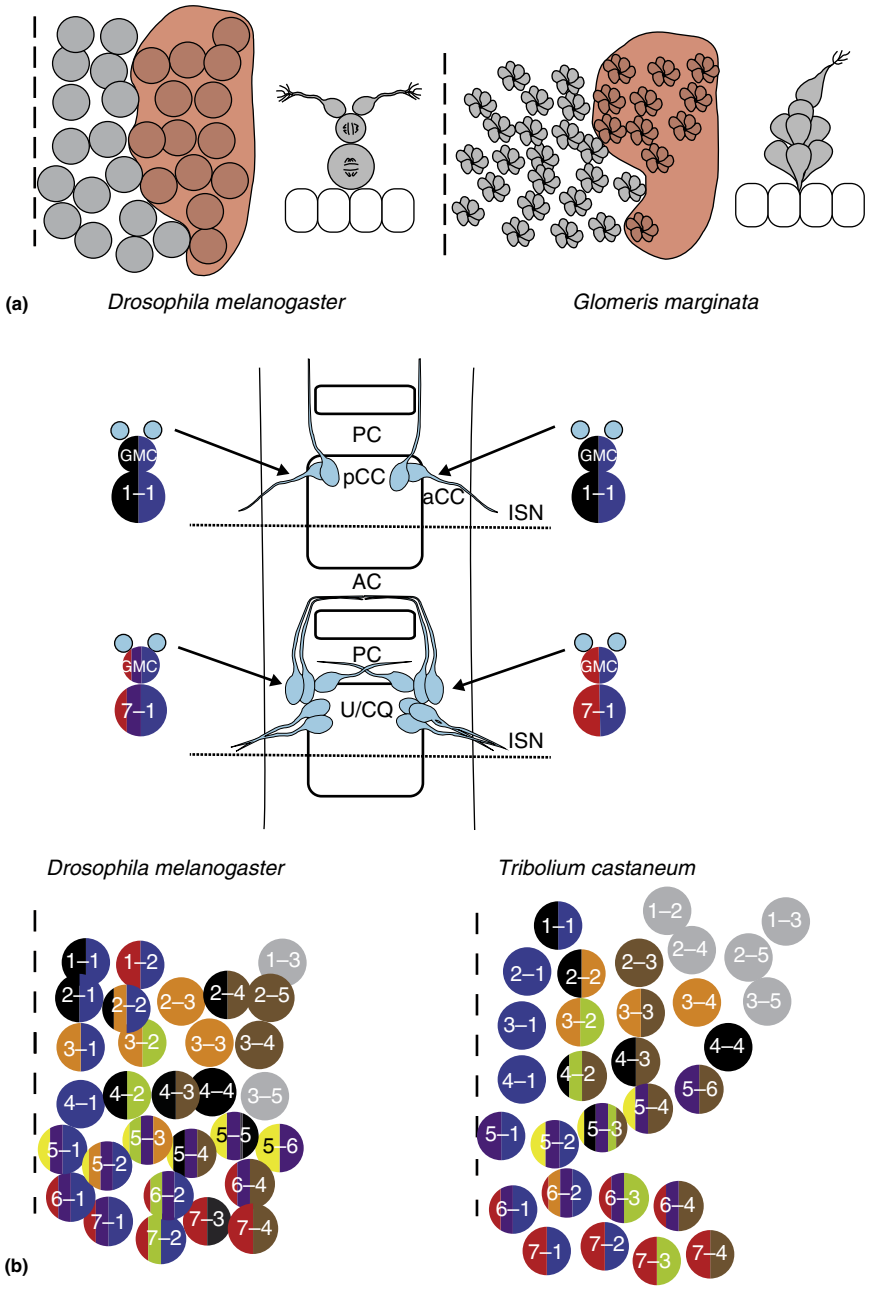

Figure 2 Evolutionary comparisons of areas of neural gene expression and neuronal lineages in euarthropods. (a) Insects (*Drosophila melanogaster)* and myriapods (*Glomeris marginata*) show different modes of neurogenesis. The left panels show horizontal views of hemi-neuromeres; the right panels show transverse views of neural progenitors/precursors. In insects neural progenitors (neuroblasts; gray circles in the left panel) divide asymmetrically to generate ganglion mother cells, which divide once to produce neurons and glial cells (right panel). In myriapods neural precursor groups (gray rosettes in the left panel) directly produce neurons and glial cells (right panel). The red shapes indicate the lateral expression of the dorso-ventral patterning gene *msh*. (b) The bottom panels show the comparative gene expression patterns in the neuroblasts of two insects, *Drosophila melanogaster* and *Tribolium castaneum*. Presumptive homologous neuroblasts show high variations in gene expression between the insects. Color code: brown, msh; green, ind; blue, vnd; black, hkb; orange, run; yellow, wg; purple, gsb; red, en; gray, none. The top panel shows the conserved axonal scaffold of euarthropods and the conserved positions of the *even-skipped (eve)* positive pioneer neurons (light blue). In both insects the eve positive aCC/pCC neurons are most likely generated by neuroblast 1-1 and the eve positive U/CQ neurons by neuroblast 7-1. AC, anterior commissure; PC, posterior commissure; GMC, ganglion mother cell, ISN, intersegmental nerve. The dashed lines indicate the segmental borders.

of genes of interest and study the functional consequences in a wide range of animal and plant phyla (Agrawal *et al.*, 2003; Fire *et al.*, 1998). RNA interference has its limitations since the double-stranded RNA has to be applied either parentally or during early stages so that later functions of the genes of interest might be obscured if their early role is vital.

Furthermore, the RNAi effect decreases over time and the injection procedure itself can lead to developmental defects (e.g., Linne and Stollewerk, 2011; Stollewerk, 2002). In *D. melanogaster*, this problem has been overcome by generating transgenes that contain a fragment of the candidate gene as an inverted repeat (Dietzl *et al.*, 2007). By using the GAL4/UAS system long double-stranded hairpin RNA is produced reducing the function of the candidate gene in a tissue and time-specific manner. This again shows the power of traditional model organisms.

Recently, the CRISPR/Cas9 system has been developed for genome editing in a variety of species including nontraditional model organisms (Gong *et al.*, 2014; Jinek *et al.*, 2012; Overballe-Petersen *et al.*, 2013). Genes are mutagenized by guiding Cas9 nucleases to specific target sequences using small RNAs. The DNA is cleaved and the repair of the lesion can introduce nucleotide substitutions or indel mutations. If the mutagenesis includes germline cells, stable mutant lines can be generated as has been shown recently in the emerging crustacean model organism *Daphnia magna*, for example (Nakanishi *et al.*, 2014). In this species, the regulator for eye development eyeless was targeted and about 8% of the mutagenized adults produced progeny with abnormal eyes.

Furthermore, next-generation sequencing has made many additional organisms accessible for EvoDevo research. Whole genomes can be sequenced and analyzed cost-effectively to study developmental pathways and their regulators (Metzker, 2010). Questions involving the expression of developmental genes and their regulatory networks can be addressed by sequencing transcripts of different developmental stages and mutant organisms as well as transcripts from organisms that have been exposed to different developmental conditions (e.g., Etges *et al.*, 2015; Staller *et al.*, 2015).

Taken together, both traditional and new model organisms have a deeply rooted place in the EvoDevo research field. While nontraditional model organisms are useful for addressing large-scale evolutionary questions such as the origin of body plans, the nervous system and novel structures, the developmental data of traditional model organisms are not only invaluable benchmarks but continuously contribute to collecting detailed knowledge of how developmental processes have been modified during evolution.

Modularity and Integration

APA Assis, BMA Costa, DM Rossoni, D Melo, and G Marroig, Universidade de São Paulo, CEP São Paulo, Brazil

Glossary

Developmental module Performs a specific role in developmental processes and corresponds to a set of cells, genes, or tissues that are relatively independent with respect to pattern formation and differentiation, or an autonomous developmental signaling pathway.

Evolutionary modules Sets of phenotypic elements evolving in coordinated fashion, because the elements are inherited together or because they are jointly selected.

Functional module Sets of traits or features that interact to perform some discrete function or task.

Genetic architecture Refers to the pattern of genetic effects that underlie the variation for a given set of phenotypic characters and its variational properties. A description of genetic architecture may include statements about gene and allele number, the distribution of allelic and mutational effects, and patterns of pleiotropy, dominance, and epistasis.

Genetic modules Sets of traits that are modular due to pleiotropy or linkage disequilibrium.

Genotype–phenotype map Depicts relationship between genetic variation and phenotypic variation; that is, it specifies which locus or loci affects each trait or traits.

Internal stabilizing selection Stabilizing selection due to the interaction of the phenotype with other internal characteristics of an organism, and is related to the need for coadaptation of traits to one another rather than to the external environment.

Linkage disequilibrium The nonrandom association of alleles at different loci.

Morphological integration Refers to the cohesion or association among morphological traits that are related functionally and/or developmentally. Traits that are integrated tend to covary together, and so this results in higher correlation between these traits when compared to traits that are not integrated.

Pleiotropy A single locus affecting two or more phenotypic traits.

Quasi-independence (quasi-autonomy) A lower than average grade of connectedness, for example, the elements of modules are highly interconnected, while being less connected to other modules. This 'quasi independence' may allow one character to change without affecting others.

Quantitative Trait Loci (QTL) Refers to DNA loci that affect quantitative traits.

Variational modules Set of covarying traits that vary relatively independently of other sets of traits. The reason for this relative independence of different sets of traits, or modules, is that pleiotropic loci with effects on traits belonging to different modules are less frequent than those within modules. These modules are recognized by higher correlations between traits in the same module and lower correlations between traits of different modules.

What Is Modularity and Integration?

Biology is rapidly embracing the challenge of dealing with multidimensional hierarchical systems as a way of moving forward and addressing questions that range from the genetic basis of diseases, behavior, or morphology, the ecological structure of communities, or the evolution of any of these features. To face this challenge we need both theoretical developments and methods capable of dealing with such complexity. At the core of all this lies the concept of modularity. In Biology, modularity refers to the pattern and magnitude of association among elements in a system. This pattern emerges whenever a high connectivity between some elements in the system exists, forming modules, and at the same time these same elements are more loosely associated to other elements that compose other modules. Modularity depends on the ability of a system to organize semi-autonomous parts, or even discrete elements, into a coherent whole. Modularity can be studied at nearly every scale of biological organization; and it has been described in a variety of contexts and observed in many model systems, in a wide range of disciplines and specialties. These include proteins (Han *et al.*, 2004), genes (Litvin *et al.*, 2009), cells (Hartwell *et al.*, 1999; Wagner, 1996), organs (Schlosser and Wagner, 2004), and ecosystems (Montoya *et al.*, 2006).

Here, we address modularity in the context of morphological quantitative traits and discuss the influence of genetic, functional, and developmental factors at this level. In this context, different parts of organisms can behave as modules because they exhibit some degree of independence, and are internally organized, reflecting their developmental origins and functions, as we will see later (Cheverud, 1996; Klingenberg, 2004).

Most of our current understanding of character correlations and on the evolution of complex continuous traits is influenced by the concept of morphological integration (Olson and Miller, 1951, 1958). Olson and Miller (1951, 1958) coined the term morphological integration to describe high levels of phenotypic correlation within subsets of morphological traits. Today, these sets of integrated traits related functionally and/or developmentally are termed modules. In a remarkable work addressing morphological variation and correlation in plants, Raissa Berg (1960) described a similar concept known as 'correlation pleiades.' As with morphological integration, correlation pleiades are based on the presence of high levels of

 doi:10.1016/B978-0-12-800049-6.00044-5

correlation between some parts of an organism, and low association between these and other parts of the same organism.

From the above definitions, we can see that modularity and integration are interrelated concepts, as both of them deal with the interdependence between different structures based on developmental, genetic, and/or functional factors, and, moreover, are quantified by the degree of correlation or covariation among traits. In fact, they can be understood as two sides of the same coin. While the concept of morphological integration describes connections among parts of an organism, the concept of modularity stresses its relative independence or autonomy (Schlosser and Wagner, 2004; Wagner, 1996).

In biology, several types of modules have been recognized, including functional, developmental, genetic, evolutionary, and variational (Cheverud, 1996; Wagner *et al.*, 2007). A functional module is composed of characters or features that interact together on performing a task or function and are relatively independent in relation to other functional sets (Cheverud, 1996; Wagner *et al.*, 2007). Developmental modules correspond to set of cells, genes, or tissues that are relatively independent with respect to pattern formation and differentiation, or an autonomous regulatory control (Wagner *et al.*, 2007). Genetic integration occurs when sets of morphological elements are inherited together as a module, due to pleiotropy and/or linkage desequilibrium. These sets of morphological elements are more or less independently of other sets or modules (Cheverud, 1996). An evolutionary module is a set of morphological traits evolving in coordinated fashion, because the elements are inherited together or because they are jointly selected (Cheverud, 1996). Variational modularity is recognized by higher correlations between traits in the same module and lower correlations between traits of different modules, and can have different causes (Armbruster *et al.*, 2014; Grabowski *et al.*, 2011; Melo and Marroig, 2015; Young and Hallgrímsson, 2005).

The Causes of Modularity: Development and Function

A variational modularity is thought to be the outcome of functional and/or developmental relationships between traits (Berg, 1960; Cheverud, 1982; Olson and Miller, 1958; Porto *et al.*, 2009). These two forms of individual level integration are related because development can be viewed as a dynamic process, and functional integration in the adult is likely achieved through developmental integration (Cheverud, 1996). Moreover, the developmental process is the path by which genetic variation is translated into phenotypic variation (genotype–phenotype map *sensu*, Wagner and Altenberg, 1996). Consequently, the study of modularity is crucial to understand these developmental pathways.

Processes of shared function and development can act as an internal stabilizing selection force on the maintenance of the modular structure observed at the phenotypic level (Estes and Arnold, 2007; Porto *et al.*, 2013, 2009; Shirai and Marroig, 2010). This can be seen with a simple example: in almost all mammals the mandible and maxilla need to work together in order to function. Furthermore, these two bones share the same developmental origins. Thus, while a multitude of dietary habits exists, the shared internal development and function keep the two traits highly correlated in all mammals.

If we extend this example a bit further to four traits we can perhaps get a firmer grip on the origins of modularity in functional and developmental factors. Empirically, functional, and developmental integration can be measured by detecting the existence of groups of highly correlated traits. Under the hypothesis of modularity, one would expect that developmentally and functionally related traits would have a relatively higher correlation between them than the correlation among those without shared function or developmental origin/interaction (Cheverud, 1982). To illustrate this concept, we can look to **Figure 1** that presents four cranial traits measured in a bat skull and mandible. The first two traits, maxilla length and mandible length, are related to chewing function. Since both share the same function, it is expected that they present relatively higher correlation. In addition, these traits correspond to bones that share a common cellular origin in the neural crest, which reiterate the expectation of high correlation for both characters. Consider now the other two traits in **Figure 1**: frontal and parietal length. These two are not directly related with mastication but instead are primarily involved in brain protection. Moreover, these two bones share a common embryonic origin in the paraxial mesoderm cells. Accordingly, we would expect to find a high correlation between maxilla and mandible as well as a high correlation between parietal and frontal measurements. On the other hand, we would expect to find a considerably lower, or even absent, correlation between these two groups (**Figure 1**).

The Origin of Modularity and Integration from a Genetic Perspective

From a genetic perspective, pleiotropy and linkage disequilibrium are the two mechanisms behind modularity and integration (Falconer and Mackay, 1996). Linkage disequilibrium is the nonrandom association of alleles at different loci. In other words, it is the presence of statistical associations between alleles compared to what would be expected if alleles were independently, randomly sampled from the population. This process leads to nonrandom co-occurrence of different combinations of trait values associated with different alleles. The relative contribution of linkage disequilibrium for modularity patterns is debatable, since recombination might break these associations. However, linkage disequilibrium can be actively maintained through natural selection (Barton and Turelli, 1989; Templeton, 2006). Pleiotropy, on the other hand, has a more established role on the emergence of modularity (Wright, 1980). Pleiotropy is a common property of many genes, and occurs when a gene affects the phenotypes of two or more traits (Cheverud, 2004; Hodgkin, 1998; Wagner and Zhang, 2011). Traditionally, it was believed that widespread pleiotropy could be prejudicial to the adaptation process. The rationale behind this is that, the more complex an organism is (in terms of a higher dimensional trait space), the less likely a pleiotropic mutation will be advantageous. This is because the larger the number of traits affected by a particular pleiotropic loci, the more unlikely it is for the changes caused by a mutation to be advantageous in all

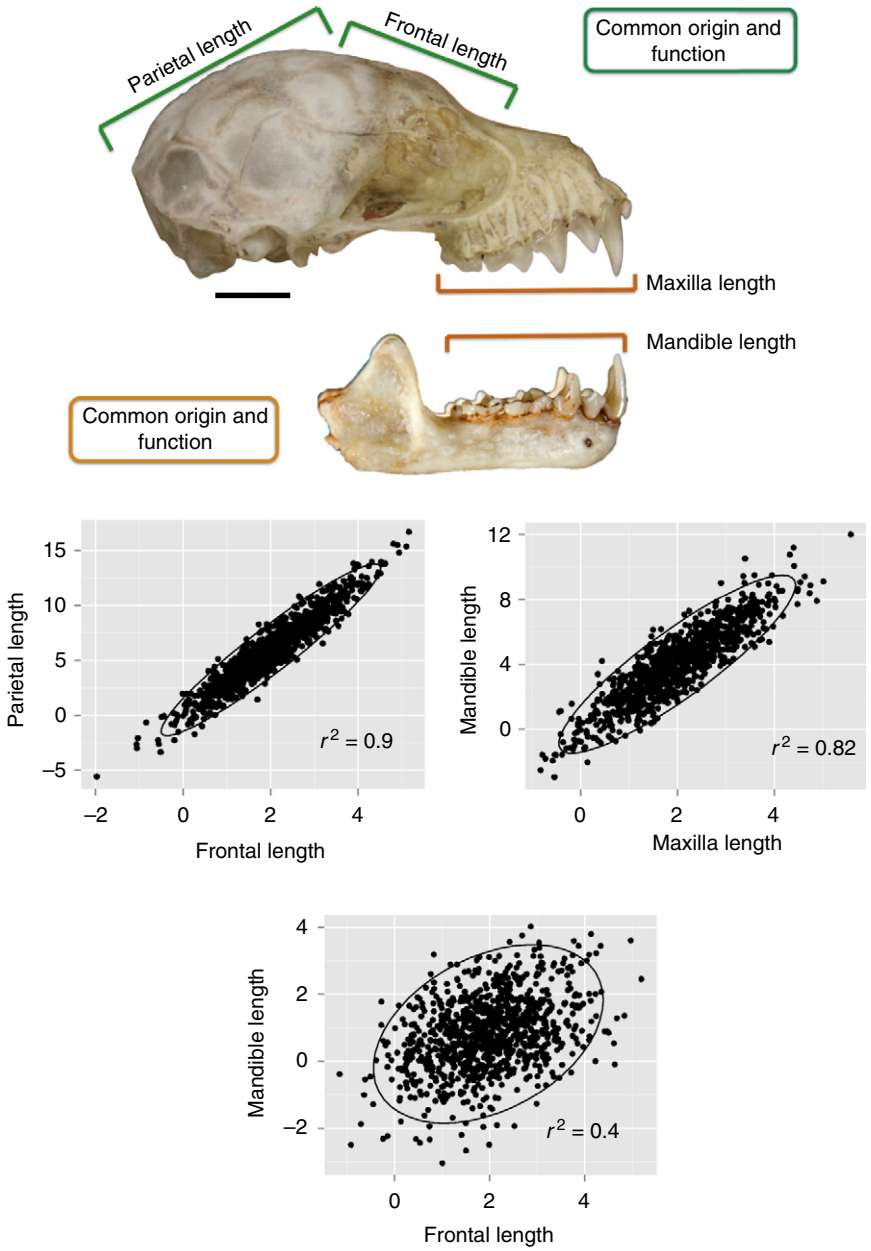

Figure 1 Hypothetical example of four cranial traits in a bat skull and mandible and their correlations. Note that developmentally and functionally related traits exhibited higher correlation. Green: parietal and frontal bones share a common embryonic origin in the paraxial mesoderm cells and are related in protect central nervous system. Orange: maxilla and mandible are related to chewing function and share a common cellular origin in the neural crest. Scale bar (black line) = 5 mm. Picture credits: *Daniela Rossoni.*

traits simultaneously; an issue known as 'the cost of complexity' (Fisher, 1930; Orr, 2000). From this point of view, the more complex an organism is, the more difficult it would be to respond to selection. Wagner (1996) was the first one to propose a model that could circumvent the complexity cost problem. He suggested that pleiotropic effects must be somewhat limited and related to function, creating modules of genetic effects that allow relative independence, in the same vein as the classical Olson and Miller modular organization. Indeed, there is considerable empirical evidence pointing to the emergence of modularity due to pleiotropic gene effects restricted to a set of functionally or developmentally related traits, a pattern known as modular pleiotropy (Cheverud, 2004, 1996; Cheverud *et al.*, 1997; Ehrich *et al.*, 2003; Leamy *et al.*, 1999; Mezey *et al.*, 2000; Pavlicev *et al.*, 2008; Vaughn *et al.*, 1999; Wagner *et al.*, 2007).

Pleiotropy can have both a constraining and a facilitating effect in the evolutionary process. It can be a constraint in the sense that the more traits a gene affects the more unlikely a mutation will be advantageous (Fisher, 1930; Orr, 2000). On the other hand, pleiotropy might be a facilitator of evolution, since populations whose individuals are organized in

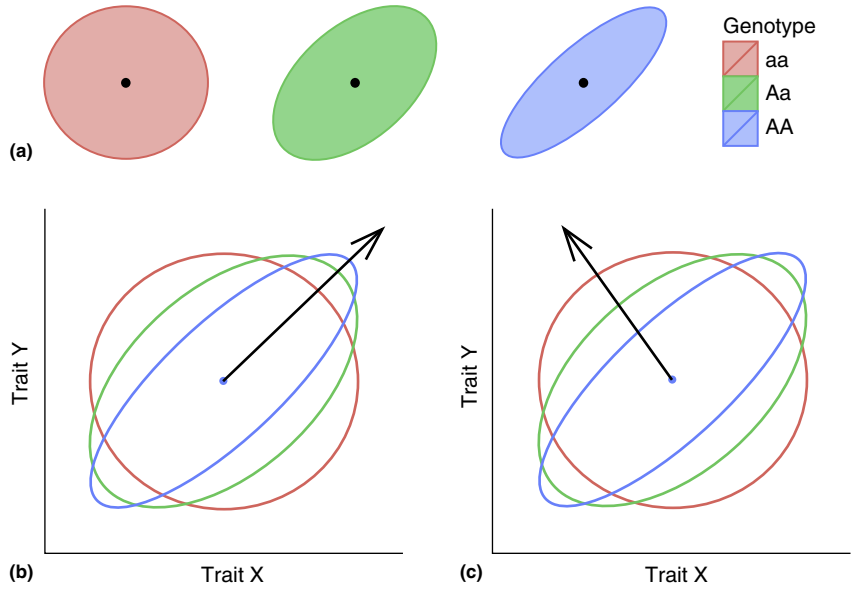

Figure 2 (a) Schematic representation of correlation between two traits for different genotypes. Genotype AA has a high correlation of 0.8 between trait X and Y; genotype *Aa* has a correlation of 0.5 and genotype *aa* has a correlation of zero between traits. The black dot in the center of each ellipse is the mean values for trait X and Y. (b and c) represent the three genotypes plotted together. In (b) we have selection (black arrow) favoring bigger individuals for both traits X and Y. In (c) we have selection favoring individuals smaller for trait X but bigger for trait Y. We might expect population b evolve in such a way to increase the positive covariation between traits and, therefore, we expect an increase of allele *A* frequency. We expect population c to evolve toward a decrease in the covariation between traits and, therefore, a decrease in frequency for allele *A* and increase for allele *a*. Adapted from Wagner, G.P., Pavlicev, M., Cheverud, J.M., 2007. The road to modularity. Nature Reviews Genetics 8 (12), 921–931.

developmentally and/or functionally restricted modules can respond to selection on a set of traits without perturbing the other sets (Griswold, 2006; Pavlicev *et al.*, 2011).

Also, pleiotropy itself can evolve, and for this there must be genetic variation in pleiotropic relations (Pavlicev *et al.*, 2011). This means that the relationship between traits can be genetically variable; and a possible source for this variation is a phenomenon called differential epistasis (Cheverud, 2004; Pavlicev *et al.*, 2011, 2008). Several studies have reported different loci presenting differential epistasis that are responsible for differences in the relationship between continuous traits. These loci are termed 'relationship Quantitative Trait Loci' or rQTL and refer to genomic regions that show variation in epistatic effects, altering pleiotropic relations and the correlation between phenotypic traits (Cheverud, 2004; Pavlicev *et al.*, 2011, 2008; Wolf *et al.*, 2005). To better understand this, let's imagine a rQTL loci with two alleles *A* and *a* (**Figure 2(a)**). Depending on the genotype, the covariation between traits X and Y is different, with a high positive correlation if the genotype is *AA*, a moderate positive correlation for genotype *Aa*, and no correlation between them for genotype *aa* (**Figure 2(a)**). As follows, we can say that the covariance between two traits depends on the genotype of this rQTL locus, although the genotype does not affect the traits means. If directional selection is favoring an increase for both traits (**Figure 2(b)**), we would expect allele A to increase its frequency in the population. This would happen because individuals with higher correlation between traits have higher values for both traits X and Y and would, therefore, be favored. On the other hand, if selection is acting for an increase of trait Y but a decrease of trait X (**Figure 2(c)**) we expect an increase of allele *a* frequency in the population. Again, the mechanistic reason for that would be that individuals *Aa* and *AA* have positive correlation between traits, which is been selected against in this case. It is easy to imagine how modular pleiotropy might appear in a population with this differential epistasis model: as long there are genetic variation in pleiotropy, natural selection can act leading to tighter or looser connections between traits (Pavlicev *et al.*, 2010).

Empirical Studies Investigating Modular Patterns

There is a vast literature on recognizing and characterizing modular patterns, especially concerning the mammalian skull. Thus, we will use the skull as a case study in order to exemplify the points raised earlier in this article. One of the forms of recognizing modules is by comparing correlation matrices from empirical data, and theoretical matrices based on hypotheses of functional/developmental relationships among characters. These theoretical hypotheses are strongly anchored on state-of-the-art literature about mammalian skull development (Cheverud, 1996, 1995; Moore, 1981; Smith, 1996, 1997, 2001). This methodology permits recognizing several different modules in different taxa, studied on a broad (orders and families), as well as on a more limited (as genus), phylogenetic framework (Ackermann and Cheverud, 2004; Cheverud, 1982; Marroig *et al.*, 2004; Marroig and Cheverud, 2001; Porto *et al.*, 2009, 2013; Shirai and Marroig, 2010).

From a developmental perspective, metatherian mammals (marsupials) present a similar modular pattern. Porto *et al.* (2009), analyzing five different orders of metatherians, reported a strong integration among facial traits, especially oral and nasal subregions. In contrast, the other 10 orders of eutherians mammals also evaluated by these authors exhibited a more variable modular pattern, with the vast majority of orders displaying a significant oral integration, but also with a broad contrast between neural and facial integration. These contrasting results between two mammals' infraclasses may reflect their developmental history, as metatherians present an early development of the facial traits because newborn survival depends directly on its ability to suckle (Smith, 1996). Differently, eutherians have more variation in neonatal states (having both highly altricial and precocial neonates) and a longer intrauterine growth (Smith, 2001, 1997). All these results indicate that shared development and function structures the current diversity of mammalian patterns of modularity/integration as expected by Olson and Miller (1958) hypothesis.

Another approach to the study of modularity is mapping QTLs in genomes. Along this line, one of the first direct evidences of modular genetic architecture organization came from the study of QTLs affecting different regions in the mouse mandible. Cheverud *et al.* (1997) used crossings between two inbreed lines of mice with very different sizes and a set of known markers to map genomic regions that affected linear distances measured on the mouse mandible. Using these experiments, they were able to show that most pleiotropic effects were restricted to one of the two regions in the mandible, the alveolar region and the ascending ramus, each related to different functions. The teeth are inserted at the alveolar region, while the ascending ramus is home to most muscle insertions. While both regions are related to mastication, the genetic effects are somewhat independent, with only 23% of the observed QTLs affecting both regions at the same time.

More recently, working with the same mouse strains as Cheverud, Kenney-Hunt *et al.* (2008) measured the number of shared QTLs between a series of skeletal traits. They expand the scope to include 70 traits, both in the skull and post-skull, painting a remarkable picture of the pleiotropic structure controlling skeletal development in mice. A total of 798 QTLs were identified, with many of the QTLs affecting more than one trait, indicating frequent pleiotropy. The authors used the information on pleiotropy to create a genetic effects adjacency matrix between traits, where traits that shared more pleiotropic QTLs were more related. This adjacency matrix was then compared to the correlation matrix between traits, and this showed a relatively high and significant correlation. These results suggested that phenotypic correlations are in part determined by shared pleiotropic effects.

On a larger scale, Wang *et al.* (2010) used a large dataset of yeast, nematode, and mouse mutants to show that the gene-trait relationship is highly modular, with most genes having small localized effects, and only a few genes having widespread pleiotropic effects and large effect sizes. This leads to an offset of Orr's cost of complexity, and allows for intermediate levels of complexity to exist via modularity.

Evolutionary Implications and Some Caveats

Studying the modularity, or the morphological integration of organisms, is fundamental to understand the evolution of complex features, as the modular structure influences multivariate evolution. The relationship between the inherited patterns of modular covariation and directional selection may, for example, restrict or facilitate certain evolutionary paths for a population. One way to appreciate the effects of genetic covariance upon the magnitude and direction of evolution is portrayed in **Figure 3** (adapted from Arnold *et al.*, 2001; Marroig and Cheverud, 2010). In this hypothetical adaptive landscape, three populations (a, b, and c) differ in their current position in relation to the adaptive peak. All three populations share the same basic genetic covariance pattern. Selection will push all three populations to the nearest adaptive peak, but the orientation of the selection gradient will differ due to their differences in current position on the landscape. While selection in all three populations specifies the shortest linear path to the peak, the realized evolutionary trajectory (Δz) from generation to generation may be quite different. In fact, if the two axes of major genetic variance are not aligned (population c) with the direction of selection, the evolutionary response to selection will be curvilinear (**Figure 3**, right panel). Furthermore, this curvilinear trajectory would be biased by the line of least resistance (defined as the linear combination having maximum genetic variance within a population, see (Schluter, 1996) embodied in the G-matrix. Because in this simple example (with only two dimensions) the first line of least resistance holds almost twice as much variation as the second one, the initial response in population c would be strongly biased in the direction of the largest genetic variance. It is also important to note how the line of least resistance influences not only the direction but also the magnitude of the evolutionary response along the path of selection. This point is made clear when comparing populations a and b. The magnitude of the response in population a is much larger than in population b. This reflects the fact that in population a, the first line of least resistance is aligned with the selected dimension; while in population b, the second line of least resistance is the one aligned with the direction of selection (β). The difference in response magnitude between a and b due to the variance differences even overcomes differences in strength of selection due to the fact that the path between a and the peak has a shallower slope than the path between b and the peak that is steeper and therefore reflects stronger selection. This example clearly shows that correlation among traits would bias the direction, influence the magnitude and pace of evolution on a microevolutionary (few generations) scale. Whether or not these modularity/integration patterns affect at macroevolutionary scales (species groups, generas, families, and so on) is an open question, but most biologists agree that such influence should decrease with time.

Finally, it is important to keep in mind that when looking at modularity/integration patterns at a given age (adults are by far the most commonly studied) we should interpret patterns as a product of a continuous development. Thus, the covariance observed in a population might not be a simple result of separate or discrete developmental factors. In fact, the development process influencing the covariance between characters

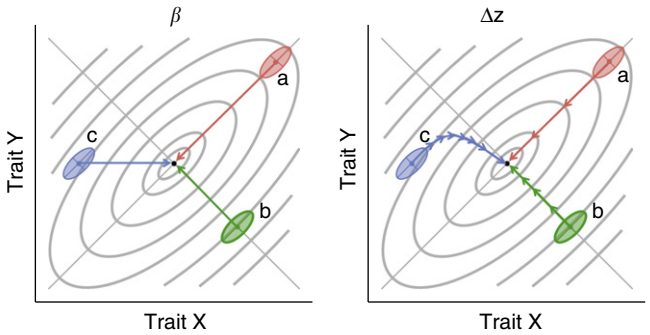

Figure 3 A hypothetical adaptive landscape for two traits (X and Y) with the black dot marking the adaptive optima (peak), and gray ellipses indicating isoclines of subsequent smaller fitness. Three populations (a, b, and c) are shown with their corresponding patterns of variance and covariance for both traits. The points inside each ellipse represent the mean value for the traits in that population. Left panel shows the direction of selection (β), and right panel the evolutionary trajectory (Δz). As we can see at the left panel, selection (β) is acting linearly in the three populations attracting them to the adaptive peak. Because each population is at a specific place in the adaptive landscape, the response to selection will be different in each population (right panel). Population a, which has its major axis of variance (represented by the longest axis of the ellipse) aligned with the adaptive landscape, will have a linear and fast response to selection. In few generations (represented by the number of arrows in the graph) it will reach the adaptive peak. Population b has its second axis of variance aligned with the adaptive landscape. Therefore, the response to selection will also be fast and linear, although not as fast as in population a. On the other hand, population c, which axis of variation is not aligned with the adaptive landscape, will take more generations to reach the adaptive peak and the trajectory will be deflected by the pattern of covariance. Adapted from Arnold, S.J., Pfrender, M.E., Jones, A.G., 2001. The adaptive landscape as a conceptual bridge between micro- and macroevolution. Genetica 112–113, 9–32; Marroig, G., Cheverud, J.M., 2010. Size as a line of least resistance II: Direct selection on size or correlated response due to constraints? Evolution 64 (5), 1470–1488.

observed at the population level is variable over time and space during ontogeny and, hence, later factors can overlap and obscure the signal of earlier factors affecting the covariance structure. The combined effect of these developmental processes suggests viewing the covariance as a palimpsest (Hallgrímsson *et al.*, 2009) where the underlying determinants of integration and modularity cannot be easily decipherable from the covariance or correlation data. Furthermore, distinct developmental factors per se are most likely not independent but instead might present various degrees of correlation among them in a hierarchical way, and thus one should not expect that modularity patterns in a population of adult organisms would be a simple amalgamate or sum of individual components parts. Thus, modules still need to be integrated in larger hierarchical functional complex structures (like the mammalian skull) and the process of growth during development is one, if not the most important, agent of such integration (Porto *et al.*, 2013). Yet, the study of variational modularity patterns can give us clues of these underlying developmental factors, since it is informative for many aspects of its underlying genetics and is critical for our comprehension of organismal evolution.

Modularity and Integration in Evo-Devo

KD Kavanagh, University of Massachusetts Dartmouth, Dartmouth, MA, USA

Glossary

Covariation Correlated variation of two or more variables.

Homology Similarity between organisms in DNA sequence, protein, or structure due to common ancestry.

Module A distinct unit that can be combined with other units to form a larger system.

Pleiotropy The phenomenon occurring when one gene affects more than one phenotypic trait.

Regulatory network A collection of regulators that interact with each other and with other substances in the cell to govern the gene expression levels of mRNA and proteins. The regulator can be DNA, RNA, protein, and their complex.

Organisms are comprised of a series of relatively independent anatomical modules, which are internally closely linked but interact less consistently with other modules. Modularity is thus essentially the result of integration among subparts of the system and therefore modularity and integration are closely related concepts (Olson and Miller, 1958). In organismal biology, study of the factors that shape these modules during development, and the impact of these modules on morphological evolution, has emerged as a primary research area in evolutionary developmental biology.

The integration among adult structures is determined by the many complex biological processes that produce the structures, therefore analysis of modularity and integration has been approached from different perspectives focusing on different levels of integration or particular developmental or functional processes. As such, the concept is rather flexible in the literature and several definitions of modularity are used commonly. Structural modularity refers to anatomical units that are cohesive tissues located close together. Functional modularity refers to body parts that interact to carry out a particular function but may not be located adjacent to each other. Developmental modularity refers to a part of the embryo that differentiates from the same tissue during development. Sometimes these modules coincide; for example, anatomical units are produced by developmental processes, therefore developmental integration may influence the patterns of anatomical covariation later in life (**Figure 1**). Modularity can also refer to integrated systems at the molecular level, through conserved interacting gene or protein networks (Raff and Sly, 2000).

Indeed, by linking different levels of biological organization, the concepts of integration and modularity aid in understanding of the developmental basis of morphological evolution (Klingenberg, 2008). Integration among developing parts leads to biased production of certain variants (e.g., different bone shapes or organ morphologies) in a population, which restricts the variants available for selection and thus biases evolutionary patterns. The concept of homology may be linked to modularity, as identifying homologous organs, for example, requires that an integrated unit is detectable as a homologous feature in different organisms (Minelli, 2015; Reippel, 2005).

Measuring Integration and Modularity
